Chapter 33

Intravenous Drug Delivery Systems

MICHEL M.R.F. STRUYS • ANTHONY R. ABSALOM • STEVEN L. SHAFER

Acknowledgment: The editors and publisher would like to thank Drs. Peter S.A. Glass and J.G. Reeves for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The pharmacokinetics of anesthetic drugs is described by multicompartment models. Accurate intravenous drug delivery requires adjusting the maintenance infusion rates to take into account the accumulation of the drug in the peripheral tissues.
- *Biophase* is the site of action of a drug. Initiation, maintenance, and titration of intravenous anesthetics must account for the delay in equilibration between plasma and the site of drug effect.
- Some drug effects directly reflect the concentration of the drug in the biophase (direct effect models). Other drug effects reflect the alteration of feedback systems by anesthetics (indirect effect models). The influence of opioids on ventilation reflects the dynamic influence of opioids on the feedback between ventilation and carbon dioxide and is thus an example of an indirect drug effect.
- The target concentration in the effect site is the same as the target concentration in plasma at steady state. Effect-site requirements are influenced by patient physiologic characteristics, surgical stimulation, and concurrent drug administration. Ideally, target concentrations should be set for the hypnotic (volatile anesthetic or propofol) and the analgesic (opioid) that properly accounts for the synergy between them.
- To achieve an effective target concentration, the conventional teaching of administering an initial dose as calculated by the product of target concentration and volume of distribution, followed by a maintenance rate as calculated as the product of target concentration and clearance, is inaccurate. The initial dose may be calculated as the product of target concentration and volume of distribution at peak effect. Maintenance rates must initially account for the distribution of drug in peripheral tissues and should only be reduced to the product of target concentration and clearance after equilibration of plasma and peripheral tissue concentrations.
- The terminal half-life does not reflect the clinical time course of drug plasma concentration. The context-sensitive decrement time is the time for a given decrement in drug concentration, as a function of the duration of infusion that maintains a steady plasma concentration. Context-sensitive decrement times properly incorporate the multicompartment behavior of intravenous anesthetics. The context-sensitive half-time is the time for a 50% decrement in concentration.
- Alfentanil, fentanyl, sufentanil, remifentanil, propofol, thiopental, methohexital, etomidate, ketamine, midazolam, and dexmedetomidine can all be administered as a continuous intravenous infusion. Specific caveats, infusion rates, and titration guidelines are presented in this text.
- Target-controlled infusions (TCIs) use pharmacokinetic models to titrate intravenous anesthetic administration to achieve specified plasma or effect-site drug concentrations. Various plasma and effect-site targeting TCI systems are commercially available worldwide (except within the United States) to administer hypnotics and opioids.
- Closed-loop drug delivery systems have used the median electroencephalographic frequency, bispectral index (BIS), or auditory-evoked potentials to control intravenous anesthetic delivery. Although these systems have generally performed well clinically, they remain under investigation.

INTRODUCTION

Drugs must reach their site of action to be effective. In 1628, William Harvey proved in *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* that venous blood was transported to the arterial circulation and thus to body organs by the heart. That drugs injected into veins could be rapidly carried to the entire body was rapidly recognized. Consequently, for intravenous drug delivery to be successful, predictable intravenous access is essential.

The development of intravenous methods of anesthetic drug delivery has been made possible by technologic advances. In the middle of the seventeenth century, Christopher Wren and his Oxford contemporaries applied a feather quill and animal bladder to inject drugs into dogs and humans and rendered them unconscious. The hollow hypodermic needle and a functional syringe were developed by Frances Rynd (1801-1861) and Charles Pravaz (1791-1853), respectively. Contemporary needles, catheters, and syringes are descendants of these early devices. In the twentieth century, equipment began to be made of plastics, first polyvinyl chloride, then Teflon, and later, polyurethane. In 1950, Massa invented the Rochester needle (Fig. 33-1),[1] which led to the revolutionary concept of the "over-the-needle" catheter, which is still the gold standard for intravenous access for nearly all intravenous drug delivery today.[2]

Although fundamental principles of intravenously administering drugs were known in the eighteenth century, intravenous induction of anesthesia became common only in the 1930s after the discovery of barbiturates. Maintenance of anesthesia by intravenously administered anesthetics has become practical, safe, and popular in the past 2 decades. Intravenous drugs such as methohexitone and thiopental, although suitable for intravenous induction of anesthesia, are not suitable for use by infusion for the maintenance of anesthesia. In the case of thiopental, accumulation can lead to cardiovascular instability and delayed recovery, whereas methohexitone is associated with the excitatory phenomenon and epileptiform electroencephalographic (EEG) changes. Although the next generation of intravenous drugs, such as ketamine, althesin, and etomidate, possessed desirable pharmacokinetic characteristics, their use has been limited as a result of other side effects, including hallucinations, anaphylaxis, and adrenal suppression, respectively. The discovery of propofol in 1977 provided the anesthetic practice an intravenous drug suitable for both induction and maintenance of anesthesia; currently, propofol is one of the most frequently used drugs for this purpose.[3] Other drugs suitable for continuous infusion used today are some of the opioids such as alfentanil and sufentanil and certainly the short-acting opioid remifentanil (also see Chapter 30). In addition, some of the nondepolarizing muscle relaxants are used as continuous infusions in specific situations (also see Chapter 34).

Drugs are still predominantly injected as a bolus or continuous infusion using standard dosing guidelines, thereby ignoring the large interindividual variability in the dose-response relationship.[4] In contrast to inhaled anesthetics, for which the inspired and end-tidal concentrations can be continuously measured in real time

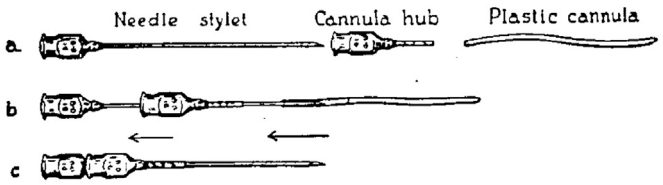

Figure 33-1. Details of the assembly of the Massa plastic needle, sold by Rochester Products Company, Rochester, Minnesota. *(From Massa DJ: A plastic needle,* Anesthesiology *12:772-773, 1951. Used with permission.)*

("online"), the actual plasma or effect organ concentration of an intravenously administered drug is not immediately measurable in clinical practice. Therefore manually adjusting the intravenous drug injection regimens to maintain an online measured plasma concentration is impossible. It becomes even more complex if a specific effect-site concentration is the target. Optimal patient-individual dosing may be achieved by the application of pharmacokinetic-pharmacodynamic principles. Additionally, recent findings suggest that the pharmacokinetic and pharmacodynamic interactions during intravenous administration of various drugs are important and, as such, should be taken into account when optimizing drug administration.[5,6] Computer technology can be used to assist the clinician in titrating intravenous drug administration by using the therapeutic end point as the feedback signal for dosing (Fig. 33-2).

The development of the first mechanical syringe pumps in the 1950s improved the quality of intravenous drug administration. A more recent technologic development in intravenous anesthesia is the introduction of computerized pharmacokinetic model–driven continuous-infusion devices, enabling the attainment of desired plasma levels of an intravenous anesthetic drug by using a computer-controlled infusion pump operated in accordance with the published pharmacokinetics of the drug.[7] These efforts have resulted in the release of the first commercial target-controlled infusion (TCI) device in Europe, developed by Zeneca specifically for the administration of propofol. Since that time, several countries (with the exception of the United States) have approved the use of TCI devices for the delivery of anesthetic drugs.

The ultimate development in anesthetic delivery systems will be devices for closed-loop administration of intravenous drugs during anesthesia. Systems have been developed for closed-loop administration of various drugs such as muscle relaxants, hypnotics, and opioids. The control variables for these systems have included various pharmacodynamic measures derived from techniques such as acceleromyography, automated blood pressure measurement, and electroencephalography.

The dose-response relationship can be divided into three parts (see Fig. 33-2): (1) the time course of the relationship between the given dose and the plasma concentration is defined as *pharmacokinetics*, (2) the relationship between the plasma concentration and/or effect-organ concentration and the clinical effect is defined as *pharmacodynamics*, and (3) the coupling between pharmacokinetics and pharmacodynamics is required when the blood is not the site of drug effect.

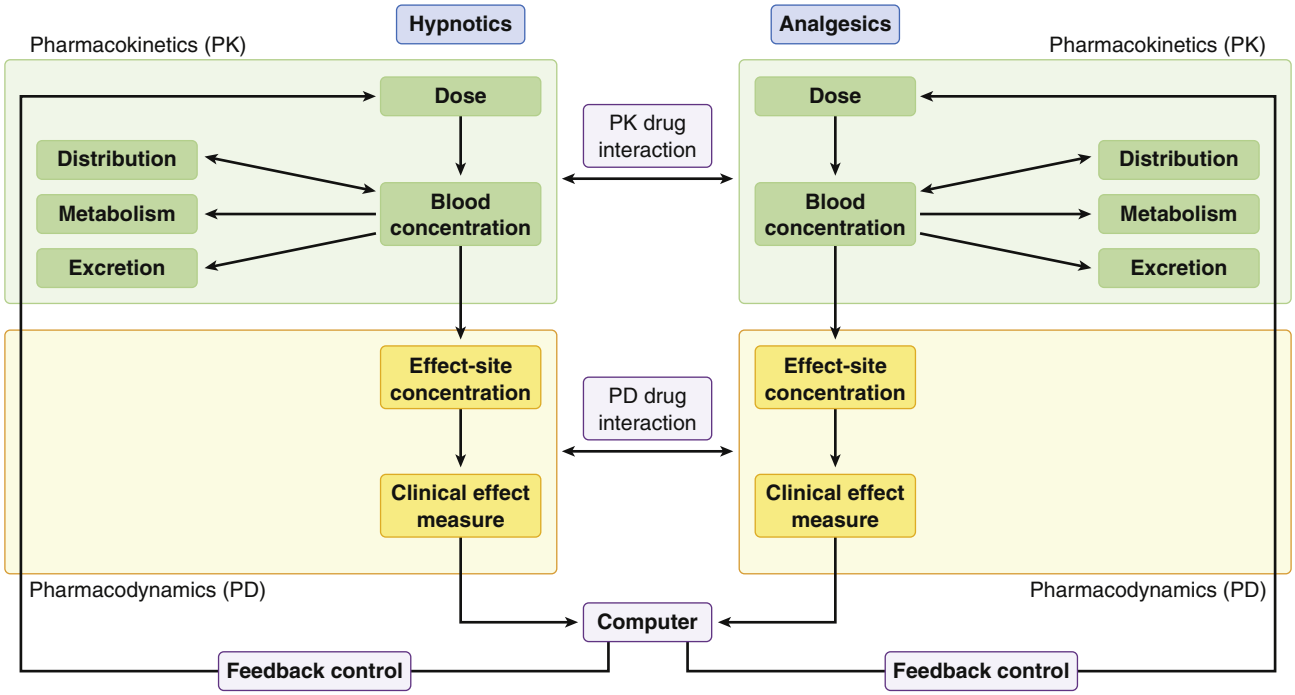

Figure 33-2. Schematic representation of the dose-response relationship for both hypnotics and opioids. The pharmacokinetic (PK) (*green area*) and the pharmacodynamic (PD) (*yellow area*) parts of this relationship are shown. Closed-loop control of drug administration using the clinical measure is indicated as *feed-back control*. Pharmacokinetic and pharmacodynamic drug interactions are indicated. *(From Sahinovic MM, Absalom AR, Struys MM: Administration and monitoring of intravenous anesthetics,* Curr Opin Anaesthesiol *23:734-734, 2010. Used with permission.)*

Before reviewing delivery techniques and devices for intravenous anesthesia, this chapter presents some pharmacokinetic and pharmacodynamic principles as background for understanding how to administer intravenous drugs to their best advantage. Further discussion of the principles of pharmacokinetics and pharmacodynamics can be found in Chapter 30.

PHARMACOKINETIC CONSIDERATIONS

The aim of optimal intravenous drug dosing is to reach and maintain a desired time course of therapeutic drug effect as accurately as possible, thereby preventing dose-related adverse drug effects. To be useful in anesthesia, this time course should include a rapid onset of clinical effects, smooth maintenance, and fast recovery after the termination of drug administration. The pharmacokinetics of many intravenous drugs can be described using mammillary multicompartment pharmacokinetic models. These models assume that the drug is directly given and mixed in the plasma, resulting in an immediate peak in its plasma concentration.

The easiest clinical technique is to administer a single dose, calculated to keep the plasma concentration above the therapeutic target concentration for the required time (Fig. 33-3). A constant concentration cannot be maintained, but it should not decrease to less than the therapeutic concentration. Unfortunately, when one single bolus is used, the initial dose must be large enough to maintain a concentration above the lowest therapeutic concentration even at the end of surgery. However, this sometimes very large dose of drug may cause numerous side effects attributable to the initially high concentrations in the body. It might be less harmful to keep the drug concentration above the lowest therapeutic level without very high initial concentrations by repeatedly injecting smaller doses; even with this technique, however, maintaining a stable plasma concentration is still impossible.

To produce a time course of drug effect that follows the time course of anesthetic requirement, a continuous infusion titrated to the perceived anesthetic requirement should be used. Typically, just enough amount of drug is given to achieve the therapeutic blood or plasma drug concentration. Drug administration thereafter should be continuously titrated throughout surgery. Although such a regimen does not overshoot the required concentration (and therefore avoids the risk of concentration-related side effects), yet another difficulty exists. Whereas, the large bolus approach produces an effective concentration (EC) from the onset, albeit with an excessive overshoot, a continuous infusion takes a long time to become effective because of the slow increase in concentration. Reaching steady state (see Fig. 33-3) takes a very long time during which the increase in concentration is rapid at first but then slows down as equilibrium is approached. For example, it will take longer than 1 hour for the propofol infusion to generate a plasma concentration that is at least 95% of the steady-state concentration. Consequently, although simple infusions are obviously very effective for maintaining constant blood concentrations once steady state is reached and for avoiding overshoot, infusions do not offer a clinically realistic approach. Therefore a combination of an initial bolus followed by a stepwise decreasing continuous infusion is more useful.[8,9]

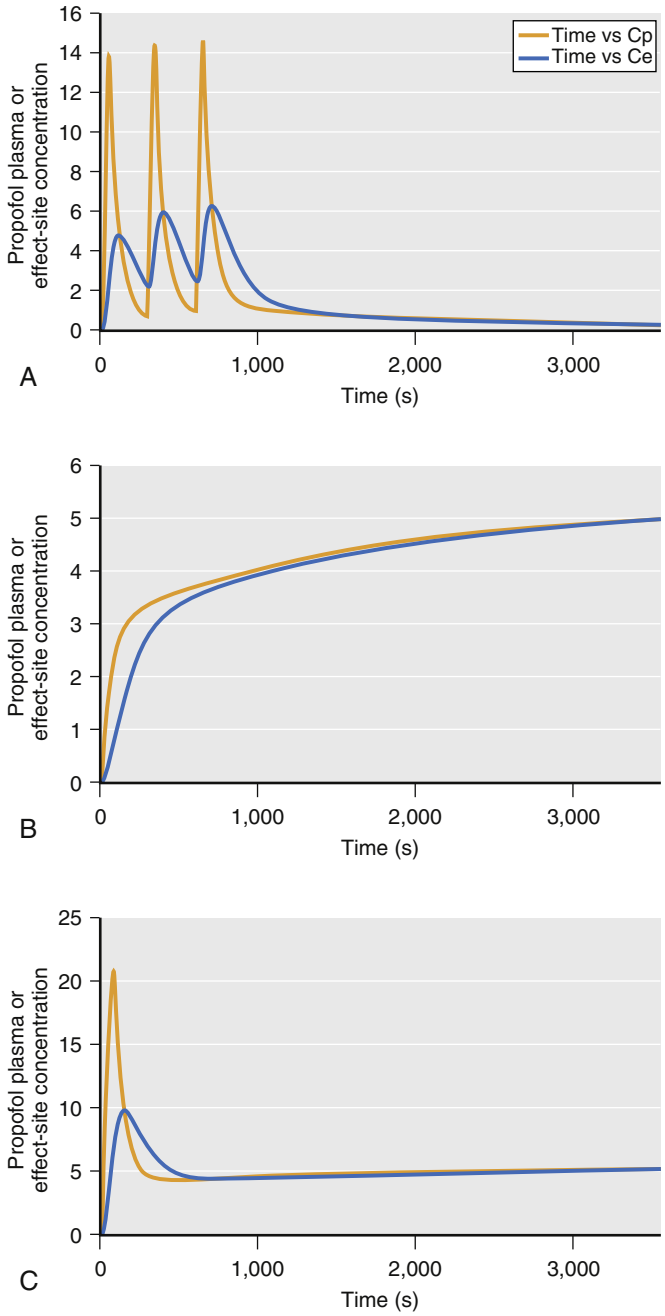

Figure 33-3. Predicted propofol plasma concentration (Cp) and effect-site concentration (Ce) for a repeated bolus dose (1 mg/kg given at time 0 and after 5 and 10 minutes) (**A**), continuous infusion (10 mg/kg/hr) (**B**), and a bolus (2 mg/kg) followed by a continuous infusion (10 mg/kg/hr). **C**, Simulated patient is a man, 45 years of age, 80 kg, 175 cm; Schnider model).

Pharmacokinetic models can be used to calculate the required drug-dosing regimen to reach and maintain a therapeutic drug concentration as fast as possible without overshooting or accumulation. In this chapter, an explanation of how pharmacokinetic models can be used to calculate accurate dosing schemes for use with intravenous drug delivery systems is offered.

Pharmacokinetic models are mathematical descriptions of how the body *disposes* of drugs. The parameters describing this process are estimated by administering a known dose of the drug and measuring the resulting plasma concentrations. A mathematical model then relates the input over time, I(t), with the concentrations over time, C(t). These models can take many forms. Figure 33-4 shows concentrations in plasma and effect site over time after a single intravenous bolus of drug at time 0. Drug concentrations continuously decrease after the bolus, and the rate of decrease is approximately proportional to the amount of drug in plasma. Typically, this behavior can be described with the use of exponential models. The curve might have a single exponent, in which case the plasma concentrations over time might be described by the function $C(t) = Ae^{-kt}$, where A is the concentration at time 0 and k is a constant that describes the rate of decrease in concentration. The relationship appears to be a straight line when graphed as the log of concentration versus time. The pharmacokinetics of intravenous anesthetic drugs is more complex because after the bolus, a period of rapid decline is observed before the terminal *log-linear* portion (i.e., the part that is a straight line when described as log concentration versus time). This process can be modeled by taking several monoexponential curves and adding them together. The result is a polyexponential curve. For example, the concentrations after an intravenous bolus might be described by an equation with two exponents, $C(t) = Ae^{-\alpha t} + Be^{-\beta t}$, or an equation with three exponents, $C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$.

The aforementioned is applied to single bolus dosing, which is, of course, only one way of administering intravenous anesthetic drugs. A more general way to think of pharmacokinetics is to decompose the input into a series of small bits (boluses) and consider each bit of drug separately. The general pharmacokinetic model of drug disposition commonly used in anesthesia independently considers each bit of drug and analyzes its contribution by means of polyexponential decay over time. The formal mathematic description of each bit of drug in terms of polyexponential decay over time is the relationship.

$$C(t) = I(t) * \sum_{i=1}^{n} A_i e^{-\lambda_i t} \qquad (1)$$

where C(t) is the plasma concentration at time t and I(t) is drug input (i.e., a bolus or infusion). The summation after the asterisk (described later in this chapter) is the function describing how each bit of drug is disposed (hence the name, *disposition function*). Note that this is again a sum of *n* exponentials, as described in the previous paragraph.

Pharmacokinetic modeling is the process of estimating the parameters within this function. The integer *n* is the number of exponentials (i.e., compartments) and is usually two or three. Each exponential term is associated with a coefficient A_i and an exponent λ_i. The λ values are inversely proportional to the half-lives (half-life = $\ln 2/\lambda = 0.693/\lambda$), with the smallest λ representing the longest (terminal) half-life. The A values are the relative contribution of each half-life to overall drug disposition. If a drug has a very long terminal half-life but a coefficient that is significantly smaller than the other coefficients, then the long half-life is likely to be clinically meaningless. Conversely, if a drug has a very long half-life with a relatively large coefficient, then the drug will be long lasting even

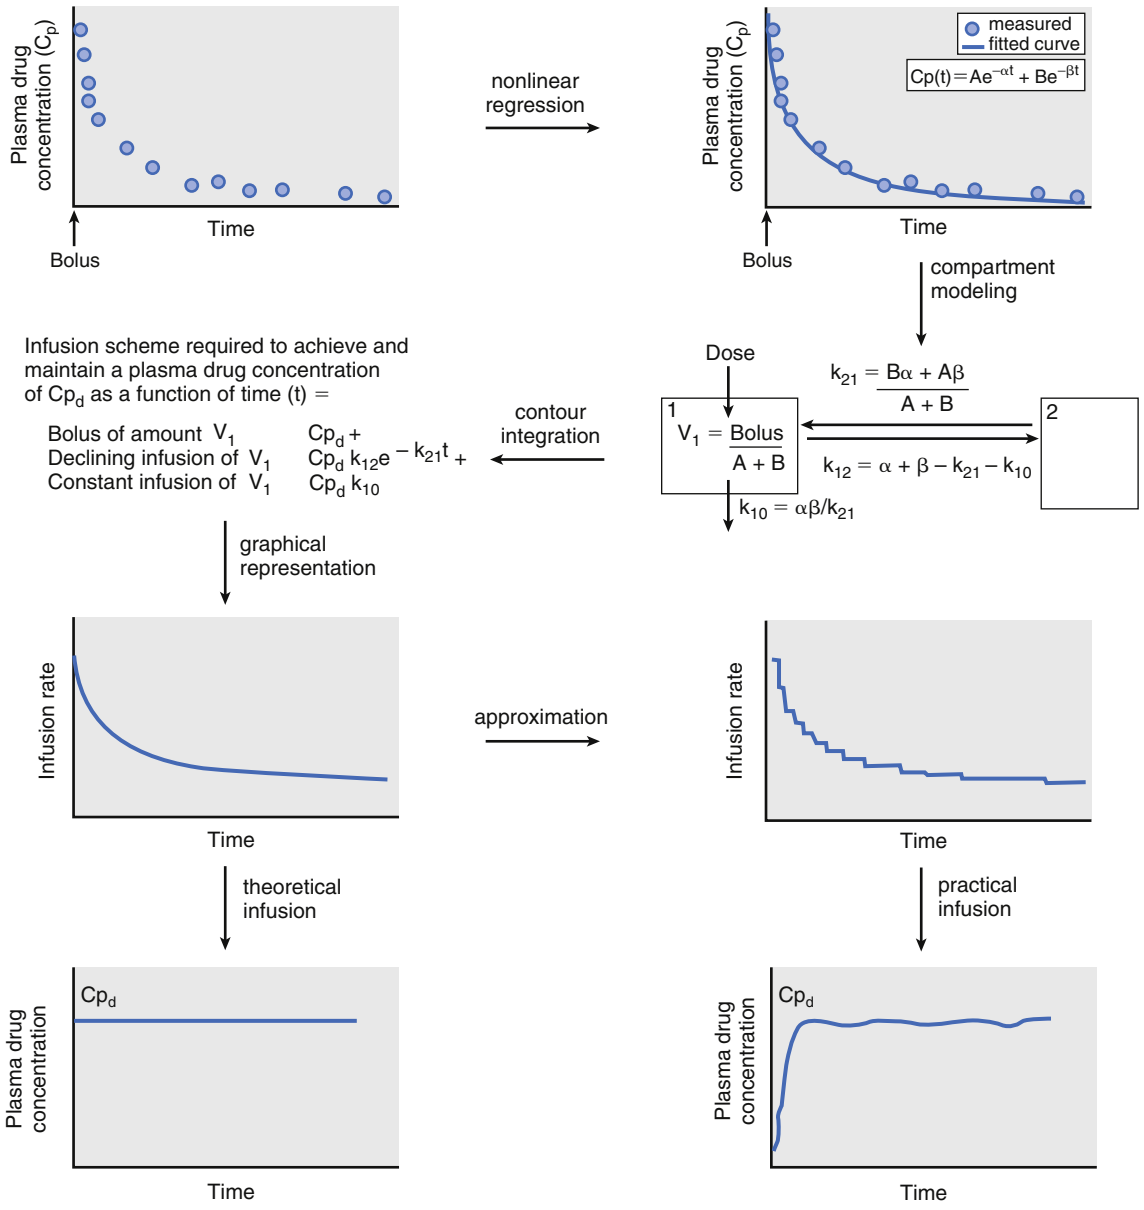

Figure 33-4. Steps involved in pharmacokinetic model–driven infusion. Typically, pharmacokinetic models are derived from experiments in which plasma drug concentrations are measured at intervals after bolus administration of the drug. Nonlinear regression is used to fit a mono-exponential, biexponential, or triexponential curve to the resulting concentration-versus-time data. An algebraic relationship exists between the exponential decay curves and a one-, two-, or three-compartment pharmacokinetic model. The bolus-elimination-transfer (BET) infusion scheme is developed and consists of a bolus, a continuous infusion to replace drug eliminated from the body, and an exponentially declining infusion to replace drug transferred out of plasma to other body compartments. BET infusion results in the maintenance of a constant specified plasma drug concentration. Practical implementation of the BET scheme with real infusion pumps and infusion rates that change only at discrete intervals of time results in a plasma drug concentration profile that approximates that resulting from a BET infusion.

after brief administration. The asterisk (*) operator is the mathematic process called *convolution*, which is simply the process of breaking the infusion into *bits* of drug and then adding up the results to observe the overall concentrations resulting from the disposition of the different bits up to a time point t.

The pharmacokinetic model shown has some useful characteristics that account for its enduring popularity in pharmacokinetic analysis. Most important, the model describes observations from studies reasonably well, the *sine qua non* for models. Second, these models have the useful characteristic of *linearity*. Simply stated, if the dose, I, is doubled (e.g., administering a bolus twice as large or an infusion twice as fast), then the resulting concentrations should be doubled.

More generally, linearity implies that the system (i.e., the body acting to produce a plasma drug concentration output from a drug dosage input) behaves in accordance with the principle of superposition. The superposition principle states that the response of a linear system with multiple inputs can be computed by determining the response to each individual input and then summing

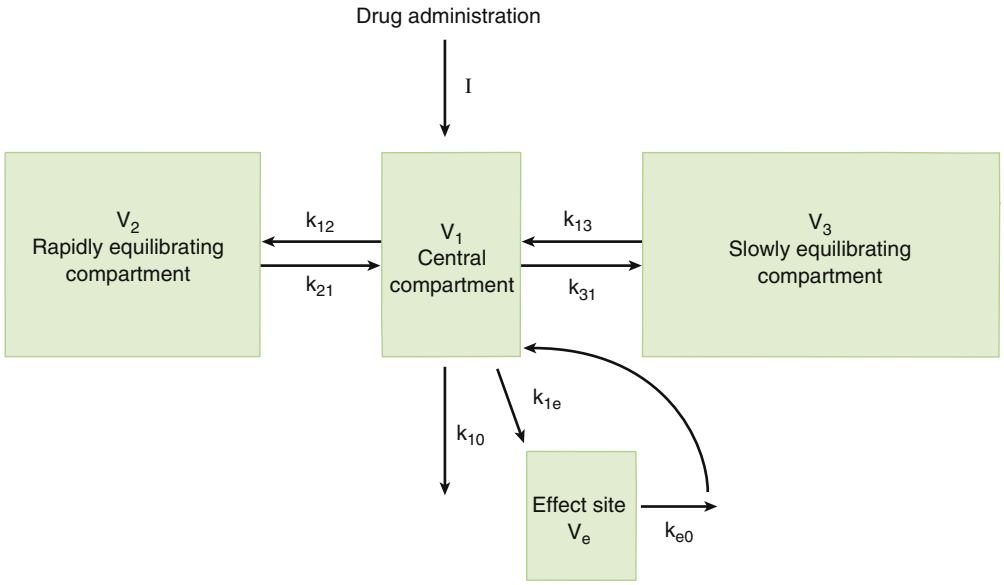

Figure 33-5. Three-compartment model (including the biophase) illustrating the basic pharmacokinetic processes that occur after intravenous drug administration. *I*, Dosing scheme as a function of time; k_{10}, rate constant reflecting all processes acting to remove drug irreversibly from the central compartment; *k*, intercompartment rate constants; V_1, central compartment volume, usually expressed in liters or liters per kilogram.

the individual responses. In other words, when the body treats each bit of drug by polyexponential decay over time, the *disposing* of each bit of drug does not influence the disposing of other bits of drug.

The third reason for the continuing popularity of these models is that they can be mathematically transformed from the admittedly nonintuitive exponential form shown earlier to a more intuitive compartment form (Fig. 33-5). The fundamental parameters of the compartment model are the volumes of distribution (central, rapidly equilibrating, and slowly equilibrating peripheral volumes) and clearances (systemic, rapid, and slow intercompartment). The central compartment (V_1) represents a distribution volume and includes the rapidly mixing portion of the blood and first-pass pulmonary uptake. The peripheral compartments are made up of tissues and organs that show a time course and extent of drug accumulation (or dissipation) different from that of the central compartment. In the three-compartment model, the two peripheral compartments may roughly correspond to splanchnic and muscle tissues (rapidly equilibrating) and fat stores (slowly equilibrating). The sum of the compartment volumes is the apparent volume of distribution at steady state (Vd_{ss}) and is the proportionality constant relating the plasma drug concentration at steady state to the total amount of drug in the body. The intercompartment rate constants (k_{12}, k_{21}, and so on) describe the movement of drug between the central and peripheral compartments. The elimination rate constant (k_{10}) encompasses processes acting through biotransformation or elimination that irreversibly removes drug from the central compartment.

Despite their physiologic flavor, compartment models are simply mathematic transformations of the polyexponential disposition functions computed from observed plasma concentrations. Thus physiologic interpretation of volumes and clearances (with the possible exception of systemic clearance and Vd_{ss} [the algebraic sum of the volumes]) is entirely speculative.

The last reason behind the popularity of these models is that they can be used to design infusion regimens. If the disposition function

$$\sum_{i=1}^{n} A_i e^{-\lambda_i t} \tag{2}$$

is abbreviated as simply D(t), then the relationship among concentration, dose, and the pharmacokinetic model D(t) can be rewritten as

$$C(t) = I(t)*D(t) \tag{3}$$

where * is the convolution operator, as noted earlier. In the usual pharmacokinetic study, I(t) is known, the dose that is given the patient, and C(t) is measured, the concentrations over time. The goal is to find D(t), the pharmacokinetic disposition function. Pharmacokinetic analysis can be thought of as a simple rearrangement of Equation 3 to solve for D(t)

$$D(t) = \frac{C(t)}{\overrightarrow{\leftarrow} I(t)} \tag{4}$$

where the symbol $\rightarrow\leftarrow$ means *deconvolution*, the inverse operation of convolution. Deconvolution is similar to division, but of functions rather than simple numbers. When dosing regimens are designed from known pharmacokinetic models and a desired course for the plasma concentration over time, the known values are D(t) (the pharmacokinetics) and $C_T(t)$ (the desired target concentrations), and the drug dosing scheme is

$$I(t) = \frac{C_T(t)}{\overrightarrow{\leftarrow} D(t)} \tag{5}$$

Thus the necessary infusion rates, I(t), can be calculated, given the desired target concentrations, $C_T(t)$, and the pharmacokinetics, D(t), by applying the same tools used to calculate the original pharmacokinetics. Unfortunately, such a solution might require some negative infusion rates, which are obviously impossible. Because drug cannot be retracted from the body (i.e., give inverse

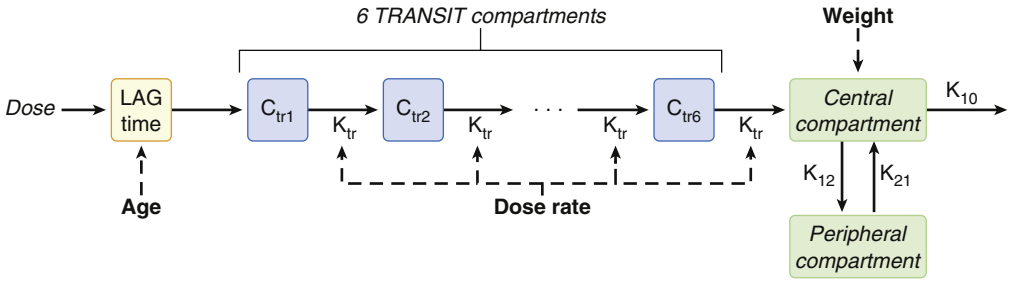

Figure 33-6. Scheme of the final two-compartment pharmacokinetic model with a LAG time and six TRANSIT compartments (C_{tr} *n*). The equilibration rate constants between the central and peripheral compartments were calculated using the following equations: $k_{12} = Cl_2 \div V_1$, $k_{21} = Cl_2 \div V_2$. The elimination rate constant was calculated using the following equation: $k_{10} = Cl_1 \div V_1$. Cl_1, Clearance of central compartment; Cl_2, clearance of peripheral compartment; V_1, distribution volume of central compartment; V_2, distribution volume of peripheral compartment. LAG time represents the time shift of dosing as if the drug was, in fact, administered to the pharmacokinetic model at a later time. TRANSIT compartments depict a multiple-step process represented by a chain of presystemic compartments. *(From Masui K, Kira M, Kazama T, et al: Early phase pharmacokinetics but not pharmacodynamics are influenced by propofol infusion rate,* Anesthesiology *111:805-817, 2009. Used with permission.)*

infusions), clinicians must restrict themselves to plasma concentrations over time that can be achieved with non-inverse infusion rates.

The standard pharmacokinetic model has one glaring shortcoming. It assumes that after a bolus injection there is complete mixing within the central compartment such that the peak concentration occurs precisely at time 0. It actually takes approximately 30 to 45 seconds for the drug to make its transit from the venous injection site to the arterial circulation. This model misspecification over the first minute or so may not seem significant, but it can cause problems in attempts to relate the drug effect after a bolus to drug concentrations in the body,[10] which becomes even more important when using effect-site TCI.[11] The standard polyexponential pharmacokinetic models are being modified to provide more accurate models of plasma drug concentration in the first minute after bolus injection, also taking into account infusion rate. Recently, Masui and associates[12] found that a pharmacokinetic model consisting of a two-compartment model with a LAG (the time shift of dosing as if the drug were, in fact, administered to the pharmacokinetic model at a later time) and presystemic compartments model accurately described the early pharmacologic phase of propofol during infusion rates between 10 and 160 mg/kg/h. The infusion rate has an influence on kinetics. Age was a covariate for LAG time (Fig. 33-6). Besides compartment models, various physiologically based models have been developed to model the pharmacokinetic behavior of anesthetics.[13] So far, these models are not superior at predicting the time course of drug concentration.[12] None of these models have been used to control intravenous drug delivery devices.

PHARMACODYNAMIC CONSIDERATIONS

THE BIOPHASE

The goal of drug titration during anesthesia is to reach and maintain a stable therapeutic drug concentration at the site of drug effect, also defined as the *effect site* or *biophase*. For most drugs used in anesthesia, the plasma is not the biophase and thus, even after the drug has reached the arterial circulation, a further delay occurs before a therapeutic effect is observed. The reason is that additional time is required for the drug to be transported to the target organ, penetrate the tissue, bind to a receptor, and induce intercellular processes that ultimately lead to the onset of drug effect. This delay between peak plasma concentration and peak concentration at the effect site is called *hysteresis*. Figure 33-7 illustrates an example of hysteresis revealed during an experiment published by Soehle and co-workers.[14] Two periods of continuous propofol infusions were given. The time course of the plasma concentration and effect-site concentration are simulated using pharmacokinetics and pharmacodynamics models. The cerebral drug effect was measured using the EEG-derived bispectral index (BIS). A clear delay between the time course of the plasma concentration and that of the BIS can be observed. The plasma concentration versus effect curve forms a counterclockwise hysteresis loop. This loop represents the plasma concentration but is not the site of drug effect. Using nonlinear mixed effect modeling, the hysteresis is minimized to reveal the effect-site concentration versus clinical effect relationship. The typical sigmoidal population model is also depicted in Figure 33-7.

The concentration of drug in the biophase cannot be measured because it is usually inaccessible, at least in human subjects. The time course of drug effect can be calculated by using rapid measures of drug effect. Knowing the time course of drug effect, the rate of drug flow in and out of the biophase (or effect site) can be calculated with the use of mathematic models. As such, the time course of the plasma concentration and the measured effect can be linked using the concept of the *effect compartment*, developed by Hull[15] and Sheiner.[16] The effect-site concentration is not a real measurable concentration but rather a virtual concentration in a theoretic compartment without a volume and, as such, also without any significant amount of drug present. For any concentration in this virtual compartment, a corresponding assumed effect is observed. This relationship between the effect-site concentration and effect is usually nonlinear and static (i.e., does not explicitly depend on time). If the plasma concentration is maintained at a constant level, then the

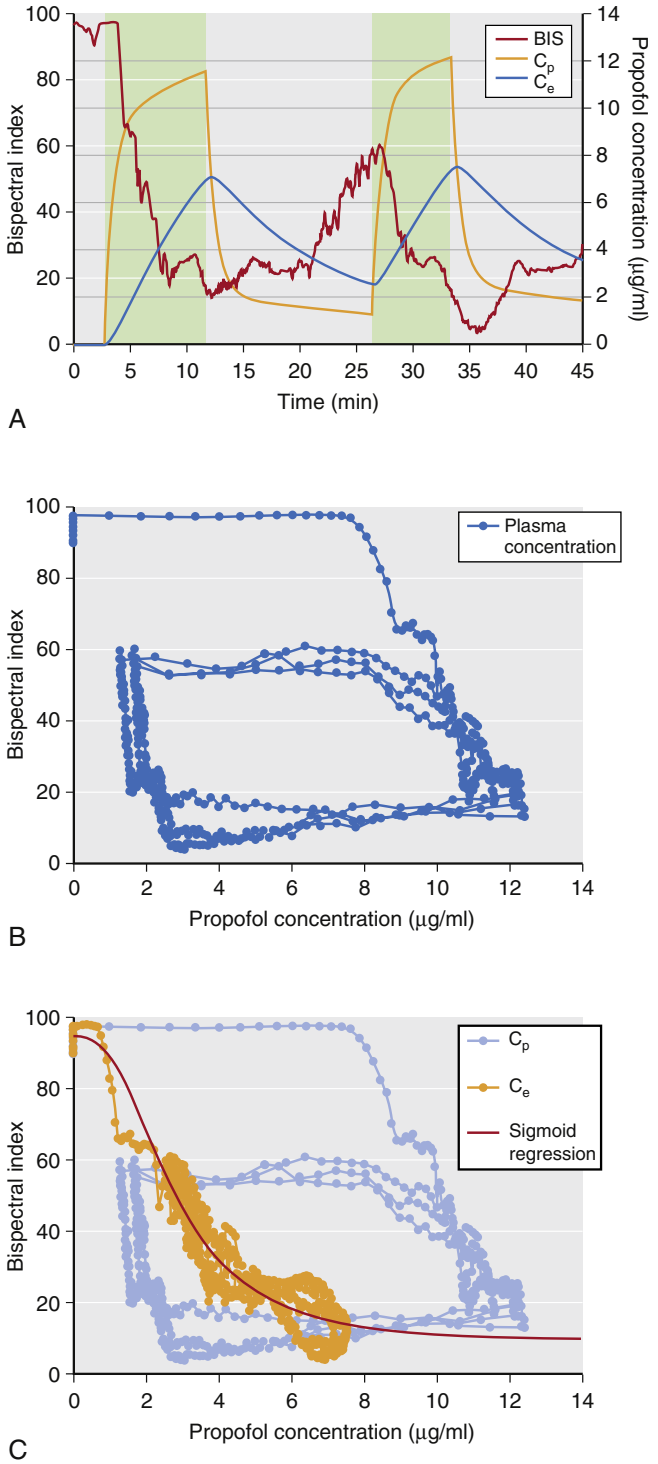

Figure 33-7. A, Time course of an experiment showing the hysteresis between plasma concentration (C_p) and hypnotic effect as measured by the electroencephalographic (EEG)-derived bispectral index (BIS). Propofol was given at a constant rate during the shaded periods, resulting in C_p (*orange line*) and effect-site concentration (C_e) (*blue line*). The corresponding BIS values are shown as a *solid blue line.* **B,** Relation between C_p and BIS using data from the experiment reveals a hysteresis loop. **C,** After modeling, this hysteresis is minimized as shown in the relation between the effect-site concentration and BIS. (**A,** *Adapted from Soehle M, Kuech M, Grube M, et al: Patient state index vs bispectral index as measures of the electroencephalographic effects of propofol,* Br J Anaesth *105:172-178, 2010. Used with permission;* **B** and **C,** *Courtesy of M. Soehle, Bonn, Germany).*

model assumes that, at equilibrium, the effect-compartment concentration equals the plasma concentration. The delay between the plasma and the effect compartment is mathematically described by a single parameter, defined as *ke0*, the effect-site equilibration rate constant[17] (see Fig. 33-5).

Measures of drug effect used to characterize the time course of drug between plasma and the biophase vary with the drug being evaluated. For some drugs, a direct measure of drug effect can be applied. For neuromuscular blocking drugs, the response from peripheral nerve stimulation (i.e., the twitch) is an ideal measure of effect. Various authors have used the T1% (percentage change of the T1 response compared with baseline T1 response during supramaximal stimulus) derived from electromyogram to measure the drug effect of newer drugs such as rocuronium[18] and cisatracurium.[19] For other categories of drugs such as opioids and hypnotics, the real clinical effects (e.g., unconsciousness, amnesia, memory loss, antinociception) are not measurable. For these reasons, surrogate measures are used to quantify the time course of clinical effects. These surrogate measures can be categorical or continuous. For example, the Observer's Assessment of Alertness/Sedation (OAA/S) scale was used to measure quantal changes in hypnotic drug effects during propofol administration.[20] Egan and colleagues[21] applied a noxious pain stimulus and used an algometer to measure the balance between nociception and antinociception during remifentanil infusion. Various spontaneous and evoked EEG-derived and processed measures were used to measure cerebral drug effects for opioids and hypnotics.[14,22-26] Ludbrook and associates measured propofol concentrations in the carotid artery and jugular bulb to establish movement of propofol into and equilibration with the brain. They simultaneously measured the BIS and found a close correlation between brain concentration (calculated by mass balance) and changes in the BIS (also see Chapter 50).[27]

DIRECT-EFFECT MODELS

As with plasma pharmacokinetics, the biophase concentration is the convolution of an input function (in this case, the plasma drug concentration over time) and the disposition function of the biophase. This relationship can be expressed as

$$C_{biophase}(t) = C_{plasma}(t) * D_{biophase}(t) \quad (6)$$

The disposition function of the biophase is typically modeled as a single exponential decay

$$D_{biophase}(t) = K_{e0} e^{-K_{e0} t} \quad (7)$$

The monoexponential disposition function implies that the effect site is simply an additional compartment in the standard compartment model that is connected to the plasma compartment (see Fig. 33-5). The effect site is the hypothetical compartment that relates the time course of plasma drug concentration to the time course of drug effect, and k_{e0} is the rate constant of elimination of drug from the effect site. By convention, the effect compartment is assumed to receive such small amounts of drug from the central compartment that it has no influence on plasma pharmacokinetics.

Neither $C_{biophase}(t)$ nor $D_{biophase}(t)$ can be directly measured, but the drug effect can be measured. Knowing that the observed drug effect is a function of the drug concentration in the biophase, the drug effect can be predicted as

$$Effect = f_{PD}\left[C_{plasma}(t)*D_{biophase}(t)\,,\,P_{PD}\,,\,K_{e0}\right] \quad (8)$$

where f_{PD} is a pharmacodynamic model (typically sigmoidal in shape), P_{PD} represents the parameters of the pharmacodynamic model, and k_{e0} is the rate constant for equilibration between plasma and the biophase. Nonlinear regression programs are used to find values of P_{PD} and k_{e0} that best predict the time course of drug effect. This method is called *loop-collapsing* (see Fig. 33-7). Knowledge of these parameters can then be incorporated into dosing regimens that produce the desired time course of drug effect.[28,29]

If a constant plasma concentration is maintained, then the time required for the biophase concentration to reach 50% of the plasma concentration ($t_{1/2}k_{e0}$) can be calculated as $0.693/k_{e0}$. After a bolus dose, the time to peak biophase concentration is a function of both plasma pharmacokinetics and k_{e0}. For drugs with a very rapid decline in plasma concentration after a bolus (e.g., adenosine with a half-life of several seconds), the effect-site concentration peaks within several seconds of the bolus, regardless of k_{e0}. For drugs with a rapid k_{e0} and a slow decrease in concentration after a bolus injection (e.g., pancuronium), the peak effect-site concentration is determined more by k_{e0} than by plasma pharmacokinetics.

An accurate estimation of k_{e0} demands an integrated pharmacokinetic-dynamic study combining rapid blood sampling with frequent measurements of drug effect, yielding an overall model for the dose-response behavior of the drug. Historically, the time constants of pharmacokinetic models and the k_{e0} of pharmacodynamic studies were sometimes naively merged, possibly leading to inaccurate predictions of the clinical drug effect. Coppens and colleagues proved that pharmacodynamic models of BIS in children developed by using estimates of plasma propofol concentrations from published pharmacokinetic models and estimating the pharmacodynamic model do not ensure good pharmacokinetic accuracy or provide informative estimates for pharmacodynamic parameters.[30] If no integrated pharmacokinetic-dynamic model exists, then the time to peak effect (t_{peak}) after a bolus injection can be used to recalculate k_{e0} using the pharmacokinetic model of interest to yield the correct time to peak effect. Under these circumstances, this alternative approach might lead to a more accurate prediction of the dose-response time course.[31,32] However, the correct covariates for t_{peak} should be estimated in a specific population.[33] A second caveat is that the time course of drug effect is specific for a given effect (e.g., cerebral drug effect as measured by a specific processed EEG). The time course of other side effects (e.g., hemodynamic effect for hypnotics) most frequently follows a different trajectory.[34,35] The time to peak effect and the $t_{1/2}$ k_{e0} for several intravenous anesthetics are listed in Table 33-1.

All methods explained so far incorporate k_{e0} values calculated on the assumption that hysteresis between plasma concentration and clinical effect is explained by a delay in drug transfer between plasma and biophase and thus that anesthesia is a smooth, path- and state-independent, symmetric process. Although still commonly used, this assumption might be suboptimal. Data from animal experiments suggest that neural processes and pathways involved in anesthesia induction and recovery are different.[36,37] In an animal study, measured brain drug concentrations at loss of consciousness and at return of consciousness were significantly different.[38] If these data are confirmed, then a more complex model (e.g., one incorporating a second, serial effect-site model) might be required to depict the time course of drug effect.

TABLE 33-1 TIME TO PEAK EFFECT AND $t_{1/2}k_{e0}$ AFTER A BOLUS DOSE*

Drug	Time to Peak Drug Effect (min)	$t_{1/2}$ k_{e0} (min)
Morphine	19	264
Fentanyl	3.6	4.7
Alfentanil	1.4	0.9
Sufentanil	5.6	3.0
Remifentanil	1.8	1.3
Ketamine	—	3.5
Propofol	1.6	1.7
Thiopental	1.6	1.5
Midazolam	2.8	4.0
Etomidate	2.0	1.5

$t_{1/2}$ k_{e0} = $0.693/k_{e0}$, Rate constant for transfer of drug from the site of drug effect to the environment.
*Measured by electroencephalography.

INDIRECT-EFFECT MODELS

Thus far, clinical effects that are an instantaneous function of drug concentration at the site of drug effect have been discussed, as implied by Equation 8. For example, once a hypnotic drug reaches the brain or a neuromuscular-blocking drug reaches the muscles, drug action is almost immediately observed. On the other hand, some effects are significantly more complex. For example, consider the effect of opioids on ventilation. Initially, opioids depress ventilation, and carbon dioxide (CO_2) gradually accumulates. Yet, the accumulation of CO_2 at normal conditions is a strong stimulant for ventilation, thereby partly counteracting the ventilatory depressant effects of opioids. Ventilatory depression is an example in which direct and indirect drug effects are incorporated. The direct effect of the opioid is to depress ventilation, and the indirect effect is to increase arterial tension of CO_2. Modeling the time course of opioid-induced ventilatory depression requires consideration of both components. Bouillon and colleagues developed a model of ventilatory depression that incorporates both direct and indirect effects.[19,20] As is generally the case with indirect-effect models, characterizing drug-induced ventilatory depression requires a consideration of the entire time course of drug therapy, which is embodied by the following differential equation:

$$\frac{d}{dt}Pa_{CO_2} = k_{el} \cdot \left[1 - \frac{Cp(t)\gamma}{C_{50}\gamma + C_p(t)\gamma}\right] \cdot \left[\frac{P_{biophase_{CO_2}}(t)}{P_{biophase_{CO_2}}(0)}\right]^F \cdot Pa_{CO_2}(t) \quad (9)$$

where partial pressure of arterial carbon dioxide (Pa_{CO_2}) is arterial CO_2, $P_{biphase_{CO_2}}$ is CO_2 in the biophase (i.e., brainstem respiratory control circuits), k_{el} is the rate constant for the elimination of CO_2, C_{50} is the effect-site opioid concentration associated with a 50% reduction in ventilatory drive, and F is the steepness or *gain* of the effect of CO_2 on ventilatory drive.

DOSE IMPLICATIONS OF THE BIOPHASE

The delay in onset of clinical effects has important clinical implications. After a bolus, the plasma concentration peaks nearly instantly and then steadily declines. The effect-site concentration starts at zero and increases over time until it equals the descending plasma concentration. The plasma concentration continues to decline. After the moment of identical concentrations, the gradient between plasma and the biophase favors removal of drug from the biophase, and the effect-site concentration decreases. The rate at which the effect-site concentration rises toward the peak after a bolus dictates how much drug must be injected into plasma to produce a given effect. For alfentanil, its rapid plasma effect-site equilibration (large k_{e0}) causes the effect-site concentration to rise rapidly, with a peak produced in approximately 90 seconds. At the time of the peak, approximately 60% of the alfentanil bolus has been distributed into peripheral tissues or eliminated from the body. For fentanyl, the effect-site concentration rises significantly more slowly and peaks 3 to 4 minutes after the bolus.[39] At the time of the peak, more than 80% of the initial bolus of fentanyl has been distributed into tissues or eliminated. As a result of slower equilibration with the biophase, relatively more fentanyl than alfentanil must be injected into plasma, which makes the rate of offset of drug effect after a fentanyl bolus slower than after an alfentanil bolus.

This difference in pharmacokinetics indicates that k_{e0} must be incorporated into dosing strategies on which rational drug selection is dependent. For rapid onset of effect, a drug with a large k_{e0} (short $t_{1/2}$ k_{e0}) should be chosen. For example, for rapid-sequence induction of anesthesia, alfentanil or remifentanil may be the optimal opioid because its peak effect-site concentration coincides with the likely time of endotracheal intubation. However, for a slower induction of anesthesia in which a nondepolarizing neuromuscular blocking drug is used, an opioid with a slower onset of drug effect should be selected to coincide with the peak effect of the neuromuscular blocking drug. In this case, a bolus of fentanyl or sufentanil at the time of induction may be more appropriate. The time to peak effect for the commonly used opioids is shown in Figure 33-8. Knowing k_{e0} (or time to peak effect) also improves titration of the drug by identifying the time at which the clinician should make an assessment of drug effect. For example, midazolam has a slow time to peak effect, and repeat bolus doses should be spaced at least 3 to 5 minutes apart to avoid inadvertent overdosing.

An accurate k_{e0} is also crucial during TCI titrating to a specific effect-site concentration because the initial bolus given to reach the targeted effect-site concentration depends on both the pharmacokinetics and the k_{e0}.[40]

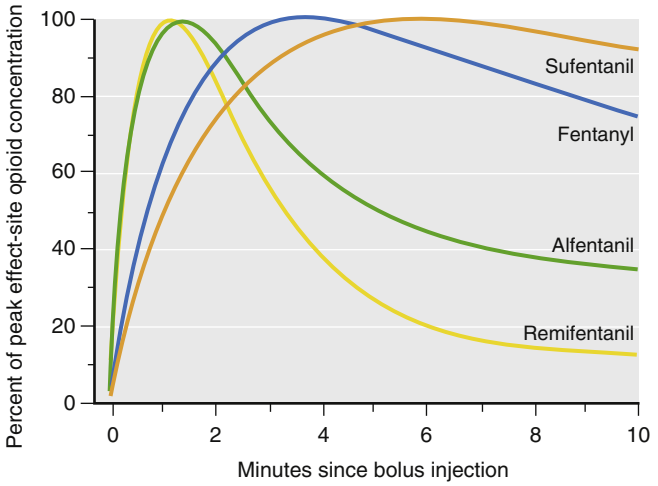

Figure 33-8. Simulated onset and time to peak effect of commonly used opioids based on their k_{e0} and pharmacokinetic parameters. k_{e0}, Rate constant for the transfer of drug from the site of drug effect to the environment.

DRUG POTENCY

Single Drugs

Knowledge about adequate therapeutic drug concentration is crucial to achieve the aim of providing optimal anesthetic conditions. Therefore information on drug potency is essential. Analagous to the concept of minimum alveolar concentration (MAC), the concentration associated with a 50% likelihood of movement in response to skin incision for inhaled anesthetics,[41] is the C_{50}, which is the concentration that produces 50% of the maximum possible drug effect. Defining the C_{50}, similar to the MAC, provides a measure of relative potency between intravenous anesthetics.

There are many ways to look upon C_{50}, taking into consideration whether the clinical effect is a binary or continuous effect. When considering binary effects, the C_{50} might be the drug concentration that prevents response (e.g., movement, hypertension, release of catecholamines) to a particular stimulus (e.g., surgical incision, endotracheal intubation, spreading of the sternum) in 50% of patients. In this case, each combination of stimulus and response may have a unique C_{50}. When C_{50} is defined as the drug concentration that produces a given response in 50% of patients, a 50% probability of response is also likely in a given patient. Defining C_{50} as the concentration that produces a given drug effect in 50% of individuals implicitly assumes that the effect can be achieved in all individuals. Some drugs exhibit a ceiling effect. For example, a ceiling effect may exist on the ability of opioids to suppress response to noxious stimulation. When a ceiling in drug effect exists, some patients may not exhibit the drug effect even at infinitely large doses. In this case, C_{50} is not the concentration that causes the drug effect in 50% of patients but is the concentration associated with the drug effect in one half of whatever fraction of patients is able to respond.

Several studies have been performed to establish appropriate concentrations of intravenous anesthetics

TABLE 33-2 **STEADY-STATE CONCENTRATIONS FOR PREDEFINED EFFECTS***

Drug	C_{50} for EEG Depression†	C_{50} for Incision or Painful Stimulus‡	C_{50} for Loss of Consciousness§	C_{50} for Spontaneous Ventilation‖	C_{50} for Isoflurane MAC Reduction	MEAC
Alfentanil (ng/mL)	500-600	200-300	—	170-230	50	10-30
Fentanyl (ng/mL)	6-10	4-6	—	2-3	1.7	0.5-1
Sufentanil (ng/mL)	0.5-0.75	(0.3-0.4)	—	(0.15-0.2)	0.15	0.025-0.05
Remifentanil (ng/mL)	10-15	4-6	—	2-3	1.2	0.5-1
Propofol (μg/mL)	3-4	4-8	2-3	1.33	—	—
Thiopental (μg/mL)	15-20	35-40	8-16	—	—	—
Etomidate (μg/mL)	0.53	—	0.55	—	—	—
Midazolam (ng/mL)	250-350	—	125-250	—	—	—

EEG, Electroencephalography; *MAC,* minimum alveolar concentration; *MEAC,* minimum effective plasma concentration providing postoperative analgesia.
*Values in parentheses are estimated by scaling to the alfentanil C_{50} (see text for details).
†C_{50} for depression of the EEG is the steady-state serum concentration that causes a 50% slowing of the maximal EEG, except for midazolam, in which the C_{50} is associated with 50% activation of the EEG.
‡C_{50} for skin incision is the steady-state plasma concentration that prevents a somatic or autonomic response in 50% of patients.
§C_{50} for loss of consciousness is the steady-state plasma concentration for absence of a response to a verbal command in 50% of patients.
‖C_{50} for spontaneous ventilation is the steady-state plasma concentration associated with adequate spontaneous ventilation in 50% of patients.

and opioids for various clinical endpoints and the effect of drug interactions (Table 33-2).[42-49]

Another interpretation of C_{50} is the concentration that produces 50% of the maximum possible physiologic response. For example, the C_{50} for an EEG response is the drug concentration that provides 50% depression of the maximal EEG effect. The C_{50} for EEG response has been measured for the opioids alfentanil,[50] fentanyl,[50] sufentanil,[51] and remifentanil.[52-54] It has also been determined for thiopental,[44,55,56] etomidate,[48] propofol,[26] and benzodiazepines[57] (see Table 33-2). Other measures such as pupillary dilation in response to a noxious stimulus[58] and pressure algometry[21] were used to measure opioid potency and revealed slightly different values for C_{50}, which indicates that observation of drug potency also depends on the applied measure of drug effect.

As mentioned, C_{50} can be used to compare potency among drugs. For example, Glass and colleagues[59] determined the potency of remifentanil compared with alfentanil using ventilatory depression as the measure of opioid effect. In their study, the C_{50} for depression of minute ventilation was 1.17 ng/mL and 49.4 ng/mL for remifentanil and alfentanil, respectively. Using this difference in C_{50}, they concluded that remifentanil is approximately 40 times more potent than alfentanil.

To be entirely independent of dosing history, C_{50} must be determined at steady state, which is rarely possible because most anesthetic drugs do not reach steady state during a continuous infusion until many hours have passed. However, if the drug exhibits rapid equilibration between plasma and the effect site and the investigator waits long enough after starting the infusion, then this choice can be reasonably satisfactory. For example, Ausems and colleagues[60,61] used a continuous infusion of alfentanil in their experiments, which quickly equilibrated. They also recorded their measurements after the effect-site concentration had equilibrated with plasma.

A second alternative to performing a true steady-state experiment is to use mathematic modeling to calculate the effect-site concentrations of drug at the time of measurement, as proposed by Hull and colleagues[15] and Sheiner and colleagues.[16] The relationship between effect-site and plasma concentrations is graphically represented in Figure 33-5 and mathematically in Equation 6. Calculating effect-site concentrations is the same as attempting to determine the steady-state plasma concentrations that produce the observed drug effect. When the C_{50} reflects effect-site concentrations, it is represented as Ce_{50} to distinguish it from values of C_{50} that are based on plasma concentrations, which are then termed Cp_{50}. However, the distinction is artificial. In both cases, C_{50} is intended to represent the steady-state plasma drug concentration associated with a given drug effect.

A third alternative to performing a steady-state experiment is to establish a pseudo–steady state with the use of computer-controlled drug delivery. This method has become the state-of-the-art for determining the C_{50} for anesthetic drugs, and many of the C_{50} values referenced earlier were determined at pseudo–steady state with the use of computer-controlled drug delivery. Typically, maintaining a constant plasma steady-state concentration for four to five plasma effect-site equilibration half-lives (e.g., 10 to 15 minutes for fentanyl) is required. Such a long delay is not necessarily needed when computer-controlled drug delivery is used. Effect-compartment TCIs can be used to target the concentration at the effect site rather than the plasma concentration and thereby rapidly establishing plasma–effect site equilibration.[28,62] For example, Kodaka and associates reported predicted values of propofol effect-site concentration C_{50} between 3.1 μg/mL and 4.3 μg/mL for insertion of various laryngeal airway masks, depending on the type of laryngeal mask.[63] Cortinez and associates used TCI to determine the C_{50} of remifentanil and fentanyl for accurate pain relief during extracorporeal shock wave lithotripsy in relation with possible side effects and found that remifentanil and fentanyl C_{50} were 2.8 ng/mL and 2.9 ng/mL, respectively.[64] At C_{50}, the probability of having a respiratory rate less than 10 breaths per minute was 4% for remifentanil and 56% for fentanyl. Thus several ways can establish C_{50} in terms of steady-state concentrations. C_{50} can be estimated through mathematic effect-site modeling or can be experimentally measured with the use of computer-controlled drug delivery to establish a pseudo–steady

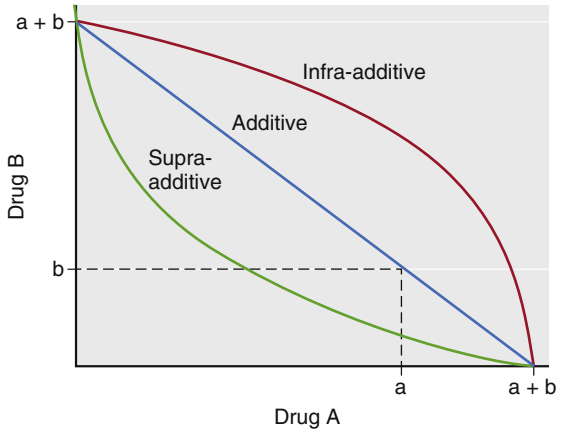

Figure 33-9. Pharmacodynamic drug interactions.

state quickly. Either way, when performing studies to define the concentration-effect relationship, equilibrium must exist or be modeled between the biophase (the site of effect) and plasma or blood (where the concentration is actually measured).

When C_{50} is defined in terms of the concentration associated with a response in one half of a population, that same C_{50} is the concentration associated with a 50% probability of response in a typical individual. However, individual patients are not typical individuals but rather will have their own value for C_{50}. Expressed in clinical terms, different patients have different anesthetic requirements for the same stimulus. For example, the minimal effective analgesic concentration of fentanyl is 0.6 ng/mL, but it varies among patients from 0.2 to 2.0 ng/mL.[65] The minimal effective analgesic concentrations of alfentanil[66] and sufentanil[67] similarly vary among patients by a factor of 5 to 10. This range encompasses both variability in the intensity of the stimulus and variability of the individual patient. However, this wide range reflects the clinical reality that must be accounted for when dosing regimens are designed. Because of this variability, intravenous anesthetics should be titrated to each patient's unique anesthetic requirement for the given stimulus.

Pharmacodynamic Drug Interactions

Drug interactions cause the C_{50} of one drug to shift in response to the administration of a second drug. This drug interaction can be additive, supra-additive (synergistic) or infra-additive (antagonistic). As observed in the isobologram (Fig. 33-9), for additive drugs with equal potency, the cumulative effect resulting from doses a and b for substances A and B, respectively, equals the effect obtained with the injection of either drug A or B solely in a dose a + b. If the drugs interact synergistically, then the combination of A and B will generate a more pronounced effect than additive. For antagonistic drug interaction, the combination of A and B will result in a less pronounced effect than additive. In general, additive drug interactions occur when combining drugs acting by the same mechanism and synergistic or antagonistic interaction when combining drugs acting by a different mechanism.[68] Hendrickx and co-workers (Fig. 33-10) reviewed the available literature and summarized the available data on drug interactions in humans and animals for hypnosis and immobility.[68]

Investigating one isobole of the interaction spectrum (at the 50% probability level of a specific drug response) provides a rudimentary insight on the interaction characteristics but reveals only limited information about other levels of drug effect (e.g., at the clinically more important level of 95% probability of drug response). As drug interactions may vary among drug effect levels (e.g., additive at the 50% level but synergistic at the 95% level), the ultimate aim is to characterize the response surface describing all levels of effect. Pharmacodynamic response surface models generate figures that are three- (or even higher) dimensional structures that have been developed to describe the relationship quantitatively between two or more drug concentrations and their combined clinical effect (Fig. 33-11). Response surface models are powerful representations of drug interactions as they combine information about the full range of isoboles resulting from the concentration response curves of all combinations of the drugs involved.[69,70] Using the mathematically defined response surface, the corresponding drug effect for any two or more drug concentrations of the interacting drugs can be predicted.[69,71] Various methodologic approaches to response surface models are found in the literature.[72]

Intravenous opioids are frequently combined with volatile anesthetics during anesthesia. The reduction of the MAC for a given volatile by a given opioid dose can be applied to investigate the potency and efficacy of opioids.[73-75] These MAC reduction studies reveal a general pattern, irrespectively of which opioid or volatile anesthetic has been used. Low concentrations of an opioid result in a substantial reduction of MAC (Fig. 33-12). With increasing concentrations of the opioid, MAC continues to decrease until a plateau is reached and, consequently, a further increase of the opioid dose is futile.[76]

The previously mentioned MAC reduction studies show the effect of a single opioid dose on a single point of a dose-response curve but, nonetheless, form the basis for more detailed surface interaction studies.[77] To characterize the interaction between sevoflurane and remifentanil in blunting responses to verbal (OAA/S scale) and painful stimuli (pressure algometry, electrical tetanic stimulus, and thermal stimulation), Manyam and coworkers constructed a response surface for each pharmacodynamic response using a Logit model approach and found synergy between sevoflurane and remifentanil for all responses. More specifically, a remifentanil effect-site concentration of 1.25 ng/mL was able to more than halve the sevoflurane requirements for preventing movement to pain.[78] Because this study suffered from nonsteady-state conditions at the moment of measurements, the authors improved their data using calculated effect-site sevoflurane concentrations and a Greco model instead of a Logit approach.[79] Accounting for the time lag between sevoflurane effect-site concentration and end-tidal concentration improved the predictions of responsiveness during anesthesia but had no effect on the accuracy of prediction of a response to a noxious stimulus in recovery. They concluded that models may be useful in predicting events of clinical interest, but large-scale evaluations with numerous patients are needed to better characterize

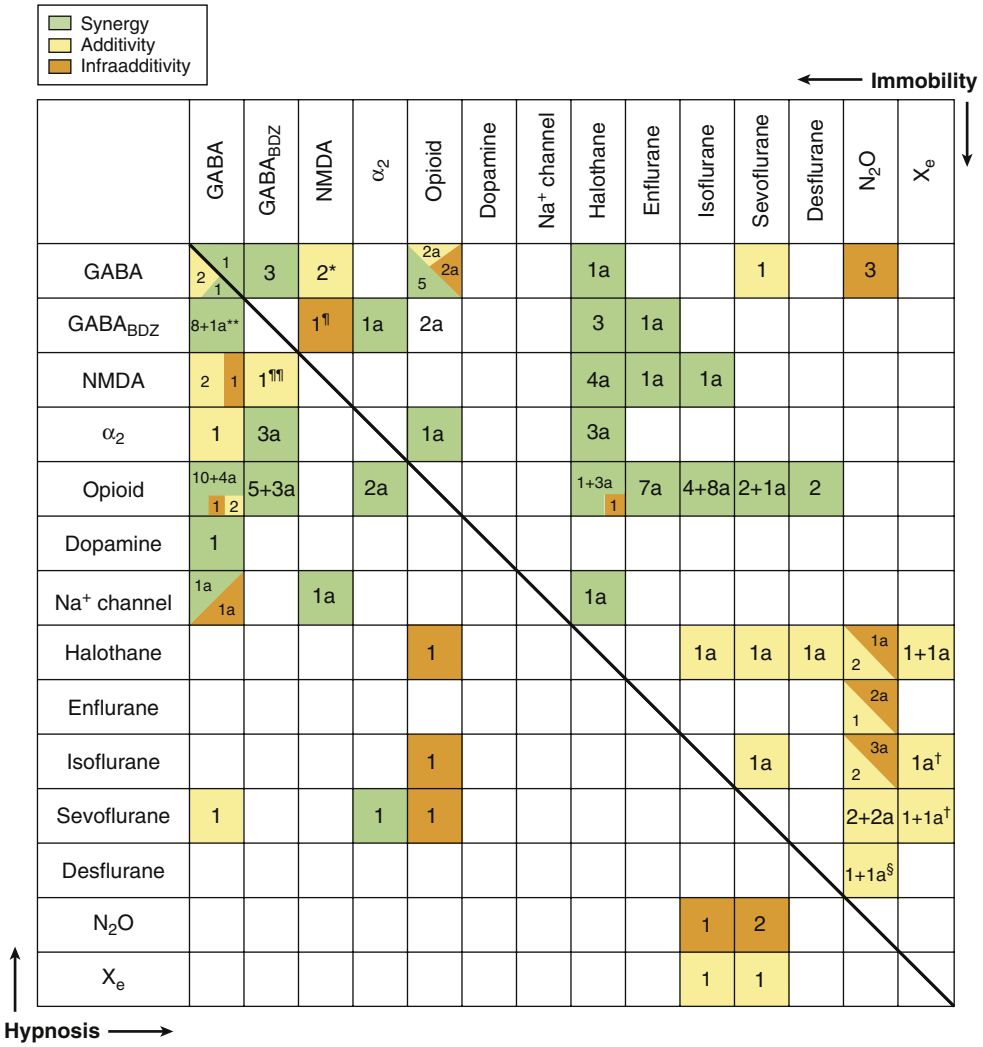

Figure 33-10. Interaction grid summarizing the available data on drug interactions in humans and animals for hypnosis and immobility. Drugs are organized by pharmacologic class: gamma-aminobutyric acid (GABA)–acting drugs (propofol, thiopental, methohexital, and etomidate); GABA agents acting at the benzodiazepine ($GABA_{BDZ}$)-binding site (midazolam, diazepam); *N*-methyl-D-aspartate (NMDA)-receptor antagonist (ketamine); adrenergic agonists (α_2) (dexmedetomidine, clonidine); opioid-acting drugs at opioid receptor (morphine, alfentanil, fentanyl, sufentanil, and remifentanil); dopamine at dopamine antagonists (droperidol, metoclopramide); sodium (Na^+) channel blockers (lidocaine, bupivacaine); and anesthetic gases. The right upper half of the grid *(above the thick diagonal)* summarizes the interactions for the endpoint of immobility; the left lower half *(below the thick diagonal)* summarizes the interactions for the endpoint of hypnosis. Synergy is coded as *green,* additivity as *yellow*, and infra-additivity as *dark orange.* The number refers to the number of studies attesting to a particular interaction; if one study documents two interactions (e.g., isoflurane with both fentanyl and alfentanil), then they are counted separately. Animal data carry the suffix *a* after the number of studies, human data have no suffix.

*Reanalysis: propofol-ketamine interaction in humans is infra-additive for immobility.

**Reanalysis: thiopental-midazolam interaction in humans is additive for hypnosis.

¶Reanalysis: ketamine-midazolam interaction in humans is infra-additive for hypnosis and additive for immobility.

§Infra-additivity between desflurane and nitrous oxide (N_2O) has been suggested in a small subgroup of 18- to 30-year-old patients.

(From Hendrickx JF, Eger EI 2nd, Sonner JM, et al: Is synergy the rule? A review of anesthetic interactions producing hypnosis and immobility, Anesth Analg *107:494-506, 2008. Used with permission.)*

model performance. Heyse and colleagues (Fig. 33-13) found that the pharmacodynamic interaction between sevoflurane and remifentanil for tolerance to shaking and shouting (TOSS), tetanic stimulation (TTET), laryngeal mask airway insertion (TLMA), and laryngoscopy (TLAR) using the Fixed C50(O) Hierarchical model was strongly synergistic for both the hypnotic and the analgesic components of anesthesia and showed the importance of exploring various surface model approaches when studying drug interactions.[72]

For total intravenous anesthesia, interactions associated with various drug combinations and concentrations have been described. The concept of *balanced* anesthesia is based on the assumption that drug combinations will be synergistic in anesthetic effect (however defined) but not in toxicity. Such synergism has been demonstrated for a variety of drug combinations but not for others[68,80] (see Fig. 33-10). Zanderigo and colleagues[81] developed the *well-being model*, a new interaction model to describe both positive and negative effects of drug combinations (Fig. 33-14).

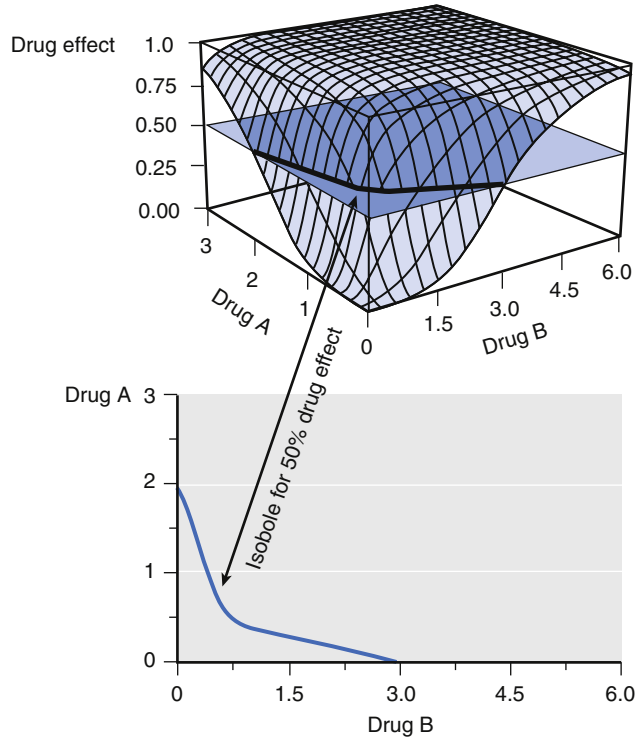

Figure 33-11. Relationship between a response surface and a standard isobologram. Conventional isobolographic analysis, whether for doses or concentrations, describes only the concentration of both drugs that yields a 50% drug effect and thus fails to capture the entire response surface. *(From Minto CF, Schnider TW, Short TG, et al: Response surface model for anesthetic drug interactions,* Anesthesiology *92:1603-1616, 2000. Used with permission.)*

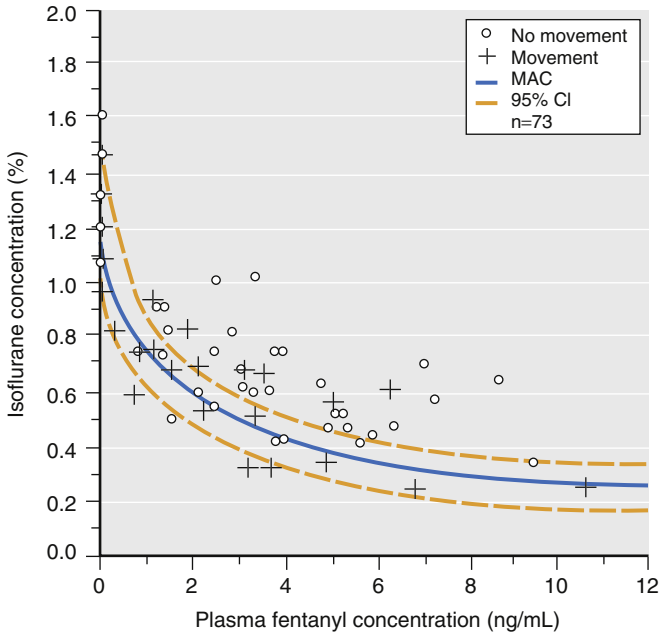

Figure 33-12. Interaction of isoflurane and fentanyl in preventing a somatic response at skin incision (i.e., minimum alveolar concentration [MAC] reduction of isoflurane). The *blue line* represents the concentrations of isoflurane and fentanyl when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. The *dotted gold lines* represent the 95% confidence interval (CI) of the MAC at each combination of fentanyl and isoflurane. *(From McEwan AI, Smith C, Dyar O, et al: Isoflurane MAC reduction by fentanyl,* Anesthesiology *78:864-869, 1993. Used with permission.)*

More profound synergy for specific endpoints related to analgesia and hypnosis has also been demonstrated for the interaction between propofol and opioids. Thus when anesthetic regimens are designed that rely on synergy to produce the anesthetic state, distinguishing the desired endpoint—loss of consciousness or ablation of response to noxious stimulation—is important. Different combinations of drugs may be required to achieve each endpoint. Vuyk and colleagues characterized the interaction between propofol and alfentanil for several endpoints: loss of response to endotracheal intubation, loss of response to incision and retraction of the peritoneum, and emergence from anesthesia (Fig. 33-15).[82] The most profound stimulation was tracheal intubation, and the abolition of that stimulus required a propofol concentration equal to or more than 2 μg/mL. More details for optimal drug combinations based on the findings from Vuyk and co-workers[82] are provided in Table 33-3.

Minto and colleagues published *response surfaces* for combinations of midazolam-alfentanil, propofol-alfentanil, and midazolam-propofol associated with the loss of response to verbal command (Fig. 33-16).[83] They also extended response surface methodology to describe the simultaneous interaction of three drugs. Rendering the full interaction surface for three drugs would require drawing the graph in four dimensions. If the graph is limited to the interaction at 50% drug effect, then it can be rendered in three dimensions (Fig. 33-17).

In addition to the quantal responses, various studies investigated the interaction between hypnotics and opioids as measured with continuous measures. The effect of combined drug administration on spontaneous and evoked EEG–derived indices was found to be important and existing but often in studies that did not provide sufficient data for full response surface model development.[26,84,85] Fortunately, more accurate designed studies[71] using surface modeling techniques revealed the interaction between hypnotics and opioids. Bouillon and colleagues found synergy between propofol and remifentanil regarding hypnosis as measured by the BIS and EEG approximate entropy. They also found that both indices were more sensitive to propofol than remifentanil.[86] Others found conflicting results for the effect of opioids on the BIS.[87] More recently, Gambus and colleagues modeled the effect of propofol and remifentanil combinations for sedation-analgesia in endoscopic procedures using an adaptive neurofuzzy inference system. Both spontaneous and evoked EEG–derived indices (e.g., BIS or autoregressive auditory-evoked potential index [AAI/2] and index of consciousness [IoC]) were used. They found, based on these models, that the propofol and remifentanil effect-site concentration pairs provide a Ramsay Sedation Score of 4 ranging from (1.8 $\mu g/mL^{-1}$, 1.5 ng/mL^{-1}) to (2.7 $\mu g/mL^{-1}$, 0 ng/mL^{-1}), associated with a BIS of 71 to 75, AAI/2 values of 25 to 30, and IoC of 72 to 76, respectively. The presence of noxious stimulation increases the requirements of propofol and remifentanil

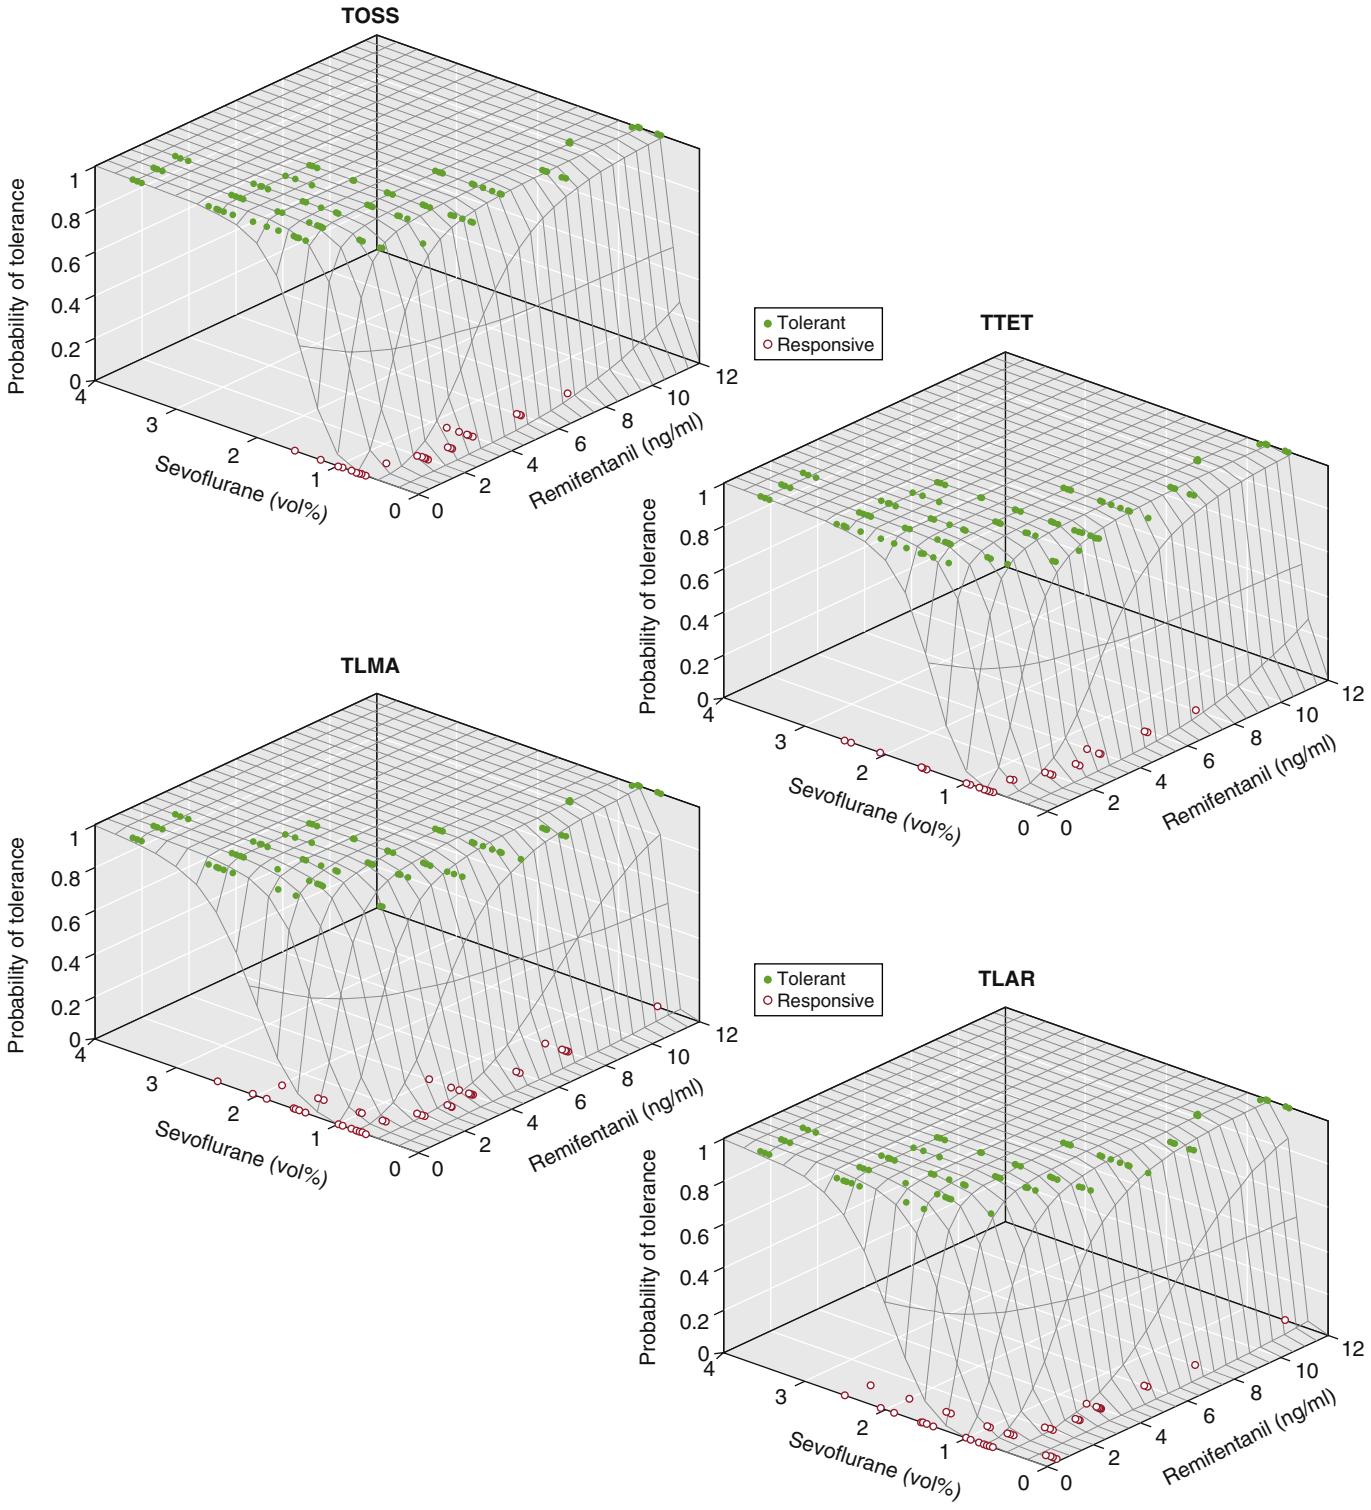

Figure 33-13. Response surface for probability of tolerance to shaking and shouting (TOSS), tetanic stimulation (TTET), laryngeal mask airway insertion (TLMA), and laryngoscopy (TLAR) for the Fixed C50(O) Hierarchical model. The solid lines at probability 0.5 represent the 50% isoboles. *(From Heyse B, Proost JH, Schumacher PM, et al: Sevoflurane remifentanil interaction: comparison of different response surface models,* Anesthesiology *116:311-323, 2012. Used with permission.)*

The optimal concentrations range results from the intersection between the well-being surface and the plane representing a well-being value of 0.8. *(From Zanderigo E, Sartori V, Sveticic G, et al: The well-being model: a new drug interaction model for positive and negative effects,* Anesthesiology *104:742-753, 2006. Used with permission.)*

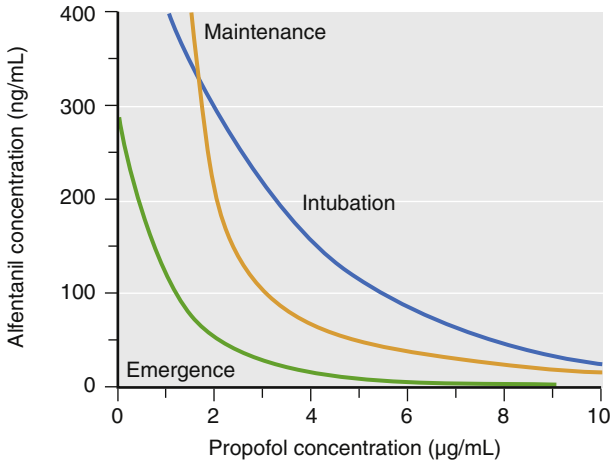

Figure 33-15. Interaction between alfentanil and propofol on three different endpoints: response to intubation (*blue line*), maintenance of anesthesia (*gold line*), and concentrations associated with emergence from anesthesia (*green line*). The curve shows the concentrations associated with a 50% probability of the respective endpoint. *(Adapted from Vuyk J, Lim T, Engbers FH, et al: The pharmacodynamic interaction of propofol and alfentanil during lower abdominal surgery in women,* Anesthesiology *83:8-22, 1995.)*

to achieve the same degree of sedative effects.[88] Other effects of drug combinations were studied. Bouillon and associates and Nieuwenhuijs and associates investigated the effects of hypnotic-opioid combinations on cardiorespiratory control.[87,89] These data show dose-dependent effects on respiration at relatively low concentrations of propofol and remifentanil. When combined, their effect on respiration is strikingly synergistic, resulting in severe respiratory depression.

Surface models were also used to optimize drug administration in challenging situations such as short-duration procedures in spontaneous breathing patients. LaPierre and co-workers[90] explored remifentanil-propofol combinations that led to a loss of response to esophageal instrumentation, a loss of responsiveness, and/or an onset of ventilatory depression requiring intervention. They found that the combinations that allowed esophageal instrumentation and avoided intolerable ventilatory depression and/or loss of responsiveness primarily clustered around remifentanil-propofol effect-site concentrations ranging from 0.8 to 1.6 ng/mL and 1.5 to 2.7 µg/mL, respectively. However, blocking the response to esophageal instrumentation and avoiding both intolerable ventilatory depression and/or a loss of responsiveness is difficult. It may be necessary to accept some discomfort and blunt, rather than block, the response to esophageal instrumentation to consistently avoid intolerable ventilatory depression and/or loss of responsiveness.

The interactions between hypnotics such as propofol and sevoflurane should be understood, because these drugs are frequently used sequentially. Schumacher and colleagues[91] used response surface methodology to examine the influence of this interaction on the probability of TOSS and three noxious stimuli (TTET, TLMA, and TLAR). They found that for both EEG suppression and tolerance to stimulation, the interaction of propofol and sevoflurane were additive. Others found similar results on the C_{50} level.[92] Hammer and colleagues[93] determined the pharmacodynamic interaction of propofol and dexmedetomidine during pediatric esophagogastroduodenoscopy and concluded that the concentration of propofol at which 50% of patients are adequately anesthetized (EC_{50}) in children was unaffected by a concomitant intravenous infusion of dexmedetomidine 1 µg/kg body weight given over 10 minutes.

DESIGNING DOSING REGIMENS

BOLUS DOSE CALCULATIONS

The definition of concentration is drug mass per unit of volume. The definition of concentration can be rearranged to find the amount of drug required to produce any desired concentration for a known volume.

$$Amount = C_T \cdot Volume \qquad (10)$$

where C_T is the desired or *target* concentration. This formula is often used to calculate the initial (loading) bolus dose required to achieve a given concentration. The problem with applying this concept to anesthetic drugs is that there are several volumes of distribution: V_1 (central compartment), V_2 and V_3 (the peripheral compartments), and Vd_{ss} (the sum of the individual volumes). V_1 is usually significantly smaller than Vd_{ss}, and thus saying that the loading dose should be something between $C_T \times V_1$ and $C_T \times Vd_{ss}$ is tempting.

Consideration should be given to the dose of fentanyl required to attenuate the hemodynamic response to endotracheal intubation when combined with thiopental. The C_{50} for fentanyl, combined with thiopental for intubation, is approximately 3 ng/mL. The V_1 and Vd_{ss} for fentanyl are 13 L and 360 L, respectively. The aforementioned

TABLE 33-3 PROPOFOL/OPIOID COMBINATIONS ASSOCIATED WITH THE FASTEST RECOVERY FROM ANESTHESIA

Infusion Duration (min)		Propofol/Alfentanil (μg/mL; ng/mL)	Propofol/Sufentanil (μg/mL; ng/mL)	Propofol/Remifentanil (μg/mL; ng/mL)
15	$C_{optimal}$	3.25/99.3	3.57/0.17	2.57/4.70
	$C_{awakening}$	1.69/65.0	1.70/0.10	1.83/1.93
	Time to awakening (min)	8.2	9.4	5.1
60	$C_{optimal}$	3.38/89.7	3.34/0.14	2.51/4.78
	$C_{awakening}$	1.70/64.9	1.70/0.10	1.83/1.93
	Time to awakening (min)	12.2	11.9	6.1
300	$C_{optimal}$	3.40/88.9	3.37/0.14	2.51/4.78
	$C_{awakening}$	1.70/64.9	1.70/0.10	1.86/1.88
	Time to awakening (min)	16.0	15.6	6.7

$C_{optimal}$ represents combinations associated with a 50% probability of a response to surgical stimuli; $C_{awakening}$ concentrations represent the estimated concentrations at which consciousness will be regained; and Time to awakening represents the estimated time from termination of the infusion to return of consciousness in 50% of patients.

(From Vuyk J, Mertens MJ, Olofsen E, et al: Propofol anesthesia and rational opioid selection: determination of optimal EC50-EC95 propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness, Anesthesiology *87:1549-1562, 1997; and modified from Absalom A, Struys MMRF:* An overview of TCI and TIVA*, ed 2, 2007. Gent, Belgium, Academia Press. Used with permission.)*

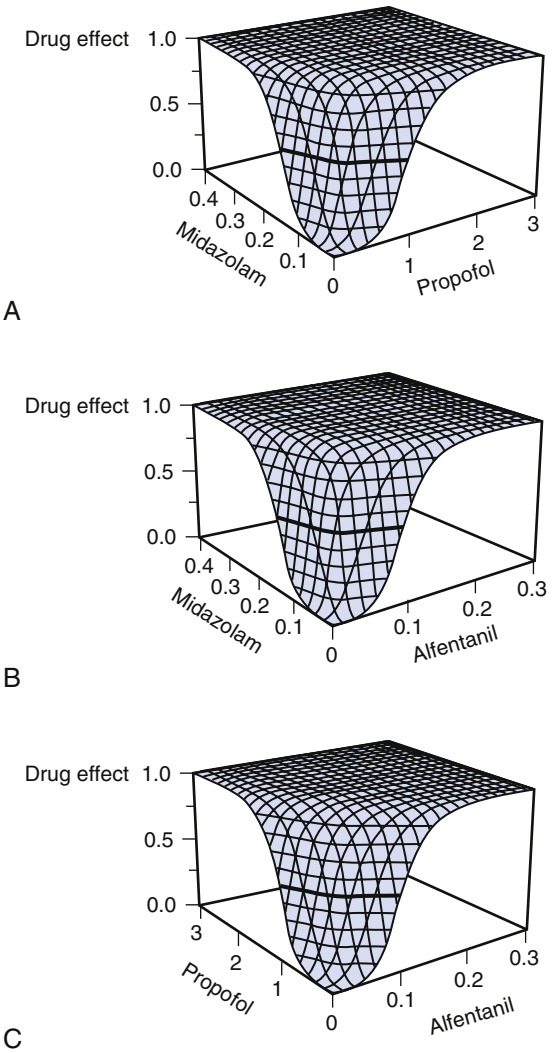

Figure 33-16. Response surface for each of the paired interactions between propofol and midazolam (**A**), alfentanil and midazolam (**B**), and alfentanil and propofol (**C**) on the probability of opening eyes to a verbal command. The isoboles for a 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, and 90% response are shown. *(From Minto CF, Schnider TW, Short TG, et al: Response surface model for anesthetic drug interactions,* Anesthesiology *92:1603-1616, 2000.)*

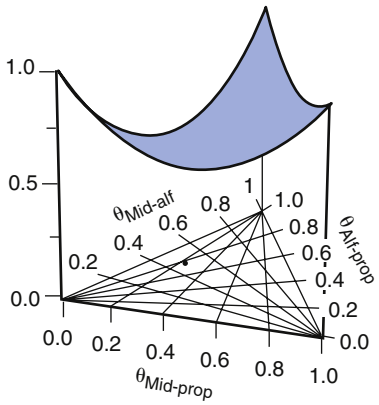

Figure 33-17. Interaction at 50% drug effect (C_{50}) among propofol, midazolam, and alfentanil. Downward deflection of the surface represents synergy, in units of fractional reduction in C_{50}. The three edges represent relative amounts of propofol to midazolam ($\theta_{Mid\text{-}prop}$), alfentanil to midazolam ($\theta_{Mid\text{-}alf}$), and alfentanil to propofol ($\theta_{Alf\text{-}prop}$). The surface between the edges represents the relative synergy of all three drugs taken together. *(From Minto CF, Schnider TW, Short TG, et al: Response surface model for anesthetic drug interactions,* Anesthesiology *92:1603-1616, 2000.)*

equations can thus be interpreted as suggesting that an appropriate dose of fentanyl to attenuate the hemodynamic response is between 39 μg (3 ng/mL × 13 L) and 1080 μg (3 ng/mL × 360 L). A fentanyl bolus of 39 μg achieves the desired concentration in plasma for an initial instant, but plasma levels almost instantly decrease below the desired target. Levels at the effect site will never be close to the desired target concentration of 3 ng/mL. A fentanyl bolus of 1080 μg, not surprisingly, produces a significant overshoot in plasma levels that persists for hours (Fig. 33-18). Additionally, using equations to calculate the fentanyl dose if the resulting recommendation is to "use a fentanyl dose between 39 and 1080 μg" is absurd.

The usual dosing guidelines for a bolus dose, presented earlier, are designed to produce a specific plasma concentration. Because plasma is not the site of drug effect, calculating the initial bolus on the basis of a desired plasma concentration is irrational. By knowing the k_{e0}

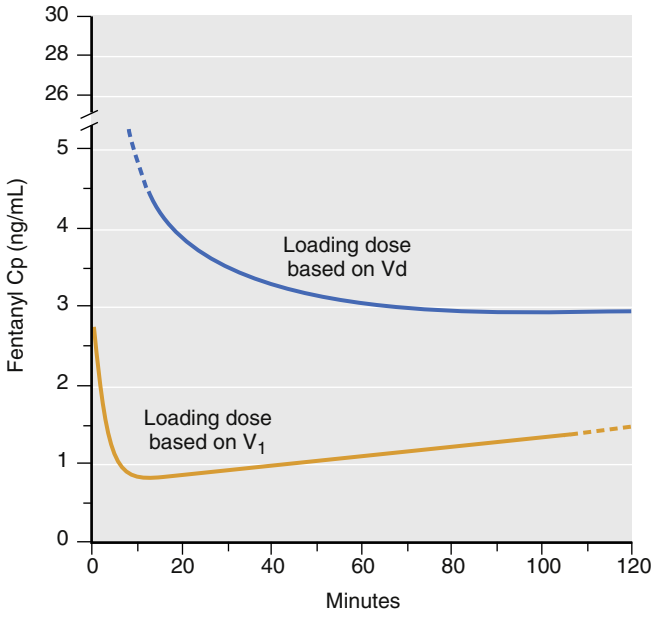

Figure 33-18. Pharmacokinetic simulation demonstrating the limitations of infusion regimens based on simple pharmacokinetic parameters with fentanyl used as an example. These infusion schemes were designed to achieve a fentanyl plasma concentration (Cp) of 3 ng/mL. The *upper blue curve* shows that a regimen using a loading dose based on the volume of distribution followed by a constant infusion based on clearance results in a transient period of very high plasma concentrations. If the same maintenance infusion is given but the loading dose is based on the volume of the central compartment, then the distribution of drug to the peripheral compartments causes the plasma concentration to fall below the desired level until the compartments reach steady-state concentrations as shown in the *lower gold curve*.

of an intravenous anesthetic, a dosing regimen can be designed that yields the desired concentration at the site of drug effect. To avoid an overdose for the patient, a bolus should be selected that produces the desired peak concentration at the effect site.

The decline in plasma concentration between the initial concentration after the bolus (amount/V_1) and the concentration at the time of peak effect can be thought of as dilution of the bolus into a larger anatomic volume than the volume of the central compartment. This introduces the concept of Vd_{pe}, the apparent volume of distribution at the time of peak effect,[28,94] or pseudoequilibration between plasma and the site of drug effect.[95] The size of this volume can be readily calculated from the observation that the plasma and effect-site concentrations are the same at the time of peak effect.

$$Vd_{pe} = \frac{Bolus\ amount}{C_{pe}} \qquad (11)$$

where C_{pe} is the plasma concentration at the time of peak effect.

If the clinical goal is to select the dose required to achieve a certain drug effect without producing an overdose, then Equation 11 can be rearranged by substituting C_T, the target concentration (which is the same in plasma and the effect site at the moment of peak effect), for C_{pe} to calculate the size of the initial bolus

$$Loading\ dose = C_T \cdot Vd_{pe} \qquad (12)$$

The Vd_{pe} for fentanyl is 75 L. To achieve a peak fentanyl effect-site concentration of 3.0 ng/mL requires 225 µg, which produces a peak effect in 3.6 minutes. This dosing guideline is more reasonable, compared with the previous recommendation of a dose between 39 and 1080 µg. Table 33-4 lists V_1 and Vd_{pe} for fentanyl, alfentanil, sufentanil, remifentanil, propofol, thiopental, and midazolam. Table 33-1 lists the time to peak effect and the $t_{1/2}$ k_{e0} of the commonly used intravenous anesthetics.

TABLE 33-4 VOLUME OF DISTRIBUTION AT THE TIME OF PEAK EFFECT

Drug	V_1 (L)	Vd_{pe} (L)
Fentanyl	12.7	75
Alfentanil	2.19	5.9
Sufentanil	17.8	89
Remifentanil	5.0	17
Propofol	6.7	37
Thiopental	5.6	14.6
Midazolam	3.4	31

V_1, Volume of the central compartment; Vd_{pe}, apparent volume of distribution at the time of peak effect.

MAINTENANCE INFUSION RATES

By definition, the rate at which active drug exits the body is systemic clearance (Cl_S) times the plasma concentration. To maintain a given target concentration (C_T) drug must be delivered at the same rate that it is exiting the body. Thus

$$\text{Maintenance infusion rate} = C_T \cdot Cl_s \qquad (13)$$

For drugs with multicompartment pharmacokinetics, which includes all of the intravenous drugs used in anesthetic practice, drug is distributed into the peripheral tissues, as well as cleared from the body. The rate of distribution into tissues changes over time as the tissues equilibrate with plasma. Equation 13 is correct only after the peripheral tissues have fully equilibrated with plasma, which requires many hours. At all other times, this maintenance infusion rate underestimates the infusion rate necessary to maintain a target concentration.

Yet, in some situations, this simple maintenance rate calculation may be acceptable. For example, if an infusion at this rate is used along with a bolus dose based on Vd_{pe} and the drug has a long delay between the bolus and peak effect, then most of the distribution of drug into tissues may have occurred by the time that the effect-site concentration reaches the target concentration. In this case, the maintenance infusion rate calculated as clearance times target concentration may be accurate because Vd_{pe} is sufficiently higher than V_1 to account for the distribution of drug into peripheral tissues. Unfortunately, most drugs used in anesthesia achieve sufficiently rapid equilibration between plasma

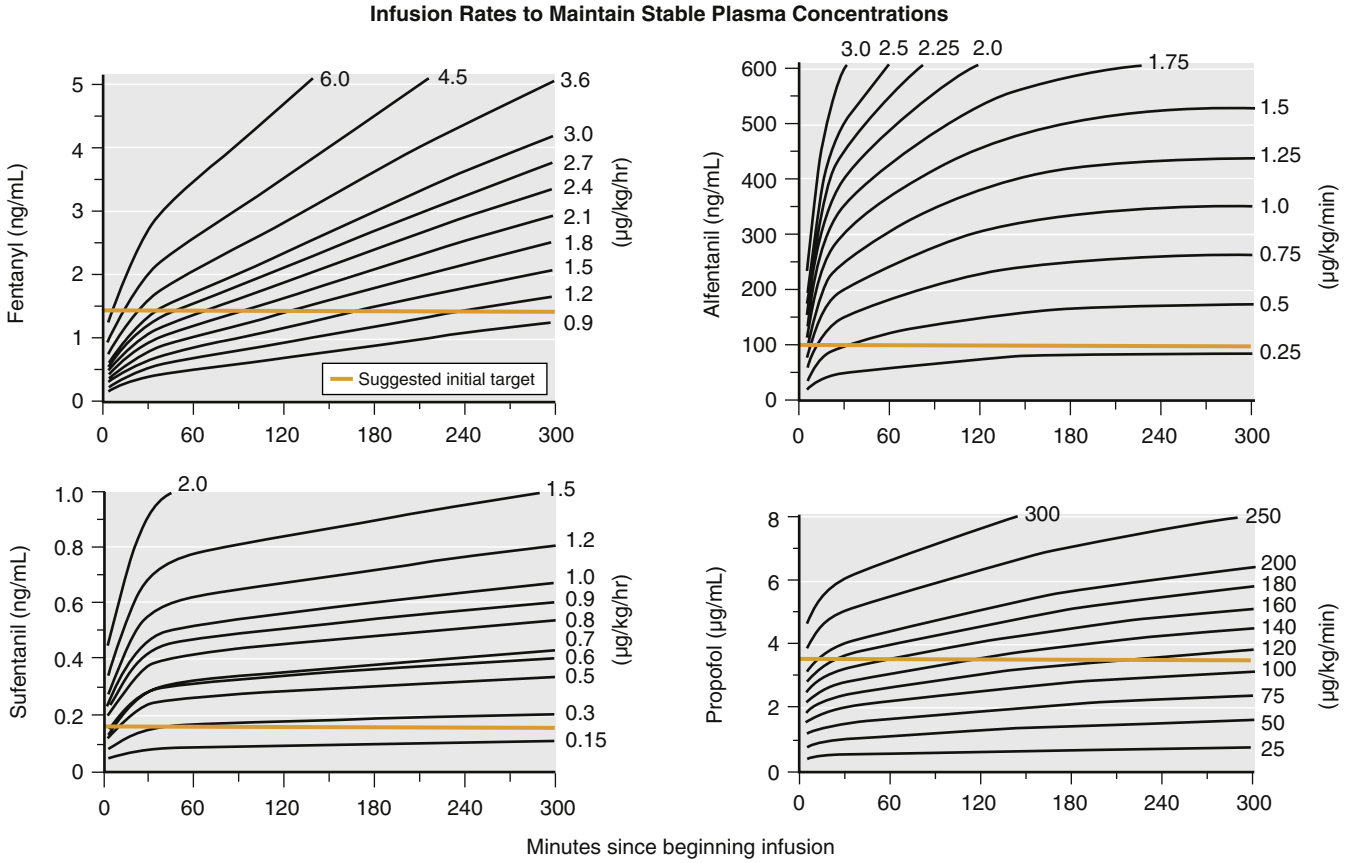

Figure 33-19. Nomogram for calculating maintenance infusion rates to maintain a stable concentration of fentanyl, alfentanil, sufentanil, or propofol. The *y* axis is the desired concentration. The *x* axis is the time relative to the initial bolus. The *diagonal lines* show the infusion rates at different times required to maintain the desired concentration selected on the *y* axis.

and the effect site that Vd_{pe} does not adequately encompass the distribution process, thus making this approach unsuitable.

As such, approaches need to be used that are mathematically and clinically sound. Because the net flow of drug into peripheral tissues decreases over time, the infusion rate required to maintain any desired concentration must also decrease over time. If the initial bolus has been based on Vd_{pe}, no infusion needs be administered until the effect-site concentration peaks. After the peak in effect-site concentration, the (nearly) correct equation to maintain the desired concentration is

$$\text{Maintenance infusion rate} = C_T \cdot V_1 \cdot \left(k_{10} + k_{12}e^{-k_{21}t} + k_{13}e^{-k_{31}t}\right) \qquad (14)$$

This equation indicates that a rapid infusion rate is initially required to maintain C_T. Over time, the infusion rate gradually decreases (see Fig. 33-14). At equilibrium ($t = \infty$), the infusion rate decreases to $C_T \times V_1 \times k_{10}$, which is the same as $C_T \times Cl_S$. Few clinicians would choose to solve such an equation during the administration of an anesthetic. Fortunately, simple techniques can be used in place of solving such a complex expression.

Figure 33-19 is a nomogram in which Equation 14 has been solved; the infusion rates at different times necessary to maintain any desired concentration of fentanyl, alfentanil, sufentanil, and propofol are shown. Because this nomogram is complex, the following review is provided:

The *y* axis represents the target concentration C_T. The *x* axis is the time since the beginning of the anesthetic (i.e., since the initial bolus). The suggested initial target concentrations (shown in gold) are based on the work of Vuyk and colleagues[82] with propofol and alfentanil (see Fig. 33-15) and are scaled to fentanyl and sufentanil according to their relative potencies.[94] The intersections of the target concentration line and the diagonal lines indicate the infusion rate appropriate at each point in time. For example, to maintain a fentanyl concentration of 1.5 ng/mL, the appropriate rates are 4.5 µg/kg/hr at 15 minutes, 3.6 µg/kg/hr at 30 minutes, 2.7 µg/kg/hr at 60 minutes, 2.1 µg/kg/hr at 120 minutes, and 1.5 µg/kg/hr at 180 minutes. Of course, selecting target concentrations and different times of rate adjustment is possible, depending on the clinical circumstances and an assessment of how accurately the intravenous drug needs to be titrated.

RECOVERY FROM ANESTHESIA

Recovery from anesthesia is determined by the pharmacokinetic principles that govern the rate of decrease in drug from the effect compartment once drug administration is terminated, as well as by the pharmacodynamics

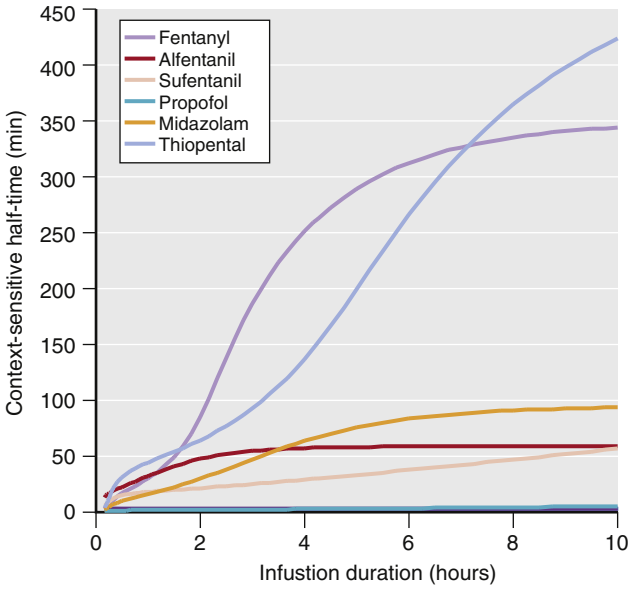

Figure 33-20. Context-sensitive half-times as a function of infusion duration (*context*) derived from pharmacokinetic models of fentanyl, sufentanil, alfentanil, remifentanil, propofol, midazolam, and thiopental. *(From Hughes MA, Glass PSA, Jacobs JR: Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs,* Anesthesiology *76:334-341, 1992.)*

of the drug. Although the terminal elimination half-life is often interpreted as a measure of how short- or long-lasting a drug is, the rate at which drug plasma concentration decreases is dependent on both elimination and redistribution of the drug from the central compartment. The contribution of redistribution and elimination toward the rate of decrease in drug concentration varies according to the duration for which the drug has been administered[94,96] and also the time since the infusion has stopped, because these processes have different rate constants.

In 1985, Schwilden[97] developed a mathematic model to relate the time course of offset of action of inhaled anesthetics to the duration of anesthetic drug delivery. Similarly, Fisher and Rosen[98] demonstrated how the accumulation of muscle relaxants in peripheral volumes of distribution results in slowed recovery with increasing duration of administration. They introduced two measures of the time course of recovery, the time for twitch tension to recover from 5% to 25% and the time for twitch tension to recover from 25% to 75%.

Since then, the time for the plasma concentration to decrease by 50% from an infusion that maintains a constant concentration (e.g., infusion given by Equation 14) has been termed the *context-sensitive half-time*[96] (Fig. 33-20), with the context being the duration of the infusion. The 50% decrease was chosen both for tradition (e.g., half-lives are the time for a 50% decrease with a one-compartment model) and because, very roughly, a 50% reduction in drug concentration appears to be necessary for recovery after the administration of most intravenous hypnotics at the termination of surgery. Depending on circumstances, decreases other than 50% may be clinically relevant. Additionally, sometimes it is the plasma concentration that is of interest, and sometimes it is the effect-site concentration that is of interest. A more general term is the context-sensitive *decrement time*,[99] in which the decrement in concentration is specifically noted, as is the compartment where the decrease is modeled (plasma or effect site). For example, the relationship between infusion duration and the time required for a 70% decrease in fentanyl effect-site concentration is the *context-sensitive 70% effect-site decrement time*.

Context-sensitive effect-site decrement times for varying percent decreases in alfentanil, fentanyl, sufentanil, and remifentanil concentration are illustrated in Figure 33-21. To determine when an infusion should be terminated (to enable awakening of the patient at the end of surgery), the clinician needs to bear in mind the decrease in concentration necessary for recovery, the duration of the infusion (the context), and the context-sensitive, effect-site decrement time required for the necessary decrease.

Context-sensitive decrement times are fundamentally different from the elimination half-life. With monoexponential decay, each 50% decrease in concentration requires the same amount of time, and this time is independent of how the drug is given. This is not true for the context-sensitive half-time. First, as the name is intended to imply, the time needed for a 50% decrease is absolutely dependent on how long the drug was given, with infusion duration being the context to which the name refers. In addition, small changes in percent decrement can result in surprisingly large increases in the time required. The time required for a 60% decrease in drug concentration can be more than twice the time required for a 50% decrease in some situations (see Fig. 33-21).

Context-sensitive decrement times are based on the assumption that plasma or the effect site is maintained at a constant concentration. Such is rarely the case clinically, but the maintenance of constant concentrations is a necessary assumption to provide a unique mathematic solution to the time required for a given percent decrement in plasma or effect-site concentration. Because plasma and effect-site concentrations are rarely kept constant, it is important that context-sensitive decrement times are used as *general* guidelines for interpreting the pharmacokinetics of intravenous drugs and not as *absolute* predictions for any given case or infusion regimen. Automated drug delivery systems can provide more precise predictions of the time required for the plasma or effect-site concentration to decrease to any desired concentration, based on the actual drug dosing in the individual patient, which provides the clinician with guidance for the most appropriate time to terminate the infusion.

Context-sensitive decrement times focus on the role of pharmacokinetics in recovery from anesthesia. Pharmacodynamics plays an important role in recovery as well. Bailey[100] used integrated pharmacokinetic-pharmacodynamic models to define the *mean effect time* as the average time to responsiveness after maintenance of anesthesia at the 90% probability of unresponsiveness. The mean effect time demonstrates that when drugs have a very shallow concentration-versus-response relationship, concentrations must decrease by a significant fraction to provide adequate emergence, which delays recovery from anesthesia. In contrast, recovery is hastened by a steep

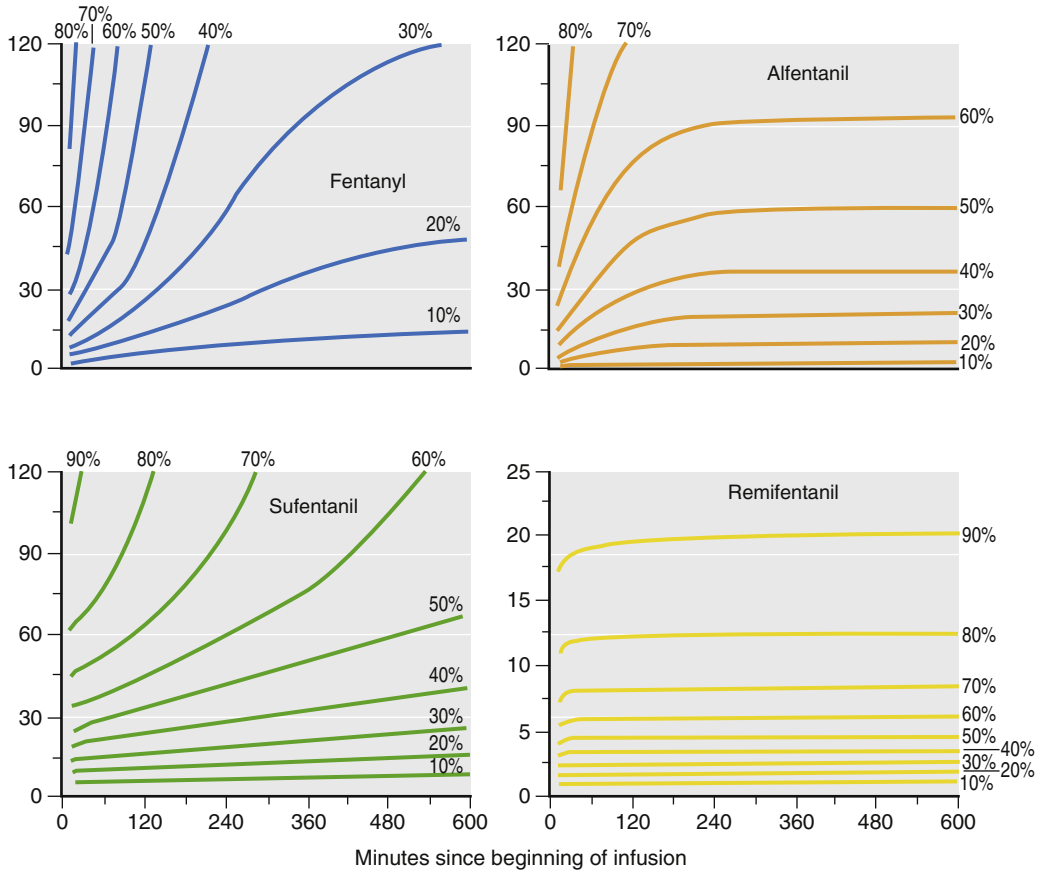

Figure 33-21. Context-sensitive effect-site decrement times for alfentanil, fentanyl, sufentanil, and remifentanil showing the time required for decreases of a given percentage (*labeled for each curve)* from the maintained effect-site concentration after termination of the infusion.

concentration-versus-response relationship, in which emergence from anesthesia occurs after a relatively small fractional decrease in concentration. Most intravenous hypnotics have a moderately steep concentration-versus-response relationship.

Pharmacodynamic drug interactions also play a role in recovery from anesthesia. Interaction relationships predict that the same anesthetic state can be achieved by different ratios of two drugs. One way of selecting the best ratio might be the combination that offers the most rapid recovery. For example, when an opioid is combined with a hypnotic, the rate of recovery from anesthesia depends on the opioid and hypnotic concentrations, the rate of decrease in both drug concentrations, and the relative synergy between them for loss of response to noxious stimulation (i.e., the state maintained during anesthesia) versus the relative synergy for loss of consciousness. Although the time course of decreases in opioid and hypnotic concentrations can be approximately described by their respective context-sensitive decrement times for both drugs (Fig. 33-22; see Fig. 33-15]), the influence of relative synergy for different endpoints must be captured by separate models of the interaction of the drugs for adequate anesthesia and emergence from anesthesia.

Vuyk and co-workers[43] modeled the predicted time to awakening from adequate anesthesia when propofol is combined with fentanyl, sufentanil, alfentanil, or

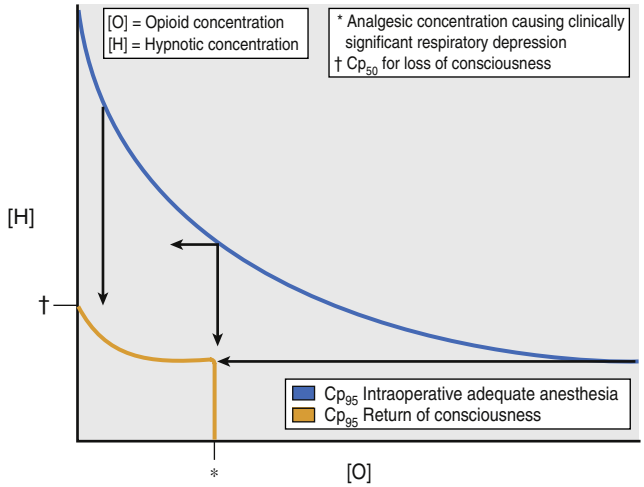

Figure 33-22. Interaction between hypnotics and opioids for the prevention of movement after a noxious stimulus and for awakening and adequate spontaneous ventilation at the end of a surgical procedure. The time to recover at the end of a procedure is dependent on the concentration of both drugs used during surgery and the time for both to decrease below that required for consciousness and adequate spontaneous ventilation (i.e., their context-sensitive decrement times).

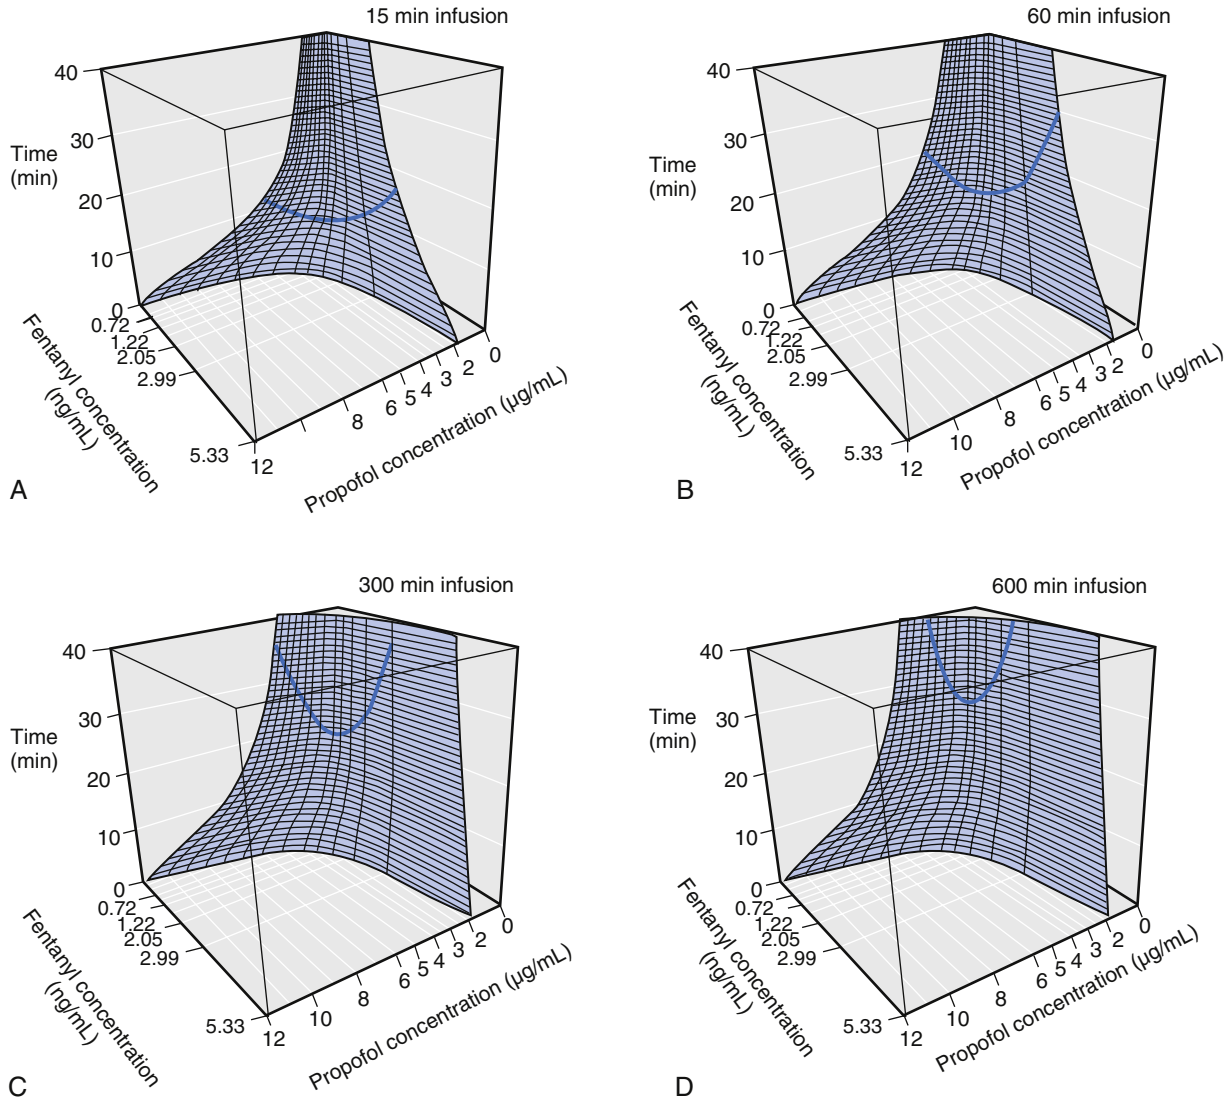

Figure 33-23. Simulation of the interaction of propofol and fentanyl in preventing a somatic response at skin incision and time to recovery. On the *x* axis is the fentanyl concentration, and on the *y* axis is the propofol concentration. The *blue curve* in the lower plane shows the propofol-fentanyl interaction required to provide adequate anesthesia. When the infusion is turned off, the concentrations of each drug decrease, as shown on the *z* axis. The *blue curve* drawn on the recovery surface shows the time to emergence from anesthesia for combinations of fentanyl and propofol after an anesthetic of 15 minutes' (**A**), 60 minutes' (**B**), 180 minutes' (**C**), and 600 minutes' (**D**) duration. The optimal combination for the most rapid recovery is a propofol concentration of 3.0 to 3.5 μg/mL, combined with 1.5 ng/mL fentanyl. As the concentration of propofol or fentanyl increases, the time for recovery increases. In addition, the longer the duration of drug infusion, the longer recovery takes, especially if the optimal combination is not used. *(Modified from Vuyk J, Mertens MJ, Olofsen E, et al: Propofol anesthesia and rational opioid selection: determination of optimal EC_{50}-EC_{95} propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness,* Anesthesiology *87:1549-1562, 1997.*)

remifentanil. Their calculations took into account the interaction between propofol and these opioids to provide adequate anesthesia and the interaction between propofol and opioids on consciousness levels on emergence from anesthesia (Figs. 33-23 and 33-24). Recovery times vary with the choice of opioid and the relative balance of opioid and propofol during maintenance of anesthesia. For example, the upper left of Figure 33-23 simulates the emergence from a propofol-fentanyl anesthetic of 15-minute duration. The simulations assume a steady concentration of fentanyl and propofol throughout the anesthesia, similar to the underlying assumption of context-sensitive decrement times. The blue curve in the lower plane is the interaction curve between fentanyl and propofol; it ranges from no fentanyl and 12 μg/mL of propofol on the left to 6 ng/mL of fentanyl and 1.8 μg/mL of propofol on the right. In theory, any point along this curve would ensure maintenance of equivalent depth of anesthesia. When the infusion is turned off after 15 minutes of anesthesia, the concentrations of both drugs decrease. The decreasing concentrations of propofol and fentanyl when the infusion is turned off can be found by the upward lines drawn from different points on the interaction curve, with the distance away from the lower plane representing time. Taken together, these upward lines represent a *recovery surface*. The blue line drawn on

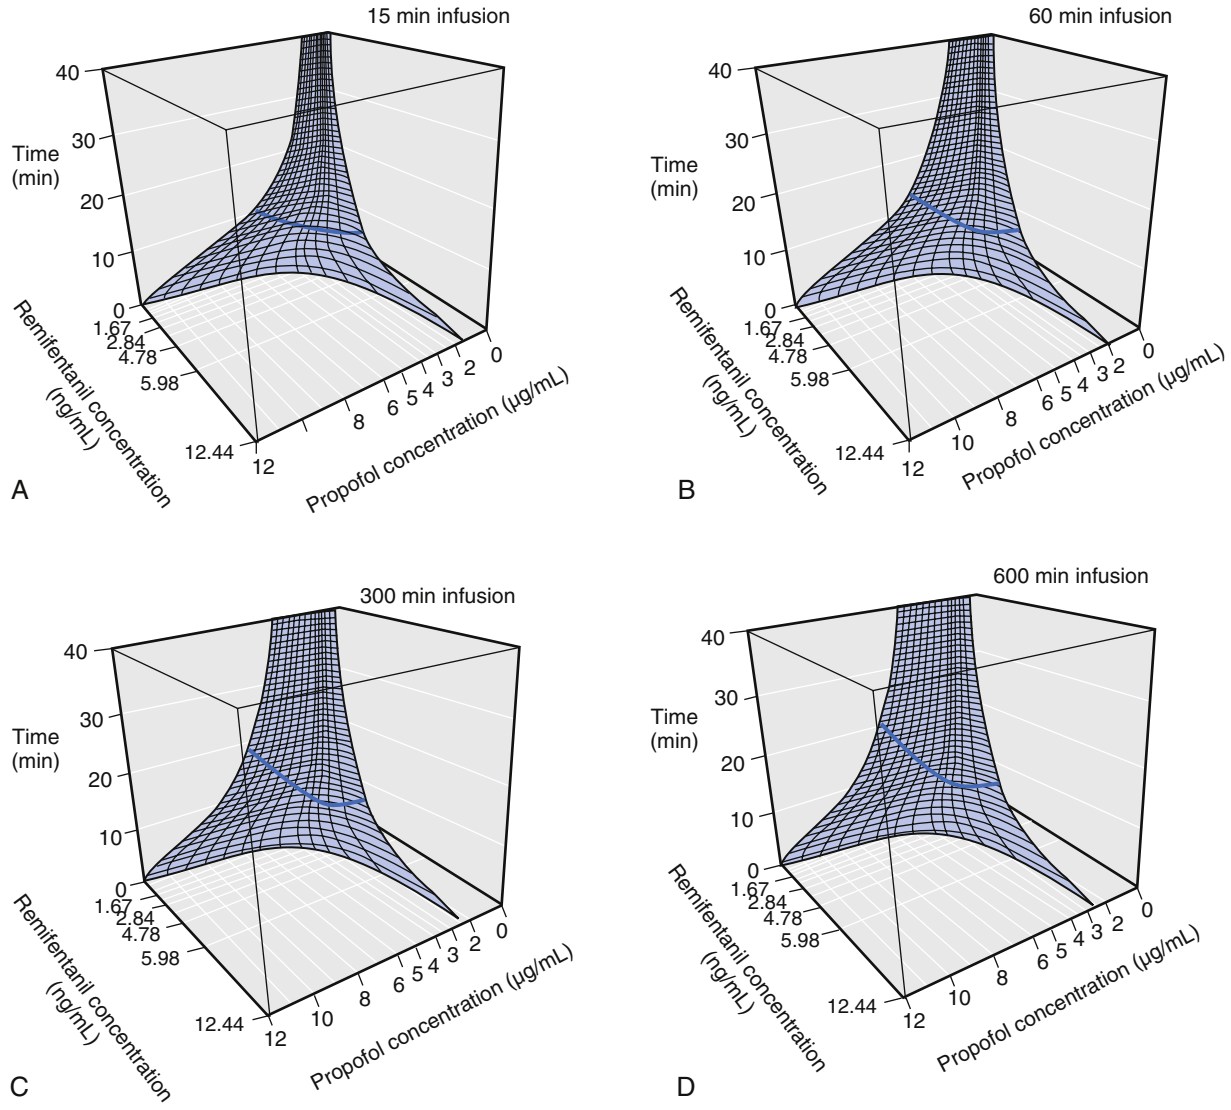

Figure 33-24. Simulation of the interaction of propofol and remifentanil in preventing a somatic response at skin incision and time to recovery. The remifentanil concentration is on the *x*-axis, and the propofol concentration is on the *y*-axis. The *blue curve* in the lower plane shows the propofol-remifentanil interaction required to provide adequate anesthesia. When the infusion is turned off, the concentrations of each drug decrease, as shown on the *z*-axis. The *blue line* drawn on the recovery surface shows the time to emergence from anesthesia for combinations of remifentanil and propofol after an anesthetic of 15 minutes' (**A**), 60 minutes' (**B**), 180 minutes' (**C**), and 600 minutes' (**D**) duration. With remifentanil, the optimal combination is a propofol concentration of 2.5 μg/mL and, with remifentanil, 5 to 7 ng/mL. In addition, increasing the duration of the infusion has minimal impact on recovery time if the optimal dose of remifentanil is not used. However, if the propofol dose is increased, then recovery is prolonged. *(Modified from Vuyk J, Mertens MJ, Olofsen E, et al: Propofol anesthesia and rational opioid selection: determination of optimal EC_{50}-EC_{95} propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness,* Anesthesiology *87:1549-1562, 1997.)*

the recovery surface shows the points at which the fentanyl-propofol interaction model predicts emergence.

After 15 minutes of maintaining 1.8 μg/mL of propofol and 6 ng/mL of fentanyl (right margin of the interaction curve), approximately 12 minutes is needed for the concentrations of both drugs to decrease sufficiently to permit emergence (see Fig. 33-23). However, if one maintains concentrations of 3.5 μg/mL of propofol and 1.5 ng/mL of fentanyl (toward the middle of the interaction curve), then emergence can be expected only 8 minutes after the infusions are turned off. Examination of the curves for 60, 300, and 600 minutes of propofol-fentanyl anesthesia suggests that the fentanyl target concentration that provides the most rapid emergence is approximately 1.0 to 1.5 ng/mL, which requires a propofol concentration of approximately 3.0 to 3.5 μg/mL to maintain adequate anesthesia. In similar simulations, Vuyk and colleagues demonstrated that maintaining alfentanil and sufentanil concentrations in excess of the analgesic range (i.e., approximately 80 ng/mL for alfentanil and 0.15 ng/mL for sufentanil) is of little clinical benefit and can be expected to delay recovery from anesthesia. A second conclusion from these simulations is that if the patient demonstrates inadequate anesthesia, increasing the hypnotic concentration rather than increasing the opioid concentration beyond the analgesic range is preferable, so as to prevent prolongation of recovery.

The situation is different for remifentanil because of its unusual pharmacokinetic properties (see Fig. 33-24). When

a remifentanil infusion is terminated, the extraordinarily fast clearance of remifentanil results in a very rapid offset of opioid drug effect. The lower plane again shows equivalent anesthetic states during maintenance with remifentanil and propofol (see Fig. 33-24). High doses of remifentanil permit a modest reduction in the dose of propofol needed for adequate anesthesia.[101] However, the recovery surfaces show that high doses of remifentanil, with a modest reduction in the propofol dose, permit considerably faster emergence from anesthesia. For example, it takes approximately 12 minutes to awaken from 600 minutes of anesthesia maintained with 3 μg/mL of propofol and 2.5 ng/mL of remifentanil (see Fig. 33-24, *D*). On the other hand, if the remifentanil concentration is increased to 5 ng/mL, then the propofol concentration can be reduced to between 2 and 2.5 μg/mL, and emergence can be anticipated within 6 minutes of discontinuation of the infusions. One might be concerned that such a technique places patients at increased risk for awareness because a propofol concentration of 2 μg/mL is below the C_{50} value for wakefulness.[102] Therefore combining such a technique with intraoperative EEG monitoring to assess anesthetic adequacy is reasonable.[20,102]

DISPLAYING PHARMACOLOGIC INFORMATION

Integrating all sources of pharmacologic information including drug interaction together with measurements of patient response to a specific drug dose might offer a powerful advisory tool to depict the complete dose-response relationship of multiple drugs, thereby optimizing drug administration and improving patient care.[103,104] For example, Figure 33-25 shows a drug interaction advisory display. Schumacher and colleagues proposed an advisory system for clinical use that offers real-time information about predicted drug concentrations, predicted combined effect, and predicted wake-up time resulting from these actions, as well as displaying the optimal drug concentration ratio for a given effect in this typical patient.[105] Others have described similar systems.[104]

INTRAVENOUS INFUSION DEVICES AND TECHNOLOGIES

MANUAL INTRAVENOUS INFUSION

When an infusion of an intravenous anesthetic is administered, the infusion regimen can be controlled by a variety of mechanisms varying from the simple Cair clamp or Dial-a-Flo (Abbott Laboratories) to complex computer-controlled infusion pumps. Simplicity of mechanical design, however, is not necessarily correlated with ease of use, which has prompted ongoing advances in infusion device technology over the past decades.

Infusion devices can be classified as either controllers or positive displacement pumps. Explicit in their title, controllers contain mechanisms that control the rate of flow produced by gravity, whereas positive displacement pumps contain active pumping mechanisms.

The most commonly used pumps for administration of intravenous anesthetics are positive displacement syringe pumps that use a variety of mechanisms. These pumps have acceptable accuracy and have several features that make them particularly suitable for anesthetic delivery. An important advance has been the introduction of a calculator feature within the pump so that the clinician can input the weight of the patient, the drug concentration, and the infusion rate in dose/unit weight/unit time and the pump will then calculate the infusion in volume/unit time. These pumps also permit simple application of a staged infusion scheme by allowing an initial dose and a maintenance infusion rate to be programmed into the pump. Numerous syringe pumps also include automated recognition of syringe size. Further enhancements are drug libraries by class of drug, suggested dosing schemes, and maximal dosing alerts. These modest advances in pump technology and design enable intravenous anesthetics to be conveniently and safely delivered.

In addition to the pumps, the complete intravenous delivery systems' hardware must perform perfectly,[5] which means that the correct amount of drug should be delivered to the venous circulation in each unit of time. When the drug administration set has too large a *dead-space*, the actual delivery rate can be altered, depending on the flow rate of co-administered fluid.[106] The use of an antireflux valve is certainly advisable to prevent flow of the medication backward into the intravenous fluid bag rather than into the patient. Other factors include excessive compliance within the administration system (in the syringe plunger or in the administration lines) and the use of syringes with suboptimal lubrication, causing the plunger to advance in small jumps when infusion rates are slow; that is, with small patients, low target concentrations, concentrated drug solutions, or large syringes.[5]

Manual intravenous drug delivery consists of a combination of a bolus dosage and a continuous infusion, as explained earlier when discussing the pharmacokinetic considerations. Table 33-5 offers recommendations for delivering intravenous anesthetics via conventional infusion pumps based on integrated pharmacokinetic-pharmacodynamic models. Ultimately, the adequate rate of drug administration is based on observation and examination. Individual patients vary significantly in their response to a given drug dose or concentration; therefore titrating to an adequate drug level for each individual patient is essential. Drug concentrations required to provide adequate anesthesia also vary according to the type of surgery (e.g., surface surgery versus upper abdominal surgery). Drug concentration requirements are often smaller during the end phase of surgery; therefore titration often involves judicious reduction of the infusion rate toward the end of surgery to facilitate rapid recovery.

If the infusion rate is insufficient to maintain adequate anesthesia, then both an additional loading (bolus) dose and an increase in infusion are required to increase the plasma (biophase) drug concentration rapidly. Various interventions also require larger drug concentrations, usually for brief periods (e.g., laryngoscopy, endotracheal intubation, skin incision). Therefore the infusion scheme should be tailored to provide peak concentrations during these brief periods of intense stimulation. An adequate drug level for endotracheal intubation is often achieved with the initial loading dose; however, for procedures such as skin incision, an additional bolus dose may be necessary.

Figure 33-25. On-line advisory displays including characteristics of drug behavior and interaction. The SmartPilot (Dräger, Lübeck, Germany) *(upper display)* is a two-dimensional display that shows the effect-site concentrations of combined drugs (opioids and intravenous or inhalation hypnotics), based on pharmacokinetic models and the resulting anesthetic effect and on pharmacodynamic models. Grey shaded areas indicate different levels of anesthesia. The *orange point* indicates the current combination of effect-site concentrations; the *white line* shows the retrospective concentrations; and a 10- and 15-minute prediction is marked by a *black point* and *arrow*—already calculated during presetting of delivery. Event markers may be set to show specific states of the patient related to the level of anesthesia: the time-based real-time curves, trends, and prediction of effect-site concentrations of individual drugs; resulting anesthetic effect (noxious stimulus response index [NSRI]) and correlated bispectral index (BIS), vital signs, and event markers as reference for interpretation. The Medvis display (Medvis, Salt Lake City, Utah) *(lower display)* shows a real-time visualization of anesthetic using pharmacokinetic and pharmacodynamic models to predict drug effect-site concentrations and drug effects in the past, current time, and 10 minutes into the future. Drug doses as boluses and infusions are administered via a separate data interface or user interface. Drugs are categorized according to sedation (*top plot*), analgesia (*middle plot*), and muscle relaxation (*bottom plot*). Effects are depicted as a population-based probability of unconsciousness (*top plot*), no response to tracheal intubation (*middle plot*), and no twitch response to a train of four stimulus *(bottom plot)*. In addition, a second pharmacodynamic endpoint, POST-OP ANALG, represents a guideline therapeutic window for postoperative pain. Synergistic interactions of sedative-hypnotics and analgesics are shown by the *white curves* in the plot. For example, the top plot shows that with only propofol, the probability of unconsciousness is between 50% and 95% *(yellow curve)*, but because propofol interacts with the opioids, the probability of unconsciousness is greater than 95% *(white curve)*. Similarly, propofol potentiates the effect of the opioids in the middle plot.

TABLE 33-5 **MANUAL INFUSION SCHEMES***

	Anesthesia		Sedation or Analgesia	
Drug	Loading Dose (μg/kg)	Maintenance Infusion (μg/kg/min)	Loading Dose (μg/kg)	Maintenance Infusion (μg/kg/min)
Alfentanil	50-150	0.5-3	10-25	0.25-1
Fentanyl	5-15	0.03-0.1	1-3	0.01-0.03
Sufentanil	0.5-5	0.01-0.05	0.1-0.5	0.005-0.01
Remifentanil	0.5-1.0	0.1-0.4	†	0.025-0.1
Ketamine	1500-2500	25-75	500-1000	10-20
Propofol	1000-2000	50-150	250-1000	10-50
Midazolam	50-150	0.25-1.5	25-100	0.25-1
Methohexital	1500-2500	50-150	250-1000	10-50
Dexmedetomidine			0.5-1 over 10 min	0.2-0.7

*After the loading dose, an initially high infusion rate to account for redistribution should be used and then titrated to the lowest infusion rate that will maintain adequate anesthesia or sedation. When using opiates as part of a nitrous-narcotic technique or for cardiac anesthesia, the dosing scheme listed under anesthesia is used. When the opiate is combined as part of balanced anesthesia, dosing listed for analgesia is needed.

†For analgesia or during sedation, an initial loading dose of remifentanil should not be given because its very rapid onset may result in apnea or muscle rigidity.

Infusion schemes (see Table 33-5) do not approach the convenience and precision of use associated with the delivery of an inhaled anesthetic via a calibrated vaporizer. This level of precision can be achieved by using TCI devices, such as the commercially available TCI pumps. These devices range from simple calculator pumps to pumps with automated drug delivery (see "Target-Controlled Infusion").

A particular method of intravenous drug administration is patient-controlled analgesia (PCA ; also see Chapter 98), mostly used for the postoperative administration of analgesics or for patient-controlled sedation (PCS) during therapeutic procedures. Although PCA can be considered as a method of computer-controlled or even closed-loop drug administration, most of these pumps do not include pharmacokinetic or pharmacodynamic algorithms. In some cases, the pump is set to deliver a low, constant or *background* flow of medication. Additional doses of medication can be self-administered by the patient pressing a button as needed. Most commonly, no background infusion is provided, and the patient controls when he or she receives an analgesic bolus. To avoid overdosing, these pumps have built-in safety mechanisms such as lock-out times and limitations of the total amount of drug delivered per time unit. PCA is a common technique for delivery of postoperative pain medication such as morphine, piritramide, fentanyl, tramadol, and other agents.[107-111] In a systematic review, Walder and colleagues showed that the literature presented some evidence that in the postoperative pain setting, PCA with opioids, compared with conventional opioid treatment, improved analgesia and decreased the risk of pulmonary complications; in general, the patients preferred the technique.[112] Strict hospital guidelines may help avoid side effects such as oversedation and respiratory depression.[113] When epidural analgesia is contraindicated during labor, remifentanil PCA has been suggested as an alternative. Pilot trials have suggested that this alternative is safe under strict observation.[114-119]

Studies on the quality and outcomes after PCS have shown that it reduces discomfort and fear by inducing sedation and amnesia during uncomfortable therapeutic procedures such as colonoscopy. Additionally, PCS facilitates the procedure by increasing the patient's tolerance. Although propofol offers no analgesic effect, several studies of patient control of propofol administration (bolus or short infusions) during procedures were performed and showed that it provided reasonably safe, light sedation, and that patients expressed a preference for being in control.[120-122] As this manual infusion regimen might produce fluctuating levels of sedation, Kenny and colleagues combined PCS with TCI of propofol to overcome this problem. Using this system, the patient can set a specific propofol target concentration. A lock-out time is set by the clinician (commonly with the default being approximately the equilibration time between plasma and effect-site concentrations). When the patient stops pushing the delivery button, the target concentration automatically decreases (see also "Target-Controlled Infusion" later in this chapter). In various applications requiring sedation, their experimental system was shown to be feasible; however, even when using an effect-site controlled TCI system, some volunteers rendered themselves unconscious. It is possible that safety can be improved further, particularly if a test or measure of responsiveness to a stimulus is added and if the control algorithm is incorporated to allow the facility to stop the infusion should the response become inadequate.[123-126] Doufas and colleagues tested an automatic response test to optimize propofol administration for conscious sedation.[127,128] Although volunteers were required to push a delivery button in response to auditory and tactile stimuli, a TCI-like algorithm guided the propofol administration. The study showed that failure to respond to automated responsiveness monitoring precedes potentially serious adverse effects of sedation such as loss of responsiveness, and that the monitor was not susceptible to false-positive responses.[129]

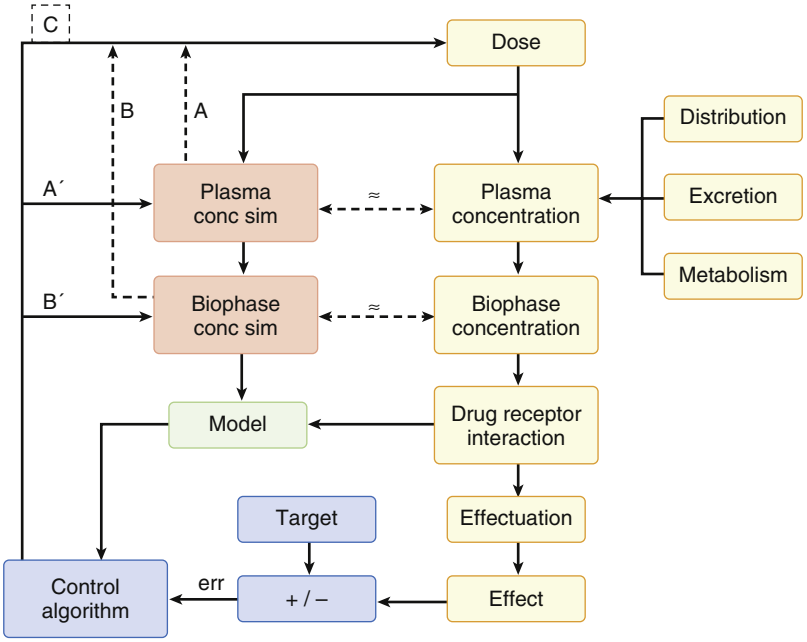

Figure 33-26. Schematic representation of the pharmacokinetic and pharmacodynamic processes determining the relationship between administered doses and resulting effect intensity of a drug *(yellow)*. Pharmacokinetic factors such as distribution, metabolism, and/or excretion determine the relationship between drug dose and drug concentration in the biophase. In the biophase, the drug interacts with the receptor, and the pharmacologic effect is accomplished via effectuation processes. Target-controlled infusion (TCI) will use a model to estimate the plasma or biophase drug concentration *(red)*, and will calculate the dose needed to approach a target concentration in plasma *(A)* or biophase/effect-site *(B)*. Computer-controlled, closed-loop feedback measures the error between the effect and the target effect to control the dose administration *(blue)*. Better closed-loop performance can result if, rather than using the dose as a direct actuator, the *simulated* variable of a TCI system is used as actuated variable *(A/A′, B/B′)*. The TCI system then compensates for part of the complexity of the dose-interaction relationship. Advanced control algorithms may take into account a continuously updated model of the interaction *(light green) (Modified from Struys M, de Smet T: Principles of drug actions: target-controlled infusions and closed-loop administration. In Evers AS, Maze M, Kharasch ED, editors:* Anesthetic pharmacology: basic principles and clinical practice. *Cambridge, 2011, Cambridge University Press, pp, 103-122. Used with permission.)*

COMPUTER-CONTROLLED DRUG DELIVERY

As discussed in the introduction of this chapter, optimal patient-individual dosing may be achieved by the application of pharmacokinetic and pharmacodynamic principles. Using the dose-response relationship, drug titration should be performed as close as possible to the drug effect. Titrating to a specific effect or, if not possible, a specific effect-site concentration offers advantages. Because the effect-site or plasma concentrations are not continuously measurable online for most intravenous anesthetics (in contrast to inhaled anesthetics), a drug model using a computer that continuously updates the anesthetic administration rate to maintain an estimated drug effect or drug concentration is required (Fig. 33-26).

If a specific plasma or effect-site concentration is titrated, then this technique is called TCI. TCI is a *closed-loop control* system. However, in this system the clinician serves as the *human controller* in the loop and, as a consequence, the control actions are intermittent and irregular in time.[132] Control theory is increasingly being applied in the development of computer-controlled drug delivery systems, among others in anesthetic closed-loop control applications. The aim of computer-controlled closed-loop systems is to formalize this process of observation and intervention to provide finer and more accurate control. Such systems use a near continuous signal of drug effect, calculate the error between the observed value and the set point value (selected by the user), and use this error figure in an algorithm to make frequent and regular adjustments to drug administration rates. Some computer-controlled drug delivery systems try to predict the future drug effect to make appropriate adjustments well in advance.[132]

TARGET-CONTROLLED INFUSION

Devices

The development of microprocessor-controlled syringe pumps and a better understanding of the dose-response relationship have enabled the development of TCI systems. TCI is an infusion controlled system that achieves a user-defined estimated drug concentration in a body compartment or tissue. A clinician using a TCI system to administer an anesthetic drug is thus able to set and adjust a desired drug concentration, usually referred to as the *target concentration*, based on clinical observation of the patient or measurement of drug effect. Multicompartment

pharmacokinetic-dynamic models are used by TCI systems to calculate the infusion rates required to achieve the target concentration (see Fig. 33-4). A computer or microprocessor is required to perform the complex calculations and to control the infusion pump. Typically, plasma or effect-site concentrations are targeted.[3,133]

TCI originates from the theoretic approach to achieve and maintain a steady-state blood concentration of a drug whose pharmacokinetic trajectory is a multicompartment model as described by Kruger-Thiemer[134] and first clinically implemented by Schwilden and colleagues.[7] The applied infusion schemes, better known as bolus-elimination-transfer (BET) schemes (see Fig. 33-4), were initially designed for two-compartment models. Briefly, the infusion starts with an initial bolus of drug required to achieve the initial target concentration. Second, an infusion is administered to replace drug lost by elimination. Since the elimination rate constant is fixed, the amount of drug eliminated in each unit of time is proportional to the plasma concentration; thus at steady-state plasma concentrations, drug removal by elimination can be compensated for by a constant rate infusion. Third, a second infusion is administered to replace drug distributed or transferred to peripheral tissues. The amount redistributed exponentially declines over time as the gradient between the central compartment and the peripheral compartment decreases. Replacing distributed drug requires an infusion at an exponentially declining rate to replace drug *lost* from the central compartment by distribution until steady state.[4]

BET schemes have some disadvantages such as the requirement of a no-drug status before infusion, which disables a change in the target concentration. In addition, more recent research concluded that the pharmacokinetics of most anesthetics is better described using a three- instead of a two-compartment model. Lastly, as previously discussed in this chapter, the plasma is not the site of drug effect. Therefore effect compartment–controlled TCI algorithms were developed.[28] During the 1990s, various computer-based TCI prototypes were developed by researchers at Stanford (STANPUMP, California), Stellenbosch (STELPUMP, South Africa), Duke (computer-assisted continuous infusion [CACI], North Carolina), and Ghent (RUGLOOP, Belgium) universities. Groups in Erlangen, Germany, and Leiden, The Netherlands, produced software able to simulate pharmacokinetic trajectories (IVA-SIM and TIVA Trainer, respectively). Finally, the Diprifusor (AstraZeneca, London) became the first commercially available TCI pump. It was based on a prototype from the Kenny group[135] and was able to control a set plasma target concentration using specific prefilled syringes from AstraZeneca. Although the technology never became available in the United States,[136] this TCI pump was the first breakthrough in an attempt to optimize drug administration in daily clinical practice in many countries. More recently, various companies have commercialized more flexible *open TCI* pumps capable of administering multiple drugs in both plasma and effect compartment–control mode (Fig. 33-27).

Effect compartment–control requires a rate constant that accurately describes the rate of equilibration between plasma (Fig. 33-28, *A*) and effect-site concentrations (Fig. 33-28, *B*). The benefits of effect compartment-controlled TCI were demonstrated for propofol by Wakeling and associates[137] and Struys and associates.[62] This mode is commonly used throughout Europe.

Evaluation of Target-Controlled Infusion Delivery

Acceptance of target-controlled drug delivery of intravenous anesthetics requires evaluation of accuracy (defined as the difference between predicted and measured concentrations) and outcomes among patients in whom automated drug delivery has been used. The inaccuracies associated with pharmacokinetic model–driven devices are attributed to both the software and hardware, as well as to pharmacokinetic variability (Fig. 33-29).

Inaccuracy in the software results from incorrect mathematic implementation of the pharmacokinetic model. Computer simulations can be used to test the infusion rates as calculated by a software program, and thus software errors are fairly simple to identify and correct.[138] Inaccurate drug delivery from the infusion pump

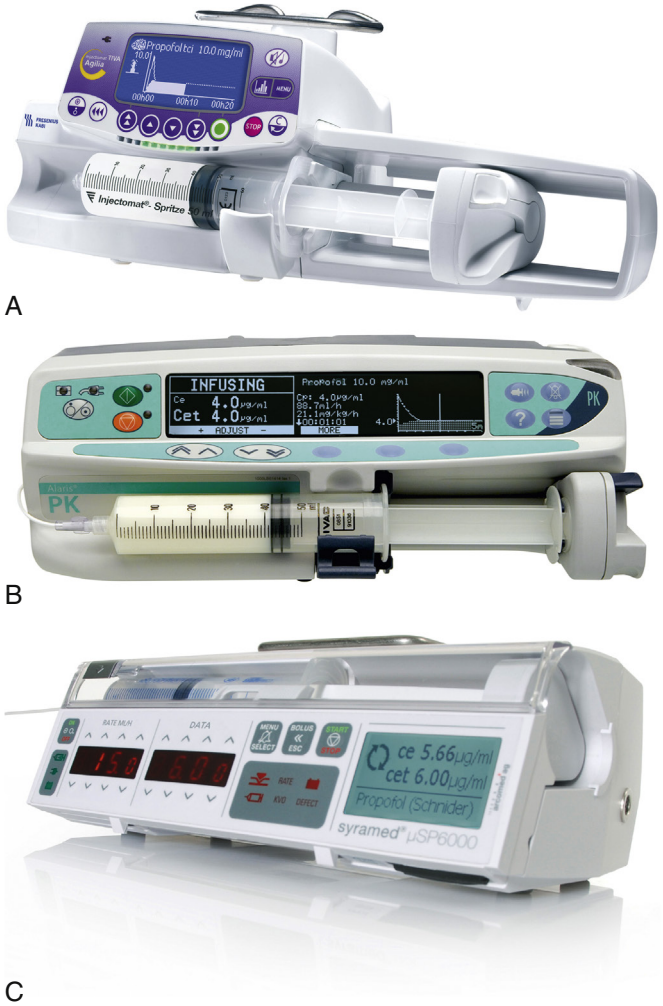

Figure 33-27. Target-controlled infusion (TCI) pumps. **A,** Injectomat TIVA Agilia from Fresenius Kabi (Bad Homburg, Germany). **B,** Alaris PK Syringe pump from Carefusion (Basingstoke, UK). **C,** Syramed µSP6000 from Arcomed (Regensdorf, Switzerland).

infrequently occurs with present syringe-pump technology and contributes little to the overall inaccuracy of these devices.[139] The major cause of inaccuracy is biologic variability, of which there are two sources: (1) the pharmacokinetic model is always wrong,[140] and (2) the pharmacokinetics of the patient is not as programmed into the model. The pharmacokinetic model is always wrong because individuals are far more complex than implied by simple compartment models, and no model can precisely predict the concentrations, even if the pharmacokinetic parameters in the individual were known with absolute precision. However, even if the pharmacokinetic model truly reflected the underlying biologic variables, the parameters of the model would be average parameters for the population and not the exact parameters of the patient. Even if the parameters were modified to reflect the influence of demographic factors such as age, gender, hypovolemia, and co-administration of other drugs, the parameters would still deviate from the true pharmacokinetic parameters in the individual. Thus biologic variability fundamentally precludes the possibility of precisely achieving the desired target concentration when automated drug delivery devices are used. Realizing that biologic variability always exists, no matter how drugs are given, and that this same biologic variability affects all methods of drug delivery is important. Nonetheless, the variability with TCI devices will always be less than the variability observed after a single bolus injection.[141] The performance of computer-controlled drug administration must be interpreted in terms of the therapeutic expectations of the clinician. Possible goals include accurately producing a desired concentration in plasma, precisely titrating the plasma drug concentration, achieving the desired drug effect, and producing the desired time course of drug effect. Over the past decade, investigators have addressed each of these goals and have refined the performance of automated drug delivery devices accordingly.

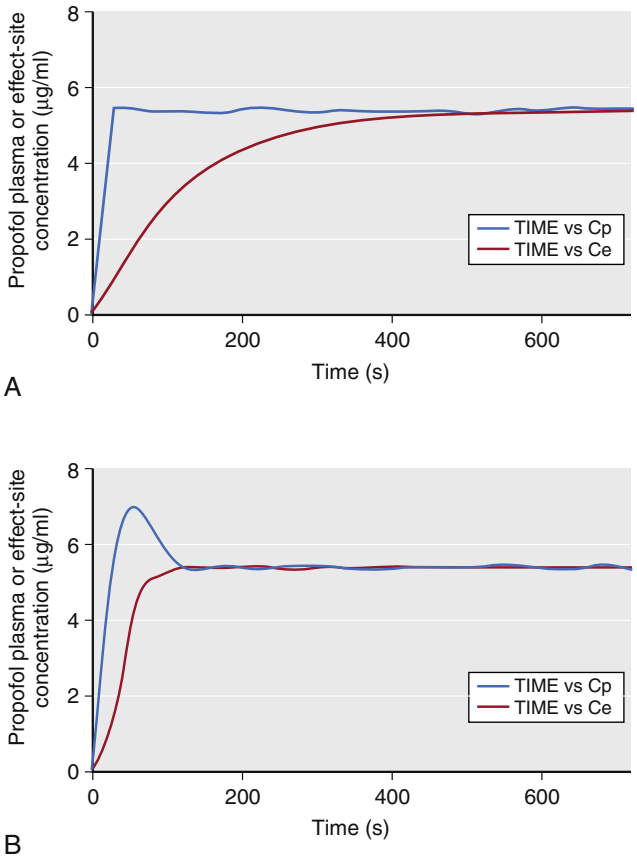

Figure 33-28. Simulation of propofol plasma (**A**) versus effect compartment–controlled (**B**) target-controlled infusion (TCI).

The ability of an automated drug delivery system to rapidly achieve and then maintain a selected target concentration is a logical measure of the performance of such a device. The difference between the measured and target concentrations can be expressed in several ways. Classic graphic representations are X-Y plots depicting predicted versus measured blood (plasma) drug concentrations (Fig. 33-30) or the relationship of the measured and predicted drug concentration versus time of administration (Fig. 33-31). Numerically, the primary concern is how far the measured concentration is from the predicted one; this relationship is now most frequently described in terms of performance error, which is the difference between the measured

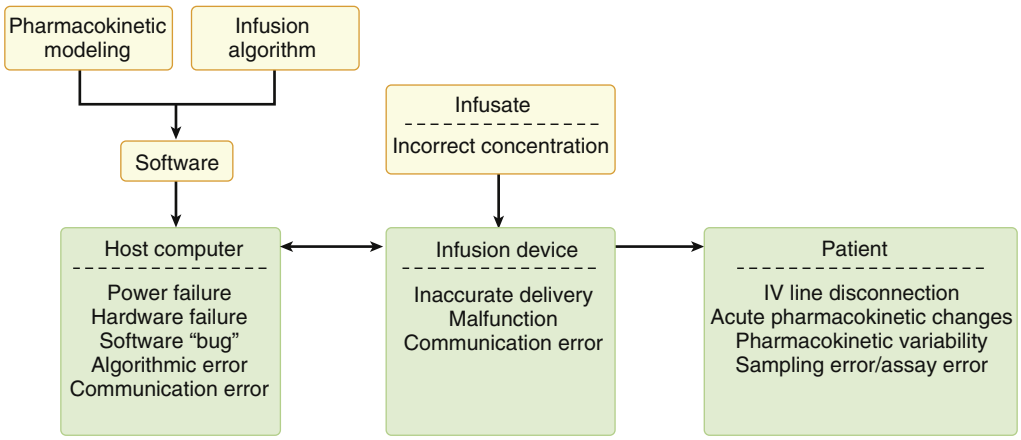

Figure 33-29. Major sources of potential error in pharmacokinetic model–driven drug delivery. In a commercial device, the computer functions are incorporated into the infusion device. *IV,* Intravenous.

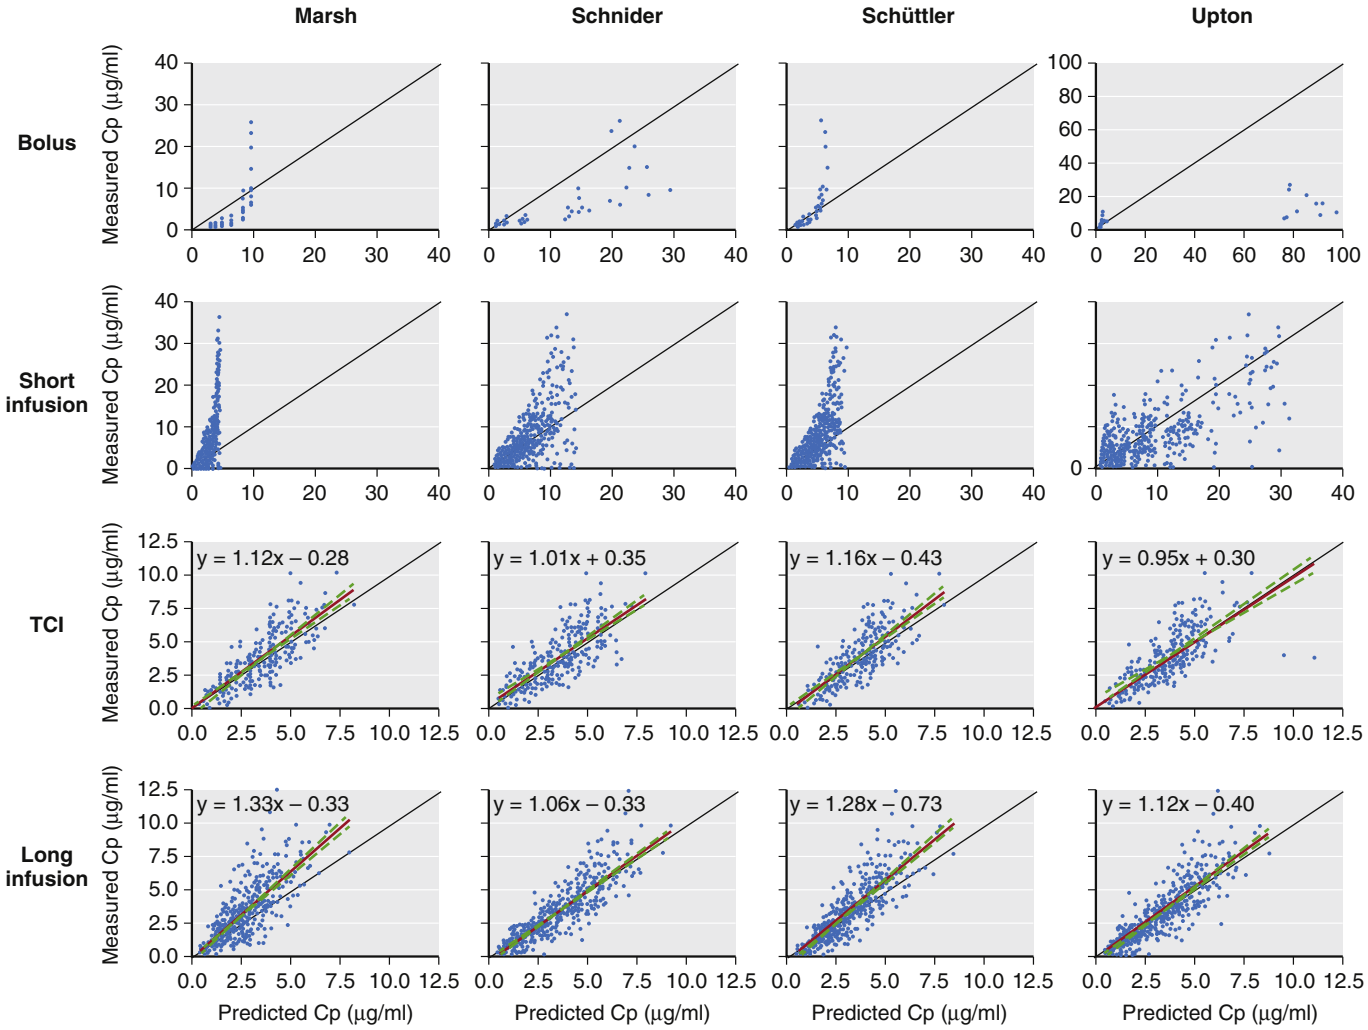

Figure 33-30. Predicted versus measured propofol plasma concentration for the four pharmacokinetic models. Each point represents a single sample. *Thin black line* represents the line of identity. For target-controlled infusion (TCI) and long infusion conditions, the bold *red line* shows the regression line and the bold *dashed green line* indicates the 95% confidence interval for the regression line. The formula represents the equation from the linear regression. *(From Masui K, Upton RN, Doufas AG, et al: The performance of compartmental and physiologically based recirculatory pharmacokinetic models for propofol: a comparison using bolus, continuous, and target-controlled infusion data,* Anesth Analg *111:368-379, 2010. Used with permission.)*

and the target concentrations as a percentage of the desired target—for example, [(measured – target) ÷ (target × 100%)].[142] The median value of the performance error for a patient or population is referred to as the median performance error (MDPE) and represents the average overshoot or undershoot of the system. The median absolute performance error (MDAPE) is the median of the absolute values of all performance errors. The MDAPE is commonly used as a measure of the inaccuracy of an automated drug delivery device. An MDAPE of zero is perfect performance, and an MDAPE of 20% means that one half the plasma concentrations will be within 20% of the target and one half will be outside that range. A further assessment of accuracy is whether the system maintains a stable target concentration, which is best measured by the wobble of the system. Varvel and colleagues[142] asked a group of clinicians to evaluate the performance of automated drug delivery devices and demonstrated that the MDAPE best predicted the adequacy of performance of the automated delivery device, as judged by experienced clinicians.

As observed earlier, expecting all performance errors to be zero is not reasonable. However, it would be desirable if positive and negative errors offset each other so that the MDPE of an automated drug delivery device were 0%. The MDPE does not indicate the range of performance errors (because positive and negative performance errors offset each other), but it does indicate whether the plasma concentrations achieved with the device tend to overshoot (+MDPE) or undershoot (–MDPE) the desired target.

Many groups have evaluated the accuracy of many different pharmacokinetic sets for virtually all the intravenous hypnotics and analgesics.[12,30,61,143-155] Based on many of these studies, the expected performance of such devices, at best, tends to be around 20% to 30% MDAPE.

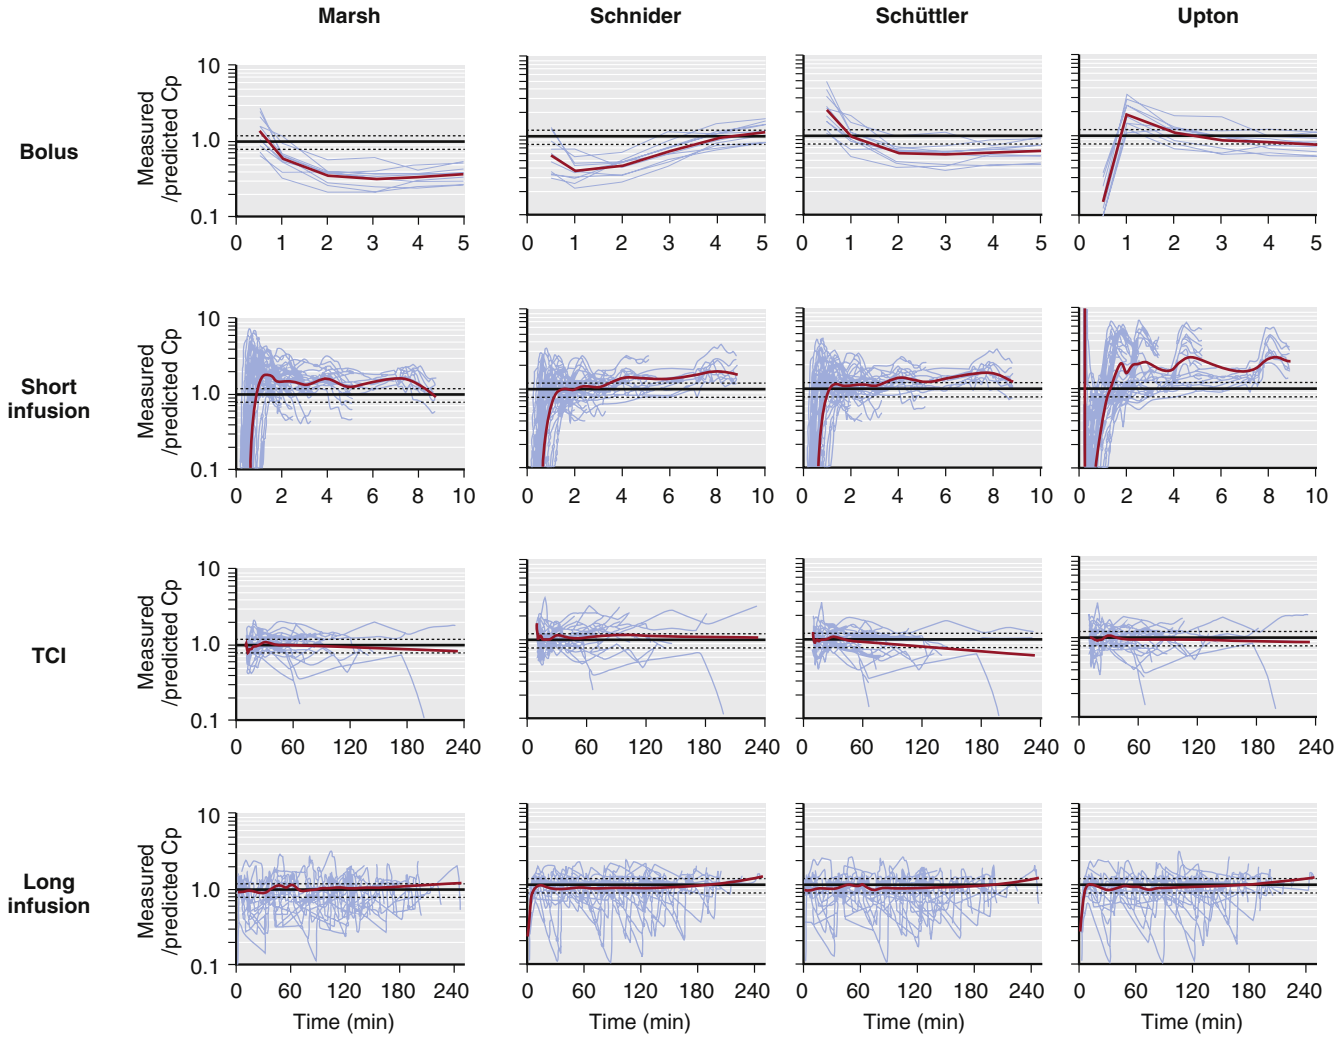

Figure 33-31. Time course of the measured/predicted concentration relationship versus time of drug administration. The *dotted lines* indicate an acceptable range of measured/predicted plasma drug concentration (Cp). The *red line* indicates the Friedman Super Smoother curve for the population data. *(From Masui K, Upton RN, Doufas AG, et al: The performance of compartmental and physiologically based recirculatory pharmacokinetic models for propofol: a comparison using bolus, continuous, and target-controlled infusion data,* Anesth Analg *111:368-379, 2010. Used with permission.)*

Model Selection for Target-Controlled Infusion

For most intravenous drugs, various multicompartment pharmacokinetic-dynamic models have been published. The pharmacokinetics of propofol have been the most frequently tested (see Fig. 33-6). Coetzee and co-workers compared the accuracy of some of the models published before 1995 and found that propofol TCI using the model published by Marsh and co-workers resulted in acceptable performance (MDPE −7%; MDAPE 18%).[148]

The Marsh model was incorporated in the first commercially available TCI system (Diprifusor). Clinical studies using this plasma-controlled TCI system showed that the technique and model were clinically useful in various clinical situations.[156-160] The major drawback of the Marsh model is the lack of effect compartment information and the fact that weight is the only covariate. More recently, Schnider and co-workers[54,161] evaluated age, height, weight, and lean body mass as covariates in a new combined pharmacokinetic-dynamic three-compartment model. The large variability of the study population (18 to 81 years of age and weighing 44 to 123 kg) provides a wide applicability of the model. Several validation studies rated this model accurate under various conditions. For example, Masui and colleagues[12] studied the measured propofol plasma concentrations versus predicted by the four published models and revealed bias in all three compartment models during the bolus and short infusion regimens (see Figs. 33-30 and 33-31).

In the long infusion, a worse measured/predicted propofol plasma concentration at higher concentration was observed for the Marsh and Schüttler[162] models than for the two other models. Less biased measured/predicted propofol plasma concentration was found for all models during TCI. In the bolus group, after 1 minute, a clear overprediction was observed for all three-compartment models for the entire 5-minute period; however, this initial error resolved after 4 minutes in the Schnider model. During the bolus and short infusion conditions, the Marsh model demonstrated worse MDPE and MDAPE

when compared with the other models. During short infusion, MDAPE for the Schnider and Schüttler models was better. All models showed similar MDPE and MDAPE during TCI simulations. During long infusion, the Marsh and the Schüttler models underestimated the higher plasma concentrations. Interestingly, the physiologically based recirculatory model developed by Upton and co-workers[13] did not reveal a better description of the pharmacokinetic time course. The Schüttler model has a major practical drawback; it defined the infusion characteristics, being bolus or infusion, as a significant covariate, thereby discouraging TCI applicability.

When comparing the Schnider and Marsh model during effect compartment–controlled TCI, Coppens and co-workers[163] found a significant difference in behavior. When targeting the effect-site concentration detected at the moment of loss of consciousness, patients in the Marsh model group woke up and those in the Schnider model group showed a further deepening of anesthesia as measured by the BIS. They concluded that targeting the effect-site concentration at which patients lose consciousness with effect-site controlled TCI does not translate into an immediate constant effect. Others have observed contradictory findings.[164] As a result, more fundamental research is required to better understand the mechanisms of anesthetic-induced loss of consciousness and to subsequently fine tune the pharmacometric principles governing effect-site modeling.[132]

An additional drawback of the Schnider model is the use of lean body mass as calculated using the equation developed by James.[165] The quadratic behavior of the lean body mass function makes it invalid (negative values!) when used in patients who are very obese. Therefore as changing population demographics such as obesity might influence the pharmacokinetics of propofol, models should ideally be applicable to a broad range of population demographics before being used in clinical practice. Recently, Cortinez and co-workers[166] derived a population pharmacokinetics model using obese and nonobese data to describe the pharmacokinetics of propofol over a wide range of body weights. A model using allometric scaling of total body weight as the size descriptor of volumes and clearances was superior to other size descriptors to characterize propofol pharmacokinetics in patients who are obese. When using allometric scaling, growth and development can be studied using classic covariates (e.g., weight, age, sex). Size is the primary covariate and can be referenced to a 70-kg person with allometric scaling using a coefficient of 0.75 for clearance and 1 for volume. Anderson and Holford[167] promote this approach because the use of these coefficients is supported by fractal geometric concepts and observations from biologically diverse areas.[168]

Two pharmacokinetic models for propofol in children are available in clinical TCI systems. Kataria and colleagues described the time course of propofol plasma concentration in a population of children between ages of 3 and 11 years using a three-compartment model with weight as the sole significant covariate. Weight-adjusting the volumes and clearances significantly improved the accuracy of the pharmacokinetics. Adjusting the pharmacokinetics for inclusion of additional patient covariates or using a mixed-effects model did not further improve the ability of the pharmacokinetic parameters to describe the observations.[169] An alternative propofol TCI model called *Paedfusor*, developed by the Glasgow research group, incorporated a preliminary model published by Schüttler and co-workers[162] and was recently found to be more accurate than the Kataria model. In this recent study, Coppens and associates[30] were the first to publish a combined pharmacokinetic-pharmacodynamic model for propofol in children, revealing a k_{e0} of 0.79 min^{-1} and a Ce_{50} of 3.85 μg/mL as measured using the BIS (Table 33-6).

Table 33-7 shows the clinically used pharmacokinetic-pharmacodynamic models for remifentanil, fentanyl, sufentanil, and alfentanil. For sufentanil, the covariate model developed by Gepts and colleagues[170] is accurate with MDPE between −2.3% and 22.3% and MDAPE between 18.5% and 29%, even in patients who are obese[150-152] (also see Chapter 71). Multiple pharmacokinetic models were developed for alfentanil. A combined analysis of these early study results using a true population analysis was used to develop a new alfentanil model.[171] A comparison showed a better performance for the Maitre alfentanil model (MDPE, 35%; MDAPE 36%) than the Scott model (MDPE, 12%; MDAPE, 28%).[154] Other studies found contradictory results.[145]

A compartment fentanyl model without covariates specifically aiming for TCI was developed[147] and tested in both lean and obese patients.[172] A simulated plasma concentration required a specific correction in patients who were obese.[172] Various three-compartment combined pharmacokinetic-pharmacodynamic models for remifentanil were developed from studies with both volunteers and patients; however, only the model published by Minto and colleagues is applied in TCI.[54,173] Evaluation of this model showed an acceptable performance, with an MDPE of −15% and an MDAPE of 20%.[155] Because combined pharmacokinetic-pharmacodynamic models are lacking for some of the opioids, the times to peak effect after a bolus administration of alfentanil (1.4 min), fentanyl (3.6 min), and sufentanil (5.6 min) can be applied to calculate the effect-site concentration using the *tpeak algorithm*.[31]

Preliminary remifentanil models in children have been developed (also see Chapter 93). For example, Rigby-Jones and colleagues[174] applied allometric scaling during a study of remifentanil pharmacokinetics in children and reported a single fixed allometric function scaled to a body mass of 10.5 kg that performed well across a broad range of patient weights. In addition to propofol and the opioids, compartment models have been published describing the time course of the plasma concentration and clinical effect of benzodiazepines, neuromuscular-blocking drugs, ketamine, and dexmedetomidine, although these drugs have not yet been included in the commercially available TCI pumps.

Rational Target Concentration Selection

No single regimen, concentration, or drug combination applies to all patients. Most of the previously mentioned pharmacokinetic-pharmacodynamic models have been derived from population pharmacologic studies. Interpatient variability limits the accuracy of the estimated drug

LBM, Lean body mass.

concentration for the individual but can be counteracted if the model is built while exploring a wide variety of possible covariates using parametric modeling, optionally nonlinear mixed-effects modeling. Consequently, caution is needed when applying these models to patients who are obese, older, very young, diabetic, alcoholic, or unwell if similar participants were not part of the study population. The current commercial implementations of TCI therefore do not function with patients with characteristics beyond the range of the model's development study population. As illustrated by Absalom and co-workers, the use of specific TCI algorithms outside the original studied population might result in dangerous drug infusion profiles.[11] These investigators compared two currently used methods for calculating the effect-site concentration for propofol in patients who were obese, one using a fixed k_{e0} and the other using a fixed t_{peak} (see also "Direct Effect Models" earlier in this chapter).

Other obvious sources of reduced single-drug model accuracy are errors such as drug spills, excessive blood loss causing shock, or pharmacokinetic drug interaction.[175-177]

Growing evidence suggests that gender, ethnic, and racial differences may be important sources of population pharmacokinetic-pharmacodynamic variability and should be considered when designing dosage regimens.[178] Xu and co-workers[47] evaluated the C_{50} for propofol-remifentanil TCI and the BIS at loss of consciousness and the response to noxious stimulus in patients of Chinese ethnicity and revealed that the predicted blood and effect-site concentrations at loss of consciousness were lower than those in previous publications involving Caucasian populations.

An additional caveat is required with the use of different formulations of a drug. For propofol, Calvo and colleagues[179] found that pharmacokinetics and pharmacodynamics were not equal for all formulations, which contributed to an increase in variability of the observed effect. Because of the aforementioned factors, no single regimen, concentration, or drug combination applies to all patients. Some guidance can be found in the effective concentrations at which 50% and 95% of patients have accurate clinical effect (see Table 33-3). As with all drug administration in anesthesia, clinical judgment is always required, and the target concentration should be titrated according to the clinical response of the patient.

The ability of TCI to rapidly achieve and maintain a steady concentration facilitates attaining a desired drug effect, irrespective of the absolute achieved drug concentration in the target compartment. The application of TCI in most cases even reduces the variability of intersubject drug-response curves.[141] As a result, clinical outcomes when comparing TCI versus manual infusion were found to be improved in various early studies, although contradictions exist in the literature. Two decades ago, Ausems and co-workers[180] compared pharmacokinetic model–driven administration with intermittent bolus administration of alfentanil. Automated drug delivery produced fewer episodes of muscular rigidity, hypotension, and bradycardia on induction. Automated drug delivery during maintenance resulted in a significantly less frequent incidence of hemodynamic response, which resulted in a larger percentage of anesthesia time within 15% of the desired arterial blood pressure and heart rate. Recovery after TCI was associated with significantly less use of naloxone for adequate ventilation. Pharmacokinetic model–driven infusion of fentanyl during cardiac surgery resulted in better hemodynamic control with fewer additional drug interventions and significantly fewer episodes of either hypotension or hypertension than with bolus dose administration.[181] Theil and colleagues[182] compared double-blind manual administration of fentanyl-midazolam with pharmacokinetic model–driven infusion of these two drugs in a small group of patients undergoing cardiac surgery. Both systems were simultaneously titrated (one containing placebo), with the aim of maintaining hemodynamics within 20% of baseline values. Both systems were equally effective in providing hemodynamic control as dictated by the protocol. The most significant difference between the two modes of delivery was the greater variability in drug plasma concentrations in the manual group, which suggested that pharmacokinetic model–driven infusion maintained patients within

a more narrow therapeutic range. Using the first commercially available TCI system (Diprifusor), early studies administering propofol by plasma-targeted TCI showed some benefits.[157,183,184] These revealed a significant preference of clinicians for the TCI system, although this was their first use of the device. Equal results between manual infusion and TCI were only observed when targeting propofol to a specific BIS value.[185,186] In a Cochrane review systemically including most studies using propofol plasma–targeting TCI devices, Leslie concluded that the evidence was insufficient to make firm recommendations about the use of target- versus manual-controlled infusion in clinical anesthetic practice.[126] The primary reason for these contradictory results is that early TCI devices targeted the plasma, which is not the site of drug effect (see also "Pharmacodynamic Considerations" earlier in this chapter).

Using experimental systems, Glass[137] and Struys[62] and their colleagues conducted similar studies in which they targeted either plasma or effect-site concentration of propofol and then observed the time and plasma versus effect-site concentration at loss of consciousness. In both studies, regardless of whether the effect-site or plasma concentration was targeted, loss of consciousness occurred when the appropriate *effect-site* concentration for loss of consciousness was achieved, thus validating the concept. Two other important observations were made during these studies. First, hemodynamic factors were not different whether plasma or the effect site was targeted, although higher plasma concentrations were achieved in the effect-site group. This finding implies, at least for propofol, that the time course for its hemodynamic effects is similar or longer[187] to that for its anesthetic effects. Second, k_{e0} is dependent on the pharmacokinetic set from which it is derived.[31] A k_{e0} value cannot be taken from one pharmacokinetic set and used with another pharmacokinetic set.[30] Just as various demographics may alter the pharmacokinetics, they may also alter k_{e0}. Therefore using the k_{e0} best adapted for the clinical milieu is desirable. An ideal test of whether targeting plasma or the effect site is better is to compare their use in a closed-loop system in which a measure of effect (e.g., the BIS) is used as the target of control. In a small study of 10 patients per group, Absalom and Kenny showed that maintenance of the targeted BIS (as measured by MDPE, MDAPE, and wobble) was somewhat improved and induction times were significantly shorter when the pharmacokinetic model was for the effect site rather than for the plasma.[188] Effect compartment–controlled TCI systems are currently commercially available in many countries (not the United States).

TCI remifentanil provided improved hemodynamic control both intraoperatively and postoperatively with less remifentanil and similar propofol infusion rates.[189] Age dramatically influences the pharmacokinetics of remifentanil; consequently, a TCI model that includes age will result in a beneficial drug titration compared with a standard μg/kg/min infusion (also see Chapter 80). For deep sedation in spontaneously breathing patients, Moerman and associates[190] found that the combination of remifentanil and propofol offered better conditions for colonoscopy than propofol alone; and that TCI remifentanil administration was associated with reduced propofol dosing and a less frequent incidence of apnea and respiratory depression, compared with manually controlled administration. Others have confirmed this finding.[191] In addition, effect compartment–controlled TCI may offer better control of the dose-response relationship.[62,192,193]

Pharmacokinetic model–driven infusion of propofol compares favorably with inhaled anesthetics. Sneyd and co-workers compared TCI propofol with sevoflurane in patients undergoing neurosurgical procedures and found little difference between the two techniques[194] (also see Chapter 70). This finding implies that given the appropriate means for administration, intravenous anesthesia can be equivalent to inhaled anesthetics in achieving the objectives of anesthesia; that is, rapid induction and recovery with stable maintenance. Passot and coworkers[195] compared TCI, manual propofol infusion, and etomidate/desflurane in high-risk older patients undergoing hip fracture surgery and concluded that TCI improved the time course of propofol-induced hemodynamic effects in these patients.

In noncomparative studies, pharmacokinetic model–driven infusion has been used to administer most of the potent opioids, as well as the hypnotics. Different anesthetic techniques have also been tested with pharmacokinetic model–driven infusion devices, including nitrous oxide–opioid anesthesia, supplementation of volatile anesthetics, total intravenous anesthesia, sedation for monitored anesthesia care, and intensive care unit (ICU) sedation. In all these studies, outcome as measured by hemodynamics and recovery has been within the expectations of normal clinical care. Etomidate, methohexital, midazolam, propofol, thiopental, dexmedetomidine, alfentanil, fentanyl, remifentanil, and sufentanil have all been used with TCI. When these drugs were used with target-controlled drug delivery systems for total intravenous anesthesia or to supplement nitrous oxide or volatile anesthetics, hemodynamics were well maintained during induction and intubation, as well as during maintenance. Recovery milestones were reached at times comparable with those achieved with similar drug combinations used in manual infusion schemes. None of these studies have reported adverse outcomes resulting from target-controlled drug delivery. TCI devices have also been used to provide PCA. For example, Van den Nieuwenhuyzen and colleagues demonstrated advantages of PCA-TCI with alfentanil over routine morphine PCA.[66,154,196,197] Analgesia support using effect-site targeted TCI of remifentanil or fentanyl during extracorporeal shock-wave lithotripsy was tested by Cortinez and colleagues. They found a remifentanil and fentanyl EC_{50} of 2.8 ng/mL and 2.9 ng/ mL. At EC_{50}, the probability of having a respiratory rate less than 10 was 4% for remifentanil and 56% for fentanyl. Hypoxemia, vomiting, and sedation were more frequent in the fentanyl group, making this drug less suitable for this clinical application than remifentanil. Lipszyc and associates[111] accurately used remifentanil effect-site PCA-TCI with a slow and progressive adapted algorithm for treatment of acute pain after uterine artery embolization and showed that it provided better care than PCA morphine in the first 4 hours of administration

Preliminary results have been published for the use of propofol TCI in the ICU (also see Chapter 101). McMurray and co-workers[198] proposed propofol plasma targets between 0.2 and 2.0 μg/mL for ICU sedation. In their study, acceptable sedation levels occurred in 84% of the sedation period and predicted propofol concentrations were close to measured concentrations.

The authors have concluded that automated drug delivery of intravenous anesthetics is at least equal to manual delivery of these drugs. Intravenous drug administration via target-controlled drug delivery is analogous to inhaled volative anesthetic delivery via a calibrated vaporizer. Similar to the vaporizer, pharmacokinetic model–driven infusion facilitates drug delivery based on plasma or biophase concentration rather than on drug dosage. Variability exists with the use of a calibrated vaporizer, including the variability in the accuracy of drug delivery with vaporizers, slow equilibration between the fresh gas flow and the circuit at low flow rates, and variable uptake by the patient. This variability does not particularly complicate the titration of inhaled anesthetics. The variability with target-controlled drug delivery is of a similar magnitude and can be demonstrated to be less than the variability associated with vaporizers and, likewise, does not particularly complicate titration of intravenous anesthetics. Indeed, the variations in surgery-dependent and patient-dependent stress responses require titrated administration of potent inhaled anesthetics by using the calibrated vaporizer as a tool. These same factors require that the clinician carefully titrate the infusion of intravenous anesthetic drugs when using automated drug delivery as a tool.

No real-time plasma concentration measurements of intravenous drugs are available for clinical use. If available, such measurements may improve drug delivery or might optimize TCI administration for the individual patient.[199] Recently, efforts have been made to measure expired air propofol concentrations and to correlate these with plasma concentrations. Several promising techniques have been described. Miekisch and co-workers have used proton transfer mass spectrometry and headspace solid-phase microextraction coupled with gas chromatography-mass spectrometry.[200] Perl and colleagues[201] used an ion mobility spectrometer coupled to a multicapillary column for preseparation (multicapillary column–ion mobility spectrometer), and Grossherr and colleagues used gas chromatography mass spectrometry.[202] The latter group also described the difference between blood/gas partition coefficient and pulmonary extraction ratio for propofol between species, which will be important when studying this technique in an animal setting.[203] More research is required before these measurements can be applied to clinical practice.

Closed-Loop Controlled Intravenous Drug Delivery

The next step in computer-controlled drug delivery is to feed a continuous measure of drug effect directly back to the automated drug delivery device, thus providing a continuous closed-loop system. This system avoids the requirement of a clinician to titrate the target concentration manually, based on intermittent observations of the desired therapeutic effect. With manual control, attempts to achieve tight titration of hypnosis require high clinical expertise and a labor-intensive process and may divert the clinician's attention from critical actions resulting in a suboptimal therapy or even threatening the patient's safety. Applying closed-loop drug administration techniques could optimize this process of dose titration.[4] The application of closed-loop systems for drug administration is complex and requires a perfect balance for all the basic components of such a system: (1) a control variable representative for the targeted therapeutic effect; (2) a clinically relevant set-point or target value for this variable; (3) a control actuator which is, in this case, the infusion pump driving the drug; (4) a system, in this case a patient; and (5) an accurate, stable control algorithm.[204]

Control algorithms are all based on measuring the error between the target and the observed effect. Various control strategies are described in the literature to steer this closed-loop administration. Proportional-integral differential (PID) controllers are frequently used in engineering applications. This controller will adjust the infusion rates in a manner that is proportional to the magnitude of the error, the integral of the error over time, and the derivative of the error over time. The fine-tuning of a PID controller might be difficult in this particular setting because of the complexity of the system to control and the interindividual pharmacologic variability and because directly counteracting the administration of excessive drug is not possible. A more appropriate approach could be to use a PID control system connected to a TCI system to decrease the order of complexity between dose and response (see Fig. 33-26).[205] An alternative control strategy is called *model-based adaptive control*. This controller has an internal model of the system, typically set up as an integrated pharmacokinetic-pharmacodynamic model that relates dose to concentration (pharmacokinetics) and concentration to drug effect (pharmacodynamics). The model is updated to explain the difference between the measured and predicted drug effect.

A reliable physiologic signal, which is a measure of the clinical drug effect, is the most important component of closed-loop technology. Vital signs such as arterial blood pressure or muscle activity have been used to guide intravenous closed-loop drug administration. For example, Kenny and co-workers[206] successfully evaluated closed-loop control of arterial blood pressure using a mixture of trimethaphan camsylate and sodium nitroprusside during controlled hypotensive anesthesia for local resection of intraocular melanoma. In the 1980s and the 1990s, various researchers investigated the accuracy of closed-loop controlled administration of atracurium[207,208] and vecuronium.[209] However, since the introduction of the novel reversal drug, sugammadex, interest in closed-loop administration of vecuronium or rocuronium has significantly declined.

The commercialization of various EEG-based *depth of anesthesia* monitors, such as the BIS, spectral entropy, and auditory-evoked potential, has renewed the interest of various research groups in closed-loop administration of intravenous hypnotics. Using an early version of

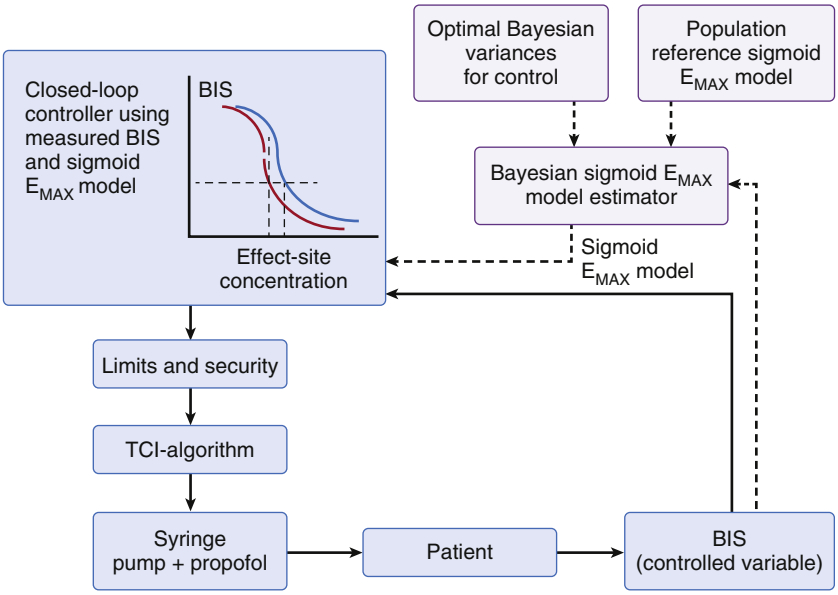

Figure 33-32. Flow chart of the closed-loop system. The *solid lines* represent the closed-loop control system. At each time the required effect-site concentration is calculated by the controller. This value is sent to an additional algorithm, taking the safety limits into account. The result of these calculations is the required effect-site concentration sent to the target-controlled infusion (TCI) algorithm, which steers a pump injecting propofol to the patient. The measured bispectral index (BIS) is used as the input of the closed-loop controller. The *dotted lines* represent the Bayesian sigmoid E_{MAX} model estimator. The estimator receives a priori information from the population sigmoid E_{MAX} model, the optimal Bayesian variances for control and the patient-measured BIS values *(From De Smet T, Struys MM, Greenwald S, et al: Estimation of optimal modelling weights for a Bayesian-based closed-loop system for propofol administration using the bispectral index as a controlled variable: a simulation study,* Anesth Analg *105:1629-38, 2007. Used with permission.)*

the BIS as the control variable, Sakai and colleagues[210] concluded that their closed-loop system provided intraoperative hemodynamic stability and a prompt recovery from sedative-hypnotic effects of propofol. A similar propofol closed-loop system using the BIS and PID control of a plasma-controlled TCI system showed acceptable control during major orthopedic surgery[211] and during sedation.[212] Although these investigators improved the performance of their control system by switching toward effect-site targeted TCI, they also concluded that the PID controller might still face some stability problems. Similarly, Liu and colleagues used a closed-loop titration of TCI based on a proportional-differential algorithm guided by the BIS, allowing induction and maintenance of general anesthesia and compared this with manual propofol TCI. They found that closed-loop control resulted in smaller propofol consumption and longer induction times but with better hemodynamic stability, less excessive anesthetic levels (BIS <40), similar hemodynamic stability, and faster recovery.[205,213] More recently, the same researchers tested a more advanced version of their system, now using full PID control, for closed-loop co-administration of both propofol and remifentanil, using the BIS as the controlled variable. A rule-based algorithm decides when to change the propofol or remifentanil targets. In a multicenter study, this system showed a better overall performance versus manual administration.[214] A similar approach was used with an alternative EEG-derived index, spectral entropy.[215]

Model-based adaptive control of BIS-guided propofol administration was previously used by Struys and colleagues for sedation during spinal anesthesia and for general anesthesia.[216,217] The control algorithm is based on a patient-specific pharmacodynamic profile estimated during induction. Compared with manually titrated propofol administration, patients in the closed-loop group reached the target BIS at a somewhat slower rate, but this resulted in less BIS overshoot and better hemodynamics after induction. During the maintenance phase, improved control of the BIS and systolic blood pressure was found in the closed-loop group and recovery was faster. Using simulations, these authors compared their model-based control system with a previously published PID controller and found that the model-based controller outperformed, even under extreme control conditions such as low and high BIS levels and abrupt changes in the BIS levels.[218] More recently, De Smet and Struys developed the adaptive part of the controller using Bayesian optimization (Fig. 33-32)[219] and compared the feasibility and accuracy of this system with manually controlled BIS-guided, effect compartment–controlled propofol TCI during ambulatory gynecologic procedures. They found that the closed-loop control system accurately titrated propofol administration resulting in BIS values close to the set point. The closed-loop control system was able to induce anesthesia in the patients within clinically accepted time limits and with less overshoot than the manual control group. Automated control resulted in beneficial recovery times. This closed-loop control group showed similar acceptable clinical performance specified by similar hemodynamic, respiratory stability, comparable movement rates, and quality scores as the manual control group.[220]

Alternative closed-loop systems have been developed for isoflurane administration using a controller with a cascade structure, originally described by Gentilini and

associates.[221,222] Recently, Moore and Doufas designed a closed-loop system using an intelligent system technique called *reinforcement learning*, known as a mathematically robust method of achieving optimal control in systems challenged with noise, nonlinearity, time delay, and uncertainty.[223,224]

So far, all developed closed-loop systems have been used under strict experimental conditions. The challenge is now to prove their safety and utility when applied in clinical practice.[225] Finally, clinicians will have to determine whether adaptive, intelligent computer systems with dual, interacting, closed-loop systems will facilitate better control and improve patient outcomes.[132]

Chapter 34

Pharmacology of Neuromuscular Blocking Drugs

MOHAMED NAGUIB • CYNTHIA A. LIEN • CLAUDE MEISTELMAN

Key Points

- Two different populations of nicotinic acetylcholine receptors exist at the mammalian neuromuscular junction. In the adult, the nicotinic acetylcholine receptor at the postsynaptic (muscular) membrane is composed of $\alpha_2\beta\delta\varepsilon$ subunits. Each of the two α subunits has an acetylcholine-binding site. The presynaptic (neuronal) nicotinic receptor is also a pentameric complex composed of $\alpha_3\beta_2$ subunits (see also Chapter 18).
- Nondepolarizing muscle relaxants produce neuromuscular blockade by competing with acetylcholine for the postsynaptic α subunits. In contrast, succinylcholine produces prolonged depolarization that results in decreased sensitivity of the postsynaptic nicotinic acetylcholine receptor and inactivation of sodium channels so that propagation of the action potential across the muscle membrane is inhibited.
- Different forms of neuromuscular stimulation test for neuromuscular blockade at different areas of the motor end plate. Depression of the response to single twitch stimulation is likely caused by blockade of postsynaptic nicotinic acetylcholine receptors, whereas fade in the response to tetanic and train-of-four stimuli results from blockade of presynaptic nicotinic receptors.
- Succinylcholine is the only available depolarizing neuromuscular blocker. It is characterized by rapid onset of effect and ultrashort duration of action because of its rapid hydrolysis by butyrylcholinesterase.
- Available nondepolarizing neuromuscular blockers can be classified according to chemical class (the steroidal, the benzylisoquinolinium, or other compounds) or, alternatively, according to onset or duration of action (long-, intermediate-, and short-acting drugs) of equipotent doses.
- The speed of onset is inversely proportional to the potency of nondepolarizing neuromuscular blocking drugs. With the exception of atracurium, molar potency is highly predictive of a drug's rate of onset of effect. Rocuronium has a molar potency ($ED_{95} \approx 0.54$ μM/kg) that is approximately 13% that of vecuronium and 9% that of cisatracurium. Its onset of effect is more rapid than either of these muscle relaxants.
- Neuromuscular blockade develops faster, lasts a shorter time, and is recovered from more quickly in the more centrally located neuromuscular units (e.g., laryngeal adductors, diaphragm, and masseter muscle) than in the more peripherally located adductor pollicis.
- The long-acting neuromuscular blockers undergo minimal or no metabolism, and they are primarily eliminated, largely unchanged, by renal excretion. Neuromuscular blockers of intermediate duration of action have more rapid clearances than the long-acting blockers because of multiple pathways of degradation, metabolism, and elimination. Mivacurium, a short-acting neuromuscular blocker, is cleared rapidly and almost exclusively by metabolism by butyrylcholinesterase.
- After the administration of nondepolarizing neuromuscular blocking drugs, it is essential to ensure adequate return of normal neuromuscular function. Residual paralysis decreases upper esophageal tone, coordination of the esophageal musculature during swallowing, and hypoxic ventilatory drive. Residual paralysis can increase morbidity and mortality.

HISTORY AND CLINICAL USE

In 1942, Griffith and Johnson described *d*-tubocurarine (dTc) as a safe drug to provide skeletal muscle relaxation during surgery.[1] One year later, Cullen described the use of this drug in 131 patients who had received general anesthesia for surgery.[2] In 1954, Beecher and Todd reported a sixfold increase in mortality in patients receiving dTc compared with patients who had not received a muscle relaxant.[3] The increased mortality resulted from a general lack of understanding of the clinical pharmacology and effects of neuromuscular blocking drugs (NMBDs). The effect of residual neuromuscular blockade postoperatively was not appreciated, guidelines for monitoring muscle strength had not been established, and the importance of pharmacologically antagonizing residual blockade was not understood.

Succinylcholine, introduced by Thesleff[4] and Foldes and associates[5] in 1952, changed anesthetic practice drastically because the drug's rapid onset of effect and ultrashort duration of action allowed for both rapid endotracheal intubation and rapid recovery of neuromuscular strength.

In 1967, Baird and Reid first reported on the clinical administration of the first synthetic aminosteroid, pancuronium.[6] The development of the intermediate-acting NMBDs built on the compounds' metabolism and resulted in the introduction of vecuronium,[7] an aminosteroid, and atracurium,[8] a benzylisoquinolinium, into clinical practice in the 1980s. Vecuronium was the first muscle relaxant to have an intermediate duration of action and minimal cardiovascular actions. Mivacurium, the first short-acting nondepolarizing NMBD, was introduced into clinical practice in the 1990s,[9] as was rocuronium,[10] an intermediate-acting nondepolarizing blocker with a very rapid onset of neuromuscular blockade. Other NMBDs have been introduced into clinical practice since the use of dTc was first advocated. These include pipecuronium, doxacurium, cisatracurium, and rapacuronium. Although all do not remain in use, each represented an advance or improvement in at least one aspect over its predecessors. Still other NMBDs, such as gantacurium and CW 002,[11] are undergoing investigation.

NMBDs should be administered only to anesthetized individuals to provide relaxation of skeletal muscles. Because this class of drugs lacks analgesic or amnestic properties, these drugs should not be administered to prevent patient movement. Awareness during surgery[12] and in the intensive care unit (ICU)[13] has been described in multiple publications. As stated by Cullen and Larson, "muscle relaxants given inappropriately may provide the surgeon with optimal [operating] conditions in…a patient[14] [who] is paralyzed but not anesthetized—a state that [is] wholly unacceptable for the patient."[15] Additionally, "muscle relaxants used to cover up deficiencies in total anesthetic management…represent an…inappropriate use of the valuable adjuncts to anesthesia."[15] Administration of NMBDs intraoperatively to maintain neuromuscular block requires that the time course of block be monitored and the depth of anesthesia be continuously assessed.

NMBDs have been integrated into most anesthetic techniques for major surgery and have become key components in the continuous improvement of safe anesthetic practice and the development of advanced surgical techniques. As earlier stated by Foldes and colleagues,[5] "…[the] first use of…muscle relaxants…not only revolutionized the practice of anesthesia but also started the modern era of surgery and made possible the explosive development of cardiothoracic, neurologic, and organ transplant surgery." Certainly, NMBDs are now used routinely to facilitate endotracheal intubation and mechanical ventilation and are commonly used to maintain neuromuscular blockade through any number of different surgical procedures. This chapter reviews the pharmacology and clinical use of NMBDs and anticholinesterases in anesthesia and intensive care settings.

PRINCIPLES OF ACTION OF NEUROMUSCULAR BLOCKERS AT THE NEUROMUSCULAR JUNCTION

A brief description of the physiology of neuromuscular blockade is presented in this chapter. A more comprehensive overview is provided in Chapter 18.

POSTJUNCTIONAL EFFECTS

In adult mammalian skeletal muscle, the nicotinic acetylcholine receptor (nAChR) is a pentameric complex of two α subunits in association with single β, δ, and ε subunits (Fig. 34-1). These subunits are organized to form a transmembrane pore, or channel, as well as extracellular binding pockets for acetylcholine and other agonists or antagonists.[16] Each of the two α subunits has an acetylcholine-binding site. These sites are located in pockets within the receptor protein, approximately 3.0 nm above the surface membrane at the interfaces of the α_H-ε and α_L-δ subunits.[17] α_H and α_L indicate the high- and low-affinity binding sites for dTc and probably result from the contribution of the different neighboring subunits.[18] For instance, the binding affinity of dTc for the α_H-ε site is approximately 100 to 500 times higher than that for the α_L-δ site.[18] The fetal nAChR contains a γ subunit instead of an adult ε subunit. Once activated by acetylcholine, the mature nAChR has a shorter opening time and a higher conductance to sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}) than does the fetal nAChR, which has a considerably longer opening time.[16]

Functionally, the ion channel of the acetylcholine receptor is closed in the resting state. Simultaneous binding of two acetylcholine molecules to the α subunits initiates conformational changes that open the channel. If one molecule of a nondepolarizer NMBD (i.e., a competitive antagonist) is bound to a subunit at the AChR, two agonists cannot bind, and neuromuscular transmission is inhibited.[19]

Succinylcholine, a depolarizing NMBD, produces prolonged depolarization of the end plate region, which results in (1) desensitization of the nAChR, (2) inactivation of voltage-gated Na^+ channels at the neuromuscular junction, and (3) increases in K^+ permeability in the surrounding membrane.[19] The end results are failure of action potential generation and neuromuscular blockade.

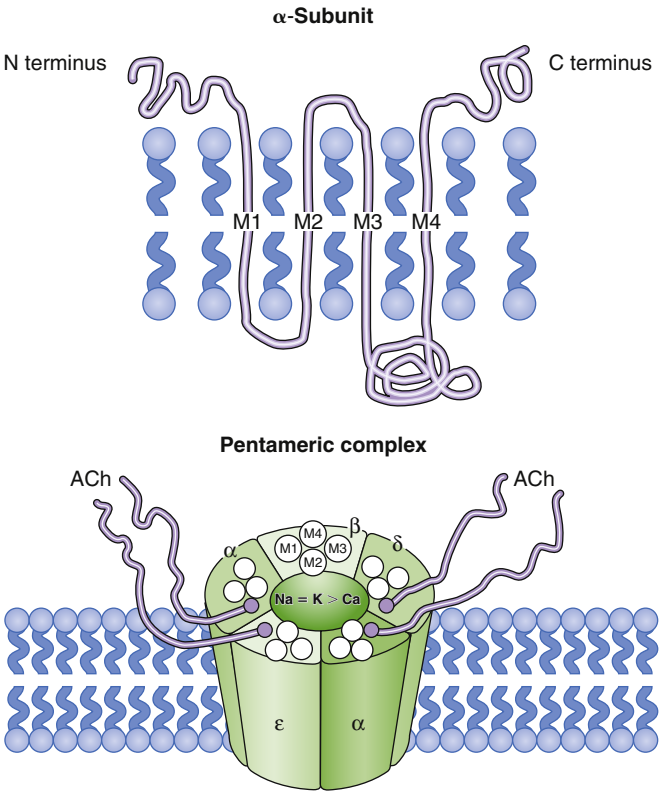

Figure 34-1. Subunit composition of the nicotinic acetylcholine receptor (nAChR) in the end plate surface of adult mammalian muscle. The adult AChR is an intrinsic membrane protein with five distinct subunits ($\alpha_2\beta\delta\varepsilon$). Each subunit contains four helical domains, labeled M_1 to M_4. The M_2 domain forms the channel pore. The *upper panel* shows a single α subunit with its N and C termini on the extracellular surface of the membrane lipid bilayer. Between the N and C termini, the α subunit forms four helices (M_1, M_2, M_3, and M_4), which span the membrane bilayer. The *lower panel* shows the pentameric structure of the nAChR of adult mammalian muscle. The N termini of two subunits cooperate to form two distinct binding pockets for acetylcholine. These pockets occur at the ε-α and the δ-α subunit interface. The M_2 membrane-spanning domain of each subunit lines the ion channel. The doubly liganded ion channel has equal permeability to sodium (Na) and potassium (K); calcium (Ca) contributes approximately 2.5% to the total permeability. *(From Naguib M, Flood P, McArdle JJ, Brenner HR: Advances in neurobiology of the neuromuscular junction: implications for the anesthesiologist,* Anesthesiology *96:202-231, 2002, with permission from* Anesthesiology.*)*

The fetal nAChR is a low-conductance channel, in contrast to the high-conductance channel of the adult nAChR. Thus, acetylcholine release causes brief activation and a reduced probability of the channel's opening.[16] The up-regulation of nAChRs found in states of functional or surgical denervation is characterized by the spreading of predominantly fetal-type nAChRs. These receptors are resistant to nondepolarizing NMBDs and are more sensitive to succinylcholine.[20] When depolarized, the immature isoform has a prolonged open channel time that exaggerates the K^+ efflux.[21] The neuronal nicotinic α7 receptor, which also is expressed after muscle denervation, has an exaggerated response to agonists associated with excessive release of K^+ from cells.[22]

PREJUNCTIONAL EFFECTS

Prejunctional receptors are involved in the modulation of acetylcholine release in the neuromuscular junction. The existence of both nicotinic and muscarinic receptors on the motor nerve endings has been described. Bowman suggested that the prejunctional nicotinic receptors are activated by acetylcholine and function in a positive-feedback control system that serves to maintain availability of acetylcholine when demand for it is high (e.g., during tetany).[23] It is now demonstrated that these presynaptic receptors are the $\alpha_3\beta_2$ neuronal subtype receptor. Although most clinically used nondepolarizing NMBDs have a distinct affinity to the $\alpha_3\beta_2$ cholinergic receptor, succinylcholine lacks affinity for this presynaptic receptor subtype. The action of nondepolarizing versus depolarizing NMBDs at this neuronal cholinergic receptor explains the typical fade phenomenon after any nondepolarizing drugs and the lack of such effect in the clinical dose range for succinylcholine.

The G-protein–coupled muscarinic receptors are also involved in the feedback modulation of acetylcholine release.[24] The prejunctional M_1 and M_2 receptors are involved in facilitation and inhibition of acetylcholine release, respectively, by modulation of Ca^{2+} influx.[24] The prejunctional nicotinic receptors are involved with mobilization of acetylcholine but not directly with the release process.[25] Hence, blockade of the prejunctional nicotinic receptors by nondepolarizing NMBDs prevents acetylcholine from being made available fast enough to support tetanic or train-of-four (TOF) stimulation. In contrast, the prejunctional muscarinic receptors are involved with up-modulation or down-modulation of the release mechanism.

PHARMACOLOGY OF SUCCINYLCHOLINE

STRUCTURE-ACTIVITY RELATIONSHIPS

All NMBDs contain quaternary ammonium compounds and as such are structurally closely related to acetylcholine. Positive charges at the quaternary ammonium sites of NMBDs mimic the quaternary nitrogen atom of acetylcholine and are the structural reason for the attraction of these drugs to muscle- and neuronal-type nAChRs at the neuromuscular junction. These receptors are also located at other sites throughout the body where acetylcholine is the transmitter. These sites include the neuronal-type nicotinic receptors in autonomic ganglia and as many as five different muscarinic receptors on both the parasympathetic and sympathetic sides of the autonomic nervous system. In addition, populations of neuronal nicotinic and muscarinic receptors are located prejunctionally at the neuromuscular junction.[19]

The depolarizing NMBD, succinylcholine, is composed of two molecules of acetylcholine linked through the acetate methyl groups (Fig. 34-2). As described by Bovet,[26] succinylcholine is a small, flexible molecule, and like the natural ligand acetylcholine, succinylcholine stimulates cholinergic receptors at the neuromuscular junction and muscarinic autonomic sites, thus opening the ionic channel in the acetylcholine receptor.

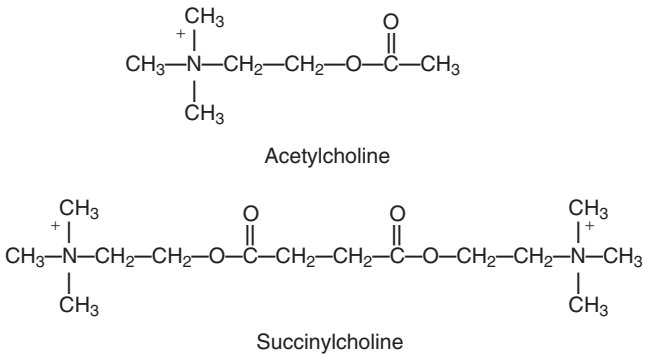

Figure 34-2. Structural relationship of succinylcholine, a depolarizing neuromuscular blocking drug, and acetylcholine. Succinylcholine consists of two acetylcholine molecules linked through the acetate methyl groups. Like acetylcholine, succinylcholine stimulates nicotinic receptors at the neuromuscular junction.

PHARMACOKINETICS AND PHARMACODYNAMICS

Succinylcholine is the only available NMBD with a rapid onset of effect and an ultrashort duration of action. The ED_{95} (the dose causing on average 95% suppression of neuromuscular response) of succinylcholine is 0.51 to 0.63 mg/kg.[27] Using cumulative dose-response techniques, Kopman and co-workers estimated that its potency is far greater,[28] and it has an ED_{95} of less than 0.3 mg/kg.

Administration of 1 mg/kg of succinylcholine results in complete suppression of response to neuromuscular stimulation in approximately 60 seconds.[29] In patients with genotypically normal butyrylcholinesterase (also known as plasma cholinesterase or pseudocholinesterase), recovery to 90% muscle strength following administration of 1 mg/kg succinylcholine requires 9 to 13 minutes.[30]

The short duration of action of succinylcholine results from its rapid hydrolysis by butyrylcholinesterase to succinylmonocholine and choline. Butyrylcholinesterase has a large enzymatic capacity to hydrolyze succinylcholine, and only 10% of the administered drug reaches the neuromuscular junction.[31] The initial metabolite, succinylmonocholine, is a much weaker NMBD than succinylcholine and is metabolized much more slowly to succinic acid and choline. The elimination half-life of succinylcholine is estimated to be 47 seconds.[32]

Because little or no butyrylcholinesterase is present at the neuromuscular junction, the neuromuscular blockade of succinylcholine is terminated by its diffusion away from the neuromuscular junction into the circulation. Butyrylcholinesterase therefore influences the onset and duration of action of succinylcholine by controlling the rate at which the drug is hydrolyzed before it reaches and after it leaves the neuromuscular junction.

DIBUCAINE NUMBER AND BUTYRYLCHOLINESTERASE ACTIVITY

Butyrylcholinesterase is synthesized by the liver and found in the plasma. The neuromuscular blockade induced by succinylcholine is prolonged when the concentration or activity of the enzyme is decreased. The activity of the enzyme refers to the number of substrate

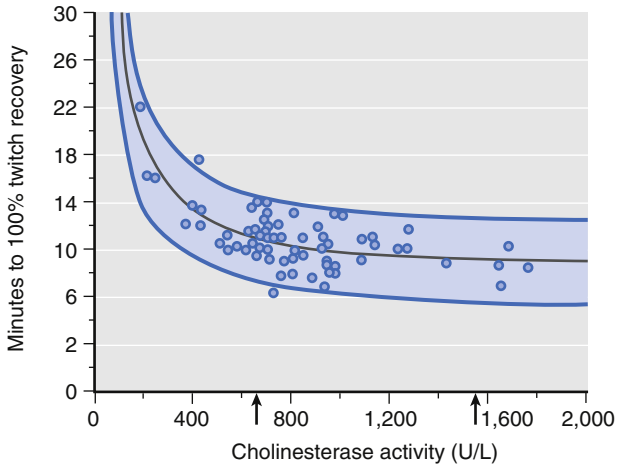

Figure 34-3. Correlation between duration of succinylcholine neuromuscular blockade and butyrylcholinesterase activity. The normal range of activity lies between the *arrows. (From Viby-Mogensen J: Correlation of succinylcholine duration of action with plasma cholinesterase activity in subjects with the genotypically normal enzyme,* Anesthesiology *53:517-520, 1980.)*

molecules (μmol) hydrolyzed per unit of time, and it is often expressed in International Units. The normal range of butyrylcholinesterase activity is quite large[30]; significant decreases in butyrylcholinesterase activity result in only modest increases in the time required to return to 100% of baseline muscle strength (Fig. 34-3).

Factors that lower butyrylcholinesterase activity include liver disease,[33] advanced age,[34] malnutrition, pregnancy, burns, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, neoplastic disease, anticholinesterase drugs,[35] tetrahydroaminacrine,[36] hexafluorenium,[37] and metoclopramide.[38] Bambuterol, a prodrug of terbutaline, produces marked inhibition of butyrylcholinesterase activity and causes prolongation of succinylcholine-induced blockade.[39] The β-blocker esmolol inhibits butyrylcholinesterase but causes only a minor prolongation of succinylcholine-induced blockade.[40]

Decreased butyrylcholinesterase enzyme activity is not a major concern in clinical practice because even large decreases in butyrylcholinesterase activity result in only moderate increases in the duration of action of succinylcholine. When butyrylcholinesterase activity is reduced to 20% of normal by severe liver disease, the duration of apnea after the administration of succinylcholine increases from a normal duration of 3 minutes to only 9 minutes. When glaucoma treatment with echothiophate decreased butyrylcholinesterase activity from 49% of control to no activity, the increase in duration of neuromuscular blockade varied from 2 to 14 minutes. In no patient did the total duration of neuromuscular blockade exceed 23 minutes.[41]

DIBUCAINE NUMBER AND ATYPICAL BUTYRYLCHOLINESTERASE ACTIVITY

Succinylcholine-induced neuromuscular blockade can be significantly prolonged if a patient has an abnormal genetic variant of butyrylcholinesterase. The variant was found by Kalow and Genest to respond to dibucaine

TABLE 34-1 RELATIONSHIP BETWEEN DIBUCAINE NUMBER AND DURATION OF SUCCINYLCHOLINE OR MIVACURIUM NEUROMUSCULAR BLOCKADE

Type of Butyrylcholinesterase	Genotype	Incidence	Dibucaine Number*	Response to Succinylcholine or Mivacurium
Homozygous typical	$E_1^uE_1^u$	Normal	70-80	Normal
Heterozygous atypical	$E_1^uE_1^a$	1/480	50-60	Lengthened by 50-100%
Homozygous atypical	$E_1^aE_1^a$	1/3200	20-30	Prolonged to 4-8 hr

*The dibucaine number indicates the percentage of enzyme inhibited.

differently than did normal butyrylcholinesterase.[42] Dibucaine inhibits normal butyrylcholinesterase to a far greater extent than the abnormal enzyme. This observation led to the establishment of the dibucaine number. Under standardized test conditions, dibucaine inhibits the normal enzyme approximately 80% and the abnormal enzyme approximately 20% (Table 34-1). Many other genetic variants of butyrylcholinesterase have since been identified, although the dibucaine-resistant variants are the most important. A review by Jensen and Viby-Mogensen provides more detailed information on this topic.[43]

Although the dibucaine number indicates the genetic makeup of an individual with respect to butyrylcholinesterase, it does not measure the concentration of the enzyme in the plasma substrate. This is determined by measuring butyrylcholinesterase activity in plasma, and it may be influenced by comorbidities, medications, and genotype.

The molecular biology of butyrylcholinesterase is well understood. The amino acid sequence of the enzyme is known, and the coding errors responsible for most genetic variations have been identified.[43] Most variants result from a single amino acid substitution error or sequencing error at or near the active site of the enzyme. For example, in the case of the "atypical" dibucaine-resistant (A) gene, a mutation occurs at nucleotide 209, where guanine is substituted for adenine. The resultant change in this codon causes substitution of glycine for aspartic acid at position 70 in the enzyme. In the case of the fluoride-resistant (F) gene, two amino acid substitutions are possible, namely, methionine for threonine at position 243 and valine for glycine at position 390. Table 34-1 summarizes many of the known genetic variants of butyrylcholinesterase: the amino acid substitution at position 70 is written as Asp ∅ Gly. New variants of butyrylcholinesterase genotypes continue to be discovered.[44]

SIDE EFFECTS

Cardiovascular Effects

Succinylcholine-induced cardiac dysrhythmias are many and varied. The drug stimulates cholinergic autonomic receptors on both sympathetic and parasympathetic ganglia[45] and muscarinic receptors in the sinus node of the heart. At low doses, both negative inotropic and chronotropic responses may occur. These responses can be attenuated by prior administration of atropine. With large doses of succinylcholine, these effects may become positive,[46] causing tachycardia. The clinical manifestation of generalized autonomic stimulation is the development of sinus bradycardia, junctional rhythms, and ventricular dysrhythmias. Clinical studies have described these dysrhythmias under various conditions in the presence of the intense autonomic stimulus of tracheal intubation. It is not entirely clear whether the cardiac irregularities are caused by the action of succinylcholine alone or by the added presence of extraneous autonomic stimulation. An in vitro study using ganglionic acetylcholine receptors subtype $\alpha_3\beta_4$ expressed in *Xenopus laevis* oocytes suggested that succinylcholine at clinically relevant concentrations had no effect on the expressed receptors.[47] Only high doses of succinylcholine caused inhibition of ganglionic acetylcholine receptors.[47] Whether or not these findings are applicable to clinical practice is unclear because the methodology (*Xenopus laevis* oocytes expression model) has no clinical equivalent.

Sinus Bradycardia. Stimulation of cardiac muscarinic receptors in the sinus node causes sinus bradycardia. This side effect is particularly problematic in individuals with predominantly vagal tone, such as in children who have not received atropine. Sinus bradycardia can occur in adults and appears more commonly after a second dose of the drug administered approximately 5 minutes after the initial dose.[48] The bradycardia may be prevented by administration of atropine, ganglion-blocking drugs, and nondepolarizing NMBDs.[49] The ability of these drugs to prevent bradycardia implies that direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation may all be involved in the bradycardic response. The greater incidence of bradycardia after a second dose of succinylcholine suggests that the hydrolysis products of succinylcholine (succinylmonocholine and choline) may sensitize the heart to a subsequent dose.

Nodal (Junctional) Rhythms. Nodal rhythms commonly occur following administration of succinylcholine. The mechanism responsible for this likely involves relatively greater stimulation of muscarinic receptors in the sinus node, thus suppressing the sinus mechanism and allowing the emergence of the atrioventricular node as the pacemaker. The incidence of junctional rhythm is greater after a second dose of succinylcholine but is prevented by prior administration of dTc.[49]

Ventricular Dysrhythmias. Under stable anesthetic conditions, succinylcholine decreases the threshold of the ventricle to catecholamine-induced dysrhythmias in monkeys and dogs. Circulating catecholamine concentrations increase fourfold, and K^+ concentrations increase by one third after succinylcholine administration to dogs.[50] Similar increases in catecholamine levels occur following

administration of succinylcholine to humans.[51] Other autonomic stimuli, such as endotracheal intubation, hypoxia, hypercarbia, and surgery, may be additive to the effect of succinylcholine. The possible influence of drugs such as digitalis, tricyclic antidepressants, monoamine oxidase inhibitors, exogenous catecholamines, and anesthetic drugs such as halothane, which may lower the ventricular threshold for ectopic activity or increase the arrhythmogenic effect of the catecholamines, should also be considered. Ventricular escape beats may also occur as a result of severe sinus bradycardia and atrioventricular nodal slowing secondary to succinylcholine administration. The incidence of ventricular dysrhythmias is further enhanced by the release of K^+ from skeletal muscle as a consequence of the depolarizing action of the drug.

Hyperkalemia

The administration of succinylcholine to an otherwise healthy individual for an elective surgical procedure increases the plasma K^+ levels by approximately 0.5 mEq/dL. This increase in K^+ results from the depolarizing action of the compound. With activation of the acetylcholine channels, movement of Na^+ into the cells is accompanied by movement of K^+ out of the cells. This slight increase in K^+ is well tolerated by most individuals and generally does not cause dysrhythmias.

Patients with renal failure are no more susceptible to an exaggerated response to succinylcholine than are those with normal renal function.[52] Patients who have uremic neuropathy may possibly be susceptible to succinylcholine-induced hyperkalemia, although the evidence supporting this view is scarce.[52,53]

However, severe hyperkalemia may follow the administration of succinylcholine to patients with severe metabolic acidosis and hypovolemia.[54] In rabbits, the combination of metabolic acidosis and hypovolemia results in a high resting K^+ level and an exaggerated hyperkalemic response to succinylcholine.[55] In this situation, the K^+ originates from the gastrointestinal tract, rather than from muscle.[56] In patients with metabolic acidosis and hypovolemia, correction of the acidosis by hyperventilation and sodium bicarbonate administration should be attempted before succinylcholine administration. Should severe hyperkalemia occur, it can be treated with immediate hyperventilation, 1.0 to 2.0 mg of calcium chloride intravenously, 1 mEq/kg of sodium bicarbonate, and 10 units of regular insulin in 50 mL of 50% glucose for adults or, for children, 0.15 units/kg of regular insulin in 1.0 mL/kg of 50% glucose.

Kohlschütter and associates found that four of nine patients with severe abdominal infections had an increase in serum K^+ levels of as much as 3.1 mEq/L after succinylcholine administration.[57] The likelihood of a hyperkalemic response to succinylcholine increases in patients who have had intraabdominal infections for longer than 1 week.

Stevenson and Birch described a single, well-documented case of a marked hyperkalemic response to succinylcholine in a patient with a closed head injury without peripheral paralysis.[58]

Hyperkalemia after administration of succinylcholine is also a risk in patients who have had physical trauma.[59] The risk of hyperkalemia occurs 1 week after the injury, at which time a progressive increase in serum K^+ occurs during an infusion of succinylcholine. The risk of hyperkalemia can persist. Three weeks after injury, three of the patients studied in this series, who had especially severe injuries, became markedly hyperkalemic with an increase in serum K^+ of more than 3.6 mEq/L. Birch and co-workers also found that the prior administration of 6 mg of dTc prevented the hyperkalemic response to succinylcholine.[59] In the absence of infection or persistent degeneration of tissue, a patient is susceptible to the hyperkalemic response for likely at least 60 days after massive trauma or until adequate healing of damaged muscle has occurred.

Additionally, patients with conditions that result in the proliferation of extrajunctional acetylcholine receptors, such as neuromuscular disease, are likely to have an exaggerated hyperkalemic response following the administration of succinylcholine. The response of these patients to NMBDs is reviewed in detail later in this chapter. Some of these disease states include cerebrovascular accident with resultant hemiplegia or paraplegia, muscular dystrophies, and Guillain-Barré syndrome (see also Chapter 42). The hyperkalemia following administration of succinylcholine may be severe enough that cardiac arrest ensues. For a review of succinylcholine-induced hyperkalemia in acquired pathologic states, see Martyn and Richtsfeld.[22]

Increased Intraocular Pressure

Succinylcholine may cause an increase in intraocular pressure (IOP). The increased IOP develops within 1 minute of injection, peaks at 2 to 4 minutes, and subsides by 6 minutes.[60] The mechanism by which succinylcholine increases IOP has not been clearly defined, but it is known to involve contraction of tonic myofibrils and/or transient dilatation of choroidal blood vessels. Sublingual administration of nifedipine may attenuate the increase in IOP caused by succinylcholine, a finding suggesting a circulatory mechanism.[61] Despite this increase in IOP, the use of succinylcholine for eye operations is not contraindicated unless the anterior chamber is open. Although Meyers and colleagues were unable to confirm the efficacy of precurarization in attenuating increases in IOP following succinylcholine,[62] numerous other investigators have found that prior administration of a small dose of nondepolarizing NMBD (e.g., 3 mg of dTc or 1 mg of pancuronium) prevents a succinylcholine-induced increase in IOP.[63] Furthermore, Libonati and associates described the anesthetic management of 73 patients with penetrating eye injuries who received succinylcholine.[64] Among these 73 patients, no extrusion occurred. Thus, despite the potential concerns, the use of succinylcholine in patients with penetrating eye injuries, after pretreatment with a nondepolarizing NMBD and with a carefully controlled rapid-sequence induction of anesthesia, can be considered. Succinylcholine is only one of many factors that may increase IOP.[62] Other factors include endotracheal intubation and "bucking" on the endotracheal tube once it is positioned. Of prime importance in minimizing the chance of increasing IOP is ensuring that the patient is well anesthetized and is not straining or coughing. Because a nondepolarizing NMBD with a short onset of effect, rocuronium, is available, it is possible to perform

a rapid sequence induction of anesthesia and endotracheal intubation without administering succinylcholine. Finally, should a patient become too lightly anesthetized during intraocular surgery, succinylcholine should not be given to immobilize the patient. Rather, the surgeon should be asked to pause while anesthesia is deepened. If necessary, the depth of neuromuscular blockade can also be increased with nondepolarizing NMBDs.

Increased Intragastric Pressure

Unlike the rather consistent increase in IOP following administration of succinylcholine, increases in intragastric pressure (IGP) are much more variable. The increase in IGP from succinylcholine is presumed to result from fasciculations of the abdominal skeletal muscle. This is not surprising because more coordinated abdominal skeletal muscle activity (e.g., straight-leg raising) may increase the IGP to values as high as 120 cm H_2O. In addition to skeletal muscle fasciculations, the acetylcholine-like effect of succinylcholine may be partly responsible for the observed increases in IGP. Greenan observed consistent increases in IGP of 4 to 7 cm H_2O with direct vagal stimulation.[65]

Miller and Way found that 11 of 30 patients had essentially no increase in IGP after succinylcholine administration, yet 5 of the 30 had an increase in IGP of greater than 30 cm H_2O.[66] The increase in IGP from succinylcholine appeared to be related to the intensity of the fasciculations of the abdominal skeletal muscles. Accordingly, when fasciculations were prevented by prior administration of a nondepolarizing NMBD, no increase in IGP was observed.

Are the increases in IGP following succinylcholine administration enough to cause incompetence of the gastroesophageal junction? Generally, an IGP greater than 28 cm H_2O is required to overcome the competence of the gastroesophageal junction. However, when the normal oblique angle of entry of the esophagus into the stomach is altered, as may occur with pregnancy or an abdomen distended by ascites, bowel obstruction, or a hiatus hernia, the IGP required to cause incompetence of the gastroesophageal junction is frequently less than 15 cm H_2O.[66] In these circumstances, regurgitation of stomach contents following succinylcholine administration is a distinct possibility, and precautionary measures should be taken to prevent fasciculation. Endotracheal intubation may be facilitated with administration of either a nondepolarizing NMBD or a defasciculating dose of nondepolarizing relaxant before the succinylcholine. Although the increase in IGP from succinylcholine is well documented, the evidence of clinical harm is not clear.

Apparently, succinylcholine does not increase IGP appreciably in infants and children. This may be related to the minimal or absent fasciculations from succinylcholine in these young patients.[67]

Increased Intracranial Pressure

Succinylcholine has the potential to increase intracranial pressure.[68] The mechanisms and clinical significance of this transient increase are unknown, but the rise in intracranial pressure does not occur after pretreatment with nondepolarizing NMBDs.[68]

Myalgias

The incidence of muscle pain following administration of succinylcholine varies widely, from 0.2% to 89%.[69] Muscle pain occurs more frequently after minor surgery, especially in women and in ambulatory rather than bedridden patients.[70] Waters and Mapleson postulated that pain is secondary to damage produced in muscle by the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis.[70] This concept has been substantiated by finding myoglobinemia and increases in serum creatine kinase following succinylcholine administration.[71] Prior administration of a small dose of a nondepolarizing NMBD clearly prevents fasciculations from succinylcholine.[71] The efficacy of this approach in preventing muscle pain is not clear, however; most investigators claim that pretreatment with a nondepolarizing NMBD has no effect.[69] Pretreatment with a prostaglandin inhibitor (e.g., lysine acetyl salicylate) has been shown to be effective in decreasing the incidence of muscle pain after succinylcholine.[72] This finding suggests a possible role for prostaglandins and cyclooxygenases in succinylcholine-induced myalgias. Other investigators have found that myalgias following outpatient surgery occur even in the absence of succinylcholine.[73]

Masseter Spasm

An increase in tone of the masseter muscle is a frequent response to succinylcholine in adults,[74] as well as in children.[75] Meakin and associates suggested that the high incidence of spasm in children may result from inadequate dosage of succinylcholine.[75] In all likelihood, this increase in tone is an exaggerated contractile response at the neuromuscular junction and cannot be used to establish a diagnosis of malignant hyperthermia. Although an increase in tone of the masseter muscle may be an early indicator of malignant hyperthermia, this finding is not consistently associated with that syndrome.[76] Currently, no indication exists to change to a "nontriggering" anesthetic in instances of isolated masseter spasm.[77]

CLINICAL USES

In spite of its many adverse effects, succinylcholine remains commonly used. Its popularity is likely the result of its rapid onset of effect, the profound depth of neuromuscular blockade it produces, and its short duration of action. Succinylcholine may not be used as regularly as in the past for routine endotracheal intubation, but it is still a muscle relaxant for rapid-sequence induction of anesthesia. Although 1.0 mg/kg of succinylcholine is recommended to facilitate endotracheal intubation at 60 seconds, as little as 0.5 to 0.6 mg/kg allows for adequate intubating conditions 60 seconds after administration.[78] Reduction in the succinylcholine dose from 1.0 to 0.6 mg/kg decreases the incidence of hemoglobin desaturation but does not shorten the time to spontaneous diaphragmatic movements.[79] Decreasing the dose of succinylcholine is appealing as long as it does not interfere with provision of adequate conditions for endotracheal intubation and subsequent adequate ventilation.[79]

Typically, after administering succinylcholine for intubation, a nondepolarizing NMBD is given to maintain

neuromuscular blockade. Prior administration of succinylcholine enhances the depth of blockade caused by a subsequent dose of nondepolarizing NMBD.[80,81] However, the effect on duration of action is variable. Succinylcholine has no effect on the duration of pancuronium,[82] but it increases the duration of atracurium and rocuronium.[80,83] The reasons for these differences are not clear.

With administration of large doses of succinylcholine, the nature of the block, as determined by a monitor of neuromuscular blockade, changes from that of a depolarizing drug to that of a nondepolarizing drug. Clearly, both the dose and the duration of administration of succinylcholine contribute to this change. The relative contribution of each has not been established, however.

Posttetanic potentiation and fade in response to TOF and tetanic stimuli can be demonstrated after bolus administration of different doses of succinylcholine.[84] It seems that some characteristics of phase 2 blockade are evident from an initial dose (i.e., as small as 0.3 mg/kg) of succinylcholine.[84] Fade in response to TOF stimulation has been attributed to the presynaptic effects on NMBDs. The etiology of the appearance of fade phenomenon in the TOF response following excessive administration of succinylcholine has been suggested to be dependent on a concentration-dependent affinity for succinylcholine to the presynaptic $\alpha_3\beta_2$ neuronal subtype AChR in concentrations exceeding the normal clinical concentration range seen after routine doses.[47]

INTERACTIONS WITH ANTICHOLINESTERASES

Neostigmine and pyridostigmine inhibit butyrylcholinesterase, as well as acetylcholinesterase. If succinylcholine is administered after antagonism of residual neuromuscular block, as it may be with laryngospasm, the effect of succinylcholine will be pronounced and significantly prolonged. Sunew and Hicks found that the effect of succinylcholine (1 mg/kg) was prolonged from 11 to 35 minutes when it was given 5 minutes after administration of neostigmine (5 mg).[35] Ninety minutes after neostigmine administration, butyrylcholinesterase activity will have returned to less than 50% of its baseline value.

NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

The use of NMBDs in anesthesia has its origin in the arrow poisons or curares of South American Indians. Several nondepolarizing NMBDs were purified from naturally occurring sources. For example, dTc can be isolated from the Amazonian vine *Chondodendron tomentosum*. Similarly, the intermediates for the production of metocurine and alcuronium, which are semisynthetic, are obtained from *Chondodendron* and *Strychnos toxifera*. Malouetine, the first steroidal NMBD, was originally isolated from *Malouetia bequaertiana*, which grows in the jungles of the Democratic Republic of Congo in central Africa. The widely used drugs pancuronium, vecuronium, pipecuronium, rocuronium, rapacuronium, atracurium, doxacurium, mivacurium, cisatracurium, gantacurium, and gallamine are all synthetic compounds.

Available nondepolarizing NMBDs can be classified according to chemical class, based on structure (steroids, benzylisoquinoliniums, fumarates, and other compounds), or, alternatively, according to onset or duration of action (long-, intermediate-, and short-acting drugs) of equipotent doses (Table 34-2).

STRUCTURE-ACTIVITY RELATIONSHIPS

Nondepolarizing NMBDs were originally classified by Bovet as pachycurares,[26] or bulky molecules having the amine functions incorporated into rigid ring structures. Two extensively studied chemical series of synthetic nondepolarizing NMBDs are the aminosteroids, in which the interonium distance is maintained by an androstane skeleton, and the benzylisoquinolinium series, in which the distance is maintained by linear diester-containing chains or, in the case of curare, by benzyl ethers. For a detailed account on structure-activity relationships, see Lee.[85]

Benzylisoquinolinium Compounds

dTc is an NMBD in which the amines are present in the form of two benzyl substituted tetrahydroisoquinoline structures (Fig. 34-4). Using nuclear magnetic resonance spectroscopy and methylation–demethylation studies, Everett and associates demonstrated that dTc contains three *N*-methyl groups.[86] One amine is quaternary (i.e., permanently charged with four nitrogen substituents),

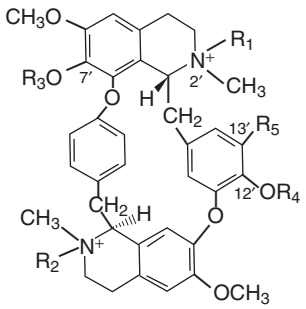

TABLE 34-2 **CLASSIFICATION OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS ACCORDING TO DURATION OF ACTION (TIME TO T1 = 25% OF CONTROL) AFTER TWICE THE DOSE CAUSING ON AVERAGE 95% SUPPRESSION OF NEUROMUSCULAR RESPONSE***

	Clinical Duration			
	Long-acting (>50 min)	Intermediate-acting (20-50 min)	Short-acting (10-20 min)	Ultrashort-acting (<10 min)

*Most nondepolarizing neuromuscular blockers are bisquaternary ammonium compounds. *d*-Tubocurarine, vecuronium, and rocuronium are monoquaternary compounds.

and the other is tertiary (i.e., pH-dependent charge with three nitrogen substituents). At physiologic pH, the tertiary nitrogen is protonated so that it is positively charged. The structure-activity relationships of the bis-benzylisoquinolines (see Fig. 34-4) have been described by Waser[87] and by Hill and associates,[88] and these relationships are as follows:

1. The nitrogen atoms are incorporated into isoquinoline ring systems. This bulky molecule favors a nondepolarizing rather than a depolarizing activity.
2. The interonium distance (distance between charged amines) is approximately 1.4 nm.
3. Both the ganglion-blocking and the histamine-releasing properties of dTc probably result from the presence of the tertiary amine function.
4. When dTc is methylated at the tertiary amine and at the hydroxyl groups, the result is metocurine, a compound and greater potency (by a factor of two in humans) with much weaker ganglion-blocking and histamine-releasing properties than dTc (see Fig. 34-4). Metocurine contains three additional methyl groups, one of which quaternizes the tertiary nitrogen of dTc; the other two form methyl ethers at the phenolic hydroxyl groups.
5. Bisquaternary compounds are more potent than their monoquaternary analogues. The bisquaternary derivative of dTc, chondocurine, is more than twice as potent as dTc (see Fig. 34-4).
6. Substitution of the methyl groups on the quaternary nitrogen with bulkier groups causes a reduction in both potency and duration of action.

Figure 34-4. Chemical structures of *d*-tubocurarine, metocurine, and chondocurine.

Atracurium is a bis-benzyltetrahydroisoquinolinium with isoquinolinium nitrogens connected by a diester-containing hydrocarbon chain (Fig. 34-5). The presence (in duplicate) of two-carbon separations between quaternary nitrogen and ester carbonyl renders it susceptible to the Hofmann elimination reaction.[89] The compound can also undergo ester hydrolysis. In a Hofmann elimination reaction, a quaternary ammonium group is converted into a tertiary amine through cleavage of a carbon-nitrogen bond. This is a pH- and temperature-dependent reaction in which higher pH and temperature favor elimination.

Atracurium has 4 chiral centers at each of the chiral carbons adjacent to the 2 amines. It is composed of 10 isomers.[89] These isomers have been separated into 3 geometric isomer groups that are designated *cis-cis*, *cis-trans*, and *trans-trans* according to their configuration about the tetrahydroisoquinoline ring system.[89] The ratio of the *cis-cis*, *cis-trans*, and *trans-trans* isomers is approximately 10:6:1, corresponding to 50% to 55% *cis-cis*, 35% to 38% *cis-trans*, and 6% to 7% *trans-trans* isomers.

Cisatracurium, the 1R *cis*–1′R *cis* isomer of atracurium, comprises approximately 15% of atracurium by weight but more than 50% in terms of neuromuscular blocking activity (see Fig. 34-5). R designates the absolute stereochemistry of the benzyl tetrahydroisoquinoline rings, and *cis* represents the relative geometry of the bulky dimethoxy and 2-alkyester groups at C(1) and N(1), respectively.[90,91] Like atracurium, cisatracurium is metabolized by Hofmann elimination. It is approximately four times as potent as atracurium, and in contrast to atracurium, it does not cause histamine release,[90,92] thus indicating that histamine release may be stereospecific.[90,93]

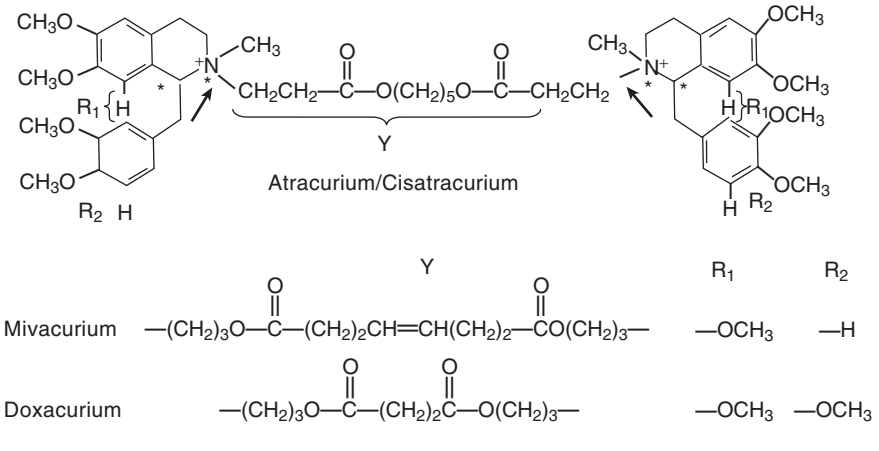

Figure 34-5. Chemical structures of atracurium, cisatracurium, mivacurium, and doxacurium. The *asterisk* indicates the chiral centers; *arrows* show cleavage sites for Hofmann elimination.

Mivacurium differs from atracurium by the presence of an additional methylated phenolic group (see Fig. 34-5). Compared with other isoquinolinium NMBDs, the interonium chain of mivacurium is longer (16 atoms).[88] Mivacurium consists of a mixture of three stereoisomers.[94] The two most active are the *trans-trans* and *cis-trans* isomers (57% and 37% weight/weight, respectively), which are equipotent; the *cis-cis* isomer (6% weight/weight) has only one tenth the neuromuscular blocking activity of the more potent isomers in cats and monkeys.[94] Mivacurium is metabolized by butyrylcholinesterase to a monoester and a dicarboxylic acid at 70% to 88% the rate at which succinylcholine is metabolized by the same enzyme.[9]

Steroidal Neuromuscular Blockers

For the steroidal compounds to have neuromuscular blocking potential, it is likely that one of the compound's two nitrogen atoms be quaternized. The presence of an acetyl ester (acetylcholine-like moiety) facilitates their interaction with nAChRs at the postsynaptic muscle membrane.

Pancuronium is characterized by the presence of two acetyl ester groups on the A and D rings of the steroidal molecule. Pancuronium is a potent NMBD with both vagolytic properties. It is also an inhibitor of butyrylcholinesterase (Fig. 34-6).[95] Deacetylation at the 3 or 17 positions decreases its potency.[96]

Vecuronium, in which the 2-piperidine substituent is not methylated, is the *N*-demethylated derivative of pancuronium (see Fig. 34-6).[7] At physiologic pH, the tertiary amine is largely protonated, as it is in dTc. The minor molecular modification results in the following: (1) a slight increase in the potency when compared with pancuronium; (2) a marked reduction in its vagolytic properties; (3) molecular instability in solution; and (4) increased lipid solubility, which results in a greater biliary elimination of vecuronium than pancuronium.[88]

Vecuronium is degraded by the hydrolysis of the acetyl esters at the C3 and the C17 positions. Hydrolysis at the C3 position is the primary degradation pathway because the acetate at the 3 position is more susceptible to hydrolysis in aqueous solutions than the acetate at the 17 position. This is because of the adjacent basic piperidine at the 2 position that facilitates hydrolysis of the 3-acetate. Therefore, vecuronium cannot be prepared as a ready-to-use solution with a sufficient shelf life, even as a buffered solution. In contrast, the 2-piperidine of pancuronium is quaternized and no longer alkaline and therefore does not facilitate hydrolysis of the 3-acetate.

Rocuronium lacks the acetyl ester that is found in the A ring of the steroid nucleus of pancuronium and vecuronium (see Fig. 34-6). The introduction of cyclic substituents other than piperidine at the 2 and 16 positions results in a compound with a more rapid onset of effect than vecuronium or pancuronium.[97] The methyl group attached to the quaternary nitrogen of vecuronium and pancuronium is replaced by an allyl group in rocuronium. As a result of this change, rocuronium is approximately 6 and 10 times less potent than pancuronium and vecuronium, respectively.[97-99] The replacement of the acetyl ester attached to the A ring by a hydroxy group means that rocuronium is stable in solution. At room temperature, rocuronium is stable for 60 days. In contrast, pancuronium is stable for 6 months. The reason for this difference in shelf life is related to the fact that rocuronium is terminally sterilized in manufacturing, and pancuronium is not. Terminal sterilization causes some degree of degradation.

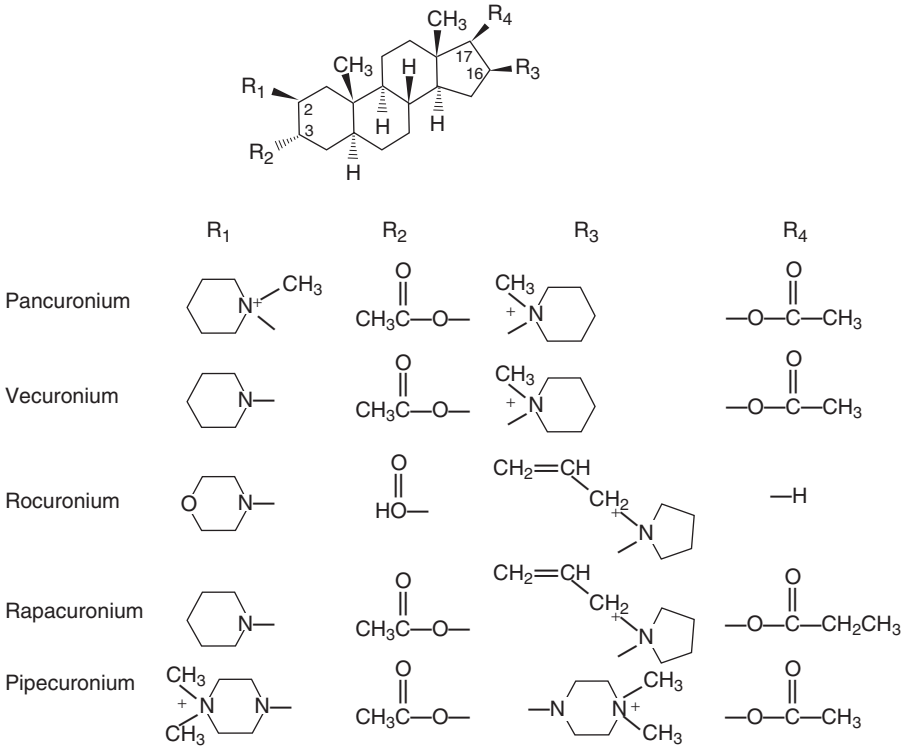

Figure 34-6. Chemical structures of different steroidal neuromuscular blockers.

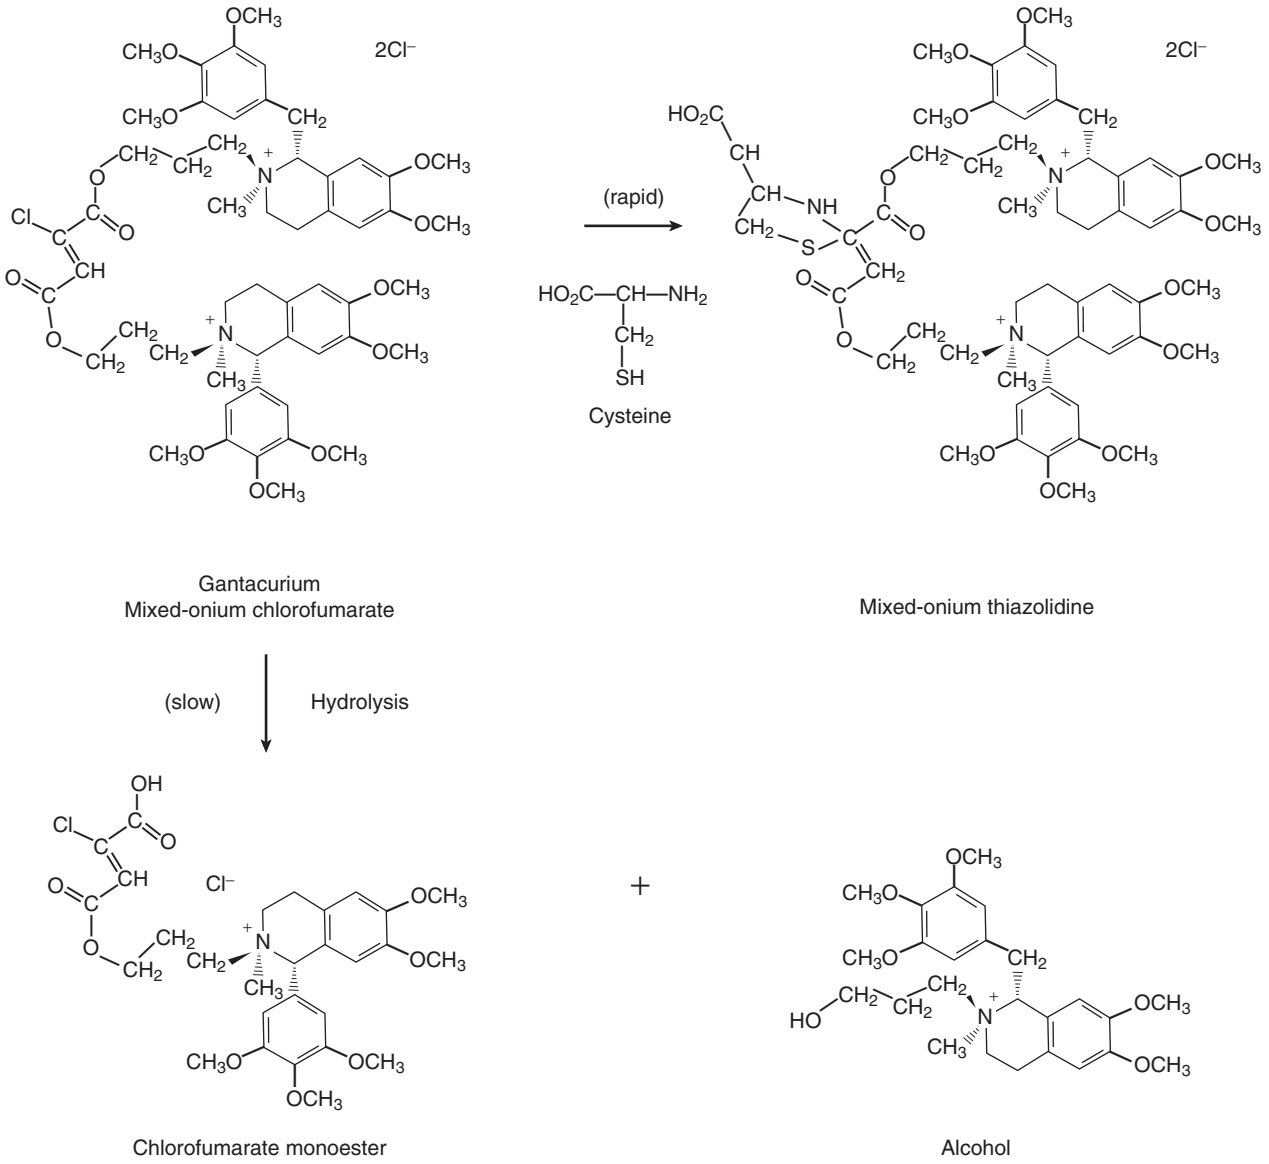

Figure 34-7. Chemical structure of gantacurium (a mixed-onium chlorofumarate). In whole human blood, two pathways of deactivation occur, neither of which is enzymatic: (1) rapid formation of an apparently inactive cysteine adduction product, with cysteine replacing chlorine, and (2) slower hydrolysis of the ester bond adjacent to the chlorine substitution to chlorofumarate monoester and alcohol. *(From Boros EE, Samano V, Ray JA, et al: Neuromuscular blocking activity and therapeutic potential of mixed-tetrahydroisoquinolinium halofumarates and halosuccinates in rhesus monkeys,* J Med Chem *46:2502-2515, 2003.)*

Asymmetric Mixed-Onium Fumarates

Gantacurium and CW 002 represent a new class of bisquaternary nondepolarizing NMBDs (Fig. 34-7). Gantacurium, an asymmetric mixed-onium chlorofumarate, is unique among nondepolarizing compounds in terms of its rapid onset of effect, its short duration of action, and its unique means of inactivation.[11,100] Because of the presence of three methyl groups between the quaternary nitrogen and oxygen atom at each end of the carbon chain, this compound does not undergo Hofmann elimination.[100]

Gantacurium has an ultrashort duration of action in human volunteers and in different animal species. In human volunteers receiving a nitrous oxide–opioid anesthetic, the ED_{95} of gantacurium is 0.19 mg/kg.[100] Onset of and recovery from block resemble that following administration of succinylcholine. Following administration of approximately 2.5 times the ED_{95} dose, onset of maximal block occurs in 1.5 minutes. Spontaneous recovery to a TOF of 0.9 or greater occurs 10 minutes after administration of an ED_{95} dose, and complete spontaneous recovery occurs in 14 to 15 minutes after administration of doses ranging from 2 to 3.5 times the ED_{95}. Recovery is accelerated by administration of edrophonium at the beginning of spontaneous recovery. Transient hypotension and tachycardia occur following administration of doses 3 times the ED_{95} and greater, a finding suggesting that histamine release occurs with administration of these doses.[100]

Gantacurium appears to undergo two pathways of inactivation. One is a slower ester hydrolysis, and the

*Data are the medians and ranges of reported values. ED_{50}, ED_{90}, and ED_{95} are the doses of each drug that produce, respectively, 50%, 90%, and 95% decrease in the force of contraction or amplitude of the electromyogram of the adductor pollicis muscle following ulnar nerve stimulation.

second one, which occurs much more quickly, occurs through the adduction of cysteine, a nonessential amino acid, to create a new compound that can no longer bind to the acetylcholine receptor of the neuromuscular junction.[101] This unique means of inactivation likely accounts for the drug's ultrashort duration of effect. It also provides a novel means of shortening recovery from gantacurium-induced neuromuscular block.[102]

An analogue of the asymmetric fumarate gantacurium, CW 002, has been synthesized to undergo slower L-cysteine adduction. Because of its slower metabolism, it has an intermediate duration of action. In animals, it causes a nondepolarizing block that can be antagonized by neostigmine. Administration of L-cysteine 1 minute after administration of CW 002 effectively speeds recovery of neuromuscular function, whereas neostigmine does not.[22] Volunteer trials are required to determine whether onset, recovery, and ease of antagonism are improved over those using compounds that are currently available.

POTENCY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

Drug potency is commonly expressed by the dose-response relationship. The dose of an NMBD required to produce an effect (e.g., 50%, 90%, or 95% depression of twitch height, commonly expressed as ED_{50}, ED_{90}, and ED_{95}, respectively) is its potency.[9,98,103-114] The NMBDs have different potencies, as illustrated in Table 34-3 and Figure 34-8. For factors affecting the potency of NMBDs, see the section on drug interactions later in this chapter. The dose-response relationship for nondepolarizing NMBDs is sigmoidal (see Fig. 34-8) and has been derived in various ways. The simplest method is to perform linear regression over the approximately linear portion of a semilogarithmic plot between 25% and 75% neuromuscular blockade. Alternatively, the curve can be subjected to probit or logit transformation to linearize it over its whole length, or the data can be subjected to nonlinear regression using the sigmoid E_{max} model of this form:

$$\text{Effect}\,(e) = .\backslash F\left(\text{dose}_e{}^{\gamma}, \text{dose}_e{}^{\gamma} + \text{dose}_{e50}{}^{\gamma}\right)$$

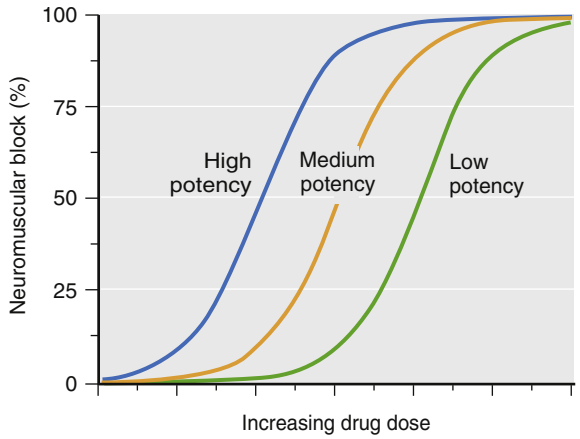

Figure 34-8. Schematic representation of a semilogarithmic plot of a muscle-relaxant dose versus neuromuscular blockade. A drug of high potency is doxacurium, one of medium potency is atracurium, and one of low potency is gallamine. The graph illustrates that the relative potencies of the muscle relaxants span a range of approximately two orders of magnitude.

More complex models relating the concentration of NMBDs at the neuromuscular junction to their pharmacologic effect have been developed, and they are discussed later.[115,116]

CLINICAL MANAGEMENT

The main goal of neuromuscular blockade during induction of anesthesia includes paralysis of the vocal cords and muscles of the jaw to facilitate endotracheal intubation. Relaxation of the respiratory muscles, particularly the diaphragm, allows controlled ventilation. Paralysis of the abdominal muscles and the diaphragm is often required intraoperatively, particularly during abdominal or laparoscopic surgery. During recovery from neuromuscular block, restoration of complete neuromuscular strength is essential to ensure adequate spontaneous ventilation with normal regulation of breathing during hypoxia and the patency of the musculature of the upper airway with maintained airway protection. The choice of

the initial dose of NMBD, timing of readministration of NMBD, timing of administration of anticholinesterase, and interpretation of monitoring require an understanding of the varying sensitivities of different muscle groups to NMBDs.

Although the practice of administering an NMBD to facilitate tracheal intubation may be routine, it has been suggested that the combination of propofol with a rapid-acting opioid may provide good to excellent intubating conditions in most patients. However, relatively large doses of opioids are required to obtain satisfactory intubating conditions. Mencke and co-workers demonstrated that adding atracurium to a propofol-fentanyl induction regimen significantly improved the quality of intubating conditions and decreased the frequency of vocal cord lesions following intubation from 42% to 8%.[117] The rate of postoperative hoarseness was also significantly decreased to 16% from 44%.[117] Combes and associates confirmed that the use of NMBD for tracheal intubation decreased the incidence of adverse postoperative upper airway symptoms, resulted in better intubating conditions, and also reduced the rate of adverse hemodynamic effects caused by deeper levels of anesthesia.[118] Patients intubated without an NMBD had three to four times more Cormack scores of 3 to 4, and difficult intubation was more common (12% versus 1%).

Several alternative approaches are available to enhance surgical relaxation when administration of additional NMBDs may be inappropriate. These options include increasing the depth of general anesthesia with a drug such as a volatile anesthetic or propofol, administering lidocaine, using regional anesthesia, positioning the patient properly on the operating table, and appropriately adjusting the depth of neuromuscular blockade. The choice of one or several of these options is determined by the estimated remaining duration of surgery, the anesthetic technique, and the surgical maneuver required. It is important to keep these options in mind to avoid relying on only neuromuscular blockade to achieve a desired degree of relaxation.

Varying Sensitivities of Different Muscle Groups

The sensitivity of the neuromuscular junctions to the effects of neuromuscular relaxants among various muscle groups varies greatly. Paton and Zaimis[118a] demonstrated in 1951 that some of the muscles of respiration, such as the diaphragm, were more resistant to curare than others. The dose of nondepolarizing NMBDs needed to block the diaphragm is 1.5 to 2 times that of the adductor pollicis. Thus, complete paralysis of the diaphragm is not expected with doses of NMBDs used to block neuromuscular transmission at the adductor pollicis.[119] Similarly, the laryngeal adductor muscles are more resistant to nondepolarizing NMBDs than the more peripheral muscles such as the adductor pollicis,[120] at which all dosing recommendations for NMBDs and their antagonists have been made. The sparing effect on the laryngeal adductor muscles has been documented with vecuronium, rocuronium, cisatracurium, and mivacurium.[120-122] Plaud and colleagues studied the pharmacokinetic-pharmacodynamic relationship of blocking drugs at the adductor pollicis and the laryngeal adductors.[123] These investigators found that the concentration in the effect compartment producing 50% of the maximum block was significantly greater at the laryngeal adductor muscles (1.5 μg/mL) than that at the adductor pollicis (0.8 μg/mL). Convincing evidence indicates that the EC_{50} for almost all drugs is 50% to 100% higher at the diaphragm or larynx than it is at the adductor pollicis. These differences may be caused by any of several factors. Waud and Waud found that following curare administration, neuromuscular transmission occurs when approximately 18% of the receptors are free at the diaphragm, whereas it does not occur at the peripheral muscles unless 29% of receptors are free.[124] The reason may be higher receptor density, greater release of acetylcholine, or less acetylcholinesterase activity. The lower density of acetylcholine receptors in slow muscle fibers, such as found in the peripheral muscles, explains, in part, the lower margin of safety for neuromuscular transmission when compared with that in the faster muscle fibers in the laryngeal adductors. Muscle sensitivity to succinylcholine is different from that of other NMBDs. Succinylcholine is the only muscle relaxant that, at equipotent doses, causes greater neuromuscular block at the vocal cords than at the adductor pollicis. Some data suggest that in contrast to nondepolarizing NMBDs, succinylcholine is more effective in blocking the muscles composed of primarily fast contracting fibers.[125]

In spite of the relative resistance to NMBDs, the onset of neuromuscular block is significantly faster at the diaphragm and the laryngeal adductors than at the adductor pollicis. Fisher and associates postulated that more rapid equilibration (shorter effect site equilibration half-life [$t_{½}k_{e0}$]) of the NMBD between plasma[126] and the effect compartment at these more centrally located muscles was the explanation for this observation. The accelerated rate of equilibrium probably represents little more than differences in regional blood flow. Therefore, muscle blood flow, rather than a drug's intrinsic potency, may be more important in determining the onset and offset time of nondepolarizing NMBDs. Greater blood flow per gram of muscle at the diaphragm or larynx results in receipt of a higher peak plasma concentration of drug in the brief period of time before rapid redistribution occurs. Plaud and colleagues confirmed this hypothesis by demonstrating a faster transfer rate constant (i.e., $t_{½}k_{e0}$) at the laryngeal adductors (2.7 minutes) than at the adductor pollicis (4.4 minutes).[123] Greater resistance to neuromuscular blockade accounts for the faster recovery of the respiratory muscles and the muscles of the abdominal wall than at the adductor pollicis. Recovery occurs more rapidly because blood concentration of the NMBD must decrease more in the muscles of respiration than in the adductor pollicis for recovery of neuromuscular function to begin.

In contrast, the muscles of the upper airway are particularly sensitive to the effects of muscle relaxants. The masseter is 15% more sensitive to nondepolarizing NMBDs than is the adductor pollicis.[127] Significant weakness of the muscles of the upper airway may exist even when strength at the adductor pollicis has recovered almost to baseline values. A TOF ratio less than 0.9 at the

ED_{95}, Dose causing on average 95% suppression of neuromuscular response; *N_2O*, nitrous oxide.
*Suggested dosages provide good intubating conditions under light anesthesia. Satisfactory abdominal relaxation may be achieved at dosages listed after intubation without a relaxant or with succinylcholine. This table is intended as a general guide to dosage. Individual relaxant requirement should be confirmed with a peripheral nerve stimulator.
†The potentiation of nondepolarizing relaxants by different anesthetic vapors has been reported to vary from 20% to 50%. More recent data suggest, however, that this variation may be much less, particularly in the case of the intermediate- and short-acting relaxants. Therefore, for the sake of simplicity, this table assumes a potentiation of 40% in the case of all volatile anesthetics.

adductor pollicis is associated with impaired pharyngeal function, reduced resting tone in the upper esophageal sphincter muscle, and decreased coordination of the muscles involved in swallowing, all of which cause an increased incidence of misdirected swallows, or aspiration.[128] Because of the resistance of the muscles of respiration to neuromuscular block, patients may be weak but able to breathe as long as an endotracheal tube is in place. Once extubated, however, they may not be able to maintain a patent airway or protect their airway.[129] This is likely the reason that patients with a TOF less than 0.9 in the postanesthesia care unit (PACU) are more likely to develop respiratory events than those whose TOF ratio is 0.9 or greater.

DOSAGE

General Dosage Guidelines

Proper selection of the dose of nondepolarizing NMBD is required to ensure that the desired effect is achieved without overdose of the relaxant (Tables 34-4 and 34-5). The intensity of maximum blockade is directly affected by dose. If a small dose of NMBD is administered, neuromuscular block may not occur because the amount administered is inadequate to overcome the margin of safety at the neuromuscular junction. When doses lower than those required to cause 100% neuromuscular block are administered, the time required to reach maximum effect is a function of the NMBD and blood flow to the muscles. It is independent of the dose administered. However, if the administered dose is high enough to cause 100% neuromuscular block, the time required for maximum block will depend on the dose of NMBD administered. Larger doses will, up to a certain point, produce a faster onset of effect.[130] Increasing the dose of NMBD beyond that point will not decrease the time to onset of maximal effect and may contribute to postoperative neuromuscular block.

In addition to a general knowledge of the pharmacodynamics and pharmacokinetics of NMBDs and understanding of the guidelines for dosing, optimal practice requires that dosing be adjusted to account for variability in individual patients' responses to NMBDs. This adjustment cannot be made without using a monitor of neuromuscular blockade any time that an NMBD is administered to a patient. Overdosage must be avoided for two reasons: to limit the duration of drug effect so that it matches the anticipated length of surgery and to avoid unwanted cardiovascular side effects.

Initial and Maintenance Dosage

The initial dose of NMBD is determined by the reason it is being administered. Traditionally, doses used to facilitate tracheal intubation are twice the ED_{95} (see Table 34-4). If, however, the trachea has been intubated without the use of an NMBD and the purpose in administering an NMBD is to produce surgical relaxation, a dose that is slightly less

than the ED_{95} (see Table 34-5) should be given. Administration of NMBDs solely for surgical relaxation does not prevent vocal cord lesions and postoperative hoarseness caused by intubation without NMBD. Administering a smaller initial dose may be necessary in the presence of any of the potent inhalational anesthetics (see the later section on drug interactions).

To avoid prolonged residual paralysis, inadequate antagonism of residual blockade, or both, the main goal in dosing NMBDs should be to use the lowest possible dose that provides adequate relaxation for surgery. Moreover, clinical management of individual patients should be guided by monitoring of the neuromuscular block, ideally with an objective neuromuscular monitoring technique (see also Chapter 53), to allow safe intraoperative administration of the NMBD and its antagonism by neostigmine or sugammadex. In an adequately anesthetized and monitored patient, little reason exists to abolish the TOF responses to peripheral nerve stimulation completely. However, if deep levels of block are required to maintain paralysis of the diaphragm and the abdominal wall muscles, response of the adductor pollicis to stimulation of the ulnar nerve may disappear. In this case, monitoring the depth of neuromuscular block can be accomplished using the posttetanic count (PTC) at the adductor pollicis or TOF at the corrugator supercilii[131,132] (see Chapter 53). Supplemental (maintenance) doses of NMBDs should be approximately one tenth (in case of long-acting NMBDs) to one fourth (in the case of intermediate- and short-acting NMBDs) the initial dose and should not be given until clear evidence of beginning recovery from the previous dose is present.

Relaxation can be maintained by continuous infusion of intermediate- and short-acting drugs. This approach is useful in maintaining a stable depth of neuromuscular block and allows adjustment of the depth of relaxation according to surgical needs. The depth of neuromuscular block maintained is moderate, if possible, to ensure complete spontaneous recovery of neuromuscular function at the end of a surgical procedure or prompt antagonism of residual effects. Table 34-4 lists the approximate dose ranges that are typically required during infusions to maintain 90% to 95% blockade of the twitch (one twitch visible on TOF stimulation) during a nitrous

oxide–oxygen anesthetic supplemented with intravenous anesthetics. Infusion dosage is usually decreased by 30% to 50% in the presence of potent volatile anesthetics.

NEUROMUSCULAR BLOCKERS AND TRACHEAL INTUBATION

Rapid onset of neuromuscular blockade is one of the requirements for securing an airway promptly. It is affected by several factors, including muscle blood flow, rate of delivery of the drug to the neuromuscular junction, receptor affinity, plasma clearance, and the mechanism of neuromuscular blockade (depolarizing versus nondepolarizing).[96,133,134] The speed of onset is inversely proportional to the potency of nondepolarizing NMBDs.[96,133] A high ED_{95} (i.e., low potency) is predictive of rapid onset of effect and vice versa (see Table 34-5 and Fig. 34-9). Onset time decreases as ED_{50} increases. This relationship can be explained on the basis of the density of receptors at the neuromuscular junction. Irrespective of their potency, NMBDs must bind to a critical number of acetylcholine receptors for blockade to occur. These receptors are concentrated at the neuromuscular junction where access is limited. When a potent NMBD is administered, fewer molecules are administered than in the case of an equipotent dose of a less potent drug. Because of this lower concentration gradient, more time is required for enough molecules of a potent drug to be delivered to the neuromuscular junction. Thus, onset time is longer. This concept was verified by Kopman and colleagues, who demonstrated that, when giving equipotent doses of gallamine, dTc, and pancuronium, onset time was slower with the more potent pancuronium and faster with the less potent gallamine. Except for atracurium,[135] the molar potency (the ED_{50} or ED_{95} expressed as μM/kg) is highly predictive of a drug's initial rate of onset of effect (at the adductor pollicis).[133] A drug's measured molar potency is the end result of many contributing factors: the drug's intrinsic potency (the CE_{50}, which is the biophase concentration resulting in 50% twitch depression), the rate of equilibration between plasma and biophase (k_{e0}), the initial rate of plasma clearance, and probably other factors as well.[136] Notably, rocuronium has a molar potency (ED_{95}) of 0.54 μM/kg, which is approximately 13% that of vecuronium and only 9% that of cisatracurium; this finding illustrates the expected faster onset of rocuronium at the adductor pollicis, as opposed to vecuronium and cisatracurium.

Donati and Meistelman proposed a model to explain this inverse potency–onset relationship.[134] Nondepolarizing NMBDs of low potency (e.g., rocuronium) have more molecules to diffuse from the central compartment into the effect compartment. Once in the effect compartment, all molecules act promptly. Weaker binding of the low-potency drugs to receptors prevents buffered diffusion,[134] a process that occurs with more potent drugs. Buffered diffusion causes repetitive binding and unbinding to receptors, thus keeping potent drugs in the neighborhood of the effector sites and potentially lengthening the duration of effect.

The times to 95% blockade at the adductor pollicis after administration of the ED_{95} dose of succinylcholine, rocuronium, vecuronium, atracurium, mivacurium, and cisatracurium are shown in Figure 34-10.[114,133,135] The illustration shows that the most potent compound, cisatracurium, has the slowest onset, and the least potent compound, rocuronium, has the most rapid onset.[114,133,135] Bevan also proposed that rapid plasma clearance is associated with a rapid onset of action.[137] The fast onset of succinylcholine's action is related to its rapid metabolism and plasma clearance.

The onset of neuromuscular blockade is much faster in the muscles that are relevant to obtaining optimal intubating conditions (laryngeal adductors, diaphragm, and masseter) than in the muscle that is typically monitored (adductor pollicis) (Fig. 34-11).[121] Thus, neuromuscular blockade develops faster, has a shorter duration of effect, and recovers more quickly in these muscles (Table 34-6).[120-122,138,139]

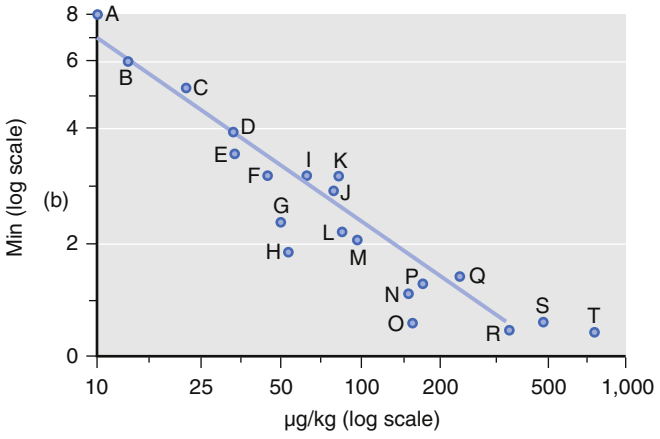

Figure 34-9. Linear regression of onset of neuromuscular blockade (ordinate) versus potency of a series of steroidal relaxants studied in the cat model by Bowman and associates.[96] The data show that onset may be increased in compounds of low potency and encouraged the eventual development of rocuronium and rapacuronium (ORG 9487). *A,* Pipecuronium; *C,* pancuronium; *D,* vecuronium.

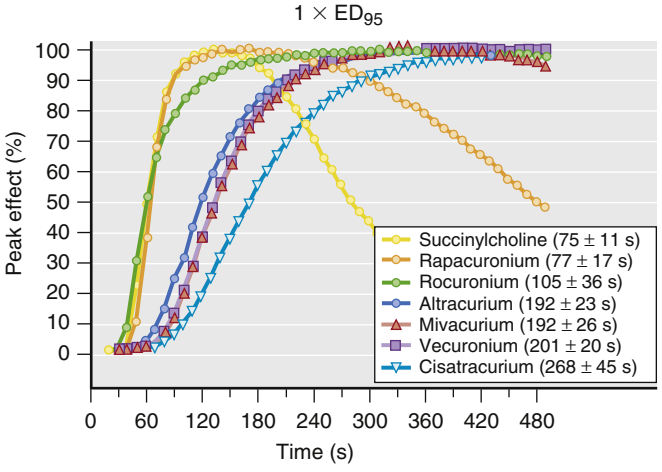

Figure 34-10. Percentages of peak effect after a dose causing on average 95% suppression of neuromuscular response (ED_{95}) of succinylcholine, rocuronium, rapacuronium, vecuronium, atracurium, mivacurium, and cisatracurium at the adductor pollicis muscle. Times (mean ± standard deviation) in seconds to 95% of peak effect are shown in parentheses. *(Data from references 114, 133, and 135.)*

Paralysis following injection does not occur instantaneously even with large doses of muscle relaxants. Onset of blockade occurs 1 to 2 minutes earlier in the larynx than at the adductor pollicis after administration of nondepolarizing NMBDs. The pattern of blockade (onset, depth, and speed of recovery) in the corrugator supercilii is similar to that in the larynx,[119] the diaphragm, and the muscles of the abdominal wall. By monitoring the onset of neuromuscular blockade at the corrugator supercilii, one can predict the quality of tracheal intubating conditions. Good to excellent intubating conditions are observed in more than 90% of patients after disappearance of the TOF at the corrugator supercilii.[131] The onset of maximal blockade in the larynx also corresponds with the point at which the adductor pollicis begins to show palpable evidence of weakening.

Rapid Tracheal Intubation

Succinylcholine is commonly used when rapid tracheal intubation is needed because it consistently provides muscle relaxation within 60 to 90 seconds. When succinylcholine is considered undesirable or contraindicated, high doses of rocuronium can be administered.[140] The onset of action of other nondepolarizing NMBDs can be accelerated by administering a priming dose of the NMBD[141] or by using combinations of NMBDs.[142] Although combinations of mivacurium and rocuronium can achieve rapid onset without undue prolongation of action and without undesirable side effects,[142] combinations of compounds of different structures may result in a marked prolongation of neuromuscular blockade. Additionally, combining different NMBDs may not consistently result in a rapid onset of neuromuscular block.

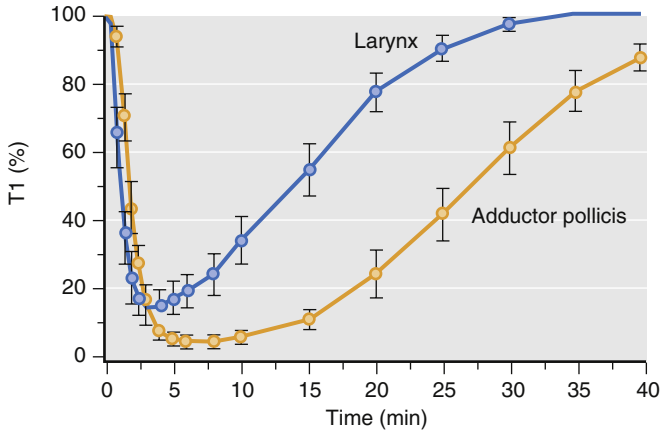

Figure 34-11. Evolution of neuromuscular blockade in the larynx and thumb (adductor pollicis) after a 0.07-mg/kg dose of vecuronium. Onset and recovery from blockade occur more rapidly in the larynx. *T1*, First twitch of train-of-four. *(From Donati F, Meistelman C, Plaud B: Vecuronium neuromuscular blockade at the adductor muscles of the larynx and adductor pollicis,* Anesthesiology *74:833-837, 1991.)*

Priming Technique. Since the introduction of rocuronium into clinical practice, the use of priming has almost disappeared. When priming, a small, subparalyzing dose of the nondepolarizer (≈20% of the ED_{95} or ≈10% of the intubating dose) is administered 2 to 4 minutes before the intubating dose of the compound.[141] This procedure accelerates the onset of blockade for most nondepolarizing NMBDs only by 30 to 60 seconds, thereby indicating that intubation can be performed within 90 seconds of the second dose. However, the intubating conditions that occur after priming are only marginally improved and do not match those that occur after succinylcholine. The size of the priming dose is limited by its effects on the awake patient. Further, priming doses can cause subtle degrees of neuromuscular blockade and increase the patient's discomfort, the risks of aspiration, and difficulty swallowing and breathing.[143] This technique is contraindicated in patients with abnormal airway anatomy or increased sensitivity to NMBDs such as patients with myasthenia gravis or those taking magnesium.

Large-Dose Regimen for Rapid Tracheal Intubation. Large doses of NMBDs are usually recommended when intubation must be accomplished in less than 90 seconds. High-dose regimens are associated with considerably prolonged duration of action and potentially increased cardiovascular side effects, however (see Table 34-5).[140,144] Increasing the dosage of rocuronium from 0.6 mg/kg (twice the ED_{95}) to 1.2 mg/kg (four times the ED_{95}) shortens the onset time of complete neuromuscular block from 89 seconds to 55 seconds but essentially doubles the clinical duration of action of the compound (the recovery

*Clinical duration is the time until the first twitch of train-of-four (T1) has recovered to 25% of its control value. Mean and standard deviation[122,138,139] or standard error of the mean.[120,121]

of the first twitch of TOF [T1] to 25% of baseline values) from 37 minutes to 73 minutes.[140]

Whatever technique of rapid-sequence induction of anesthesia and intubation is chosen, the following four principles are important: (1) preoxygenation must be performed, (2) sufficient doses of intravenous drugs must be administered to ensure that the patient is adequately anesthetized, and (3) intubation within 60 to 90 seconds must be considered acceptable; and (4) cricoid pressure should be applied subsequent to injection of the induction agent.

Small-Dose Relaxants for Tracheal Intubation

Small doses of NMBDs can be used for routine tracheal intubation. The use of smaller doses of NMBDs has the following two possible advantages: (1) it shortens the time to recovery from neuromuscular blockade, and (2) it reduces the requirement for anticholinesterase drugs. Rocuronium has the shortest onset time of all the nondepolarizing NMBDs currently available.[121,122] The maximal effect of either 0.25 or 0.5 mg/kg of rocuronium at the laryngeal muscles occurs after 1.5 minutes.[121] This interval is shorter than the 3.3 minutes reported after administration of equipotent doses of vecuronium (0.04 or 0.07 mg/kg),[120] and it is only slightly more than the 0.9 minutes reported after 0.25 or 0.5 mg/kg of succinylcholine (see Table 34-6).[125]

With a better understanding of the multiple factors that contribute to satisfactory conditions for intubation, it is now possible to administer NMBDs thoughtfully in this fashion. Intubating conditions are related more closely to the degree of neuromuscular blockade of the laryngeal adductor muscles than to the degree of blockade typically monitored at the adductor pollicis. Figure 34-12 demonstrates this principle.[136] In the presence of an adequate depth of anesthesia, complete blockade at the larynx or diaphragm, or both, may not be a prerequisite for satisfactory intubating conditions. Kopman and colleagues noted that 0.5 mg/kg of rocuronium (1.5 times the ED_{95}) provided very satisfactory conditions for intubation in patients anesthetized with 12.5 μg/kg of alfentanil and 2.0 mg/kg of propofol if laryngoscopy was delayed for 75 seconds after drug administration.[145] It was furthermore estimated that 1.5 times the ED_{95} of rocuronium would produce at least 95% blockade in 98% of the population.[145] A similar or lower multiple of rocuronium's ED_{95} was shown to have a faster onset and shorter duration of action than those of atracurium[146] or cisatracurium.[109] In most patients receiving 15 μg/kg of alfentanil followed by 2.0 mg/kg of propofol and 0.45 mg/kg of rocuronium, good to excellent conditions for intubation are present 75 to 90 seconds after the completion of drug administration.

METABOLISM AND ELIMINATION

The specific pathways of the metabolism (biotransformation) and elimination of NMBDs are summarized in Table 34-7. Of the nondepolarizing NMBDs listed, pancuronium, pipecuronium, vecuronium, atracurium, cisatracurium, and mivacurium are the only drugs that are metabolized or degraded. Nearly all nondepolarizing NMBD molecules contain ester linkages, acetyl ester groups, and hydroxy or methoxy groups. These substitutions, especially the quaternary nitrogen groups, confer a high degree of water solubility with only slight lipid solubility. The hydrophilic nature of relaxant molecules enables easy elimination in the urine through glomerular filtration, with no tubular resorption or secretion. Therefore, all nondepolarizing NMBDs show elimination of the parent molecule in the urine as the basic route of elimination; those with a long duration of action thus have a clearance rate that is limited by the glomerular filtration rate (1 to 2 mL/kg/minute).

Steroidal Compounds

Long-Acting Neuromuscular Blocking Drugs. Pancuronium is cleared largely by the kidney[147] and, to a limited extent, by hepatic uptake and elimination. A small amount (15% to 20%) is deacetylated at the 3 position in the liver, but this makes a minimal contribution to the total clearance. Deacetylation also occurs at the 17 position but to such a small extent as to be clinically

	Muscle X	Adductor pollicis
EC_{50} (μg/mL)	3.00	1.18
$t_{1/2}k_{e0}$ (min)	1.93	3.85
Hill coefficient	4.00	4.50

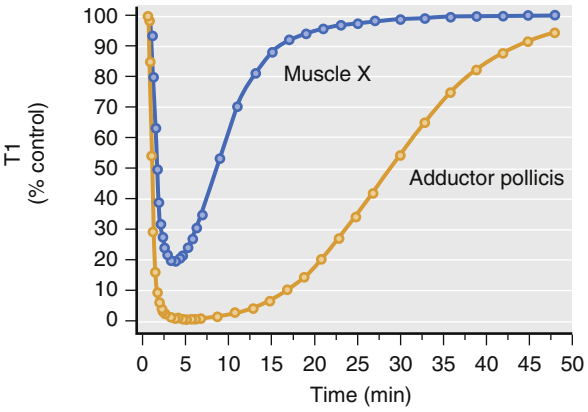

Figure 34-12. A computer simulation based on Sheiner's model[115] and data reported by Wierda and colleagues. The dose causing on average 95% suppression of neuromuscular response (ED_{95}) of rocuronium at the adductor pollicis from this model is 0.33 mg/kg. Rocuronium, 0.45 mg/kg, is given as a bolus at time zero. Muscle X represents a muscle (e.g., the diaphragm or the laryngeal adductors) that is less sensitive to the effects of nondepolarizing relaxants than the adductor pollicis but has greater blood flow. In this example, the concentration of rocuronium producing 50% block (EC_{50}) of muscle X is 2.5 times that of the adductor pollicis, but the half-life of transport between the plasma and effect compartment ($t_{½}k_{e0}$) of muscle X is only half as long. The rapid equilibration between plasma concentrations of rocuronium and muscle X results in the more rapid onset of blockade of muscle X than of the adductor pollicis. The greater EC_{50} at muscle X explains the faster recovery of this muscle than of the adductor pollicis from neuromuscular blockade. Lower blood concentrations of rocuronium must be achieved at the adductor pollicis than at muscle X before recovery begins. *T1,* First twitch of train-of-four *(From Naguib M, Kopman AF: Low dose rocuronium for tracheal intubation,* Middle East J Anesthesiol *17:193-204, 2003, with permission from the* Middle East Journal of Anesthesiology.*)*

TABLE 34-7 METABOLISM AND ELIMINATION OF NEUROMUSCULAR BLOCKING DRUGS

Drug	Duration	Metabolism (%)	Elimination		Metabolites
			Kidney (%)	Liver (%)	
Succinylcholine	Ultrashort	Butyrylcholinesterase (98-99%)	<2%	None	Monoester (succinyl monocholine) and choline; the monoester is metabolized much more slowly than succinylcholine
Gantacurium	Ultrashort	Cysteine (fast) and ester hydrolysis (slow)	?	?	Inactive cysteine adduction product, chloroformate monoester, and alcohol
Mivacurium	Short	Butyrylcholinesterase (95-99%)	<5% (Metabolites eliminated in urine and bile)	None	Monoester and quaternary alcohol; the metabolites are inactive and most likely are not metabolized any further
Atracurium	Intermediate	Hofmann elimination and nonspecific ester hydrolysis (60-90%)	10-40% (Metabolites eliminated in urine and bile)	None	Laudanosine, acrylates, alcohols, and acids; although laudanosine has CNS-stimulating properties, the clinical relevance of this effect is negligible
Cisatracurium	Intermediate	Hofmann elimination (77%?)	Renal clearance is 16% of total		Laudanosine and acrylates; ester hydrolysis of the quaternary monoacrylate occurs secondarily; because of the greater potency of cisatracurium, laudanosine quantities produced by Hofmann elimination are 5 to 10 times lower than in the case of atracurium, thus making this a nonissue in practice
Vecuronium	Intermediate	Liver (30-40%)	40-50% (Metabolites excreted in urine and bile) ≈40%	50-60% ≈60%	The 3-OH metabolite accumulates, particularly in renal failure; it has ≈80% the potency of vecuronium and may be responsible for delayed recovery in ICU patients
Rocuronium	Intermediate	None	10-25%	>70%	None
Pancuronium	Long	Liver (10-20%)	85%	15%	The 3-OH metabolite may accumulate, particularly in renal failure; it is approximately two thirds as potent as the parent compound
d-Tubocurarine	Long	None	80% (?)	20%	None

CNS, Central nervous system; *ICU,* intensive care unit.

irrelevant. The three known metabolites have been individually studied in anesthetized humans.[148] The 3-OH metabolite is the most potent of the three, being approximately half as potent as pancuronium, and is the only one present in detectable concentrations in the plasma. This metabolite has pharmacokinetics and duration of action similar to those of pancuronium.[148] The 3-OH metabolite is most likely excreted largely by the kidney.[148] The parent compound and the 3-OH metabolite are also cleared in small amounts through a minor liver pathway. The total clearance is delayed, and the duration of action is significantly lengthened by severe disorders of renal or hepatic function.[149-151]

Intermediate-Acting Neuromuscular Blockers. Vecuronium, the 2-desmethyl derivative of pancuronium, is more lipid soluble than pancuronium because of the absence of the quaternizing methyl group at the 2 position. It undergoes two to three times more metabolism than does pancuronium. Vecuronium is taken up into the liver by a carrier-mediated transport system,[152] and it is then deacetylated at the 3 position by liver microsomes. Approximately 12% of vecuronium clearance is through conversion to 3-desacetylvecuronium,[153] and 30% to 40% of the drug is cleared in the bile as the parent compound.[154] Although the liver is the principal organ of elimination for vecuronium, the drug also undergoes significant (up to 25%) renal excretion, and this combined organ elimination gives it a clearance rate of 3 to 6 mL/kg/minute.[153,155]

The principal metabolite of vecuronium, 3-desacetylvecuronium, is a potent (≈80% of vecuronium) NMBD in its own right. The metabolite, however, has slower plasma clearance and longer duration of action than vecuronium.[153] 3-Desacetylvecuronium has a clearance rate of 3.5 mL/kg/minute, and renal clearance accounts for approximately one sixth of its elimination.[153] In patients with renal failure in the ICU, 3-desacetylvecuronium can accumulate and produce prolonged neuromuscular blockade.[156] Other putative metabolites are 17-desacetylvecuronium and 3,17-bisdesacetylvecuronium, neither of which occurs in clinically significant amounts.

Rocuronium is eliminated primarily by the liver, with a small fraction (≈10%) eliminated in the urine.[157] It is taken up into the liver by a carrier-mediated active transport system.[158] The putative metabolite, 17-desacetylrocuronium, has not been detected in significant quantities.

Benzylisoquinolinium Compounds

Short-Acting Neuromuscular Blocking Drugs. Mivacurium is hydrolyzed in the plasma by butyrylcholinesterase to a monoester and an amino alcohol,[9] which are excreted in urine and bile. They have less than 1% of the neuromuscular blocking activity of the parent compound. Less than 5% of mivacurium is excreted in the urine as the parent compound.

Mivacurium consists of three stereoisomers, and the clearances of the two most pharmacologically active isomers, the *cis-trans* and *trans-trans*, are approximately 100 and 50 to 70 mL/kg/minute, respectively.[94,159,160] These two isomers show elimination half-lives of 2 to 3 minutes.[94] The third stereoisomer, the *cis-cis*, is present as only 4% to 8% of the mivacurium mixture and has less than 10% of the neuromuscular blocking potency of the other two isomers.[94] Consequently, even though it has a much longer elimination half-life (55 minutes) and lower clearance (≈4 mL/kg/minute) than the two other isomers, it does not contribute significantly to the duration of action of mivacurium.[94] This rapid enzymatic clearance of mivacurium accounts for its short duration of action.[9,94] When butyrylcholinesterase activity is significantly decreased, however, as in the rare patient who is homozygous for genetically atypical enzymes, the duration of action of mivacurium is prolonged for up to several hours.[161-164]

Intermediate-Acting Neuromuscular Blocking Drugs. Atracurium is metabolized through two pathways: Hofmann elimination and nonspecific ester hydrolysis. Hofmann elimination is a purely chemical process that results in loss of the positive charges by molecular fragmentation to laudanosine (a tertiary amine) and a monoquaternary acrylate, compounds that are thought to have no neuromuscular and little or no cardiovascular activity of clinical relevance.[165]

Because it undergoes Hofmann elimination, atracurium is relatively stable at pH 3.0 and 4° C and becomes unstable when it is injected into the bloodstream. Early observations of the breakdown of the drug in buffer and plasma showed faster degradation in plasma, a finding suggesting a possible enzymatic hydrolysis of the ester groups. Further evidence suggested that ester hydrolysis may be more important than originally realized in the breakdown of atracurium.[166] By using a pharmacokinetics analysis, Fisher and associates concluded that a significant amount of clearance of atracurium may be by routes other than ester hydrolysis and Hofmann elimination.[167] Thus, it appears that atracurium's metabolism is complicated and may not be completely understood.[167]

Laudanosine, a metabolite of atracurium, has central nervous system (CNS)–stimulating properties. However, adverse effects are unlikely to occur with atracurium use in either the operating room or the ICU.

Atracurium is a mixture of 10 optical isomers. Cisatracurium is the 1R *cis*–1′R *cis* isomer of atracurium.[90] Like atracurium, cisatracurium is metabolized by Hofmann elimination to laudanosine and a monoquaternary acrylate.[168,169] In contrast, however, no ester hydrolysis of the parent molecule occurs. Hofmann elimination accounts for 77% of the total clearance of 5 to 6 mL/kg/minute. Twenty-three percent of the drug is cleared through organ-dependent means, and renal elimination accounts for 16% of this.[169] Because cisatracurium is approximately four or five times as potent as atracurium, approximately five times less laudanosine is produced, and, as with atracurium, accumulation of this metabolite is not thought to be of any consequence in clinical practice.

Long-Acting Neuromuscular Blocking Drugs. dTc has no active metabolism. The kidney is the major pathway of elimination, with approximately 50% of a dose eliminated through renal pathways. The liver is likely a secondary route of elimination.

Asymmetric Mixed-Onium Fumarates

Gantacurium and CW 002 are degraded by two chemical mechanisms, neither of which is enzymatic: (1) rapid formation of an apparently inactive cysteine adduction product and (2) slower hydrolysis of the ester bond to presumably inactive hydrolysis products (see Fig. 34-7).[11,170]

In summary, the only short-acting nondepolarizing NMBD, mivacurium, is cleared rapidly and almost exclusively by metabolism by butyrylcholinesterase, thus resulting in much greater plasma clearance than that of any other nondepolarizing NMBD.[9] NMBDs of intermediate duration, such as vecuronium, rocuronium, atracurium, and cisatracurium, have clearance rates in the range of 3 to 6 mL/kg/minute because of multiple pathways of degradation, metabolism, and/or elimination. Atracurium is cleared two to three times more rapidly than the long-acting drugs.[171-174] Similar clearance values have been obtained for rocuronium[175-179] and cisatracurium.[168,169,180] Finally, the long-acting NMBDs undergo minimal or no metabolism, and they are eliminated largely unchanged, mostly by renal excretion. Hepatic pathways are less important in their metabolism.

ADVERSE EFFECTS OF NEUROMUSCULAR BLOCKERS

NMBDs seem to play a prominent role in the incidence of adverse reactions that occur during anesthesia. The Committee on Safety of Medicines in the United Kingdom reported that 10.8% (218 of 2014) of adverse drug reactions and 7.3% of deaths (21 of 286) were attributable to the NMBDs.[181]

Autonomic Effects

NMBDs may interact with nicotinic and muscarinic cholinergic receptors within the sympathetic and parasympathetic nervous systems and at the nicotinic receptors of the neuromuscular junction.

Dose-response ratios comparing the neuromuscular blocking potencies of these drugs (the ED_{95}) with their potencies in blocking vagal (parasympathetic) or

sympathetic ganglionic transmission (the ED_{50}) can be constructed (Table 34-8). These ratios are termed the autonomic margin of safety of the relaxant in question. The higher the dose ratio, the lower is the likelihood of, or the greater the safety ratio for, the occurrence of the particular autonomic effect. The side effect is considered absent (none) in clinical practice if the safety ratio is greater than 5; it is weak or slight if the safety ratio is 3 or 4, moderate if 2 or 3, and strong or prominent if the ratio is 1 or less.

These autonomic responses are not reduced by slower injection of the muscle relaxant. They are dose related and additive over time if divided doses are given. If identical to the original dose, subsequent doses will produce a similar response (i.e., no tachyphylaxis will occur). This is not the case, however, when the side effect of histamine release is in question. Cardiovascular responses secondary to histamine release are decreased by slowing the injection rate, and the response undergoes rapid tachyphylaxis. The autonomic effects of NMBDs are summarized in Table 34-9.

Histamine Release. Quaternary ammonium compounds (e.g., NMBDs) are generally weaker histamine-releasing substances than are tertiary amines such as morphine. Nevertheless, when large doses of certain NMBDs are administered rapidly, erythema of the face, neck, and upper torso may develop, as well as a brief decrease in arterial pressure and a slight to moderate increase in heart rate. Bronchospasm in this setting is very rare. The clinical effects of histamine are seen when plasma concentrations increase 200% to 300% of baseline values, and these effects involve chemical displacement of the contents of mast cell granules containing histamine, prostaglandin, and possibly other vasoactive substances.[182] The serosal mast cell, located in the skin and connective tissue and near blood vessels and nerves, is principally involved in the degranulation process.[182]

The side effect of histamine release is most often noted following administration of the benzylisoquinolinium class of muscle relaxants, although it has also been noted in steroidal relaxants of low potency. The effect is usually of short duration (1 to 5 minutes), is dose related, and is clinically insignificant in healthy patients. Hatano and colleagues showed that the hypotensive cardiovascular response to 0.6 mg/kg of dTc in humans is prevented not only by antihistamines but also by nonsteroidal anti-inflammatory drugs (e.g., aspirin).[183] Those investigators concluded that the final step in dTc-induced hypotension is modulated by prostaglandins that are vasodilators.[183] This side effect can be reduced considerably by using a slower injection rate. It is also prevented by prophylaxis with combinations of $histamine_1$ and $histamine_2$ blockers.[184] If a minor degree of histamine release such as described earlier occurs after an initial dose of an NMBD, subsequent doses will generally cause no response at all, as long as they are no larger than the original dose. This is clinical evidence of tachyphylaxis, an important characteristic of histamine release. A much more significant degree of histamine release occurs during anaphylactic or anaphylactoid reactions; these reactions are very rare.

Clinical Cardiovascular Manifestations of Autonomic Mechanisms

Hypotension. The hypotension seen with the use of atracurium and mivacurium results from histamine release, whereas dTc causes hypotension by histamine release and ganglion blockade.[185,186] The effects of dTc occur closer to the dose required to achieve neuromuscular blockade.[113] The safety margin for histamine release is approximately three times greater for atracurium and mivacurium than it is for dTc.[182,183,186] Rapid administration of atracurium in doses greater than 0.4 mg/kg and of mivacurium in doses greater than 0.15 mg/kg has been associated with transient hypotension secondary to histamine release (Fig. 34-13).

Tachycardia. Pancuronium causes a moderate increase in heart rate and, to a lesser extent, in cardiac output, with little or no change in systemic vascular resistance.[187] Pancuronium-induced tachycardia has been attributed to the following: (1) vagolytic action,[187] probably from inhibition of M_2 receptors; and (2) sympathetic stimulation that involves both direct (blockade of neuronal uptake of norepinephrine) and indirect (release of norepinephrine from adrenergic nerve endings) mechanisms.[188] In studies in humans, Roizen and associates surprisingly found decreases in plasma norepinephrine levels after administration of either pancuronium or atropine.[189] These

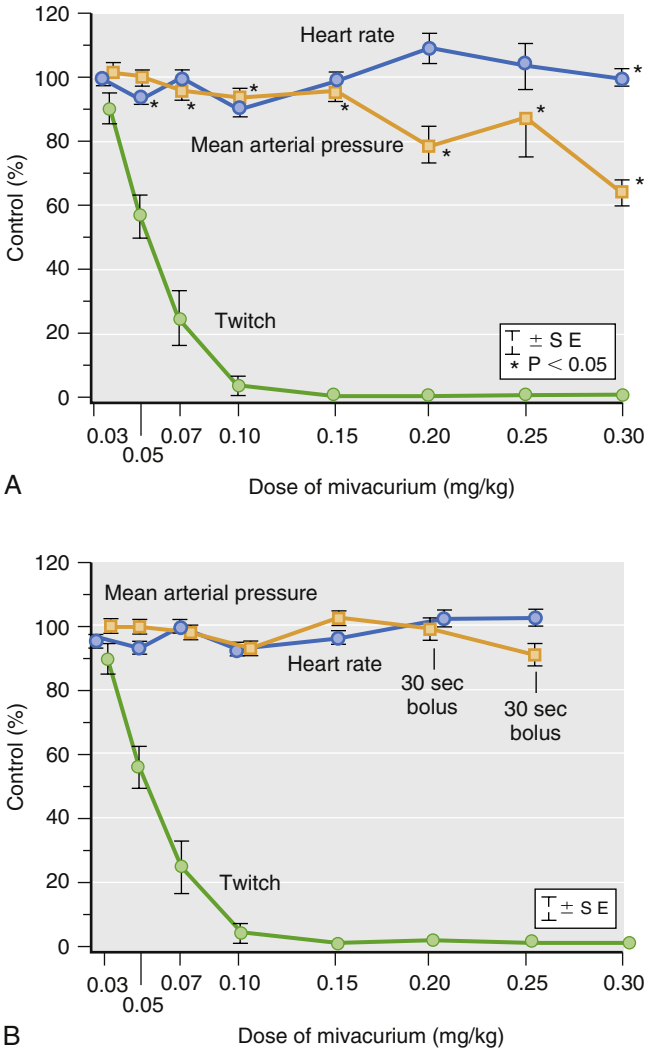

Figure 34-13. Dose response to mivacurium in patients under nitrous oxide–oxygen–opioid anesthesia. Maximum changes at each dose are shown; $n = 9$ subjects per group. **A,** With fast injection, a 15% to 20% decrease in arterial pressure occurred at 2.5 to 3 times the ED_{95} (0.20 to 0.25 mg/kg). **B,** The changes were less than 10% when slower injection (30 seconds) was done. *(From Savarese JJ, Ali HH, Basta SJ, et al: The cardiovascular effects of mivacurium chloride (BW B1090U) in patients receiving nitrous oxide–opiate-barbiturate anesthesia,* Anesthesiology *70:386-394, 1989.)*

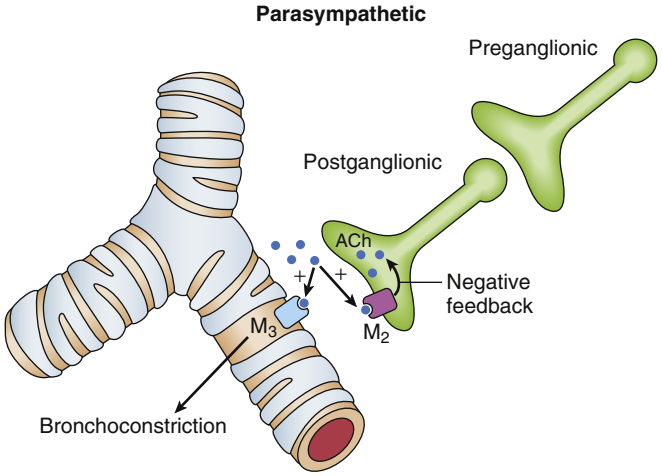

Figure 34-14. The muscarinic (M_3) receptors are located postsynaptically on airway smooth muscle. Acetylcholine (ACh) stimulates M_3 receptors to cause contraction. M_2 muscarinic receptors are located presynaptically at the postganglionic parasympathetic nerve endings, and they function in a negative-feedback mechanism to limit the release of ACh.

investigators postulated that the increase in heart rate or rate-pressure product occurs because pancuronium (or atropine) acts through baroreceptors to reduce sympathetic outflow.[189] More specifically, the vagolytic effect of pancuronium increases heart rate and hence blood pressure and cardiac output, in turn influencing the baroreceptors to decrease sympathetic tone. Support for this concept is provided by the finding that prior administration of atropine attenuates or eliminates the cardiovascular effects of pancuronium.[187] However, a positive chronotropic effect that places emphasis on the vagolytic mechanism has not been found in humans.[190] The tachycardia seen with benzylisoquinolinium compounds is the result of histamine release.

Dysrhythmias. Succinylcholine and dTc actually reduce the incidence of epinephrine-induced dysrhythmias.[191] Possibly because of enhanced atrioventricular conduction,[192] the incidence of dysrhythmias caused by pancuronium appears to increase during halothane anesthesia.[187] Edwards and colleagues observed rapid tachycardia (>150 beats/minute) that progressed to atrioventricular dissociation in two patients anesthetized with halothane who also received pancuronium.[193] The only other factor common to those two patients was that both were taking tricyclic antidepressant drugs.

Bradycardia. Several case reports described the occurrence of severe bradycardia and even asystole after vecuronium or atracurium administration.[194,195] All these cases were also associated with opioid administration. Subsequent studies indicated that administration of vecuronium or atracurium alone does not cause bradycardia.[196] When combined with other drugs that do cause bradycardia (e.g., fentanyl), however, the nonvagolytic relaxants such as vecuronium, cisatracurium, and atracurium allow this mechanism to occur unopposed. Thus, the moderate vagolytic effect of pancuronium is often used to counteract opioid-induced bradycardia (see also Chapter 31).

Respiratory Effects. The muscarinic cholinergic system plays an important role in regulating airway function. Five muscarinic receptors have been cloned,[197] three of which (M_1 to M_3) exist in the airways.[198] M_1 receptors are under sympathetic control, and they mediate bronchodilation.[199] M_2 receptors are located presynaptically (Fig. 34-14), at the postganglionic parasympathetic nerve endings, and they function in a negative-feedback mechanism to limit the release of acetylcholine. The M_3 receptors, which are located postsynaptically (see Fig. 34-14), mediate contraction of the airway smooth muscles (i.e., bronchoconstriction).[199] Nondepolarizing NMBDs have different antagonistic activities at both M_2 and M_3 receptors.[200] For example, blockage of M_3 muscarinic receptors on airway smooth muscle inhibits vagally induced bronchoconstriction (i.e., causes bronchodilation), whereas

blockage of M_2 receptors results in increased release of acetylcholine that acts on M_3 receptors, thus causing bronchoconstriction.

The affinity of the compound rapacuronium to block M_2 receptors is 15 times higher than its affinity to block M_3 receptors.[200] This explains the high incidence (>9%) of severe bronchospasm[201-203] seen with this drug and that resulted in its withdrawal from the market.

The administration of benzylisoquinolinium NMBDs (with the exception of cisatracurium) is associated with histamine release, which may result in increased airway resistance and bronchospasm in patients with hyperactive airway disease.

Allergic Reactions. The frequency of life-threatening anaphylactic (immune-mediated) or anaphylactoid reactions occurring during anesthesia has been estimated at 1 in 10,000 to 20,000 anesthetic procedures, whereas it is estimated at 1 in 6500 administrations of NMBDs in some countries.[204,205] In France, the most common causes of anaphylaxis in patients who experienced allergic reactions were reported to be NMBDs (58.2%), latex (16.7%), and antibiotics (15.1%).[206] Anaphylactic reactions are mediated through immune responses involving immunoglobulin E antibodies fixed to mast cells. Anaphylactoid reactions are not immune mediated and represent exaggerated pharmacologic responses in very rare and very sensitive individuals.

However, anaphylaxis to nondepolarizing NMBDs is not uncommon in patients without any previous exposure to any nondepolarizing NMBDs. Cross-reactivity occurs between NMBDs and food, cosmetics, disinfectants, and industrial materials.[207] Sensitization to nondepolarizing NMBDs may be related to pholcodine, a cough-relieving medicine. Cross-reactivity is seen in 70% of patients with a history of anaphylaxis to an NMBD.[206]

Steroidal compounds (e.g., rocuronium, vecuronium, or pancuronium) result in no significant histamine release.[186] For example, four times the ED_{95} of rocuronium (1.2 mg/kg) causes no significant histamine release.[208] Nevertheless, rocuronium and succinylcholine are reportedly associated with a 43.1% and 22.6% incidence, respectively, of anaphylaxis in France.[206] Rose and Fisher classified rocuronium and atracurium as having intermediate levels of risk for causing allergic reactions.[209] These investigators also noted that the increased number of reports of anaphylaxis with rocuronium is in line with the market share of that drug's usage. Watkins stated, "The much higher incidence of rocuronium reactions reported in France is currently inexplicable and is likely to remain so if investigators continue to seek a purely antibody-mediated response as an explanation of all anaphylactoid reaction presentations."[210] All nondepolarizing NMBDs may elicit anaphylaxis. More recent publications have highlighted the need for standardization of diagnostic procedures of anaphylactic reactions. Biochemical tests should be performed rapidly after occurrence of an anaphylactic reaction. An early increase in plasma histamine is observed 60 to 90 minutes after anaphylactic reactions. Serum tryptase concentrations typically reach a peak between 15 and 120 minutes, depending on the severity of the reaction. It is highly suggestive of mast cell activation. Skin testing remains the gold standard for detection of the culprit agent.[211] For many years, dilution thresholds have been debated. For instance, Laxenaire used a 1:10 dilution of rocuronium for interdermal skin testing,[212] whereas Rose and Fisher used a 1:1000 dilution.[209] Levy and associates showed that rocuronium in a 1:10 dilution can produce false-positive results in intradermal testing and suggested that rocuronium be diluted at least 100-fold to prevent such results.[213] Those authors also reported that high concentrations ($\geq 10^{-4}$ M) of both rocuronium and cisatracurium were capable of producing a wheal-and-flare response to intradermal testing, which was associated with mild to moderate mast cell degranulation in the cisatracurium group only.[213] However, in contrast to control patients, skin tests with nondepolarizing NMBDs that were performed in patients who had an anaphylactic reaction were considered reliable.

All NMBDs can cause noncompetitive inhibition of histamine-*N*-methyltransferase, but the concentrations required for that inhibition greatly exceeds those that would be used clinically, except in the case of vecuronium, with which the effect becomes manifest at 0.1 to 0.2 mg/kg.[214] This finding could explain the occurrence of occasional severe bronchospasm in patients after receiving vecuronium.[215] For goals of treatment of anaphylactic reactions, see Chapters 6 and 7.

DRUG INTERACTIONS AND OTHER FACTORS AFFECTING RESPONSE TO NEUROMUSCULAR BLOCKERS

A drug-drug interaction is an in vivo phenomenon that occurs when the administration of one drug alters the effects or kinetics of another drug. In vitro physical or chemical incompatibilities are *not* considered drug interactions.[216]

Many drugs interact with NMBDs or their antagonists, or both, and it is beyond the scope of this chapter to review them all.[216,217] Some of the more important drug interactions with NMBDs and their antagonists are discussed in the following sections.

Interactions Among Nondepolarizing Neuromuscular Blocking Drugs

Mixtures of two nondepolarizing NMBDs are considered to be either additive or synergistic. Antagonistic interactions have not been reported in this class of drugs. Additive interactions have been demonstrated after administration of chemically related drugs, such as atracurium and mivacurium,[218] or after coadministration of various pairs of steroidal NMBDs.[98] Conversely, combinations of structurally dissimilar (e.g., a steroidal with a benzylisoquinolinium) NMBDs, such as the combinations of pancuronium and dTc,[219] pancuronium and metocurine,[219] rocuronium and mivacurium,[142] or rocuronium and cisatracurium,[109] produce a synergistic response.

The administration of two NMBDs in combination was first introduced by Lebowitz and associates in an attempt to reduce the cardiovascular side effects of NMBDs by giving smaller doses of each drug in combination.[219] An additional advantage (rapid onset and short duration) is noted for mivacurium-rocuronium

combinations.[142] Although the precise mechanisms underlying a synergistic interaction are not known, hypotheses that have been put forward include the existence of multiple binding sites at the neuromuscular junction (presynaptic and postsynaptic receptors)[220] and the nonequivalence of binding affinities of the two α subunits (α_H and α_L). Further, inhibition of butyrylcholinesterase by pancuronium results in decreased plasma clearance of mivacurium and marked potentiation of the neuromuscular blockade.[221]

The pharmacodynamic response to the use of two different nondepolarizing NMBDs during the course of anesthesia depends not only on the specific drugs used but also on the sequence of their administration.[222,223] Approximately three half-lives are required for a clinical changeover (so that 95% of the first drug has been cleared) and for the duration of the blockade to begin to take on the characteristics of the second drug. After the administration of pancuronium, recovery from the first two maintenance doses of vecuronium is reportedly prolonged, although this effect becomes negligible by the third dose.[222] Similarly, Naguib and colleagues noted that the mean duration of the first maintenance dose of mivacurium to 10% recovery of the first twitch was significantly longer after atracurium (25 minutes) than after mivacurium (14.2 minutes).[218] However, the duration of the second maintenance dose of mivacurium after atracurium (18.3 minutes) was similar to that of mivacurium after mivacurium (14.6 minutes).

The apparent prolongation of action of the first maintenance dose of mivacurium administered after atracurium,[218] and of those reported with vecuronium after pancuronium,[222,223] is not related to synergism. Combinations of atracurium and mivacurium[218] and of vecuronium and pancuronium[98] are simply additive. However, this prolongation in the duration of action could be attributed to the relative concentrations of these drugs at the receptor site. Because most receptors remain occupied by the drug administered initially, the clinical profile depends on the kinetics or dynamics (or both) of the drug administered first rather than on those of the second (maintenance) drug. However, with further incremental doses of the second drug, a progressively larger proportion of the receptors is occupied by that drug, and its clinical profile becomes evident.

Interactions Between Succinylcholine and Nondepolarizing Neuromuscular Blocking Drugs

The interaction between succinylcholine and nondepolarizing NMBDs depends on the order of administration and the doses used.[81,224,225] Small doses of different nondepolarizing NMBDs administered before succinylcholine to prevent fasciculations have an antagonistic effect on the development of subsequent depolarizing block produced by succinylcholine.[27,81] Therefore, it is recommended that the dose of succinylcholine be increased after the administration of a defasciculating dose of a nondepolarizing NMBD.[27]

Studies of the effects of administering succinylcholine before nondepolarizing NMBDs have produced conflicting results. Several investigators reported potentiation of the effects of pancuronium,[224] vecuronium, and atracurium[225] by prior administration of succinylcholine. In contrast, other investigators found no significant influence of succinylcholine on subsequent administration of pancuronium, rocuronium, or mivacurium.[81,226,227]

Interactions with Inhaled Anesthetics

Deep anesthesia induced with potent volatile anesthetics (in the absence of neuromuscular blockade) may cause a slight reduction of neuromuscular transmission, as measured by depression of sensitive indicators of clinical neuromuscular function, such as tetanus and TOF.[228] Inhaled anesthetics also enhance the neuromuscular blocking effects of nondepolarizing NMBDs. Inhaled anesthetics decrease the required dose of NMBDs, as well as prolong both the duration of action of the blocker and recovery from neuromuscular block,[229] depending on the duration of anesthesia,[228,230,231] the specific inhaled anesthetic,[232] and the concentration (dose) given.[233] The rank order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide–barbiturate–opioid or propofol anesthesia (Fig. 34-15).[234-236]

The greater clinical muscle-relaxing effect produced by less potent anesthetics is mainly caused by their larger aqueous concentrations.[237] Desflurane and sevoflurane have low blood-gas and tissue-gas solubility, so equilibrium between the end-tidal concentration and the neuromuscular junction is reached more rapidly with these anesthetics than with older inhaled anesthetics.

The interaction between volatile anesthetics and NMBDs is one of pharmacodynamics, not pharmacokinetics.[238] The proposed mechanisms behind this interaction include (1) a central effect on α motoneurons and interneuronal synapses,[239] (2) inhibition of postsynaptic nAChR,[240] and (3) augmentation of the antagonist's affinity at the receptor site.[237]

Interactions with Antibiotics

Most antibiotics can cause neuromuscular blockade in the absence of NMBDs. The aminoglycoside antibiotics, the

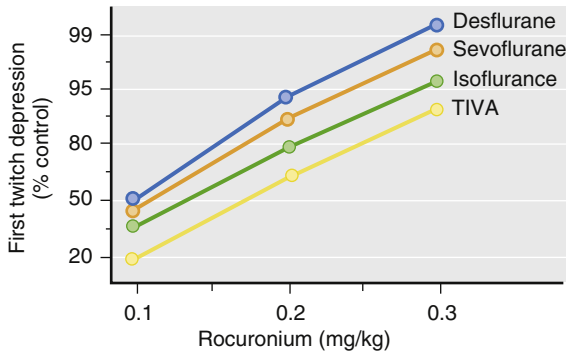

Figure 34-15. Cumulative dose-response curves for rocuronium-induced neuromuscular blockade during 1.5 minimum alveolar concentration (MAC) anesthesia with desflurane, sevoflurane, isoflurane, and total intravenous anesthesia (TIVA). *(From Wulf H, Ledowski T, Linstedt U, et al: Neuromuscular blocking effects of rocuronium during desflurane, isoflurane, and sevoflurane anaesthesia,* Can J Anaesth *45:526-532, 1998, with permission from the* Canadian Journal of Anaesthesia.*)*

polymyxins, and lincomycin and clindamycin primarily inhibit the prejunctional release of acetylcholine and also depress postjunctional nAChR sensitivity to acetylcholine.[241] The tetracyclines, in contrast, exhibit postjunctional activity only. When combined with NMBDs, the aforementioned antibiotics can potentiate neuromuscular blockade.[242] The cephalosporins and penicillins have not been reported to potentiate neuromuscular blockade. Because antagonism of neuromuscular blockade has been reported to be more difficult after the administration of aminoglycosides,[243] ventilation should be controlled until the neuromuscular blockade terminates spontaneously. Ca^{2+} should not be used to hasten the recovery of neuromuscular function for two reasons: the antagonism it produces is not sustained, and it may prevent the antibacterial effect of the antibiotics.

Temperature

Hypothermia prolongs the duration of action of nondepolarizing NMBDs.[244-246] The force of contraction of the adductor pollicis decreases by 10% to 16% per degree Celsius decrease in muscle temperature lower than 35.2° C.[247,248] To maintain the muscle temperature at or higher than 35.2° C, the central temperature must be maintained at 36.0° C.[244] The recovery to 10% twitch height with 0.1 mg/kg of vecuronium increases from 28 minutes at a mean central temperature of 36.4° C to 64 minutes at 34.4° C.[244] The mechanism or mechanisms underlying this prolongation may be pharmacodynamic or pharmacokinetic, or both.[246] They include diminished renal and hepatic excretion, changing volumes of distribution, altered local diffusion receptor affinity, changes in pH at the neuromuscular junction, and the net effect of cooling on the various components of neuromuscular transmission.[244,249] Hypothermia decreases the plasma clearance and prolongs the duration of action of rocuronium and vecuronium.[246] Temperature-related differences in the pharmacodynamics of vecuronium have also been reported. The k_{e0} decreases (0.023/minute/° C) with lower temperature, a finding suggesting slightly delayed equilibration of drug between the circulation and the neuromuscular junction during hypothermia.[246] The Hofmann elimination process of atracurium is slowed by a decrease in pH and especially by a decrease in temperature.[250] In fact, atracurium's duration of action is markedly prolonged by hypothermia.[245] For instance, the duration of action of a dose of 0.5 mg/kg atracurium is 44 minutes at 37° C but 68 minutes at 34.0° C.

Changes in temperature also affect the interpretation of the results of monitoring neuromuscular blockade. For example, the duration of action of vecuronium measured in an arm cooled to a skin temperature of 27° C is prolonged, and monitoring by PTC in that arm is unreliable.[251] In the same patient, TOF responses are different if the arms are at different temperatures, and the correlation of responses in the two arms becomes progressively poorer as the temperature difference between the arms increases.[252]

The efficacy of neostigmine is not altered by mild hypothermia.[253-255] Hypothermia does not change the clearance, maximum effect, or duration of action of neostigmine in volunteers.[255]

Interactions with Magnesium and Calcium

Magnesium sulfate, given for treatment of preeclampsia and eclamptic toxemia, potentiates the neuromuscular blockade induced by nondepolarizing NMBDs[256,257] (see Chapter 77). After a dose of 40 mg/kg of magnesium sulfate, the ED_{50} of vecuronium was reduced by 25%, the onset time was nearly halved, and the recovery time nearly doubled.[257] Neostigmine-induced recovery is also attenuated in patients treated with magnesium.[256] The mechanisms underlying the enhancement of nondepolarizing block by magnesium probably involve both prejunctional and postjunctional effects. High magnesium concentrations inhibit Ca^{2+} channels at the presynaptic nerve terminals that trigger the release of acetylcholine.[16] Further, magnesium ions have an inhibitory effect on postjunctional potentials and cause decreased excitability of muscle fiber membranes. In patients receiving magnesium, the dose of nondepolarizing NMBDs must be reduced and carefully titrated using a nerve stimulator to ensure adequate recovery of neuromuscular function at the end of surgery.

The interaction between magnesium and succinylcholine is controversial. However, more recent results suggest that magnesium antagonizes the block produced by succinylcholine.[258]

Ca^{2+} triggers the release of acetylcholine from the motor nerve terminal and enhances excitation-contraction coupling in muscle.[16] Increasing Ca^{2+} concentrations decreased the sensitivity to dTc and pancuronium in a muscle-nerve model.[259] In hyperparathyroidism, hypercalcemia is associated with decreased sensitivity to atracurium and thus a shortened time course of neuromuscular blockade.[260]

Interactions with Lithium

Lithium remains the drug of choice for treatment of bipolar affective disorder (manic-depressive illness). The lithium ion resembles Na^+, K^+, magnesium, and Ca^{2+} ions and therefore may affect the distribution and kinetics of all these electrolytes.[261] Lithium enters cells via Na^+ channels and tends to accumulate within the cells.

By its activation of K^+ channels, lithium inhibits neuromuscular transmission presynaptically and muscular contraction postsynaptically.[262] The combination of lithium and pipecuronium results in a synergistic inhibition of neuromuscular transmission, whereas the combination of lithium and succinylcholine results in additive inhibition.[262] Prolongation of neuromuscular blockade was reported in patients taking lithium carbonate and both depolarizing and nondepolarizing NMBDs.[263] Only one report did not demonstrate prolongation of recovery from succinylcholine in patients receiving lithium.[264] In patients who are stabilized on lithium therapy and undergoing surgery, NMBDs should be administered in incremental and reduced doses and titrated to the degree of blockade required.

Interactions with Local Anesthetic and Antidysrhythmic Drugs

Local anesthetics act on the presynaptic and postsynaptic part of the neuromuscular. In large intravenous doses, most local anesthetics block neuromuscular transmission;

in smaller doses, they enhance the neuromuscular blockade produced by both nondepolarizing and depolarizing NMBDs.[265] The ability of neostigmine to antagonize a combined local anesthetic–neuromuscular blockade has not been studied. Procaine also inhibits butyrylcholinesterase and may augment the effects of succinylcholine and mivacurium by decreasing their hydrolysis by the enzyme.

In small intravenous doses, local anesthetics depress posttetanic potentiation, and this is thought to be a neural prejunctional effect.[266] With larger doses, local anesthetics block acetylcholine-induced muscular contractions, a finding suggesting that local anesthetics have a stabilizing effect on the postjunctional membrane.[267] Procaine displaces Ca^{2+} from the sarcolemma and thus inhibits caffeine-induced contracture of skeletal muscle.[268] Most of these mechanisms of action probably apply to all the local anesthetics.

Several drugs used for the treatment of dysrhythmias augment the blockade induced by NMBDs. Single-fiber electromyography disclosed that verapamil and amlodipine impair neuromuscular transmission in subjects without neuromuscular disease.[269] Clinical reports suggested potentiation of neuromuscular block with verapamil[270] and impaired reversal of vecuronium in a patient receiving disopyramide.[271] However, the clinical significance of these interactions is probably minor.

Interactions with Antiepileptic Drugs

Anticonvulsants have a depressant action on acetylcholine release at the neuromuscular junction.[272,273] Patients receiving long-term anticonvulsant therapy demonstrated resistance to nondepolarizing NMBDs (except mivacurium[274] and probably atracurium as well[273]), as evidenced by accelerated recovery from neuromuscular blockade and the need for increased doses to achieve complete neuromuscular blockade. Vecuronium clearance is increased twofold in patients receiving long-term carbamazepine therapy.[275] Other investigators, however, attribute this resistance to the increased binding (i.e., decreased free fraction) of the NMBDs to α_1-acid glycoproteins or to up-regulation of neuromuscular acetylcholine receptors (or to both mechanisms).[276] The latter could also explain the hypersensitivity seen with succinylcholine.[277] The slight prolongation of succinylcholine's action in patients taking anticonvulsants has few clinical implications. Conversely, the potential hyperkalemic response to succinylcholine in the presence of receptor up-regulation is of concern.

Interactions with Diuretics

Early results showed that in patients undergoing renal transplantation, the intensity and duration of dTc neuromuscular blockade was increased after a dose of furosemide (1 mg/kg intravenously).[278] Furosemide reduced the concentration of dTc required to achieve 50% twitch tension depression in the indirectly stimulated rat diaphragm and intensified the neuromuscular blockade produced by dTc and succinylcholine.[279] Furosemide appears to inhibit the production of cyclic adenosine monophosphate. In addition, the breakdown of adenosine triphosphate is inhibited, resulting in reduced output of acetylcholine. Acetazolamide antagonized the effects of anticholinesterases in the rat phrenic-diaphragm preparation.[280] However, in one report, 1 mg/kg of furosemide facilitated recovery of the evoked twitch response after pancuronium.[281] Long-term furosemide treatment had no effect on either dTc- or pancuronium-induced neuromuscular blockade.[282]

In contrast, mannitol appears to have no effect on a nondepolarizing neuromuscular blockade. Furthermore, increasing urine output by the administration of mannitol or other osmotic or tubular diuretics has no effect on the rate at which dTc and presumably other NMBDs are eliminated in the urine.[283] However, this lack of effect on the excretion of dTc should not be surprising. Urinary excretion of all NMBDs that are long acting depends primarily on glomerular filtration. Mannitol is an osmotic diuretic that exerts its effects by altering the osmotic gradient within the proximal tubules so that water is retained within the tubules. An increase in urine volume in patients with adequate glomerular filtration therefore would not be expected to increase the excretion of NMBDs.

Interactions with Other Drugs

Dantrolene, a drug used for the treatment of malignant hyperthermia, prevents Ca^{2+} release from the sarcoplasmic reticulum and blocks excitation-contraction coupling (see Chapter 43). Although dantrolene does not block neuromuscular transmission, the mechanical response to stimulation is depressed, resulting in potentiation of the nondepolarizing neuromuscular blockade.[284]

Azathioprine, an immunodepressant drug that is used in patients undergoing renal transplantation, has a minor antagonistic action on muscle relaxant–induced neuromuscular blockade.[285]

Steroids antagonize the effects of nondepolarizing NMBDs in both humans[286] and animals.[287] Possible mechanisms for this interaction include facilitation of acetylcholine release because of the effect of steroids on the presynaptic motor nerve terminal[288] and channel blockade of the nAChR.[289] Endogenous steroids act noncompetitively on nAChRs.[290] Prolonged treatment with a combination of corticosteroids and NMBDs can result in prolonged weakness in patients receiving critical care (see the later section on NMBDs and weakness syndromes in critically ill patients).

Antiestrogenic drugs such as tamoxifen appear to potentiate the effects of nondepolarizing NMBDs.[291]

SPECIAL POPULATIONS

PEDIATRIC PATIENTS

The development of the neuromuscular junction is not complete at birth.[16] In humans, maturation of neuromuscular transmission occurs after the first 2 months of age, although immature junctions have been found up to 2 years of age The main evolution during the first months of life is that the fetal receptors located outside the neuromuscular junction will disappear and will be replaced by mature receptors with ε subunits instead of γ

subunits. These changes suggest that that the neonate's neuromuscular junction may exhibit evidence of its immaturity by changes in response to NMBDs, although NMBDs can be used safely in term and preterm infants (see also Chapter 93).

The routine administration of succinylcholine to healthy children should be discontinued. In apparently healthy children, intractable cardiac arrest with hyperkalemia, rhabdomyolysis, and acidosis may develop after succinylcholine administration, particularly in patients with unsuspected muscular dystrophy of the Duchenne type[292] (see the section on complications of succinylcholine).

Significant age-related differences in the potency of nondepolarizing NMBDs exist in infants and children when compared with adults. Children require higher doses of nondepolarizing NMBDs than any other age group of patients. In infants less than 1 year old, the ED_{95} at the adductor pollicis is approximately 30% less than in older children. It is not apparent from older studies whether the neonate is more sensitive than adults to nondepolarizing NMBDs,[293] although most of the studies showed a wider range of dosage requirement in the neonate. These apparent discrepancies were been explained by studies by Fisher and associates on the pharmacokinetics and pharmacodynamics of NMBDs in infants, children, and adults,[294-296] and they made it possible to understand the clinical pharmacology of these drugs in pediatric patients more clearly (see Chapter 93). Neonates and infants are more sensitive than adults to the neuromuscular blocking effects of dTc.[294] Plasma concentrations required to achieve a desired level of neuromuscular blockade are 57% and 32% lower in neonates and infants, respectively, when compared with children. However, the dosage should not be decreased as much because neonates and infants have a larger volume of distribution at steady state. This increased volume of distribution results from the increase in extracellular fluid volume during the first months of life. This increase, in association with a lower elimination clearance, contributes to a longer elimination half-life.[294,297] In infants, less frequent dosing (longer dosing intervals) of nondepolarizing NMBDs may be required than in older children.

Atracurium, vecuronium, cisatracurium, rocuronium, and mivacurium are commonly administered to children because many surgical procedures are of short duration in children and are compatible with the duration of action of a single intubating dose. Onset time of neuromuscular block is faster in infants (30%) and children (40%) when compared with adults. This age-related effect is probably caused by circulatory factors such as the relative decrease of cardiac output and increase of circulation time with age.

As with the long-acting NMBDs, the sensitivity of infants to vecuronium is more intense than in children (ED_{95} 0.047 mg/kg versus 0.081 mg/kg, respectively).[298,299] An increased duration of action in infants is most likely secondary to the increased volume of distribution of vecuronium because its clearance is unchanged.[295,297] An age-dependent prolongation of action has been demonstrated in infants. A dose of 0.1 mg/kg of vecuronium produces almost a complete neuromuscular block of approximately 60 minutes' duration in infants but of only 20 minutes' duration in children and adults. Vecuronium therefore acts as a long-acting muscle NMBD in the neonate.[295,297]

In contrast, the duration of action of atracurium is not significantly different in the pediatric patient from that in the adult.[300] As with vecuronium and dTc, the volume of distribution is increased in infants.[296] However, the clearance of atracurium is also more rapid.[296] Therefore, the same dose (0.5 to 0.6 mg/kg) can be used in infants, children, and adults for tracheal intubation without any major differences among the three groups in the drug's duration of action. Atracurium recovery from neuromuscular block is little affected by age in pediatric patients more than 1 month old. Histamine release and the occurrence of an untoward reaction caused by atracurium are less frequent in children than in adults. In children, a dose of 0.1 µg/kg of cisatracurium has an onset just longer than 2 minutes and a clinical duration of approximately 30 minutes during balanced or halothane anesthesia.[301] The calculated ED_{95} doses of cisatracurium in infants and children are 43 and 47 µg/kg, respectively.[302] The mean infusion rate necessary to maintain 90% to 99% neuromuscular block is also similar in infants and children.[302]

Rocuronium in adults is an intermediate-acting NMBD with a faster onset of action than other nondepolarizing NMBDs, and this is also true in infants and children.[303,304] The ED_{95} is approximately 0.4 mg/kg in children; it is approximately 20% to 30% greater than that in adults, but its onset is faster in adults.[304] In children, 0.6 mg/kg of rocuronium produces better conditions for rapid tracheal intubation (60 seconds) than does 0.1 mg/kg of vecuronium (100 seconds) or 0.5 mg/kg of atracurium (180 seconds).[303] Evidence indicates that, even during sevoflurane induction in infants, the addition of 0.3 mg/kg rocuronium significantly improves intubating conditions and significantly decreases the frequency of respiratory adverse events such as desaturation of laryngospasm during induction.[305] As with adults, for rapid-sequence intubation (60 seconds) in the presence of a full stomach, a 1.2 mg/kg dose of rocuronium is suggested to provide excellent intubating conditions in patients.

OLDER PATIENTS

The pharmacodynamics of NMBDs may be altered in older patients (see also Chapter 80). Certain physiologic changes that accompany the aging process occur, including decreases in total body water and lean body mass, increases in total body fat, decreases in hepatic and renal blood flow and hepatic enzyme activity, and decreases in glomerular filtration rate (≈20%/year in adults). These changes may account for the altered responses of older adults to NMBDs. Some physiologic and anatomic changes at the neuromuscular junction also occur with aging. These include an increase in the distance between the junctional axon and the motor end plate, flattening of the folds of the motor end plate, a decreased concentration of acetylcholine receptors at the motor end plate, a decrease of the amount of acetylcholine in each vesicle in the prejunctional axon, and decreased release of

acetylcholine from the preterminal axon in response to a neural impulse.[16]

Several studies found no differences in the initial dose requirement for nondepolarizing muscle relaxants in older adults. The dose-response curves of atracurium, pancuronium, and vecuronium were slightly to the right of the curves for the younger adult subjects; however, no significant differences were noted. After a bolus dose of pancuronium, no significant difference was observed at any of the plasma concentrations corresponding to a fixed degree of neuromuscular block. Such results confirm that nondepolarizing muscle relaxants are as potent in older as in young adult patients. The onset of neuromuscular block can be delayed and can be correlated with age.[306] This age-related effect is probably caused by circulatory factors such as the decrease in cardiac output and increase in circulation time in older adults. These factors induce slower biophase equilibration. The onset of rocuronium neuromuscular block was prolonged to 3.7 from 3.1 minutes in older adults. Similarly, the onset of cisatracurium is approximately 1 minute longer in this age group.

A prolongation of the duration of action of nondepolarizing muscle relaxants and a decrease in dose requirements for the maintenance of neuromuscular block have been observed with several currently available muscle relaxants in older adults. These results are explained by pharmacokinetic changes in this population. The distribution and elimination may be altered by any of the multitude of physiologic changes that accompany the aging process. The effect of aging alone, as opposed to disease states often associated with the aging process, may be difficult to distinguish in identifying mechanisms of altered NMBD action in older adults.

Pancuronium,[307] vecuronium,[295,308] and rocuronium[177] depend on the kidney or the liver (or both) for their metabolism and elimination. Therefore, they all show altered pharmacodynamics and pharmacokinetics in older patients. Pancuronium has delayed recovery in older adults because of decreased plasma clearance secondary to delayed urinary excretion. The clinical duration of action is prolonged from 44 to 73 minutes in this age group.[2] Vecuronium dose requirements to maintain a constant neuromuscular block are decreased by approximately 36% in patients more than 60 years old, and spontaneous recovery is significantly longer in older patients.[25] Lien and co-workers showed that plasma clearance was reduced by more than 50% and elimination half-life prolonged by 60% in older patients.[308] The prolongation of vecuronium action appears to be secondary to decreased drug elimination consistent with age-associated decreases in hepatic and renal blood flows. The duration of action of rocuronium and the recovery index are also increased in older adults. The prolongation of action can be explained by a 27% decrease in plasma clearance.

In the case of drugs whose elimination is independent of hepatic or renal blood flow, pharmacokinetics and pharmacodynamics should not be significantly altered by age. Atracurium has multiple routes of elimination. Degradation by Hofmann elimination and ester hydrolysis is independent of the liver and the kidney and is not affected by age. The only pharmacokinetic change is a slight increase of the volume of distribution at steady state leading to a modestly increased elimination half-life. Consequently, the duration of action, the recovery index, and the dose requirement during a continuous infusion are independent of age. Cisatracurium exhibits a slightly delayed onset of effect in older patients because of slower biophase equilibration. Clearances are not decreased in patients of advanced age. The slight prolongation of the elimination half-life of the drug in older adults is secondary to an increased volume of distribution at steady state (+10%). These minor pharmacokinetic changes are not associated with changes in the recovery profile of older patients.

Butyrylcholinesterase activity in older adults, although still in the normal range, is approximately 26% lower than that in young adults.[309] Because mivacurium is metabolized by butyrylcholinesterase, its clearance is likely to be slightly reduced in older patients, thus resulting in a 20% to 25% longer duration of action,[310] as well as a decreased infusion requirement to maintain a stable depth of block. Succinylcholine metabolism is unaffected by these changes.

In general, when maintaining neuromuscular blockade with nondepolarizing NMBDs in older patients, one can expect that, with the exception of atracurium and cisatracurium, the dosing interval will be increased to maintain the desired depth of neuromuscular blockade. The choice of drug and monitoring the depth of blockade are exceptionally important in this population because recovery of neuromuscular function is generally delayed in older patients. Inadequate or incomplete recovery of muscle strength after the use of pancuronium is associated with an increased incidence of perioperative pulmonary complications in this patient population.[129] The clear relationship between incomplete recovery from neuromuscular block and occurrence of critical respiratory events in the PACU highlights the need for objective recovery of neuromuscular block in older patients.

OBESE PATIENTS

The level of plasma pseudocholinesterase activity and the volume of extracellular fluid, which are the main determinants of the duration of action of succinylcholine, are increased in obese patients (see also Chapter 71). Lemmens and Brodsky demonstrated that for complete neuromuscular paralysis and a predictable intubating condition, a 1 mg/kg dose based on total-body weight (TBW) was recommended.[311]

Initial studies showed that obese subjects needed significantly more pancuronium than nonobese patients to maintain a constant 90% depression of twitch height. However, when corrected for body surface area (BSA), no significant difference was noted in dose requirement to maintain neuromuscular block.

The use of NMBDs with an intermediate duration of action should be preferred. Vecuronium doses based on TBW induce a prolonged duration of action in obese patients, although vecuronium pharmacokinetics is unaltered by obesity. The prolonged recovery in obese patients can be explained by the larger total dose administered in these patients. With larger doses, when administration is based on TBW, recovery occurs during the elimination

phase when plasma concentration decreases more slowly than during the distribution phase.[312] The pharmacokinetics of rocuronium is not altered by obesity. In the same way, the duration of action of rocuronium is significantly prolonged when the dose is calculated according to TBW. In contrast, when rocuronium is dosed according to ideal body weight (IBW), the clinical duration is less than half.[313,314]

A correlation exists between the duration of action of atracurium and TBW when the dose is given as milligrams per kilogram of TBW. The clinical duration of action is doubled when the drug is given based on TBW versus IBW. Varin and colleagues reported the lack of difference between obese and normal-weight patients in atracurium elimination half-life (19.8 versus 19.7 minutes), volume of distribution at steady state (8.6 versus 8.5 L), and total clearance (444 versus 404 mL/minute).[315] The finding that IBW avoids prolonged recovery of atracurium-induced blockade can be explained by an unchanged muscle mass and an unchanged volume of distribution in morbidly obese patients compared with normal-weight patients.[316] The duration of cisatracurium is also prolonged in obese patients when the drug is given on the basis of TBW versus IBW.

Nondepolarizing NMBDs should be given to obese patients on the basis of IBW rather than on their actual body weight, to ensure that these patients are not receiving relative overdoses and to avoid prolonged recovery. When using maintenance doses, objective monitoring is strongly recommended to avoid accumulation.

SEVERE RENAL DISEASE

NMBDs contain quaternary ammonium groups that make them very hydrophilic (see also Chapters 72 and 74). They are therefore usually completely ionized at 7.4 pH and are poorly bound to plasma proteins. The predominant pathway of elimination of steroidal muscle relaxants is ultrafiltration by the glomeruli before urinary excretion. Renal failure influences the pharmacologic characteristics of nondepolarizing NMBDs by producing either decreased elimination of the drug or its metabolites through the kidney. Only atracurium, cisatracurium, and, to some extent, vecuronium are independent of renal function. Succinylcholine elimination is mainly independent of kidney function. However, succinylcholine is metabolized by plasma cholinesterases, and concentrations may be slightly decreased in patients with severe renal failure (Table 34-10). The decrease in plasma cholinesterase activity is always moderate (30%) and does not result in prolongation of succinylcholine-induced neuromuscular block. Succinylcholine induces a transient increase in plasma K^+ concentration (<0.5 mmol/L). Therefore, succinylcholine is not contraindicated in severe renal failure when plasma K^+ concentrations are within the normal range. Consequently, the duration of action of NMBDs may be prolonged in patients with renal failure.

Renal failure does not alter the sensitivity (dose response) of patients to the neuromuscular blocking action of pancuronium,[317] atracurium,[318] vecuronium,[319] or rocuronium.[320] All long-lasting muscle relaxants are eliminated predominantly through the kidney, and renal failure is associated with reduced plasma clearance and increased elimination half-life for these drugs as well.[103] The elimination half-life of pancuronium is increased by 500% in patients with severe renal failure. As a consequence of these pharmacokinetic changes, the duration of neuromuscular blockade produced by these drugs is longer and more variable than in patients with normal renal function. Because of the potential for prolonged

blockade and the availability of intermediate- and short-acting NMBDs, long-acting NMBDs should not be used in patients with renal failure.

The pharmacokinetics and duration of action of atracurium are unaffected by renal failure.[321,322] This lack of effect is in part because Hofmann elimination and ester hydrolysis[173] account for 50% of its total clearance.[167] Laudanosine, the principal metabolite of atracurium, is eliminated unchanged by the kidney. The elimination half-life of laudanosine increases in renal failure.[322] Even during continuous administration of atracurium, laudanosine plasma concentrations are 10 times less than concentrations associated with convulsions in dogs.

In patients with chronic renal failure, the duration of action of cisatracurium is not prolonged.[323] Hofmann elimination accounts for 77% of the total clearance of cisatracurium,[169] and renal excretion accounts for 16% of its elimination.[169] The peak plasma laudanosine concentration is 10 times lower than after equipotent doses of atracurium. In patients with end-stage renal failure, the volume of distribution is unchanged, but Eastwood found a 13% reduction in clearance and an increase from 30 to 34 minutes in the elimination half-life in the renal failure group.

Vecuronium relies principally on hepatic mechanisms for its elimination. However, its clearance is reduced and its elimination half-life is increased in patients with renal failure.[324,325] In one study, the duration of action of 0.1 mg/kg of vecuronium was both longer and more variable in patients with renal failure than in those with normal renal function.[325] In three other studies, the duration of action of 0.05 to 0.14 mg/kg of vecuronium was not prolonged by renal failure, but this result was likely caused by the use of relatively small doses or inadequate sample sizes.[324] The principal metabolite of vecuronium, 3-desacetylvecuronium, has 80% of the neuromuscular blocking activity of vecuronium[153]; it may cause prolonged paralysis in patients with renal failure in the ICU.[156] In patients with renal failure, the duration of action and the rate of recovery from vecuronium- or atracurium-induced neuromuscular blockade during surgery are similar.[326]

The major routes of elimination of rocuronium are biliary and urinary excretion. Rocuronium is taken up by the liver and metabolized, excreted, or both, in bile and feces in high concentrations. After 0.6 mg/kg rocuronium, up to one fifth of the dose is recovered unchanged from the urine within 24 hours, and no active metabolites can be found in humans. More recent pharmacokinetic studies showed that the clearance of rocuronium was reduced by 33% to 390% in patients with renal failure. The distribution volume of this drug remained unchanged or slightly increased.[175] The elimination half-life was 70 and 57 minutes in patients with and without renal failure, respectively. The duration of action of single and repeated doses, however, was not significantly affected.[320]

HEPATOBILIARY DISEASE

In comparison with renal elimination, liver function is a modest determinant of the pharmacokinetics of nondepolarizing muscle relaxants (see also Chapters 73 and 74). The influence of hepatobiliary disease on the pharmacokinetics of NMBDs can be complex because of the different types of liver failure (Table 34-11). Cirrhosis is associated with an increased extracellular water

compartment, edema, and often kidney dysfunction. Cholestasis induces decreased biliary excretion but is not associated with significant liver failure, contrary to acute hepatic failure.

A delayed onset of action and an apparent resistance to nondepolarizing muscle relaxants occur in patients with cirrhosis, although studies demonstrated that the sensitivity of the neuromuscular junction was unaltered. This is the consequence of the increased volume of distribution, which induces greater dilution of muscle relaxants in cirrhotic patients. The increase of terminal half-life can be secondary to either the increased volume of distribution or decreased biliary excretion for muscle relaxants dependent on hepatic function for elimination. Following a single dose of nondepolarizing muscle relaxant, in most of the cases, no prolongation of the duration of action occurs because it is dependent on distribution. However, for muscle relaxants dependent on hepatic elimination, prolongation of neuromuscular block can be observed following repeated doses or continuous infusion.

Pancuronium is mainly eliminated through the kidney, although one third of a dose is metabolized and excreted through the liver. The elimination half-life increases from 114 to 208 minutes in cirrhotic patients. This is the consequence of a 50% increase of the volume of distribution in conjunction with a 22% decrease in plasma clearance. Cholestasis induces a 50% decrease in pancuronium clearance leading to a prolonged elimination half-life of 270 minutes. Severe acute hepatic failure also induces reduced plasma clearance and a prolonged elimination half-life.

Vecuronium elimination is mainly through the bile. Only a small fraction is metabolized to 3-hydroxyvecuronium, which still has 60% of the potency of vecuronium. This metabolic process is presumed to occur in the liver because 40% of the total dose of vecuronium is found in the liver and bile as both parent drug and metabolite.[147] The elimination half-life is increased in mildly decompensated cirrhotic patients as the result of a decreased clearance, whereas the volume of distribution of the central compartment and the volume of distribution at steady state can be increased. In cirrhotic patients, the duration of action of vecuronium is related to the dose. A dose of 0.1 mg/kg has a slower onset of action and a shorter duration of action because the volume of distribution is increased. In contrast, after 0.2 mg/kg vecuronium, the duration of action is increased from 65 minutes to 91 minutes in cirrhotic patients because elimination is impaired. Cholestasis can increase plasma concentration of bile salts and thus reduce the hepatic uptake of vecuronium,[147] as well as pancuronium. This may explain the decreased clearance observed by some investigators. The duration of action of vecuronium is increased by 50% in patients with biliary obstruction.

Rocuronium is mainly excreted into the bile. The volume of both the central compartment (+33%) and the volume of distribution at steady state (+43%) are increased in cirrhotic patients, whereas clearance may be decreased. The duration of action is prolonged in patients with hepatic disease, and a correlation exists between the increased volume of distribution and the slower onset of action when compared with controls.

Atracurium and cisatracurium share organ-independent modes of elimination.[165,168,169] As a consequence, their clearance should be little affected by hepatic disease. In fact, and in contrast to all other NMBDs, the plasma clearances of atracurium and cisatracurium are slightly increased in patients with liver disease (see Table 34-11).[174,180] Because elimination of atracurium and cisatracurium occurs outside of, as well as from within, the central compartment, investigators have suggested that a larger distribution volume should be associated with greater clearance.[169] In two studies,[174,180] volumes of distribution and clearances of the drugs increased with liver disease, thereby lending support to this hypothesis.[169] The increased clearance of the relaxant in patients with liver disease is not reflected in a decrease in the drug's duration of action.[174,180]

One concern raised about administering atracurium to patients with hepatic disease is the possible accumulation of laudanosine. Although laudanosine relies principally on hepatic mechanisms for its elimination, the concentrations encountered during liver transplantation are unlikely to be associated with clinical sequelae.[327]

Because of the wide interindividual variations seen in the response to nondepolarizing muscle relaxants in patients with hepatic disease, monitoring of neuromuscular block is required with titration of doses.

In patients with severe liver disease, butyrylcholinesterase activity is decreased because of decreased synthesis of the hepatic enzymes. Consequently, the plasma clearance of the isomers of mivacurium is decreased by approximately 50%[159] (see Table 34-11), and the drug's duration of action is prolonged and may be almost tripled.[159]

BURNS

In patients with burn injuries, muscle relaxants can be used to facilitate mechanical ventilation, which can be associated with sustained improvement in oxygenation (see also Chapter 101). After a period of immobilization, burn injury causes up-regulation of both fetal ($\alpha_2\beta\gamma\delta$) and mature ($\alpha_2\beta\varepsilon\delta$) nAChRs.[328] This up-regulation of nAChRs usually is associated with resistance to nondepolarizing NMBDs and increased sensitivity to succinylcholine.[329] Causes of up-regulation of nAChRs are listed in Table 34-12. A significant increase in the quantal content of

evoked acetylcholine release is noted by 72 hours after scald injury in rats.[330] This increase also contributes to the resistance to NMBDs in patients with burn injuries. In mice, thermal injury induces changes in diaphragm acetylcholinesterase with respect to total content and specific molecular forms.[331]

Resistance to the effects of nondepolarizing NMBDs is usually seen in patients with burns over at least 25% of their total body surface area.[329,332,333] Recovery of neuromuscular function to preburn levels may take several months or even years after the burn injury.[334] The increase in serum K^+ concentration that normally follows succinylcholine administration is markedly exaggerated in burned patients.[335] K^+ concentrations as high as 13 mEq/L, resulting in ventricular tachycardia, fibrillation, and cardiac arrest have been reported.[335] The magnitude of the hyperkalemic response does not appear to correlate closely with the magnitude of the burn injury. Potentially lethal hyperkalemia was seen in a patient with only an 8% total body surface area burn.[336] Succinylcholine has been safely administered within 24 hours of a burn injury. It is the drug of choice for prehospital or emergency room intubation, particularly when patients have a full stomach. After an initial 24-hour interval, however, sufficient alteration in muscle response may have occurred. Because of the unpredictability of occurrence of hyperkalemia, the use of succinylcholine is best avoided 48 to 72 hours after a burn injury.

The time course of abnormal muscle membrane function corresponds with that of the healing process. Once normal skin has regrown and any infection subsides, the normal acetylcholine receptor populations appear to return.[334] Although normal responses to succinylcholine have been demonstrated in burned patients studied 3 years after injury,[334] the actual length of time during which a patient with a burn injury may be at risk for the hyperkalemic response is not well defined. A conservative guideline therefore would be to avoid the use of succinylcholine in patients 24 to 48 hours after a thermal injury and for at least 1 or 2 years after the burned skin has healed.

USE OF NEUROMUSCULAR BLOCKING DRUGS AND WEAKNESS SYNDROMES IN CRITICALLY ILL PATIENTS

NMBDs are frequently used in conjunction with sedatives and analgesics in ICUs (see also Chapter 101). The indications for the use of NMBDs in the ICU are outlined in Box 34-1. Few available data support their use, and evidence for a beneficial effect on pulmonary function or patient oxygenation is inconclusive.[337] However, a multicenter, double-blind trial showed that, in a subset of patients with acute respiratory distress syndrome, early and short-term administration of cisatracurium for 48 hours could be beneficial.[338] Half of the patients in the placebo group in that study received one or more doses of cisatracurium. The study was underpowered, and the effect on mortality was statistically borderline, with no between-group difference in crude mortality rate. Yet, nondepolarizing NMBDs are sometimes used in ICU patients. Of particular concern in intensive care settings is the risk that paralyzed patients receive inadequate analgesia and sedation.[339] This reason for this concern may be that ICU nurses and physicians are unfamiliar with the pharmacology of the NMBDs.[339,340] For instance, pancuronium was thought to be an anxiolytic by 50% to 70% of ICU nurses and house staff, and 5% to 10% thought it was an analgesic.[339] In the United Kingdom, the erroneous use of NMBDs as sedatives in intensive care was not uncommon in the 1980s.[341] Approximately 96% of ICU patients received NMBDs to aid mechanical ventilation in 1980. By 1986, their use had fallen to 16% of ventilated patients.[341] Currently, intensivists are aware of the side effects and avoid giving NMBDs to critically ill ICU patients unless these drugs are needed to facilitate mechanical ventilation.

A prolonged ICU stay during critical illness is associated with disorders of neuromuscular function that contribute to morbidity, length of hospital stay, weaning difficulties, and prolonged rehabilitation.[342] The complications of long-term administration of NMBDs in the ICU are outlined in Box 34-2. In the ICU, duration of mechanical ventilation, sepsis, the dysfunction of two or more

organs, female sex, administration of steroids, and hypercapnia are known risk factors for developing neuromuscular dysfunction. Syndromes of weakness in critically ill patients are relatively common and likely polymorphic in origin. In a retrospective study of 92 critically ill patients with clinically diagnosed weakness, electromyographic studies indicated that acute myopathy (critical illness myopathy [CIM]) is 3 times as common as acute axonal neuropathy (critical illness neuropathy): 43% versus 13%, respectively.[342] The additional health care cost of a single case of persistent weakness was estimated at approximately $67,000.[343] Conditions to consider when making a differential diagnosis of neuromuscular weakness in the ICU are listed in Box 34-3.

Critical Illness Myopathy

Lacomis and colleagues suggested using the term *critical illness myopathy* (CIM),[344] instead of the current terms used in the literature, such as acute quadriplegic myopathy,[345] acute (necrotizing) myopathy of intensive care, thick filament myopathy, acute corticosteroid myopathy, and critical care myopathy (see also Chapters 81 and 101).

Initial published reports of CIM in the ICU focused on patients with status asthmaticus.[346] Affected individuals typically had been treated with corticosteroids and nondepolarizing NMBDs. Nevertheless, myopathy has also been documented in asthmatic patients and in patients with chronic lung disease without paralysis who received corticosteroids,[347] as well as in critically ill patients with sepsis who received neither corticosteroids nor nondepolarizing NMBDs.[348] Animal studies revealed that the number of cytosolic corticosteroid receptors is increased in immobilized muscles relative to that in contralateral controls.[349] It seems—at least in some patients—that prolonged immobility may be the key risk factor for myopathy in corticosteroid-treated patients,[350] and selective muscle atrophy is a result of changes in glucocorticoid sensitivity.[349]

Sepsis, immobility, and the catabolism associated with negative nitrogen balance may also result in myopathy.[16] Skeletal muscle hypoperfusion is noted in patients with severe sepsis despite normal or elevated whole blood oxygen delivery.[351] Antibodies to nAChRs were demonstrated in a rodent model of sepsis.[352] Thus, myasthenia-like syndrome is also seen in critically ill patients. Evidence for local immune activation by cytokine expression in the skeletal muscle was reported in patients with CIM.[353]

The major feature of CIM is flaccid weakness that tends to be diffuse and sometimes also includes the facial muscles and diaphragm.[344] The clinical features of CIM overlap with those of critical illness polyneuropathy (CIP) and prolonged neuromuscular blockade.[344] Electrophysiologic studies and increases in serum creatine kinase concentrations may differentiate neuropathy from myopathy.[344] Lacomis and colleagues stated, "muscle biopsy should be considered if another myopathic process such as an inflammatory myopathy is suspected or if the histologic findings would affect management."[344]

Critical Illness Polyneuropathy

CIP is the polyneuropathy seen in critically ill patients. It affects both sensory and motor nerves and occurs in 50% to 70% of patients with multisystem organ failure and systemic inflammatory response syndrome.[354] Investigators have postulated that systemic inflammatory response syndrome contributes to CIP by releasing cytokines and free radicals that damage the microcirculation of the central and peripheral nervous systems.[353] Dysregulation of the microcirculation may render the peripheral nervous system susceptible to injury.

Although no pharmacologic treatment for muscle weakness syndromes in the critically ill patient currently exists, increasing evidence indicates the positive effects of early physical rehabilitation during ICU stay. Previously, intensive insulin therapy during critical illness was found to decrease the risk of CIP, and the maintenance of blood glucose at or below 110 mg/mL in critically ill patients may reduce the risk of CIP.

The outcomes from CIM and CIP appear to be similar. The reported mortality rate of patients with CIP syndrome is approximately 35%. In one study, 100% (13 of 13) of the patients who survived had abnormal clinical or neurophysiologic findings 1 to 2 years after the onset of the CIP syndrome, and quality of life was markedly impaired in all patients.[355]

Clinical Implications

Nondepolarizing NMBDs are the most common chemical agents producing immobilization and inducing a

denervation-like state. In such circumstances, besides the mature or junctional nAChR formed of two α and one each of β, ε, and δ subunits, two other isoforms, the immature AChR or γAChR and the neuronal α7AChR, are expressed in the muscle. The immature AChR is also referred as extrajunctional because it is expressed mostly in the extrajunctional part of the muscle. Up-regulation of nAChRs was noted in the muscles of deceased critically ill adults who had received long-term infusions of vecuronium.[356] Up-regulation refers to changes in the number of available receptors, but these changes usually do not involve a change in isoform changes. These three types of receptors can coexist in the muscle.

Should Succinylcholine Be Used in Patients in the Intensive Care Unit?

It is likely that up-regulation of nAChRs induced by immobilization and by prolonged administration of nondepolarizing NMBDs contributes to (1) the higher incidence of cardiac arrest associated with the use of succinylcholine in ICU patients[356] and (2) increased requirements for nondepolarizing NMBDs in ICU patients.[357] Even more important, succinylcholine more easily depolarizes immature nAChRs that may induce profound K^+ flux outward, with subsequent hyperkalemia. Moreover, the α7AChR can also be depolarized by succinylcholine, thus contributing to the K^+ efflux from the cell to the extracellular space. Therefore, succinylcholine should be avoided in ICU patients in whom total body immobilization exceeds 24 hours.[16]

Should Nondepolarizing Neuromuscular Blockers Be Used in Patients in the Intensive Care Unit?

NMBD-associated persistent weakness appears to be a distinct pathologic entity and is not simply a manifestation of weakness syndromes in critically ill patients (see also Chapter 101). In a prospective study, Kupfer and associates showed a 70% incidence of persistent weakness in ICU patients who received NMBDs for more than 2 days, compared with a 0% incidence in similar ICU patients who received no NMBD.[358] This is compelling evidence for the effects of nondepolarizing NMBDs in this complication.

Long-term weakness has been described after nondepolarizing NMBDs.[156,359,360] Approximately 20% of patients who received NMBDs for more than 6 days,[359] 15% to 40% of asthmatic patients who also received high-dose steroids,[346] and 50% of patients with renal failure who received vecuronium developed prolonged weakness.[156] Clinically, it appears that prolonged recovery from neuromuscular blockade occurs more frequently when steroidal NMBDs are used.[156,359]

However, prolonged weakness was also noted after the use of atracurium in ICU patients.[360] Further, the use of atracurium has raised concerns about its metabolite, laudanosine. Laudanosine, also detected in the cerebrospinal fluid (CSF) of ICU patients given atracurium,[361] is an analeptic and can trigger seizures in animals.[362] The toxic dose in humans is not known, but case reports have noted patients having seizures while receiving atracurium, and laudanosine has not been ruled out as a cause of these seizures.[363-365] Evidence also indicates that laudanosine can activate neuronal nicotinic receptors.[366] Cisatracurium is a single isomer of atracurium, and because it is four to five times more potent than atracurium, it is given in smaller doses. Therefore, the risk of laudanosine-related adverse effects should be minimal.[367]

Nondepolarizing NMBDs are polar molecules and do not readily cross the blood-brain barrier, but vecuronium and its long-acting active metabolite, 3-desacetylvecuronium, have been detected in the CSF of patients in the ICU. The CNS effects of NMBDs and their metabolites in humans have not been well studied, but in rats, atracurium, pancuronium, and vecuronium injected into the CSF caused dose-related cerebral excitation culminating in seizures.[362] Cerebral excitation with consequent increased cerebral oxygen demand is undesirable in ICU patients at risk of cerebral ischemia. Investigators have also suggested that nondepolarizing NMBDs can gain access to nerves during systemic inflammatory response syndrome, thus resulting in direct neurotoxicity.[362]

When nondepolarizing NMBDs are necessary, the use of a peripheral nerve stimulator is recommended, and periodic return of muscle function should be allowed. However, routine monitoring of neuromuscular function alone is insufficient in eliminating prolonged recovery and weakness syndromes in ICU patients.[368] Adjusting the dosage of NMBDs by peripheral nerve stimulation versus standard clinical dosing in critically ill patients reduces drug requirements, produces faster recovery of neuromuscular function, and results in a total cost savings of $738 per patient.[369] Daily interruption of sedative-drug infusions decreases the duration of mechanical ventilation and the length of stay in the ICU.[370] The effect of such an approach on the weakness syndromes in the ICU patient is unknown. When nondepolarizing NMBDs are used, the guidelines in Box 34-4 may help minimize the incidence of complications. As stated in the clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient,[337] "*Independent of the reasons for using neuromuscular blockers, we emphasize that all other modalities to improve the clinical situation must be tried, using neuromuscular blockers only as a last resort.*"

BOX 34-4 ***Recommendations for the Use of Neuromuscular Blockers in the Intensive Care Unit***

- Avoid the use of neuromuscular blockers by
  - Maximal use of analgesics and sedatives
  - Manipulation of ventilatory parameters and modes
- Minimize the dose of neuromuscular blocker
  - Use a peripheral nerve stimulator with train-of-four monitoring
  - Do not administer for more than 2 days continuously
  - Administer by bolus rather than infusion
  - Administer only when required and to achieve a well-defined goal
  - Continually allow recovery from paralysis
- Consider alternative therapies

Chapter 35

Reversal (Antagonism) of Neuromuscular Blockade

GLENN S. MURPHY • HANS D. DE BOER • LARS I. ERIKSSON • RONALD D. MILLER

Acknowledgment: The editors and the publisher would like to thank Drs. Mohamed Naguib and Cynthia A. Lien who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Appropriate reversal of a nondepolarizing neuromuscular blockade is essential to avoid adverse patient outcomes. Complete recovery of muscle strength should be present, and the residual effects of neuromuscular blocking drugs (NMBDs) should be fully pharmacologically reversed (or spontaneously recovered).
- Sufficient recovery from neuromuscular blockade for tracheal extubation can be confirmed by an adductor pollicis train-of-four (TOF) ratio of at least 0.90 (or 1.0 if acceleromyography [AMG] is used). Quantitative neuromuscular monitoring is the only method of assessing whether a safe level of recovery of muscular function has occurred.
- Residual neuromuscular blockade is not a rare event in the postanesthesia care unit (PACU). Approximately 30% to 50% of patients can have TOF ratios less than 0.90 following surgery.
- Patients with TOF ratios less than 0.90 in the PACU are at increased risk for hypoxemic events, impaired control of breathing during hypoxia, airway obstruction, postoperative pulmonary complications, symptoms of muscle weakness, and prolonged PACU admission times. Appropriate management of neuromuscular blockade can decrease the incidence of, or eliminate, residual blockade, which will reduce the risks of these adverse postoperative events.
- Neostigmine, pyridostigmine, and edrophonium inhibit the breakdown of acetylcholine, resulting in an increase in acetylcholine in the neuromuscular junction. However, there is a "ceiling" effect to the maximal concentration of acetylcholine that can be achieved with these drugs. Reversal of neuromuscular blockade with these drugs should not be attempted until some evidence of spontaneous recovery is present. Neostigmine in the dose range of 30 to 70 μg/kg body weight antagonizes moderate to shallow levels of neuromuscular blockade. However, if these reversal drugs are given in the presence of full neuromuscular recovery, paradoxical muscle weakness theoretically may be induced.
- Sugammadex is a modified γ-cyclodextrin that shows a high affinity for the steroidal NMBDs rocuronium and vecuronium. Sugammadex is able to form a tight inclusion complex with either of these steroidal NMBDs, thereby inactivating the effects of rocuronium and vecuronium, resulting in rapid reversal of neuromuscular blockade.
- Sugammadex is able to reverse a moderate/shallow and a profound neuromuscular blockade with a dose of 2.0 mg/kg and 4.0 mg/kg, respectively. An immediate reversal of neuromuscular blockade induced by rocuronium is possible with a dose of sugammadex 16 mg/kg. Reversal of neuromuscular blockade by sugammadex is rapid and without side effects encountered with anticholinesterase drugs.
- Fumarates (gantacurium [GW280430A, AV430A], CW002, and CW011) represent a new class of NMBDs in development that are inactivated primarily via adduction of cysteine to the double bond of the compounds, resulting in inactive breakdown products. Laboratory studies have shown that the administration of exogenous L-cysteine results in complete reversal of deep neuromuscular blockade within 2 to 3 minutes.

HISTORY

The paralytic effects of curare have been recognized since the time of Sir Walter Raleigh's voyage on the Amazon in 1595.[1] In 1935, the name *d*-tubocurarine was assigned to an alkaloid isolated from a South American vine (*Chondrodendron tomentosum*). At approximately the same time, experiments from pharmacology and physiology laboratories in London suggested that acetylcholine was the chemical neurotransmitter at motor nerve endings.[2] Investigations from these same laboratories demonstrated that eserine (physostigmine)-like substances could reverse the effects of curare at the neuromuscular junction of frog nerve-muscle preparations.[2] In the clinical setting, Bennett (1940) described the use of curare in the prevention of traumatic complications during convulsive shock therapy.[3] In l942, Griffith and colleagues described the use of an extract of curare in 25 surgical patients; all patients appeared to recover fully without administration of an antagonist such as neostigmine.[4]

The importance of pharmacologic reversal of neuromuscular blockade was suggested in 1945. Specifically, use of neostigmine or physostigmine to antagonize curare was recognized and was recommended to be available whenever muscle relaxants were given in the operating room.[5] The first large case series examining the use of curare was published by Cecil Gray in 1946.[1] A crystalline extract, *d*-tubocurarine chloride, was administered in 1049 general anesthesia cases. No postoperative complications directly attributable to *d*-tubocurarine were noted, and physostigmine was administered to only two patients in the series. However, in a later review article (1959) from the same anesthesia department, the authors concluded that "it is safer to always use neostigmine when nondepolarizing relaxants have been administered."[6] By the mid-1960s, significant differences in neuromuscular management existed between the United States and Europe. As noted in an editorial from this time, "In Great Britain the majority of anesthetists have arbitrarily adopted the attitude that the dangers of reversal are far less than those of latent paresis, so that most patients receive at least some anticholinesterase drug at the end of anesthesia." In the United States, however, where smaller doses of curare were used, the emphasis was more on the mortality and morbidity associated with reversal drugs. Emphasis was placed on using muscle relaxants in smaller doses so reversal drugs were not necessary.[7] In fact, in the senior author's training (Miller), the prevailing thinking was that emphasis in anesthesia should be on "properly anesthetizing rather than paralyzing" a patient; it was commonly said that "curare is not an anesthetic."

Despite more than 7 decades of research, significant differences in opinion still exist regarding management of neuromuscular blockade at the conclusion of surgery and anesthesia. Some clinicians routinely pharmacologically antagonize a nondepolarizing neuromuscular blocking drug (NMBD), whereas others antagonize neuromuscular blockade only when obvious clinical muscle weakness is present. The issue is whether clinically important weakness exists when it is not clinically apparent. Will monitoring of neuromuscular blockade improve patient care? The aim of this chapter is to review the consequences of incomplete neuromuscular recovery, the use of anticholinesterase agents in clinical practice (benefits, risks, and limitations), and the recent developments in novel drugs to reverse/antagonize residual neuromuscular blockade.

ANTAGONISM OF NEUROMUSCULAR BLOCKADE: CURRENT MANAGEMENT PRACTICES

A number of survey studies have been conducted to determine how clinicians evaluate and manage neuromuscular blockade in the perioperative period. In the late 1950s, a survey was sent to anesthetists in Great Britain and Ireland.[6] Forty-four percent of the respondents used neostigmine "always" or "almost always" when *d*-tubocurarine chloride or gallamine was used. Two thirds of respondents administered 1.25 to 2.5 mg when antagonizing these NMBDs.[6] Despite accumulating data demonstrating a continued frequent incidence of residual neuromuscular blockade, more-recent surveys indicate that attitudes toward reversal of neuromuscular blockade have changed little over the intervening decades. A questionnaire sent to German anesthesiologists in 2003 revealed routine reversal with neostigmine at the end of surgery was not practiced in 75% of anesthesia departments.[8] A similar survey of 1230 senior anesthetists in France reported that pharmacologic antagonism of neuromuscular blockade was "systematic" or "frequent" in only 6% and 26% of surgical cases, respectively.[9] In contrast, reversal of nondepolarizing NMBDs was routinely performed in Great Britain.[10]

A large-scale, comprehensive survey of neuromuscular management practices in the United States and Europe was conducted in order to better understand attitudes about doses of NMBDs, monitoring, and pharmacologic reversal.[11] Only 18% of European respondents and 34.2% of respondents from the United States "always" administered an anticholinesterase drug when a nondepolarizing relaxant was used. The findings from these surveys suggest that there is little agreement about best practices related to reversal of neuromuscular blockade. Despite perioperative guidelines from several national organizations, surveys from many countries reveal that most clinicians do not monitor or reverse a neuromuscular blockade in the operating room. Surprisingly, most anesthesiologists have not witnessed obvious adverse events directly attributable to incomplete recovery from neuromuscular blockade.[11] Therefore, the potential hazards of reversal of neuromuscular blockade using an anticholinesterase drug (see later) are likely estimated to be more frequent than the risks of residual neuromuscular blockade. In the following sections, the definitions, incidence, and clinical implications of residual neuromuscular blockade are reviewed.

RESIDUAL NEUROMUSCULAR BLOCKADE

Assessment of Residual Neuromuscular Blockade

In order to optimize patient safety, tracheal extubation in the operating room should not occur until complete

recovery of muscle strength is present and the residual effects of NMBDs have been fully reversed (or spontaneously recovered). Therefore, clinicians have methods to detect and treat residual muscle weakness. Three methods are commonly used in the operating room to determine the presence or absence of residual neuromuscular blockade: clinical evaluations for signs of muscle weakness, qualitative neuromuscular monitors, and quantitative neuromuscular monitors. A more detailed description of the types of neuromuscular monitors used perioperatively is provided in Chapter 53.

Clinical Evaluation for Signs of Muscle Weakness. Following the introduction of *d*-tubocurarine into clinical practice, residual paralysis and the need for neostigmine was determined primarily by the observation of "shallow, jerky movements of the diaphragm" at the end of surgery.[12] In the absence of any clinically observable respiratory impairment, neuromuscular function was assumed to be adequate, and no reversal drugs were administered. A peripheral nerve stimulator was first used in the 1960s by Harry Churchill-Davidson in the United Kingdom and later in the United States. However, routine use of a peripheral nerve stimulator did not occur. In fact, several decades later, the most commonly applied technique for evaluation of recovery of neuromuscular function continues to be the use of clinical tests for signs of apparent muscle weakness.[13] Furthermore, one of the primary factors that determines whether clinicians elect to administer a reversal drug at the end of surgery is the presence of signs of muscle weakness.[11] However, for decades clinical studies have consistently shown that tests of muscle strength are not sensitive or reliable indices of adequate neuromuscular recovery. The most commonly applied criteria used to determine suitability for extubation of the trachea are a "normal" pattern of ventilation and a sustained head lift.[13] Unfortunately, the sensitivity of each test in detecting residual blockade is poor. At a level of neuromuscular recovery that allows for adequate ventilation in a patient whose trachea is intubated, the muscles responsible for maintaining airway patency and protection are significantly impaired.[14] Other investigators have observed that the majority of subjects could maintain a 5-second head lift at a train-of-four (TOF) ratio of 0.50 or less.[15,16] Additional clinical tests of muscle strength, such as sustained hand-grip, leg-lift, or eye opening, have been demonstrated to have a low sensitivity in predicting recovery of neuromuscular function[17,18] (Table 35-1).

Qualitative Neuromuscular Monitoring. Qualitative neuromuscular monitors—or more accurately, peripheral nerve stimulators—deliver an electrical stimulus to a peripheral nerve, and the response to nerve stimulation is subjectively assessed by clinicians either visually or tactilely (i.e., placing a hand on the thumb to detect the muscle contraction after ulnar nerve stimulation) (Fig. 35-1; also see Chapter 53). Three patterns of nerve stimulation are used in the clinical setting to assess patients for residual blockade: TOF, tetanic, and double-burst stimulation. TOF stimulation delivers four supramaximal stimuli every 0.5 seconds, tetanic stimulation consists of a series of extremely rapid (usually 50 or 100 Hz) stimuli typically applied over 5 seconds, and double-burst stimulation delivers two short bursts of 50-Hz tetanic stimuli separated by 750 msec (see Chapter 53). The presence of fade with these patterns of nerve stimulation indicates incomplete neuromuscular recovery. Although qualitative monitoring may guide management during early recovery from neuromuscular blockade, the sensitivity of these devices in detecting small degrees of residual paresis (TOF ratios between 0.50 and 1.0) is limited (Fig. 35-2). When using TOF stimulation, investigators have consistently observed that clinicians are unable to detect fade when TOF ratios exceed 0.30 to 0.4.[19-21] Similarly, the observation of fade during a 5-second, 50-Hz tetanic stimulation is difficult when TOF ratios are greater than 0.30.[21-22] The ability of clinicians to detect fade is improved with double-burst stimulation; the threshold for detection of fade is approximately

TABLE 35-1 SENSITIVITY, SPECIFICITY, POSITIVE, AND NEGATIVE PREDICTIVE VALUES OF AN INDIVIDUAL CLINICAL TEST FOR A TRAIN-OF-FOUR <90% IN 640 SURGICAL PATIENTS

Variable	Sensitivity	Specificity	Positive Predictive Value	Negative Predictive Value
Inability to smile	0.29	0.80	0.47	0.64
Inability to swallow	0.21	0.85	0.47	0.63
Inability to speak	0.29	0.80	0.47	0.64
General weakness	0.35	0.78	0.51	0.66
Inability to lift head for 5 sec	0.19	0.88	0.51	0.64
Inability to lift leg for 5 sec	0.25	0.84	0.50	0.64
Inability to sustain hand grip for 5 sec	0.18	0.89	0.51	0.63
Inability to perform sustained tongue depressor test	0.22	0.88	0.52	0.64

From Cammu G, De Witte J, De Veylder J, et al: Postoperative residual paralysis in outpatients versus inpatients, Anesth Analg *102:426-429, 2006.*

The sensitivity of a test is the number of true positives ÷ the sum of true positives + false negatives; the specificity is the number of true negatives ÷ the sum of true negatives + false positives. True positives are patients scoring positive for a test and having a train-of-four (TOF) <90%. False negatives are patients with a negative test result but a TOF <90%. True negatives have a negative test score and a TOF not <90%; false positives score positively but have a TOF not <90%. A *positive* test result means *inability* to smile, swallow and speak, general muscular weakness, and so on.

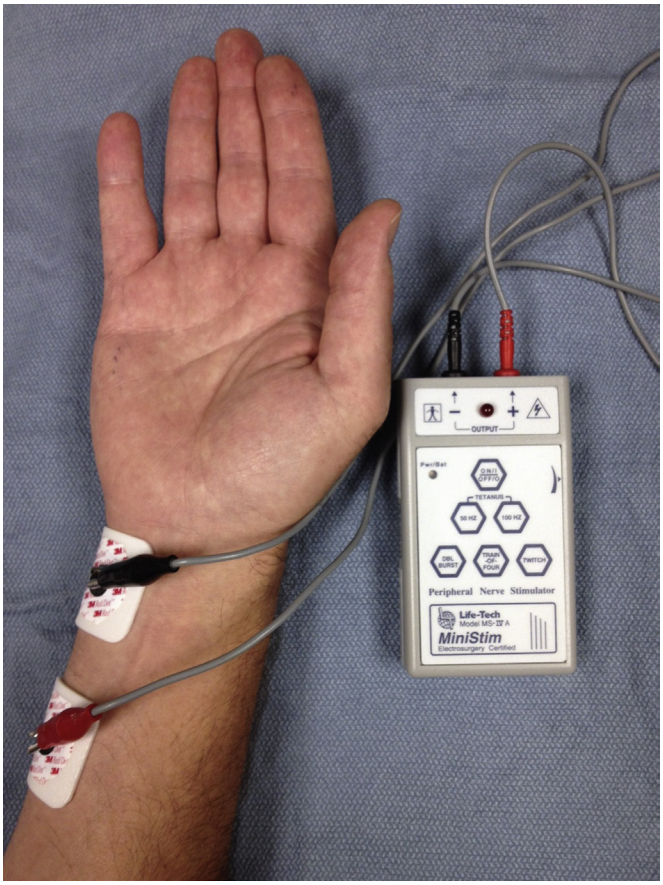

Figure 35-1. Example of a qualitative neuromuscular monitor (or more appropriately, a peripheral nerve stimulator). A peripheral nerve is stimulated, and the response to nerve stimulation is subjectively (qualitatively) assessed using either visual or tactile (hand placed on the muscle) means. In this illustration, the ulnar nerve is stimulated, and movement of the thumb subjectively evaluated.

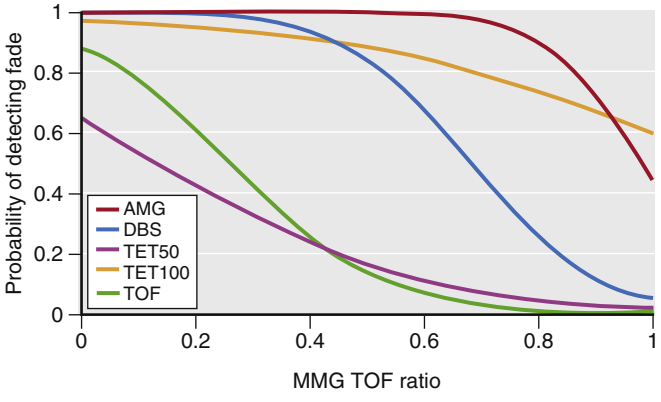

Figure 35-2. Detection of fade with various neuromuscular monitoring techniques. Residual neuromuscular blockade was evaluated using acceleromyography (AMG), tactile assessment of train-of-four (TOF), double-burst stimulation (DBS), 50-Hz tetanus, or 100-Hz tetanus. The mechanomyographic (MMG) adductor pollicis TOF ratio was measured at one extremity. During recovery, a blinded observer estimated tactile fade in the other extremity. Probability of detection of fade by logistic regression is presented. *(From Capron F, Fortier LP, Racine S, Donati F: Tactile fade detection with hand or wrist stimulation using train-of-four, double-burst stimulation, 50-hertz tetanus, 100-hertz tetanus, and acceleromyography,* Anesth Analg *102:1578-1584, 2006.)*

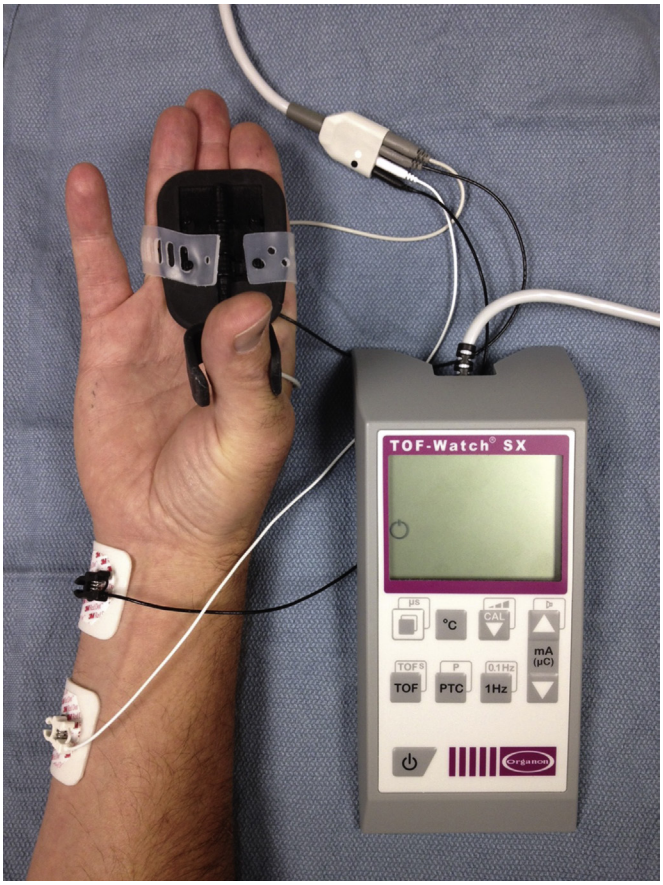

Figure 35-3. Example of a quantitative neuromuscular monitor (acceleromyography [AMG]). Ulnar nerve stimulation results in thumb movement, which is sensed by a piezoelectric sensor attached to the thumb. To improve the consistency of responses, a hand adapter applies a constant preload. Acceleration of the thumb is sensed by the piezoelectric sensor, and is proportional to the force of muscle contraction.

0.6 to 0.7 using this mode of stimulation.[20,21,23] However, regardless of the mode of nerve stimulation used, residual neuromuscular blockade cannot always be reliably excluded using qualitative monitoring.

Quantitative Neuromuscular Monitoring. Quantitative neuromuscular monitors are instruments that permit both stimulation of a peripheral nerve and the quantification and recording of the evoked response to nerve stimulation. Quantitative monitors allow an accurate assessment of the degree of muscle weakness using either TOF stimulation (TOF ratio displayed) or single-twitch stimulation (response compared with control "twitch" as a percentage). Although five different methods of quantifying neuromuscular function in the operating room have been developed, only one technology, acceleromyography (AMG, available as the TOF-Watch, Bluestar Enterprises), is commercially produced as a stand-alone monitor (Fig. 35-3). In a study comparing AMG with standard qualitative tests (tactile fade to TOF, double-burst, 5-Hz tetanic, and 100-Hz tetanic stimulation), AMG was the most accurate technique in detecting residual paralysis[21] (see Fig. 35-2). In addition, the use of AMG in the operating room has been demonstrated to reduce the risk of residual

neuromuscular blockade in the postanesthesia care unit (PACU)[24-27] and to decrease adverse respiratory events and symptoms of muscle weakness associated with incomplete neuromuscular recovery.[26,27] In clinical practice, AMG is a valuable monitor in determining whether full recovery of neuromuscular function has occurred before tracheal extubation, and provides objective data to guide dosing of reversal agents at the conclusion of surgery (see later).

A careful evaluation of the degree of residual blockade at the conclusion of a general anesthetic is essential in order to avoid the potential hazards of incomplete neuromuscular recovery following tracheal extubation. However, the methods used by most clinicians (ability to perform a head lift or maintain a stable pattern of ventilation; no fade observed to TOF or tetanic nerve stimulation) are insufficient in assuring safe recovery. At the present time, quantitative neuromuscular monitoring is the only method of determining whether full recovery of muscular function has occurred and reversal drugs safely avoided. In order to exclude with certainty the possibility of residual paresis, quantitative monitoring should be used.

Definitions of Residual Neuromuscular Blockade

Quantitative Neuromuscular Monitoring: TOF Ratio Less Than 0.70 and Less Than 0.90. Traditionally, residual neuromuscular blockade has been defined using quantitative neuromuscular monitoring. Although peripheral nerve stimulation was used in the l960s, Ali and colleagues first described the application of peripheral nerve stimulation for neuromuscular monitoring using the ulnar nerve–adductor pollicis unit as the site of monitoring in the early 1970s.[28,29] By comparing the amplitude of the fourth (T4) to the first (T1) evoked mechanical or electromyographic response (TOF response), the degree of neuromuscular recovery could be measured. Shortly thereafter, these same investigators performed several studies examining the association between the degree of residual blockade in the hand (defined using quantified T4/T1 ratio, i.e., TOF ratio) with symptoms of peripheral muscle weakness and spirometry measurements.[30-32] At adductor pollicis TOF ratios less than 0.60, signs of muscle weakness, tracheal tug, and ptosis were observed. When TOF ratios recovered to 0.70, the majority of patients were able to sustain head lift, eye opening, hand grasp, tongue protrusion, and a vital capacity exceeding 15 mL/kg. On the basis of these data, a TOF ratio of 0.70 was previously agreed on to represent acceptable neuromuscular recovery at the end of a general anesthetic that included administration of nondepolarizing NMBDs. Yet, more recently, clinically significant muscle weakness and impaired respiratory control have been observed at TOF ratios of up to 0.90. At TOF ratios less than 0.90, awake volunteers exhibit impaired pharyngeal function, airway obstruction, an increased risk of aspiration of gastric contents, an impaired hypoxic ventilatory control, and unpleasant symptoms of muscle weakness.[33-37] In surgical patients, an association between TOF ratios less than 0.90 and adverse respiratory events and prolonged PACU length of stay has been observed.[38,39] At the present time, it is generally agreed that adequate recovery of neuromuscular function is represented by an adductor pollicis TOF ratio of at least 0.90 (or even 1.0 when AMG is used).

Clinical Signs and Symptoms. A variety of clinical signs may be present in patients with residual neuromuscular blockade, including the following: inability to perform a head lift, hand grip, eye opening, or tongue protrusion; inability to clench a tongue depressor between the incisor teeth; inability to smile, swallow, speak, cough, track objects with eyes; or inability to perform a deep or vital capacity breath.[40] Symptoms of residual blockade that have been reported include subjective difficulty performing the aforementioned tests, as well as blurry vision, diplopia, facial weakness, facial numbness, and general weakness.[37,40] Although the majority of patients with TOF ratios of 0.90 to 1.0 will have recovered satisfactory strength in most muscle groups, signs and symptoms of muscle weakness may be present in some of these patients. In contrast, a few patients with significant residual blockade (TOF ratios <0.70) may exhibit no apparent muscle weakness. The most inclusive and precise definition of residual neuromuscular blockade should include not only objective and quantifiable monitoring data (a TOF ratio <0.90 demonstrated with AMG, mechanomyography, or electromyography) but also clinical evidence of impaired neuromuscular recovery (swallowing impairment, inability to speak or perform a head lift, diplopia, and/or general weakness).

Incidence of Residual Neuromuscular Blockade

Residual neuromuscular Blockade is not a rare event in the PACU. In 1979, Viby-Mogensen examined the efficacy of neostigmine in reversing *d*-tubocurarine, gallamine, or pancuronium blockade.[41] On arrival to the PACU, 42% of patients had a TOF ratio less than 0.70, and 24% were unable to perform a 5-second head lift (the majority of these subjects had TOF ratios <0.70). The authors concluded that the average dose of neostigmine given (2.5 mg) was insufficient for reversing neuromuscular blockade. Subsequent studies demonstrated a similarly frequent incidence of residual blockade in patients receiving long-acting NMBDs; 21% to 50% of patients in the early postoperative period had TOF ratios less than 0.70.[42-44] Subsequently, the risk of postoperative residual blockade was reduced if intermediate-acting NMBDs were used instead of long-acting drugs.[44-46] As the use of long-acting NMBDs began to decrease in clinical practices, many investigators hoped that residual blockade would become an uncommon occurrence in the PACU. However, incomplete neuromuscular recovery continues to be a common postoperative event. Large-scale studies (150 to 640 subjects) have demonstrated that approximately 31% to 50% of patients have clinically significant residual neuromuscular blockade with adductor pollicis TOF ratios less than 0.90 following surgery.[17,47,48] In a meta-analysis of data from 24 clinical trials, Naguib and colleagues calculated the incidence of residual blockade by NMBD type and TOF ratio.[44] The pooled rate of residual blockade, defined as a TOF ratio less than 0.90, was 41% when studies using intermediate-acting NMBDs were analyzed (Table 35-2). In conclusion, a frequent incidence of residual neuromuscular blockade still occurs worldwide in the immediate postoperative period; with current practice and inadequate monitoring, the incidence of this complication is not decreasing over time.

The observed incidence of postoperative residual blockade varies widely between studies, ranging from 5% to 93%.[44] A number of factors may influence the degree

of neuromuscular recovery measured following tracheal extubation, accounting for the reported variability in the incidence of residual blockade (Box 35-1). The observed incidence of residual blockade is more frequent if a threshold definition of 0.90 is used (versus the previous threshold of 0.70) (see Table 35-2). Similarly, a frequent incidence of residual paralysis is observed if there is a short time interval between reversal of NMBDs and quantification of TOF ratios (TOF ratios measured at the time of extubation versus measurement in the PACU).[49] Furthermore, the technology used to quantify neuromuscular recovery may influence the percentage of patients with TOF ratios less than 0.90 following surgery. For example, when compared with mechanomyography (MMG), AMG frequently overestimates the degree of neuromuscular recovery.[21] Additional factors influencing the degree of residual paralysis are discussed later.

Adverse Effects of Residual Blockade

Many investigations have demonstrated that approximately one half of patients will be admitted to the PACU with TOF ratios less than 0.90, as measured with AMG, MMG, or electromyography (EMG).[44] The impact of this residual muscle weakness on clinical outcomes has been less well-documented. Yet even minimal levels of neuromuscular blockade may have clinical consequences. The following section reviews the effects of residual blockade in both awake volunteer studies and in postoperative surgical patients.

TABLE 35-2 POOLED ESTIMATED INCIDENCE OF RESIDUAL NEUROMUSCULAR BLOCKADE BY MUSCLE RELAXANT TYPE AND TRAIN-OF-FOUR RATIO

Sub-population	Pooled Rate of RNMB*	Confidence Interval	Heterogeneity	
			P-value	Inconsistency† (%)
Long-acting MR (TOF <0.70)	0.351	(0.25-0.46)	<.001	86.7
Intermediate-acting MR (TOF <0.70)	0.115	(0.07-0.17)	<.001	85.9
Long-acting MR (TOF <0.90)	0.721	(0.59-0.84)	<.001	88.1
Intermediate-acting MR (TOF <0.90)	0.413	(0.25-0.58)	<.001	97.2

MR, Muscle relaxant; *RNMB*, residual neuromuscular blockade; *TOF*, train-of-four.
*Pooled rate of RNMB is the weighted average. The weight in the random-effect model takes into account both between and within studies variation.
†Inconsistency is the proportion of between studies variability that cannot be explained by chance.

BOX 35-1 ***Factors Influencing the Measured Incidence of Postoperative Residual Neuromuscular Blockade***

Preoperative Factors

1. Definition of residual neuromuscular blockade
   - TOF ratio <0.70 (before 1990)
   - TOF ratio <0.90 (after 1990)
   - Presence of signs or symptoms of muscle weakness
2. Patient factors
   - Age (higher risk in older adults)
   - Gender
   - Preexisting medical conditions (renal or liver dysfunction, neuromuscular disorders)
   - Medications known to affect neuromuscular transmission (antiseizure medications)

Intraoperative Anesthetic Factors

1. Type of NMBD administered intraoperatively
   - Intermediate-acting NMBD (lower risk)
   - Long-acting NMBD (higher risk)
2. Dose of NMBD used intraoperatively
3. Use of neuromuscular monitoring
   - Qualitative monitoring (studies inconclusive)
   - Quantitative monitoring (lower risk)
4. Depth of neuromuscular blockade maintained
   - "Deeper blockade" (TOF count of 1-2) (higher risk)
   - "Lighter blockade" (TOF count of 2-3) (lower risk)
5. Type of anesthesia used intraoperatively
   - Inhalational agents (higher risk)
   - TIVA (lower risk)

Factors Related to Antagonism of Residual Blockade

1. Use of reversal agents (lower risk)
   - Neostigmine
   - Pyridostigmine
   - Edrophonium
   - Sugammadex
2. Dosage of reversal agent used
3. Time interval between reversal agent administration and quantification of residual blockade

Factors Related to Measurement of Residual Blockade

1. Method of objective measurement of residual neuromuscular blockade
   - Mechanomyography (MMG)
   - Electromyography (EMG)
   - Acceleromyography (AMG)
   - Kinemyography (KMG)
   - Phonomyography (PMG)
2. Time of measurement of residual neuromuscular blockade
   - Immediately before tracheal extubation (higher risk)
   - Immediately after tracheal extubation (higher risk)
   - On arrival to PACU (lower risk)

Postoperative Factors

1. Respiratory acidosis and metabolic alkalosis (higher risk)
2. Hypothermia (higher risk)
3. Drug administration in the PACU (antibiotics, opioids) (higher risk)

NMBD, Neuromuscular blocking drug; *PACU*, postanesthesia care unit *TIVA*, total intravenous anesthetic; *TOF*, train-of-four.

Adverse Effects of Residual Blockade—Awake Volunteer Studies. Surgical patients receive a variety of anesthetics in the perioperative period, which complicates an assessment of the particular effect of residual neuromuscular blockade on clinical outcomes. Conducting awake volunteer trials allows investigators to more precisely quantify the impact of NMBDs and various degrees of neuromuscular blockade on physiologic systems in the absence of anesthetics. In general, these studies have titrated NMBDs to various TOF ratios in awake subjects, and measured the effects on the respiratory system and on signs and symptoms of muscle weakness.

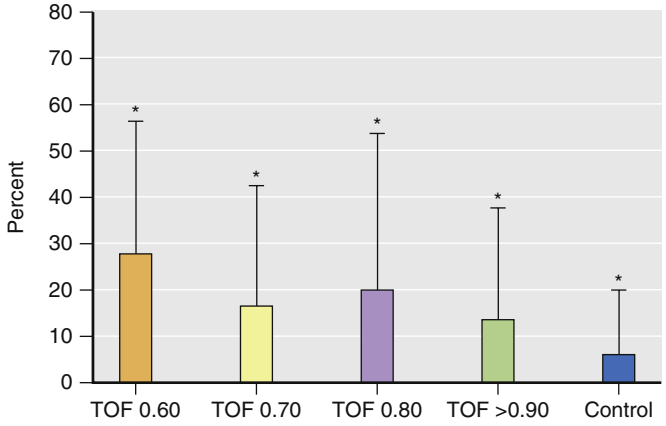

Fig 35-4. Incidence of pharyngeal dysfunction during atracurium-induced partial neuromuscular blockade corresponding to steady-state adductor pollicis TOF ratio of 0.70, 0.80, >0.90 and control in young volunteers. *(Modified from Sundman E, Witt H, Olsson R, et al: The incidence and mechanisms of pharyngeal and upper esophageal dysfunction in partially paralyzed humans,* Anesthesiology *92:977-984, 2000.)*

Early volunteer investigations concluded that respiratory impairment was minimal at TOF ratios of 0.60 to 0.70.[32] Respiratory frequency, tidal volume, vital capacity, and peak expiratory flow rates were not altered during the study, although vital capacity and inspiratory force were both significantly reduced compared with control values at a TOF ratio of 0.60.[32] The authors concluded that these changes were of minor clinical importance. Subsequent investigations have revealed that pharyngeal and respiratory function is impaired at TOF ratios as high as 0.90 to 1.0. Return of pharyngeal muscle function is essential for airway control following tracheal extubation. In series of human studies from the Karolinska Institutet, Sweden, a functional assessment of the pharynx, upper esophageal muscles, and the integration of respiration with swallowing was performed during various levels of neuromuscular blockade.[33-34] At adductor pollicis TOF ratios less than 0.90, pharyngeal dysfunction was observed in 17% to 28% of young adult volunteers[33] (Fig. 35-4), increasing more than twofold in patients older than 60 years and associated with reduced upper esophageal sphincter resting tone and misdirected swallowing and aspiration (laryngeal penetration) of oral contrast material.[33-34a] Eikermann and colleagues conducted several investigations examining the effect of residual paresis on respiratory muscle function in awake volunteers. Awake subjects were administered a rocuronium infusion, which was titrated to a TOF ratio 0.50 to 1.0. At a minimal level of residual blockade (approximately 0.80), the authors observed impaired inspiratory air flow and upper airway obstruction,[35] a marked decrease in upper airway volumes and upper airway dilator muscle function,[50] and increased upper airway closing pressure and collapsibility[51] (Fig. 35-5). In addition, evidence from human studies of respiratory control suggest that residual blockade inhibits hypoxic ventilatory control while leaving the ventilatory

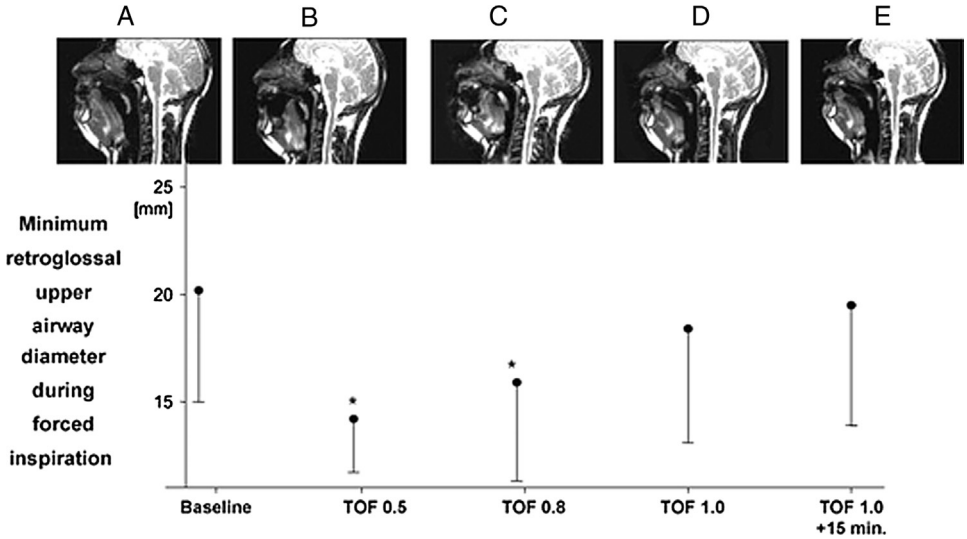

Figure 35-5. An investigation examining the effect of residual neuromuscular blockade on respiratory muscle function in awake volunteers. Subjects were administered a rocuronium infusion, which was titrated to a train-of-four (TOF) ratio 0.5 to 1.0. Supraglottic airway diameter and volume was measured by respiratory-gated magnetic resonance imaging. Minimum retroglossal upper airway diameter during forced inspiration (**A**) before neuromuscular blockade (baseline), at a steady-state TOF ratio of (**B**) 0.50 and (**C**) 0.80, (**D**) after recovery of the TOF ratio to 1.0, and (**E**) 15 minutes later. Images from the volunteer show that a partial paralysis evokes an impairment of upper airway diameter increase during forced inspiration. **P* <.05 versus baseline. *(From Eikermann M, Vogt FM, Herbstreit F, et al: The predisposition to inspiratory upper airway collapse during partial neuromuscular blockade,* Am J Respir Crit Care Med *175:9-15, 2007.)*

control during hypercapnia unaffected. In human volunteers, the hypoxic ventilatory response was attenuated by 30% after administration of either atracurium, vecuronium, or pancuronium at an adductor pollicis TOF ratio of 0.70, returning to normal after spontaneous recovery to a TOF ratio of greater than 0.90[52] (Fig. 35-6). An increase in ventilatory drive during hypoxia is primarily mediated by afferent input from peripheral chemoreceptors in the carotid bodies located bilaterally at the carotid artery bifurcation, whereas ventilatory regulation during hypercapnia is mediated via CO_2 interaction with brainstem chemoreceptors. In experimental animals, the firing frequencies of carotid body chemoreceptors is almost abolished by the administration of a nondepolarizing NMBD because of a cholinergic blockade of nicotinic acetylcholine receptors within the carotid body oxygen signaling pathway.[53]

Awake volunteer studies have also revealed that unpleasant symptoms of muscle weakness are present in subjects with small degrees of residual neuromuscular blockade. Conscious subjects given a small "priming" dose of pancuronium noted blurred vision, difficulty swallowing and keeping their eyes open, and jaw weakness at a TOF ratio of 0.81.[54] Symptoms of diplopia, dysarthria, and subjective difficulty swallowing were reported by subjects at TOF ratios of 0.60 and 0.70.[34] Reduced clarity of vision was described in all subjects receiving a mivacurium infusion at a TOF ratio of 0.81.[55] Kopman and associates examined 10 volunteers for symptoms and signs of residual paralysis at various TOF ratios.[37] Testing was performed at baseline (before an infusion of mivacurium), at a TOF ratio of 0.65 to 0.75, at 0.85 to 0.95, and at full recovery (1.0). All subjects had significant signs and symptoms at a TOF ratio of 0.70 (inability to maintain incisor teeth apposition, sit without assistance, or drink from a straw, visual disturbances, facial numbness, difficulty speaking and swallowing, general weakness), and in seven subjects, visual symptoms persisted for up to 90 minutes after the TOF ratio had recovered to unity.

Adverse Effects of Residual Blockade—Postoperative Surgical Patients. Awake volunteers have impairment of respiratory function and a variety of symptoms of muscle weakness at TOF ratios of 0.50 to 0.90. Similar adverse events have been observed in postoperative surgical patients with TOF ratios less than 0.90 measured in the PACU. Incomplete neuromuscular recovery is a risk factor for hypoxemic events, airway obstruction, unpleasant symptoms of muscle weakness, delayed PACU length of stay, and pulmonary complications during the early postoperative period.

Clearly, an association exists between neuromuscular management characteristics and postoperative morbidity and mortality. Beecher and colleagues collected data from 10 university hospitals between the years 1948 to 1952 to determine anesthetic-related causes of mortality.[56] Risk of death related to anesthesia was six times more frequent in patients receiving NMBDs (primarily tubocurarine and decamethonium) compared with those administered no NMBDs (1:370 versus 1:2100). Although the authors conclude that there is "an important increase in anesthesia death rate when muscle relaxants are added"[56] to an anesthetic, the use or omission of pharmacologic reversal in patients receiving NMBDs was not reported or analyzed. In another large-scale study, mortality data associated with anesthesia were collected over a 10-year period (1967-1976) at a single institution in South Africa.[57] An analysis of 240,483 anesthetics revealed that "respiratory inadequacy following myoneural blockade" was the second-most common cause of death. Again, data relating to the use of pharmacologic reversal drugs were not provided. A study from the Association of Anaesthetists of Great Britain and Ireland examined deaths that were judged "totally due to anesthesia" and reported that postoperative respiratory failure secondary to neuromuscular management was a primary cause of mortality.[58] Rose and associates examined patient, surgical, and anesthetic factors associated with critical respiratory events in the PACU.[59] Of the anesthetic management factors assessed,

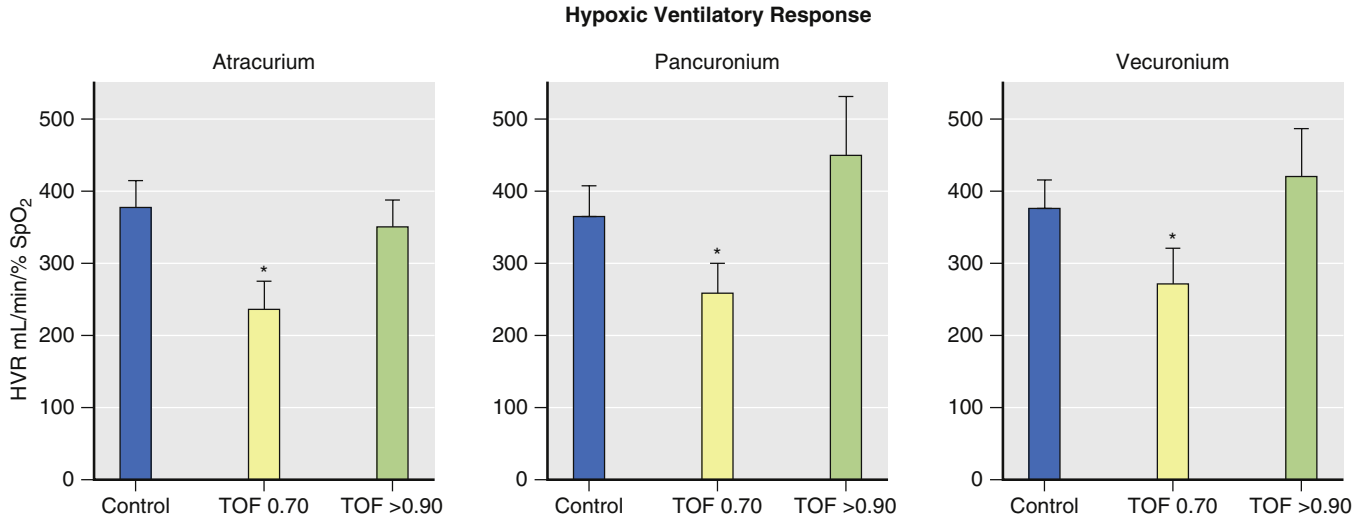

Figure 35-6. Hypoxic ventilatory response (HVR) before (control); during steady-state infusion at train-of-four (TOF) ratio 0.70 of atracurium, pancuronium and vecuronium; and after recovery (TOF ratio >0.90). Data presented as means ± SD. * = $P < .01$. *(From Eriksson LI: Reduced hypoxic chemosensitivity in partially paralysed man: a new property of muscle relaxants,* Acta Anaesthesiol Scand *40:520-523, 1996.)*

the most frequent rate of critical respiratory events was observed in patients receiving large doses of NMBDs (the use of reversal drugs was not analyzed). Two investigations of anesthetic complications resulting in admissions to the intensive care unit determined that "failure to reverse after muscle relaxants" and "ventilatory inadequacy after reversal of muscle relaxants" were the most common causes of admission.[60,61] Sprung and colleagues reviewed the medical records of patients who experienced a cardiac arrest over a 10-year period (223 of 518,284 anesthetics).[62] The most important category was the use of NMBDs, involving either hypoxia caused by inadequate pharmacologic reversal or asystole induced by anticholinesterase drugs. A large case-control investigation was performed of all patients undergoing anesthesia over a 3-year period (n = 869,483) in The Netherlands assessing the impact of anesthetic management characteristics on the risk of coma or death within 24 hours of surgery.[63] Reversal of the effects of NMBDs was associated with a significant reduction (odds ratio, 0.10, 95% CI, 0.03-0.31) in the risk of these complications. Epidemiologic studies thus suggest an association between incomplete neuromuscular recovery and adverse events in the early postoperative period. Notably, an important limitation of these outcome studies is that residual paresis was not quantified at the end of surgery. Therefore, causality (residual blockade results in postoperative complications) can only be suggested but not proven.

In order to address these limitations, more recent studies have quantified TOF ratios in the PACU and documented a relationship between residual blockade and adverse outcomes. Several clinical investigations have documented an association between postoperative residual blockade and adverse respiratory events. In an observational study by Bissinger and colleagues, patients with TOF ratios less than 0.70 in the PACU had a more frequent incidence of hypoxemia (60%) compared with patients with TOF ratios 0.70 or greater (10%, $P < .05$).[64] Another small study of orthopedic surgical patients randomized to receive either pancuronium or rocuronium revealed that patients with TOF ratios less than 0.90 on arrival to the PACU were more likely to develop postoperative hypoxemia (24 of 39 patients) than those with TOF ratios greater than 0.90 (7 of 30 patients, $P = .003$).[65] Murphy and associates conducted a case-control study examining the incidence and severity of residual blockade in patients who developed critical respiratory events in the PACU.[38] Seventy-four percent of patients in the group with critical respiratory events had TOF ratios less than 0.70, compared with 0% in the matched control group (matched for age, sex, and surgical procedure). Because the two cohorts did not differ in any perioperative characteristics with the exception of neuromuscular recovery, these findings suggest that unrecognized residual paralysis is an important contributing factor to postoperative adverse respiratory events. Another investigation by this same group examined the effect of AMG monitoring on postoperative respiratory events.[26] Few patients randomized to AMG monitoring had postoperative TOF ratios less than 0.90, and a less frequent incidence of early hypoxemia and airway obstruction was observed in this group (compared with patients randomized to standard qualitative monitoring). A study of 114 patients randomized to neostigmine reversal or placebo (saline) documented a significantly more frequent incidence of both postoperative residual blockade and hypoxemia in the placebo group.[66] Residual blockade in the PACU may also result in pulmonary complications within the first postoperative week. Berg and colleagues randomized 691 patients to receive pancuronium, atracurium, or vecuronium.[67] TOF ratios were quantified in the PACU, and subjects followed for 6 days for pulmonary complications. In the pancuronium group, significantly more patients with TOF ratios less than 0.70 developed a pulmonary complication (16.9%) compared with patients with TOF 0.70 or greater (4.8%). Notably, the study also demonstrated a continuously increased risk for postoperative pulmonary complications with increased age, a finding of significant clinical relevance for older adult patients, a growing part of the surgical patient population.

Residual blockade causes unpleasant symptoms of muscle weakness. This symptom of "general weakness" was the most sensitive "test" for determining whether patients had a TOF ratio of less than 0.90 in the PACU.[17] Orthopedic surgical patients given pancuronium had a more frequent risk of exhibiting both TOF ratios less than 0.90 and symptoms of blurry vision and general weakness during the PACU admission, compared with patients randomized to receive rocuronium.[65] Similar findings were observed in a cardiac surgical patient population not receiving anticholinesterase drugs.[68] The subjective experience of residual neuromuscular blockade after surgery was determined by examining 155 patients for 16 symptoms of muscle weakness during the PACU admission.[27] The presence of symptoms of muscle weakness was predictive of a TOF ratio less than 0.90 (good sensitivity and specificity).

The residual effects of NMBDs on postoperative muscle strength may impair clinical recovery and prolong PACU discharge times. In a small study of patients randomized to receive either pancuronium or rocuronium, the times required to meet and achieve discharge criteria were significantly longer in the pancuronium group, and patients in the cohort as a whole with postoperative TOF ratios less than 0.90 were more likely to have a prolonged PACU stay compared with those with TOF ratios greater than 0.90.[65] A larger investigation measured TOF ratios in 246 consecutive patients on arrival to the PACU.[39] The PACU length of stay was significantly longer in patients with TOF ratios less than 0.90 (323 minutes) compared with patients with adequate recovery of neuromuscular function (243 minutes). Multiple regression analysis revealed that only age and residual blockade were independently associated with PACU length of stay.

In conclusion, a number of studies conducted over the past 5 decades have documented the effects of small degrees of residual blockade in human volunteers and surgical patients. Awake volunteer investigations have demonstrated that subjects with TOF ratios less than 0.90 have reduced upper airway tone and diameters, upper airway obstruction, pharyngeal dysfunction with impaired airway integrity, decreased upper esophageal tone, and an increased risk of aspiration, impaired hypoxic ventilatory control, and unpleasant symptoms of muscle weakness. Epidemiologic outcome investigations have suggested an association between incomplete neuromuscular recovery and major morbidity and mortality. Prospective clinical

trials have revealed that patients with TOF ratios less than 0.90 in the PACU are at increased risk for hypoxemic events, airway obstruction, postoperative pulmonary complications, symptoms of muscle weakness, and prolonged PACU admission times. These data suggest that residual blockade is an important patient safety issue in the early postoperative period. Therefore, appropriate management of reversal of neuromuscular blockade is essential to optimize patient outcomes.

DRUGS USED TO ANTAGONIZE (REVERSE) NEUROMUSCULAR BLOCKADE

Reversal of neuromuscular blockade is theoretically possible by three principal mechanisms: (1) an increase in presynaptic release of acetylcholine; (2) a decrease in enzymatic metabolism of acetylcholine by cholinesterase, thereby increasing receptor binding competition; and (3) a decrease in the concentration of the NMBD at the effect-site, freeing the postsynaptic receptors.

ANTICHOLINESTERASE REVERSAL OF NEUROMUSCULAR BLOCK ADE

Nondepolarizing NMBDs inhibit neuromuscular transmission primarily by competitively antagonizing or blocking the effect of acetylcholine at the postjunctional nicotinic acetylcholine receptor (nAChR). Binding of nondepolarizing NMBDs to the nAChR occurs in a competitive fashion. If larger concentrations of acetylcholine are present at the neuromuscular junction, acetylcholine will attach to the postsynaptic receptor and facilitate neuromuscular transmission and muscle contraction. Conversely, if larger concentrations of a nondepolarizing NMBD are present at the neuromuscular junction, binding to α subunits of the receptor will preferentially occur, preventing central pore opening and muscle depolarization from occurring. A more detailed description of the neuromuscular junction is provided in Chapter 18.

One mechanism of reversing the effects of NMBDs is by an increase in the concentration of acetylcholine at the neuromuscular junction. This can be accomplished using an inhibitor of cholinesterase, which constrains the enzyme that breaks down acetylcholine at the neuromuscular junction (acetylcholinesterase). Three anticholinesterase drugs are commonly used in clinical practice: neostigmine, edrophonium, and pyridostigmine. Neostigmine is likely the most commonly administered drug. Over the prior 6 decades, anticholinesterases have been the only drugs used clinically to reverse neuromuscular blockade (until the recent introduction of sugammadex).

Mechanism of Action of Anticholinesterases

Acetylcholine is the primary neurotransmitter that is synthesized, stored, and released by exocytosis at the distal motor nerve terminal. Acetylcholinesterase is the enzyme responsible for the control of neurotransmission at the neuromuscular junction by hydrolyzing acetylcholine. Rapid hydrolysis of acetylcholine removes excess neurotransmitter from the synapse, preventing overstimulation and tetanic excitation of the postsynaptic muscle. Nearly half

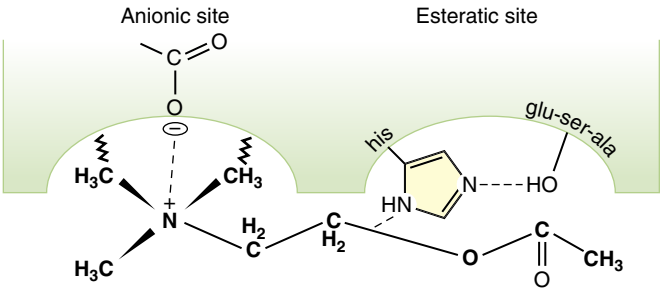

Figure 35-7. Active binding sites on acetylcholinesterase. The positively charged quaternary nitrogen group on acetylcholine (Ach) binds by electrostatic forces to the negatively charged anionic site on the enzyme. The carbamate group at the opposite end of the Ach molecule forms covalent bonds with and is metabolized at the esteratic site. *(From Caldwell JE: Clinical limitations of acetylcholinesterase antagonists,* J Crit Care, *24:21-28, 2009.)*

of the acetylcholine molecules released from the presynaptic nerve membrane are hydrolyzed by acetylcholinesterase before reaching the nAChR.[69] The action of acetylcholinesterase is quite rapid; acetylcholine molecules are hydrolyzed in approximately 80 to 100 μs (microseconds). Acetylcholinesterase is concentrated at the neuromuscular junction, and there are approximately 10 enzyme-binding sites for each molecule of acetylcholine released.[70] However, lower concentrations of acetylcholinesterase are present along the length of the muscle fiber. Each molecule of acetylcholinesterase has an active surface with two important binding sites, an anionic site and an esteratic site. The negatively charged anionic site on the acetylcholinesterase molecule is responsible for electrostatically binding the positively charged quaternary nitrogen group on the acetylcholine molecule. The esteratic site forms covalent bonds with the carbamate group at the opposite end of the acetylcholine molecule and is responsible for the hydrolytic process[70] (Fig. 35-7). In addition, a secondary or peripheral anionic site has been proposed. Binding of ligands to the peripheral anionic site results in inactivation of the enzyme.

The anticholinesterase drugs used by anesthesiologists interact with the anionic and esteratic sites of acetylcholinesterase. These drugs are characterized as either prosthetic inhibitors (edrophonium) or oxydiaphoretic (acid-transferring) inhibitors (neostigmine, pyridostigmine) of the enzyme. Edrophonium rapidly binds to the anionic site via electrostatic forces and to the esteratic site by hydrogen bonding.[69,70] Rapid binding may account for the short onset of action of edrophonium in clinical practice. During the time edrophonium is bound, the enzyme is inactive and edrophonium is not metabolized. However, the interaction between edrophonium and acetylcholinesterase is weak and short-lived. The dissociation half-life of this interaction is approximately 20 to 30 seconds, and the interaction between drug and enzyme is competitive and reversible. Because the nature of the binding is relatively brief, the efficacy of edrophonium in reversing neuromuscular blockade may be limited. Neostigmine and pyridostigmine are oxydiaphoretic inhibitors of acetylcholinesterase, which also bind to the anionic site. In addition, these drugs transfer a carbamate group to acetylcholinesterase, creating a covalent bond at the esteratic site.[69,70] This reaction results in an inactivation of the enzyme, as

well as the hydrolysis of the drug. The stronger interaction between neostigmine and enzyme results in dissociation half-life of approximately 7 minutes.[70] Therefore, the duration of enzyme inhibition is longer with neostigmine and pyridostigmine compared with edrophonium. These interactions at the molecular level likely have little impact on the duration of action in clinical practice. Duration of clinical effect is primarily determined by removal of anticholinesterase from the plasma.[71]

The administration of anticholinesterases has also been reported to produce presynaptic effects.[71] Laboratory investigations have demonstrated that these prejunctional effects may actually facilitate neuromuscular transmission. Anticholinesterases produce a reversible increase in the duration of the action potential and refractory period of the nerve terminal. Because the quantity of acetylcholine released is a function of the extent and duration of the depolarization of the terminal membrane, the period of acetylcholine release in response to nerve stimulation may be increased by anticholinesterase agents.[71] Excessive release of acetylcholine, coupled with decreased hydrolysis due to acetylcholinesterase inhibition, results in prolonged end-plate potentials and repetitive firing of muscle fibers. These prejunctional effects appear to account for the observations that spontaneous contractions of muscles can occur when anticholinesterases are given in the absence of NMBDs.[71]

Although neostigmine, pyridostigmine, and edrophonium inhibit the breakdown of acetylcholine, resulting in an increase in acetylcholine in the neuromuscular junction, there is a clinically relevant "ceiling" effect to the maximal concentration of acetylcholine. As concentrations of acetylcholine increase, some of the neurotransmitter diffuses away from the neuromuscular junction, while additional acetylcholine undergoes reuptake into motor nerve terminals. As the processes of diffusion and reuptake reach equilibrium with augmented release by enzyme inhibition, a "peak" level at the neuromuscular junction is reached.[70] Once the acetylcholinesterase enzyme is maximally inhibited by an anticholinesterase agent and peak concentrations of acetylcholine are present, the administration of additional drug will not further increase acetylcholine levels or enhance recovery of neuromuscular blockade. This "ceiling" effect of anticholinesterases is an important limitation of all clinically used agents; neuromuscular blockade cannot be adequately reversed if high concentrations of NMBDs are present at the neuromuscular junction.

Pharmacokinetic and Pharmacodynamic Properties of Anticholinesterases

A large number of clinical studies have examined the pharmacokinetic and pharmacodynamic characteristics of neostigmine, pyridostigmine, and edrophonium. Neostigmine has been the most extensively investigated anticholinesterase agent over the past 5 decades. The favorable pharmacokinetic profile of neostigmine likely explains its popularity in clinical practice as a reversal drug.

The pharmacokinetic profiles of neostigmine, pyridostigmine, and edrophonium are presented in Table 35-3. Most studies have used a two-compartment model to establish pharmacokinetic characteristics of each agent. Following a bolus administration, plasma concentrations peak rapidly and decline significantly within the first 5 to 10 minutes. This is followed by a slower decline in plasma concentrations due to the elimination phase.[71] In general, the pharmacokinetic profiles of all three muscle relaxants are similar. Early studies suggested that the duration of edrophonium was too short for clinical use. However, studies using larger doses (0.5 or 1.0 mg/kg) demonstrated that the elimination half-life of edrophonium was not significantly different from that of neostigmine or pyridostigmine and that edrophonium could produce prompt and sustained reversal of neuromuscular blockade.[72,73] The longer elimination half-life of pyridostigmine likely accounts for the longer duration of action compared with the other anticholinesterase drugs.[74]

TABLE 35-3 PHARMACOKINETICS OF NEOSTIGMINE, PYRIDOSTIGMINE, AND EDROPHONIUM IN PATIENTS WITHOUT AND WITH RENAL FAILURE

The pharmacokinetics of anticholinesterases can be influenced by renal function, age, and body temperature. The elimination half-lives of all three agents are altered by the presence of renal insufficiency or failure (see Table 35-3). Renal excretion accounts for approximately 50% of plasma clearance of neostigmine; elimination half-life is significantly prolonged and serum clearance decreased in anephric patients.[75] Similarly, renal function accounts for 70% to 75% of serum clearance of pyridostigmine and edrophonium.[74,76] The reduced plasma clearance of the anticholinesterases in renal failure patients provides a "margin of safety" against the risk of postoperative "recurarization" (the effects of the NMBD persist longer than that of the reversal agent, resulting in a worsening of residual paresis). The pharmacokinetics of edrophonium have been examined in older adult (age >70 years) patients. When compared with a younger cohort, older adult patients exhibited a significant decrease in plasma clearance (5.9 ± 2 versus 12.1 ± 4 mL· kg^{-1}· min^{-1}) and a prolonged elimination half-life (84.2 ± 17 versus 56.6 ± 16 minutes).[77] Mild hypothermia (reduction in core

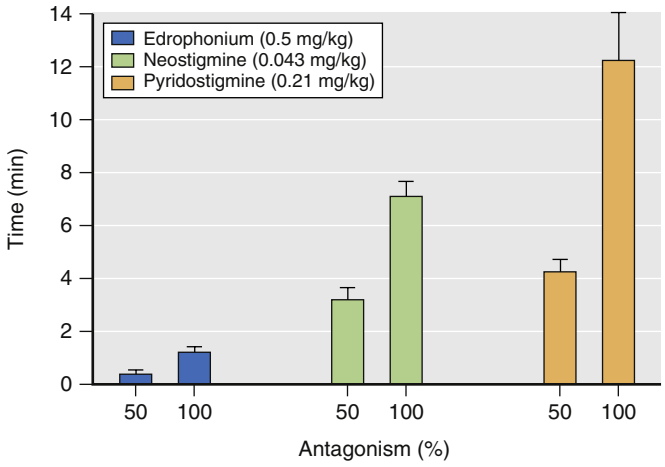

Figure 35-8. Comparison of onset of action for edrophonium, neostigmine, and pyridostigmine. Values plotted are means ± SE. Edrophonium's onset was significantly faster than neostigmine or pyridostigmine. *(From Cronnelly R, Morris RB, Miller RD: Edrophonium: duration of action and atropine requirement in humans during halothane anesthesia,* Anesthesiology *57:261-266, 1982.)*

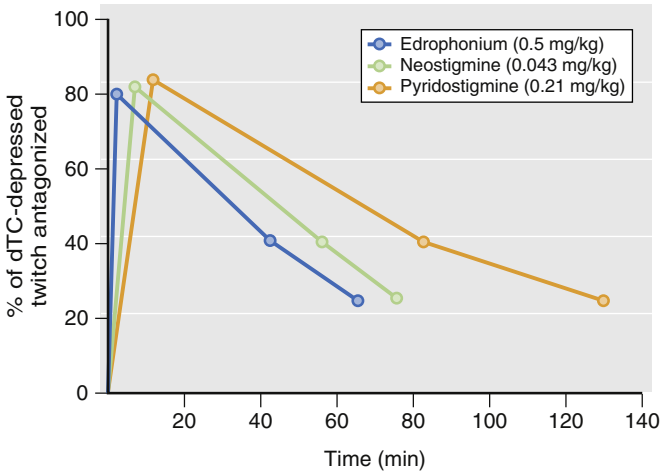

Figure 35-9. Duration of antagonism compared at equipotent doses of neostigmine, pyridostigmine, and edrophonium. Values plotted are means. Edrophonium did not differ from neostigmine in duration, however, both were shorter than pyridostigmine. *(From Cronnelly R, Morris RB, Miller RD: Edrophonium: duration of action and atropine requirement in humans during halothane anesthesia,* Anesthesiology *57:261-266, 1982).*

temperature of 2° C) more than doubles the duration of action of intermediate-acting NMBDs.[78] In a study of human volunteers cooled to 34.5° C, the central volume of distribution of neostigmine decreased 38% and the onset time of maximal blockade increased from 4.6 to 5.6 minutes.[79] However, the clearance, maximal effect, and duration of action of neostigmine were not altered by a reduction in body temperature. Therefore, if hypothermia influences the degree of neuromuscular recovery, it is likely secondary to an effect on the pharmacology of NMBDs (not the anticholinesterase).

Onset of action may be more rapid with edrophonium than with either neostigmine or pyridostigmine. When *d*-tubocurarine neuromuscular blockade was reversed with approximately equipotent doses of the three clinically used anticholinesterases, the peak effect of antagonism was reached significantly faster with edrophonium (0.8 to 2.0 minutes) than with neostigmine (7 to 11 minutes) or pyridostigmine (12 to 16 minutes)[72] (Fig. 35-8). Similar findings have been observed in patients receiving other long- and intermediate-acting NMBDs. When larger doses (0.5 to 1.0 mg/kg) of edrophonium are administered during moderate levels of neuromuscular blockade (10% recovery of single-twitch height after pancuronium or atracurium), the onset time of edrophonium was faster than neostigmine.[80,81] During deeper levels of blockade (<10% recovery of single twitch), edrophonium 1.0 mg/kg and neostigmine 0.04 mg/kg had similar onset times when vecuronium was used (and both were faster than edrophonium 0.5 mg/kg).[82] When pancuronium was antagonized during deep blockade, edrophonium 1.0 mg/kg had a shorter onset time than neostigmine 0.04 mg/kg.[82] These findings suggest that onset time of antagonism is influenced by the type and dose of anticholinesterase used, the choice of NMBD administered intraoperatively, and the depth of neuromuscular blockade at the time of antagonism.

The duration of action of anticholinesterases is determined not only by the pharmacokinetic properties of the drugs, but also by the concentration of NMBD present at the neuromuscular junction at the time of reversal. Duration of neuromuscular blockade will naturally decrease over time as a result of metabolism and elimination of NMBDs. To accurately assess the duration of action of anticholinesterases during a stable, constant level of neuromuscular blockade, investigators have administered these agents to patients receiving an infusion of *d*-tubocurarine titrated to a 90% depression of single-twitch height.[72] The investigators observed that the duration of action of equipotent doses of neostigmine (0.043 mg/kg) and edrophonium (0.5 mg/kg) were similar (Fig. 35-9). The duration of both drugs, however, was significantly less than with pyridostigmine (0.21 mg/kg).

The comparative potencies of clinically used anticholinesterases have been calculated by constructing dose-response curves. In general, neostigmine is more potent than pyridostigmine, which is more potent than edrophonium. Neostigmine-to-pyridostigmine potency ratios of 4.4 to 6.7 have been reported (neostigmine is 4.4 to 6.7 times more potent than pyridostigmine).[72,83] Neostigmine is even more potent than edrophonium, with potency ratios of 5.7 to 19.5 estimated from dose-response curves.[72,83,84] The great variability in potency ratios described in the literature is related to several factors, which include the type of NMBD used in the studies, the endpoint selected to represent neuromuscular recovery, and the depth of blockade at the time of anticholinesterase administration.

In conclusion, pharmacokinetic and pharmacodynamic studies suggest that neostigmine, pyridostigmine, and edrophonium are all effective in reversing neuromuscular blockade when used in appropriate and equipotent doses. The following section will review factors that determine the efficacy of these agents in reversing neuromuscular blockade in the clinical setting.

Factors Determining the Adequacy of Recovery Following Administration of Anticholinesterases

Depth of Neuromuscular Blockade or Train-of-Four Count at the Time of Reversal. The primary anesthetic management variable determining the effectiveness of anticholinesterase agents in completely antagonizing neuromuscular blockade at the end of surgery is the depth of neuromuscular blockade at the time of reversal. As opposed to sugammadex (see later in this chapter), reversal of blockade by anticholinesterases should not be attempted until some evidence of spontaneous recovery is present. Kirkegaard-Nielsen and associates examined the optimal time for neostigmine reversal of an atracurium blockade.[85] Administration of neostigmine 0.07 mg/kg during deep blockade (before the first twitch height reached 8%) resulted in significant prolongation of reversal times. In a similar investigation, atracurium was antagonized with neostigmine during intense blockade (posttetanic count [PTC] of 1 to >13).[86] Early administration of neostigmine did not shorten total recovery time and offered no clinical advantages. Similar findings have been observed during reversal of deep vecuronium blockade.[87] The total time to achieve a TOF ratio of 0.75 was the same whether neostigmine (0.07 mg/kg) was given 15 minutes after an intubating dose of vecuronium or whether single-twitch height had recovered to 10% of control.

The time required to achieve a TOF ratio of 0.90 after anticholinesterase administration is significantly shorter when a higher TOF count is present at reversal. Two studies have examined the efficacy of antagonizing residual blockade at varying TOF counts. Kirkegaard and colleagues randomized patients receiving cisatracurium to reversal with neostigmine (0.07 mg/kg) at the reappearance of the first, second, third, and fourth tactile TOF response (TOF count 1-4).[88] The median (range) time required to achieve a TOF ratio of 0.90 was 22.2 (13.9 to 44.0) minutes when reversal was attempted at a TOF count of 1. However, even when four responses were present, the time needed to attain a TOF ratio of 0.90 was 16.5 (6.5 to 143.3) minutes (Table 35-4). Kim and associates performed a similar study in which patients administered rocuronium were randomized to be reversed at the first through fourth tactile TOF responses.[89] In those patients receiving sevoflurane for anesthetic maintenance, the median (range) time required to achieve a TOF ratio of 0.90 was 28.6 (8.8 to 75.8) minutes when reversed at a TOF count of 1 and 9.7 (5.1 to 26.4) minutes when reversed at a TOF count of 4. In both investigations, a large interindividual variability in reversal times was observed.[88,89] This is likely a reflection of the individual response to the NMBD administered. The reason for marked prolongation of reversal times in some patients (up to 143 minutes) was not determined, but may be due to the "ceiling effect" with respect to the blockade (peak effect of the antagonist is followed by a plateau phase in which the balance between diminishing anticholinesterase activity and spontaneous recovery determines the slope of the recovery curve).[88] Both studies demonstrated that it was not possible to reliably achieve full neuromuscular recovery (TOF ratio of >0.90) in the majority of patients within 10 minutes of anticholinesterase administration.

Time Interval Between Anticholinesterase Administration and Tracheal Extubation. As noted in the studies by Kirkegaard and Kim, if four responses to TOF nerve stimulation are present, approximately 15 minutes are needed to reach a TOF ratio of 0.90 in most patients.[88,89] Achieving a TOF ratio of 0.90 will require significantly longer (20 to 30 minutes) if a TOF count of 1 to 3 is observed at the time of reversal. In order to ensure patient safety, full recovery of neuromuscular function should be present at the time of tracheal extubation. Therefore, anticholinesterase drugs should be given, on average, 15 to 30 minutes before clinicians anticipate removal of the endotracheal tube in the operating room. In many clinical situations, however, anticholinesterases are often administered at the conclusion of surgical closure, with tracheal extubation performed shortly thereafter. A survey of anesthesiologists from Europe and the United States revealed that approximately one half of respondents allowed only 5 minutes or less between anticholinesterase administration and tracheal extubation.[11] In a study of 120 surgical patients, TOF ratios were quantified at the time of tracheal extubation when clinicians had determined that full recovery of neuromuscular function had occurred using clinical criteria and qualitative neuromuscular monitoring (Fig. 35-10).[49] Mean TOF ratios of 0.67 were observed immediately before extubation, with 88% of patients exhibiting TOF less than 0.90. Of note, the median TOF count at reversal was 4, and the average time interval between neostigmine administration and tracheal extubation was only 8 minutes. The frequent incidence of residual blockade reported in multiple studies is likely attributable to the fact that anticholinesterases are not given early enough during the intraoperative anesthetic to ensure full neuromuscular recovery.

Type of NMBD Used Intraoperatively (Long-Acting Versus Intermediate-Acting). Two separate processes

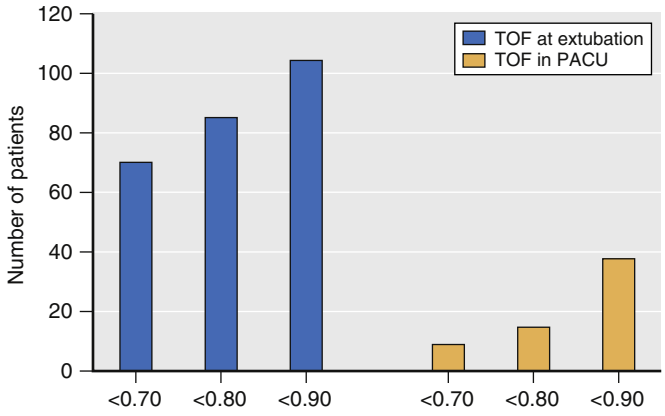

Figure 35-10. Train-of-four (TOF) ratios measured immediately before tracheal extubation and again on admission to the postanesthesia care unit (PACU). The graphs illustrate the number of patients (of a total of 120) with TOF ratios <0.70, 0.80, and 0.90 at each measurement interval. *(From Murphy GS, Szokol JW, et al: Residual paralysis at the time of tracheal extubation.* Anesth Analg *100:1840-1845, 2005.)*

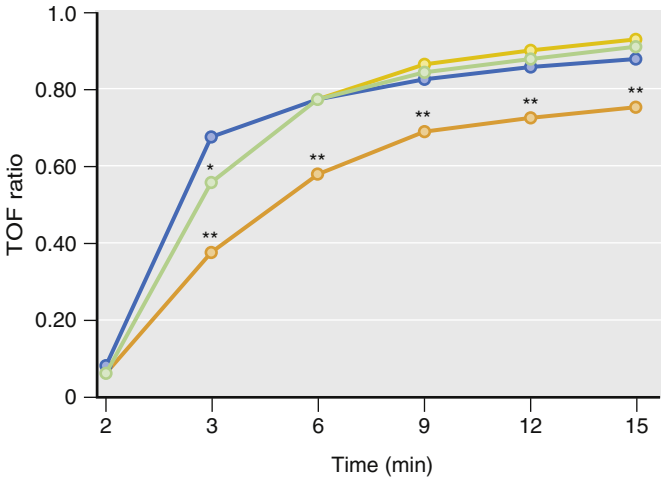

Figure 35-11. Evolution of the train-of-four (TOF) ratio (mean) recorded at 3-minute intervals after administration of neostigmine 40 μg kg^{-1} when twitch height had returned to 25% of its initial value in groups of Roc (*green*), Vec (*blue*), Atr (*yellow*) and Pan (*orange*). *$P < .05$, one-way analysis of variance and Duncan multiple classification range tests (group Vec versus groups Roc and Atr). **$P < .01$, one-way analysis of variance and Duncan multiple classification range tests (group Pan versus groups Vec, Roc, Atr). *(From Baurain MJ, Hoton F, D'Hollander AA, et al: Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium?* Br J Anaesth *77: 496-499, 1996.)*

contribute to recovery of neuromuscular function following anticholinesterase administration. The first is the inhibition of acetylcholinesterase at the neuromuscular junction produced by neostigmine, pyridostigmine, or edrophonium. The second is the spontaneous process of decrease in the concentration of the NMBD at the neuromuscular junction over time due to redistribution and elimination. Therefore, NMBDs that are redistributed and eliminated more rapidly from the plasma should be associated with more rapid recovery profiles after anticholinesterase use. Not surprisingly, the probability of satisfactorily antagonizing neuromuscular blockade is a function of the NMBD used to provide muscle relaxation. The ability of edrophonium (0.75 mg/kg) and neostigmine (0.05 mg/kg) to antagonize neuromuscular blockade produced by atracurium, vecuronium, and pancuronium following termination of steady-state infusions (single-twitch depression 10% of control) has been examined.[90] TOF ratios 20 minutes postreversal were 0.80 and 0.95 (atracurium with edrophonium or neostigmine), 0.76 and 0.89 (vecuronium with edrophonium or neostigmine), and 0.44 and 0.68 (pancuronium with edrophonium or neostigmine). Another clinical study investigated recovery of neuromuscular function in patients randomized to receive either intermediate-acting (rocuronium, vecuronium, atracurium) or long-acting (pancuronium) NMBDs.[91] Neostigmine (0.04 mg/kg) was given at 25% recovery of control twitch height, and TOF ratios were measured for 15 minutes. Mean TOF ratios had recovered to 0.88 to 0.92 in patients receiving intermediate-acting NMBDs, versus only 0.76 in the pancuronium group (Fig. 35-11).

A number of clinical investigations have examined the incidence of residual blockade in the PACU in patients receiving either intermediate- or long-acting NMBDs. These studies have consistently demonstrated that fewer patients given intermediate-acting NMBD have residual blockade compared with those receiving long-acting agents. A meta-analysis of 24 clinical trials examined the pooled estimated incidence of residual blockade (defined as a TOF ratio <0.90) by muscle relaxant type.[44] The risk of residual blockade was significantly less in patients given intermediate-acting NMBDs (41%) versus long-acting NMBDs (72%). In conclusion, the probability of incomplete neuromuscular recovery in the early postoperative period is decreased when shorter-acting NMBDs are used intraoperatively.

Type and Dose of Anticholinesterase. Complete recovery of neuromuscular function within 10 to 15 minutes with neostigmine, edrophonium, or pyridostigmine is difficult to achieve when profound neuromuscular blockade is present. Some investigations have suggested that edrophonium is less effective than neostigmine when reversing deep blockade; this may occur because the slopes of the dose-response relationships of neostigmine and edrophonium are not parallel (flatter dose-response curves are observed with edrophonium; Fig. 35-12).[82,84] In contrast, the recovery profile of edrophonium with larger doses (approximately 1.0 mg/kg) does not differ from neostigmine and pyridostigmine, and edrophonium can produce rapid and sustained reversal of neuromuscular blockade.[80,82] At moderate levels of neuromuscular blockade all three agents appear to be similarly effective in reversing blockade, although the onset of edrophonium may occur more quickly.

In general, larger doses of anticholinesterases result in more rapid and complete reversal of neuromuscular blockade than smaller doses. This relationship remains true until the maximal dose of anticholinesterase has been administered. At this point, acetylcholinesterase is maximally inhibited, and additional amounts of anticholinesterase will result in no further antagonism. Maximal effective doses of neostigmine and edrophonium have not been clearly defined, but likely vary in relation to depth of blockade and type of NMBD used

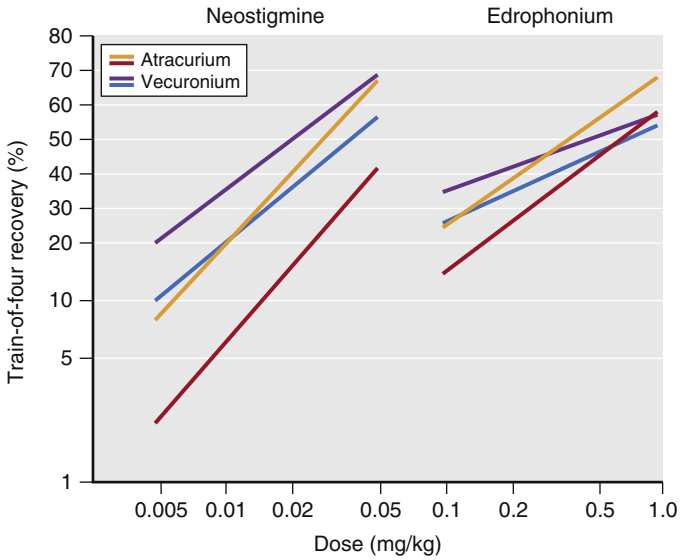

Figure 35-12. Dose-response relationships of train-of-four assisted recovery evaluated 5 minutes *(blue lines)* or 10 minutes *(purple lines)* after administration of the antagonist as a function of the dose of neostigmine or edrophonium. The slopes of the curves obtained with edrophonium were usually flatter than the corresponding curves for neostigmine. *(From Smith CE, Donati F, Bevan DR: Dose-response relationships for edrophonium and neostigmine as antagonists of atracurium and vecuronium neuromuscular blockade,* Anesthesiology *71: 37-43, 1989).*

intraoperatively. Providing additional anticholinesterase beyond these maximum dose limits (neostigmine 60 to 80 μg/kg, edrophonium 1.0 to 1.5 mg/kg) provides no further benefit. When administered during deep neuromuscular blockade, a second dose of neostigmine (70 μg/kg) usually does not enhance recovery times beyond that observed with a single dose.[87]

Age

Infants and Children. The dose of neostigmine producing 50% antagonism of a *d*-tubocurarine neuromuscular blockade was slightly smaller in infants (13 μg/kg) and children (15 μg/kg) compared with adults (23 μg/kg) (also see Chapter 93).[92] The times to peak antagonism and duration of antagonism did not differ between infants, children, and adults. Pharmacokinetic modeling revealed that distribution half-lives and volumes were similar in all three cohorts, although elimination half-life was shorter in infants and children than adults. As in adults, the depth of neuromuscular blockade at the time of antagonism was a primary factor determining adequacy of recovery.[93,94] Spontaneous recovery from neuromuscular blockade is more rapid in children compared with adults.[94] However, when neostigmine was administered at various levels of blockade, the times to achieve neuromuscular recovery were similar in children and adults (the times to reach a TOF ratio of 0.90 were reduced by 30% to 40% compared with spontaneous recovery).[94] Thus, in the clinical setting, reversal of neuromuscular blockade does not appear to differ significantly between children and adults.

Older Adults. Physiologic changes occur during the aging process that result in alterations in the response of older patients to NMBDs (also see Chapter 80). These changes include an increase in body fat, a decrease in total body water, and declines in cardiac, hepatic, and renal function. In addition, anatomic alterations occur at the neuromuscular junction in older adults, such as a decrease in the concentration of nAChRs at the motor endplate and a reduction in the release of acetylcholine from the preterminal axon. All of these factors contribute to a prolongation of effect of most NMBDs in older patients (see also Chapter 34). In a study comparing older adults (age >70) to younger controls, plasma clearance of edrophonium was decreased and elimination half-life prolonged in the aged cohort.[77] Despite higher plasma concentrations of edrophonium, however, duration of antagonism was not increased. In contrast, Young and colleagues observed that the duration of action of both neostigmine and pyridostigmine was significantly longer in older adults (age >60) compared with younger subjects.[95] These findings suggest that plasma concentrations and/or duration of action of both NMBDs and anticholinesterases (neostigmine and pyridostigmine) are prolonged in older patients, which should reduce the risk of recurarization. Whether older patients who have received anticholinesterases are at greater risk for residual blockade in the PACU is not documented.

Type of Anesthesia

Volatile anesthetics intensify the action of nondepolarizing NMBDs when compared with intravenous anesthetics. Furthermore, volatile anesthetics interfere with the antagonism of neuromuscular blockade.[96] Kim and colleagues randomized patients to receive a propofol or sevoflurane anesthetic (Table 35-5).[89] The times required to achieve a TOF ratio of 0.70, 0.80, and 0.90 were significantly longer in patients given the sevoflurane-based anesthetic compared with the propofol-based technique. Similar findings have been observed in patients randomized to receive either isoflurane or propofol (neuromuscular recovery was delayed when a volatile anesthetic was used).[96,97] These findings suggest that the probability of achieving a TOF ratio greater than 0.90 within 10 to 15 minutes of anticholinesterase administration is increased if a total intravenous anesthetic technique is administered as opposed to a volatile anesthetic.

Continuous Infusion Versus Bolus Administration of NMBDs. Recovery from neuromuscular blockade may also be influenced by mode of NMBD administration. Jellish and colleagues examined recovery characteristics of rocuronium and cisatracurium when given as either a bolus or continuous infusion.[97] The time required to reach a TOF ratio of 0.75 in the cisatracurium group was similar whether bolus or infusion techniques were used, whereas recovery was delayed when rocuronium was given as an infusion.[97] The authors conclude that cisatracurium may be the agent of choice for prolonged procedures since its recovery is not affected by length of infusion.

Renal Function. As previously noted, renal excretion accounts for 50% to 75% of plasma clearance of neostigmine, pyridostigmine, and edrophonium. In anephric patients, elimination half-life of all three anticholinesterases is prolonged, and total plasma clearance of these agents is decreased (see Table 35-3). Similar changes in the pharmacokinetics characteristics of nondepolarizing NMBDs have been noted in patients with renal failure. Therefore, management of anticholinesterase reversal should be similar in patients with normal and impaired renal function. Postoperative residual neuromuscular

blockade in patients with renal failure is more likely secondary to improper titration of NMBDs intraoperatively rather than to inappropriate dosing of anticholinesterase agents.

Acid-Base Status. The influence of metabolic status and respiratory acid-base balance on reversal of neuromuscular blockade has been investigated in the laboratory setting. Miller and associates noted that respiratory alkalosis and metabolic acidosis did not alter the dose of neostigmine needed to reverse a *d*-tubocurarine or pancuronium blockade. However, during respiratory acidosis and metabolic alkalosis, the dose of neostigmine needed to produce a comparable level of neuromuscular recovery was nearly twice as large.[98,99] Although clinical studies have not been performed, the findings from laboratory investigations suggest that complete reversal of neuromuscular blockade may be difficult in the presence of respiratory acidosis and metabolic alkalosis. In particular, clinicians should be aware of the risk of residual blockade in the setting of respiratory acidosis. A number of anesthetics (opioids, benzodiazepines, volatile anesthetics) can potentially depress the ventilatory drive in the early postoperative period. This respiratory depression may result in respiratory acidosis, which limits the ability of anticholinesterases to reverse neuromuscular blockade. The resultant residual blockade may further depress the respiratory muscle strength and ventilatory drive and increase the risk of adverse postoperative events.

Neuromuscular Monitoring. Qualitative and quantitative neuromuscular monitoring (also see Chapter 53) should be used to guide dosing of both NMBDs and their reversal in the operating room. In general, if deeper levels of neuromuscular blockade are present at the end of surgery (1 to 2 responses to TOF stimulation), larger doses of anticholinesterases should be given. In these clinical scenarios, maximal doses of neostigmine (70 μg/kg), edrophonium (1.0 to 1.5 mg/kg), or pyridostigmine (350 μg/kg) should be considered. If three to four responses to TOF stimulation are present with observable fade of the fourth response, moderate doses of anticholinesterase should be administered (40 to 50 μg/kg of neostigmine, 0.5 mg/kg of edrophonium, 200 μg/kg pyridostigmine). If four responses are present with no fade, low doses of anticholinesterases can be considered (e.g., 20 μg/kg of neostigmine; see later).

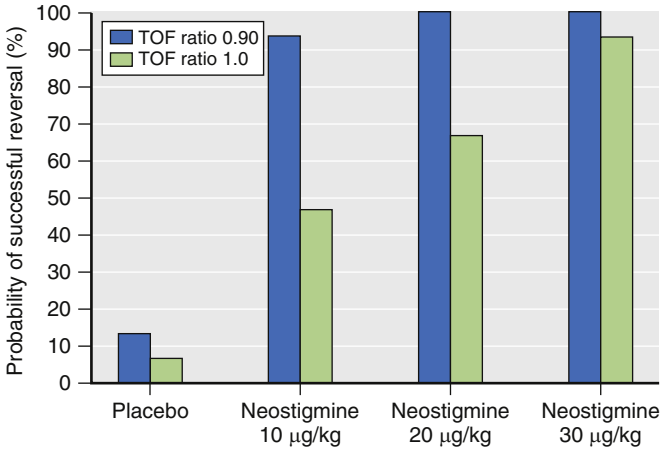

Figure 35-13. Probability of successful reversal within 10 minutes after different doses of neostigmine or placebo. Neostigmine or placebo was given at a train-of-four ratio of 0.40. *(From Fuchs-Buder T, Meistelman C, Alla F, et al: Antagonism of low degrees of atracurium-induced neuromuscular blockade: dose-effect relationship for neostigmine,* Anesthesiology *112:34-40, 2010).*

Quantitative monitoring is also useful in guiding the dosing of anticholinesterases. Fuchs-Buder and colleagues investigated the dose-response relationship of neostigmine when administered at shallow levels of an atracurium neuromuscular blockade (Fig. 35-13).[100] Neuromuscular function was monitored with AMG, and neostigmine (10, 20, or 30 μg/kg) was given at a TOF ratio of 0.40 or 0.60. All patients were able to achieve a TOF ratio of 0.90 within 10 minutes of receiving 20 μg/kg of neostigmine. These findings demonstrate that small doses of neostigmine can be safely used if neuromuscular recovery is measured with quantitative monitoring. If muscle

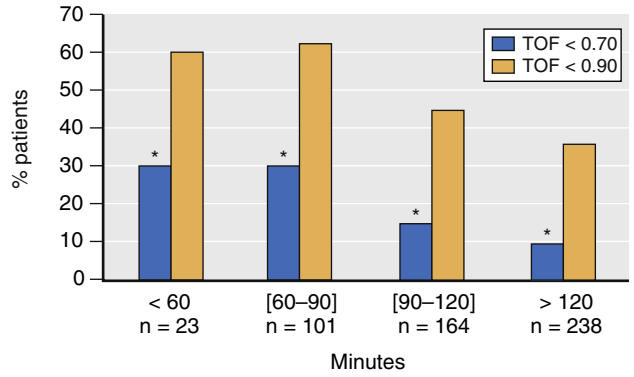

Figure 35-14. The incidence of residual neuromuscular blockade after a single intubating dose of intermediate-duration nondepolarizing relaxant (rocuronium, vecuronium, or atracurium). Partial paralysis rate (percent) according to the delay between the administration of muscle relaxant and the arrival in the postanesthesia care unit (PACU). Partial paralysis was defined as a train-of-four (TOF) ratio less than 0.70 or less than 0.90. *n* = number of patients. *Significantly different from TOF <0.90. *(From Debaene B, Plaud B, Dilly MP, Donati F: Residual paralysis in the PACU after a single intubating dose of nondepolarizing muscle relaxant with an intermediate duration of action,* Anesthesiology *98:1042-1048, 2003.)*

function is monitored with a simple nerve stimulator and no fade is detected with TOF stimulation, the TOF ratio is likely at least 0.40, but may be as high as 0.90 or 1.0. In the setting of full neuromuscular recovery, neostigmine administration may produce paradoxical muscle weakness (see later). This potential risk should be considered if neostigmine is used to reverse shallow blockade based on the results of qualitative neuromuscular monitoring.

In many clinical settings neuromuscular monitoring is unfortunately not utilized and decisions relating to the administration of anticholinesterases are based on the time that has elapsed between the last dose of NMBD and the conclusion of the anesthetic. Clinical studies do not support this practice. In a study of patients receiving a single intubating dose of vecuronium (0.1 mg/kg), 8.4% of patients had TOF ratios less than 0.80 4 hours after NMBD administration.[101] Debaene and colleagues examined the incidence of residual blockade in a large cohort of patients given a single intubating dose of vecuronium, rocuronium, or atracurium.[47] Of the 239 patients who were tested 2 or more hours after administration of the NMBD, 37% had a TOF ratio less than 0.90 (Fig. 35-14). These investigations, as well as a number of pharmacokinetic and pharmacodynamic studies, demonstrate that the time course of spontaneous neuromuscular recovery is extremely variable from patient to patient. In order to detect and appropriately manage patients in whom delayed neuromuscular recovery may be present, quantitative neuromuscular monitoring is required.

Patients With Cholinesterase Deficiency. The duration of neuromuscular blockade following the administration of either succinylcholine or mivacurium is primarily determined by their rate of hydrolysis by plasma cholinesterase (also see Chapter 34). Patients with abnormal plasma cholinesterase phenotypes and activity can demonstrate significant prolongation of clinical effect of these NMBDs. Mivacurium is four to five times more potent in patients phenotypically homozygous for the atypical plasma cholinesterase gene than in patients with normal cholinesterase activity.[102] Following standard intubating doses of mivacurium, recovery of neuromuscular function may require up to 4 to 8 hours in patients with cholinesterase deficiency.[103] Similar prolonged recovery times have been observed in patients administered succinylcholine who have atypical plasma cholinesterase genes.[104]

Human plasma cholinesterase has been used clinically to reverse neuromuscular blockade in patients with atypical serum cholinesterase. In 1977, Scholler and associates reported data on 15 patients with unexpected prolonged apnea lasting several hours after a dose of succinylcholine.[105] Adequate spontaneous ventilation was restored within an average time of 10 minutes in all subjects following the administration of human serum cholinesterase. Naguib and associates reported successful reversal of a profound mivacurium-induced neuromuscular blockade with three doses of a purified human plasma cholinesterase preparation and, in a subsequent study, established a dose-response relationship for plasma cholinesterase as a reversal agent for mivacurium in normal subjects.[103,106] The efficacy of exogenously administered plasma cholinesterase in antagonism of a mivacurium neuromuscular blockade was assessed in 11 patients phenotypically homozygous for atypical plasma cholinesterase.[107] A purified concentrate of cholinesterase (2.8 to 10 mg/kg) was administered 30 or 120 minutes after an intubating dose of mivacurium. Administration of cholinesterase restored plasma cholinesterase to normal levels, resulting in a 9- to 15-fold increased clearance and a shorter elimination half-life of mivacurium. The first response to TOF stimulation was observed in 13.5 minutes, and the time to achieve a TOF ratio of 0.80 ranged from 30 to 60 minutes. These data suggest that prolonged neuromuscular blockade secondary to low or abnormal plasma cholinesterase activity can be successfully managed with purified human plasma cholinesterase. Decisions relating to management of prolonged neuromuscular blockade in patients with atypical plasma cholinesterase should be based on the availability and cost of human plasma cholinesterase versus delaying tracheal extubation until spontaneous neuromuscular recovery has occurred.

Box 35-2 summarizes clinical management strategies that can be used by clinicians to reduce the risk of residual blockade when NMBDs are antagonized with anticholinesterases.

Complications Associated With Inhibitors of Acetylcholinesterase

Anticholinesterase-Associated Muscle Weakness. Anticholinesterases can antagonize moderate to shallow levels of neuromuscular blockade. However, if given when neuromuscular function is completely recovered, paradoxical muscle weakness theoretically may be induced. Large doses of neostigmine, pyridostigmine, and edrophonium may result in cholinergic hyperactivity and more intense fade in response to multiple nerve stimuli (decrease in TOF ratio) in an in vitro model.[108] The administration of a second dose of neostigmine (2.5 mg) to patients with small degrees of residual blockade resulted in a decrease in TOF ratios, tetanic height, and tetanic fade.[109,110] Caldwell

BOX 35-2 *Clinical Management Strategies to Reduce the Risk of Residual Neuromuscular Blockade When Anticholinesterase Reversal Agents Are Used*

Quantitative Monitoring Used (e.g., acceleromyography)

1. TOF count of 1 or no TOF response—delay reversal until neuromuscular recovery is more complete (TOF count of 2 or greater).
2. TOF count of 2 or 3—administer doses of anticholinesterases (neostigmine [70 μg/kg], edrophonium [1.0-1.5 mg/kg], or pyridostigmine [350 μg/kg]). Extubate when the adductor pollicis TOF ratio has reached 0.90.
3. TOF ratio ≥ 0.40—administer moderate pharmacologic reversal doses of anticholinesterases (neostigmine [40-50 μg/kg], edrophonium [0.5 mg/kg], or pyridostigmine [200 μg/kg]). Extubate when the adductor pollicis TOF ratio has reached 0.90.
4. TOF ratio between 0.40 and 0.70—administer pharmacologic reversal, consider a low dose of neostigmine (20 μg/kg).
5. TOF ratio > 0.70—avoid anticholinesterase reversal; risk of anticholinesterase-induced muscle weakness if given.

Qualitative Monitoring Used (Peripheral Nerve Stimulator)

1. TOF count of 1 or no TOF response—delay reversal until neuromuscular recovery is detectable (TOF count of 2 or greater)
2. TOF count of 2 or 3 at the end of surgery—administer anticholinesterases (neostigmine [70 μg/kg], edrophonium [1.0-1.5 mg/kg], or pyridostigmine [350 μg/kg]). Allow at least 15-30 minutes before tracheal extubation is performed.
3. TOF count of 4 with observable fade at the end of surgery (likely adductor pollicis TOF ratio < 0.40)—administer anticholinesterases (neostigmine [40-50 μg/kg], edrophonium [0.5 mg/kg], or pyridostigmine [200 μg/kg]). Allow at least 10-15 minutes before tracheal extubation is performed.
4. TOF count of 4 with no perceived fade at the end of surgery (likely adductor pollicis TOF ratio ≥ 0.40)—administer pharmacologic reversal, consider a low dose of neostigmine (20 μg/kg).

No Neuromuscular Monitoring Used

1. Anticholinesterases should be considered. Spontaneous recovery of neuromuscular function may require several hours in a significant percentage of patients, even after a single intubating dose of an intermediate-acting NMBD.
2. Anticholinesterases should not be given until some evidence of recovery of muscle strength is observed since administration of an anticholinesterase during deep levels of paralysis may delay neuromuscular recovery.
3. Decisions relating to the use or avoidance of anticholinesterases should not be based upon clinical tests of muscle strength (5-second head lift). Many patients can perform these tests even in the presence of profound neuromuscular blockade (TOF ratio < 0.50). Other muscle groups may be significantly impaired (pharyngeal muscles) at the time when patients can successfully perform these tests.

NMBD, Neuromuscular blocking drug; *TOF*, train-of-four.

and co-workers examined neostigmine reversal (20 or 40 μg/kg) of residual neuromuscular blockade 1 to 4 hours after a single dose of vecuronium.[101] TOF ratios increased in 52 patients and decreased in 8 patients; TOF ratio decreases were only observed in patients with TOF ratios 0.90 or greater at the time of reversal (with 40 μg/kg doses of neostigmine but not 20 μg/kg dosing).

The clinical implications of administration of neostigmine after neuromuscular recovery has occurred have been examined in studies by Eikermann and colleagues. Rats were administered neostigmine after TOF ratios recovered to 1.0. Neostigmine administration resulted in decreases in upper airway dilator muscle tone and volume, impairment of diaphragmatic function, and reductions in minute ventilation.[111,112] In healthy volunteers given rocuronium, the administration of neostigmine after the recovery of the TOF to 1.0 induced genioglossus muscle impairment and increased upper airway collapsibility.[113] The adverse physiologic effects of neostigmine in the setting of complete neuromuscular recovery can potentially have negative respiratory consequences in postoperative surgical patients. The mechanisms proposed for this effect include sensitivity of the upper airway muscles to an overabundance of acetylcholine with desensitization of the ACh receptor, depolarizing blockade, or an open channel blockade. In contrast, sugammadex does not appear to produce adverse effects on upper airway tone or normal breathing when given after neuromuscular recovery.[111]

Nausea and Vomiting. The impact of anticholinesterases on the incidence of postoperative nausea and vomiting remains controversial (also see Chapter 97). Systemic anticholinesterases produce effects outside of the neuromuscular junction that may influence the risk of unwanted side effects following anesthesia and surgery. In addition to the action within the neuromuscular junction, anticholinesterase drugs result in muscarinic effects on the gastrointestinal tract, resulting in stimulation of secretion of gastric fluid and increases in gastric motility. The use of smaller doses of neostigmine in combination with atropine decreases lower esophageal sphincter tone.[114] Furthermore, neostigmine may produce nausea and vomiting via a central effect. Intrathecal neostigmine increases the incidence of nausea and vomiting, likely through a direct effect on the brainstem.

Anticholinergic drugs (e.g. atropine, glycopyrrolate) are routinely administered with anticholinesterases in order to attenuate the undesirable muscarinic effects of these reversal agents. Perhaps anticholinergic drugs have antiemetic properties.[115] When given to children receiving sedation (in the absence of anticholinesterases), atropine was associated with significantly less vomiting (5.3%) than either glycopyrrolate (10.7%) or no anticholinergic (11.4%)[116] (also see Chapter 93). Similarly, surgical patients who were randomized to receive atropine had significantly less nausea than those given glycopyrrolate.[117] Atropine is a tertiary amine that can readily cross the blood-brain barrier and produce central effects, whereas glycopyrrolate is a quaternary amine that does not penetrate the blood-brain barrier. The beneficial effects of atropine on nausea and vomiting are likely secondary to a central nervous system effect.

TABLE 35-6 **EARLY AND DELAYED POSTOPERATIVE NAUSEA AND VOMITING WITH NEOSTIGMINE VERSUS CONTROL—RESULTS OF A META-ANALYSIS**

Outcome	Anticholinergics	Number of Studies	Number of Participants	Relative Risk (95% CI)
Early nausea (0-6 hr)	Atropine and Glycopyrrolate	6	584	1.24 (0.86-1.80)
	Atropine	1	79	0.67 (0.36-1.26)
	Glycopyrrolate	5	505	1.39 (0.97-1.99)
Early vomiting (0-6 hr)	Atropine and Glycopyrrolate	8	768	1.05 (0.72-1.55)
	Atropine	2	199	0.75 (0.52-1.08)
	Glycopyrrolate	6	568	1.35 (0.88-2.06)
Delayed nausea (6-24 hr)	Glycopyrrolate	4	337	1.09 (0.76-1.57)
Delayed vomiting (6-24 hr)	Glycopyrrolate	4	337	1.01 (0.58-1.78)

From Cheng CR, Sessler DI, Apfel CC: Does neostigmine administration produce a clinically important increase in postoperative nausea and vomiting? Anesth Analg *101:1349-1355, 2005.*
CI, Confidence interval.

Several randomized clinical trials have been performed to determine whether anticholinesterase administration results in an increase in the incidence of postoperative nausea and vomiting. Unfortunately, most study populations were small (39 to 120 patients). Two systematic reviews have been conducted to address this limitation. Tramer and Fuchs-Buder analyzed eight trials with data on 1134 patients that compared reversal with neostigmine or edrophonium with spontaneous recovery from long- or intermediate-acting NMBDs.[118] An analysis of the neostigmine data across all trials and doses revealed no evidence of an increased risk of early and late nausea and vomiting when neostigmine was administered. However, some evidence in adults suggested that antagonism with larger doses of neostigmine (2.5 mg) might increase the incidence of these events. No evidence was found for this effect with edrophonium. A later systematic review evaluated the effect of neostigmine on postoperative nausea and vomiting while considering the different anticholinergics as confounding variables.[115] Ten randomized trials (933 patients) that compared neostigmine to inactive control were included. The combination of neostigmine with either glycopyrrolate or atropine did not increase the incidence of nausea or vomiting, nor was there an increased risk when large doses of neostigmine were compared with smaller doses (Table 35-6). Atropine was associated with a reduction in the risk of vomiting, but glycopyrrolate was not. In conclusion, there is at present insufficient evidence to conclude that neostigmine or edrophonium is associated with an increased risk of postoperative nausea and vomiting.

Cardiovascular Effects. Pronounced vagal effects are observed following the administration of anticholinesterases—bradycardia and other bradyarrhythmias, such as junctional rhythms, ventricular escape beats, complete heart block, and asystole, have been reported. The time course of these bradyarrhythmias parallels the onset of action of the anticholinesterases, with the most rapid onset observed with edrophonium, slower for neostigmine, and slowest for pyridostigmine.[71] In order to counteract these cardiovascular effects, atropine and glycopyrrolate are administered concurrently with anticholinesterases. Atropine and glycopyrrolate have muscarinic (parasympathetic) blocking effects, but do not block nicotinic receptors. Atropine has a more rapid onset of action (approximately 1 minute) compared with glycopyrrolate (2 to 3 minutes), although the duration of action of both agents is similar (30 to 60 minutes). Despite the concurrent administration of anticholinergic drugs, a high incidence of bradyarrhythmias is observed following anticholinesterase reversal (up to 50% to 60% of patients in some studies).[72,119] The risk of arrhythmias is influenced by the type of anticholinesterase and anticholinergic used, the dose of anticholinesterase and anticholinergic administered, and background anesthetic used (opioid-based versus volatile anesthetic and type of NMBD).

Several investigations have examined the heart rate and rhythm responses to various anticholinesterase/anticholinergic combinations. In general, it is preferable to use atropine with edrophonium, because the onset of action of both drugs is rapid. Edrophonium-atropine mixtures induced small increases in heart rate, whereas edrophonium-glycopyrrolate mixtures caused decreases in heart rate and occasionally severe bradycardia.[120] Similarly, the onset of cholinergic effects of neostigmine coincides with the onset of the anticholinergic effects of glycopyrrolate; glycopyrrolate is superior to atropine in protecting against neostigmine-induced bradyarrhythmias.[121] When atropine is given with edrophonium (0.5 to 1.0 mg/kg), doses of 5 to 7 μg/kg are recommended, although larger doses may be used in certain circumstances.[120,122] If glycopyrrolate is given with neostigmine, minimal changes in heart rate are observed if a dose equivalent of one fourth the dose of neostigmine is used (e.g., 1 mg glycopyrrolate with 4 mg of neostigmine).[71,121] Because the onset of action is slow with pyridostigmine, tachycardia may be observed when either atropine or glycopyrrolate is coadministered.[71]

More recent investigations have examined the impact of atropine and glycopyrrolate, given with neostigmine, on autonomic control in the postoperative period. During physiologic stressful events, control of heart rate and arterial blood pressure is regulated by the sympathetic and parasympathetic nervous systems. Anticholinergic drugs attenuate the efferent parasympathetic regulation of heart rate and suppress cardiac baroreflex sensitivity and heart rate variability. This suppression of the parasympathetic system may predispose patients to cardiac arrhythmias following

surgery. Marked decreases in baroreflex sensitivity and high-frequency heart rate variability have been observed in healthy volunteers given either atropine (20 μg/kg) or glycopyrrolate (7 μg/kg).[123] Although the times required to return to baseline values were prolonged in both groups, recovery times were significantly longer in the subjects given atropine (177 to 212 minutes) compared with those administered glycopyrrolate (82 to 111 minutes). Similar effects have been observed in healthy patients undergoing general anesthesia reversed with neostigmine and anticholinergics.[124] Neuromuscular blockade was antagonized with neostigmine 50 μg/kg and either atropine 20 μg/kg or glycopyrrolate 8 μg/kg. Two hours after giving neostigmine, patients given atropine had persistent impairment of baroreflex sensitivity and high-frequency heart rate variability, whereas these variables had returned to baseline values in patients receiving glycopyrrolate. These investigations demonstrate that the parasympathetic nervous system control of heart rate is less impaired by glycopyrrolate than by atropine.

Bronchoconstriction. Bronchospasm can occur after the administration of neostigmine in surgical patients.[125,126] Anticholinesterases (e.g., neostigmine) stimulate muscarinic receptors in airway smooth muscle; stimulation of these receptors can provoke bronchoconstriction. Neostigmine and pyridostigmine induce a phosphatidylinositol response (a reflection of smooth muscle contraction induced by a muscarinic agonist) in airway muscle, which can result in bronchoconstriction.[127] This response was inhibited in the presence of atropine, a direct bronchodilator. Edrophonium did not induce a phosphatidylinositol response. In patients with cervical spinal cord injuries, neostigmine alone caused bronchoconstriction, whereas neostigmine combined with glycopyrrolate caused bronchodilation.[128] The risk of perioperative bronchospasm appears low if anticholinesterases are administered concurrently with anticholinergics.

SUGAMMADEX REVERSAL OF NEUROMUSCULAR BLOCKADE

Sugammadex (Org 25969) is a modified γ-cyclodextrin and the first selective relaxant–binding agent based on an encapsulating principle for inactivation of a neuromuscular blocking agent (*su* refers to sugar, and *gammadex* refers to the structural molecule γ-cyclodextrin). This principle for reversal of rocuronium- and vecuronium-induced neuromuscular blockade was first introduced into clinical practice in 2008 and is now available for pediatric and adult anesthesia in most countries worldwide. The complex formation of sugammadex and rocuronium or vecuronium occurs at all levels of neuromuscular blockade (profound through shallow) and results in a more fast-acting pharmacologic reversal when compared with anticholinesterase drugs. Consequently, sugammadex may markedly reduce postoperative residual neuromuscular blockade in the PACU.[129]

Structure-Activity Relationships and Mechanism of Action

The three natural unmodified cyclodextrins consist of six, seven, and eight cyclic oligosaccharides (i.e., dextrose units joined through one to four glycosyl bonds) and are

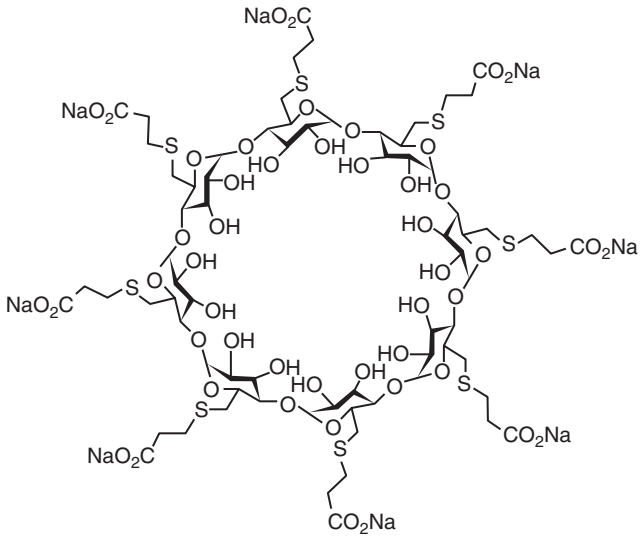

Figure 35-15. Structure of the synthetic γ-cyclodextrin sugammadex (Org 25969). *(From Bom A, Bradley M, Cameron K, et al: A novel concept of reversing neuromuscular block: chemical encapsulating of rocuronium bromide by a cyclodextrin-based synthetic host,* Angew Chem *41:266-270, 2002.)*

called α-, β-, and γ-cyclodextrins, respectively.[130, 131] Their three-dimensional structure resembles a hollow, truncated cone or a doughnut. The structure has a hydrophobic cavity and hydrophilic exterior because of the presence of polar hydroxyl groups. Hydrophobic interactions trap the lipophilic molecules in the cyclodextrin cavity, thereby resulting in the formation of a water-soluble guest-host complex. Sugammadex is built on this principle ring structure but is a modified γ-cyclodextrin. Although an unmodified γ-cyclodextrin possesses a larger lipophilic cavity (7.5 to 8.3 Å) than α- or β-cyclodextrins, it is still not deep enough to accommodate the larger rigid structure of the rocuronium molecule. Therefore, the cavity is modified by adding eight side chains to extend it to 11 Å for better accommodation of the four hydrophobic steroidal rings of rocuronium. Furthermore, at the end of these side chains, negatively charged carboxyl groups are added to enhance electrostatic binding to the positively charged quaternary nitrogen of rocuronium (Fig. 35-15).[131,132] The stability of the rocuronium-sugammadex complex is a result of the combination of intermolecular forces (van der Waals forces), including thermodynamic (hydrogen bonds) and hydrophobic interactions.[131-133] Sugammadex forms a rigid complex in a 1:1 ratio with steroidal neuromuscular blocking drugs (rocuronium and vecuronium) (Fig. 35-16).[131] There is some binding affinity with pancuronium, but this interaction is too low to have a significant clinical effect. The molecular mass of the sugammadex-rocuronium complex is 2532 g/mol (sugammadex 2002 g/mol and rocuronium 530 g/mol), and that of the sugammadex-vecuronium complex is 2640 g/mol (vecuronium 638 g/mol).[131] The rocuronium-sugammadex complex exists in an equilibrium with an association/dissociation rate of 1 molar concentration of sugammadex and rocuronium of 25,000,000:1, which

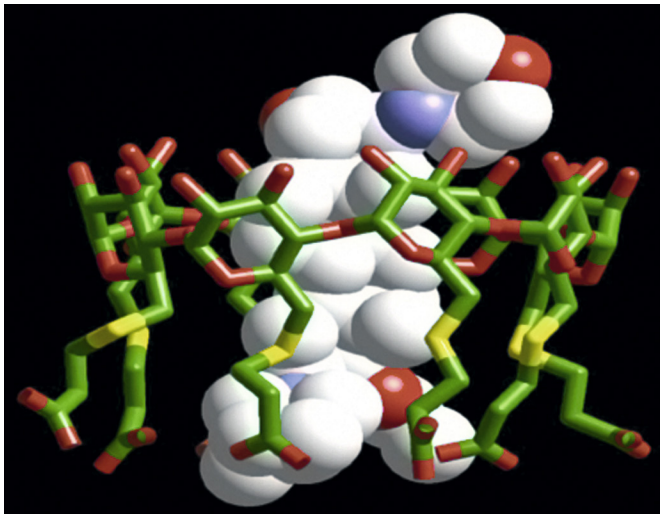

Figure 35-16. The sugammadex-rocuronium complex. *(From Bom A, Bradley M, Cameron K, et al: A novel concept of reversing neuromuscular block: chemical encapsulating of rocuronium bromide by a cyclodextrin-based synthetic host,* Angew Chem *41:266-270, 2002.)*

means that sugammadex forms a very rigid complex and encapsulates rocuronium at 25 million times the rate that one molecule complex dissociates. The affinity of sugammadex toward vecuronium is 2.5 times smaller, but still high enough to form a tight complex.[131] Rapid binding of rocuronium and sugammadex results in removal of free rocuronium molecules from the plasma. This creates a concentration gradient favoring movement of the remaining rocuronium molecules from the effect site at the neuromuscular junction into plasma, where the drug is encapsulated by free sugammadex molecules. Neuromuscular blockade is quickly reversed as rocuronium is removed from the binding sites at the neuromuscular junction. Sugammadex administration results in an increase in the total plasma concentration of rocuronium (free and that bound to sugammadex).[134] Because sugammadex acts as a selective binding agent and has no direct or indirect action on the molecular components of cholinergic transmission (cholinesterase, nicotinic receptors, or muscarinic receptors), the need for coadministration of anticholinergic drugs is eliminated.[135]

Pharmacokinetics

The pharmacokinetic profile of sugammadex and rocuronium has been investigated in healthy volunteers and surgical patients.[136] Sugammadex, in a dose range of 0.1 to 8.0 mg/kg in healthy adult volunteers (without neuromuscular blockade), exhibited a dose-linear pharmacokinetic profile, a volume distribution of 18 L, an elimination half-life of 100 minutes, and a plasma clearance rate of 120 mL/min, with up to 80% of the dose being excreted in urine over 24 hours.[136] After encapsulation by sugammadex, rocuronium is less free to distribute to compartments other than those associated with the compartment in which sugammadex resides. During an infusion of rocuronium to maintain a stable depth of neuromuscular blockade, administration of sugammadex increased the measured plasma concentration of rocuronium; rocuronium redistributed from the effect compartment (including the neuromuscular junction) to the central compartment (mostly as the sugammadex complex) as it was encapsulated by sugammadex.[134] The volume of distribution of rocuronium decreases with increasing doses of sugammadex until the volume of distribution of rocuronium approaches the volume of distribution of sugammadex at higher doses.[134] Encapsulation changes the pharmacokinetics of rocuronium. In the absence of sugammadex, rocuronium is eliminated mainly by biliary excretion (>75%) and to a lesser degree by renal excretion (10% to 25%).[137] The main difference in the pharmacokinetic profile of sugammadex and rocuronium is that the clearance of sugammadex is approximately three times slower than that of rocuronium.[136] The rate and amount of urinary excretion of rocuronium when administered alone is slow and small, but when sugammadex (a dose of 2.0 mg/kg or more) is administered, the plasma clearance of rocuronium was decreased by a factor of more than two.[136] This decreased clearance occurs because the biliary route of excretion becomes unavailable for the rocuronium-sugammadex complex as the large size of this complex prohibits additional renal excretion. The clearance of rocuronium after binding by sugammadex decreases to a value approaching the glomerular filtration rate (120 mL/min).[137] However, the renal excretion of rocuronium is increased by more than 100% after administration of 4.0 to 8.0 mg/kg of sugammadex.[137] Following the administration of sugammadex, encapsulation of rocuronium in the plasma results in a rapid decrease in free rocuronium in this compartment, although the total plasma concentration of rocuronium (both free and bound by sugammadex) increases. This results in a concentration gradient between the relatively high level of free rocuronium in the effect compartment (the neuromuscular junction) and the low level in the plasma compartment.[134] As a result, free rocuronium molecules return to the plasma compartment and are encapsulated by sugammadex. Thus, the increase in plasma levels of rocuronium after sugammadex administration illustrates the mechanism responsible for the rapid reversal of neuromuscular blockade by sugammadex.

Because renal excretion is the primary route for the elimination of sugammadex and the rocuronium-sugammadex complex, studies on elimination by dialysis have considerable relevance in clinical practice. In a small subset of patients with severe renal impairment, an investigation on dialysis showed that the clearance of sugammadex and rocuronium in blood was 78 and 89 mL/min, respectively. Therefore, hemodialysis using a high-flux dialysis method is effective in removing sugammadex and the sugammadex-rocuronium complex in patients with severe renal impairment.[138]

Pharmacodynamics

Clinical Use of Sugammadex in Healthy Patients. The first human exposure of sugammadex in male volunteers showed a large dose-dependent, more rapid recovery time from a rocuronium-induced neuromuscular blockade with sugammadex (0.1 to 8.0 mg/kg) as compared with placebo.[136] Administration of 8 mg/kg of sugammadex 3 minutes after a bolus dose of 0.6 mg/kg of rocuronium resulted in a recovery of the TOF ratio to 0.90 within 2 minutes compared with

52 minutes for placebo. Decreasing the dose of sugammadex to 4 mg/kg resulted in recovery of the TOF ratio to 0.90 in less than 4 minutes.[136] Similar recovery times were found in a study in which surgical patients received 0.6 mg/kg rocuronium, followed by different doses of sugammadex or placebo administered at a TOF count of 2.[139] Sugammadex reduced the median recovery time in a dose-dependent manner from 21 minutes in the placebo group to 1.1 minutes in the group receiving 4.0 mg/kg of sugammadex.[139] In another study, administration of sugammadex resulted in a more rapid and effective recovery from a rocuronium (0.6 mg/kg) or vecuronium (0.1 mg/kg) neuromuscular blockade.[140] After a dose of 4.0 mg/kg of sugammadex, the mean recovery time to a TOF ratio of 0.90 was 1.1 minutes and 1.5 minutes after rocuronium and vecuronium, respectively (Figs. 35-17 and 35-18).[140] Reversal of neuromuscular blockade with larger doses of rocuronium (1.0 to 1.2 mg/kg) by different doses of sugammadex (2.0 to 16.0 mg/kg) at different time points (3 to 15 minutes after rocuronium) showed a dose dependent, rapid, and effective reversal compared with placebo.[141-144]

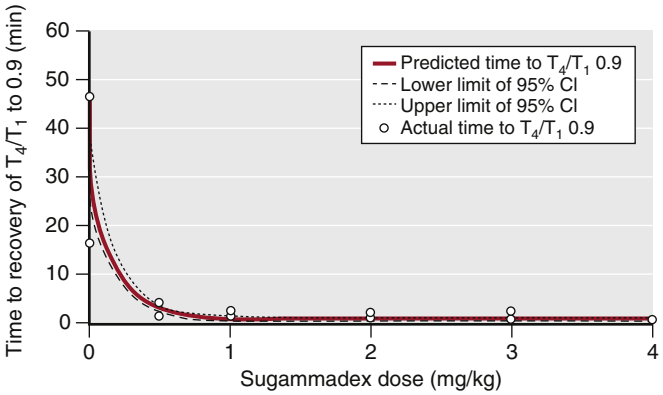

Figure 35-17. The dose-response relation of sugammadex dose and time to recovery of the T4/T1 ratio to 0.9 with rocuronium 0.6 mg/kg. *(From Suy K, Morias K, Cammu G, et al: Effective reversal of moderate rocuronium- or vecuronium-induced neuromuscular block with sugammadex, a selective relaxant binding agent,* Anesthesiology *106:283-288, 2007.)*

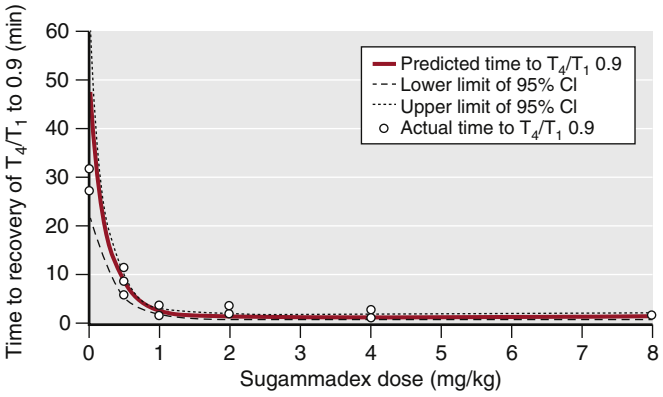

Figure 35-18. The dose-response relation of sugammadex dose and time to recovery of the T4/T1 ratio to 0.9 with vecuronium 0.1 mg/kg. *(From Suy K, Morias K, Cammu G, et al: Effective reversal of moderate rocuronium- or vecuronium-induced neuromuscular block with sugammadex, a selective relaxant binding agent,* Anesthesiology *106:283-288, 2007.)*

Whereas anticholinesterase drugs, such as neostigmine, are unable to reverse deeper levels of neuromuscular blockade (e.g., posttetanic count of 1 to 2) because of a ceiling effect, sugammadex is effective in reversing profound neuromuscular blockade.[141,145] Optimal doses of sugammadex of 4.0 mg/kg produced prompt recovery of the TOF ratio to 0.90 within minutes (Table 35-7).[140-145] Therefore, reversal of moderate and profound rocuronium and vecuronium neuromuscular blockades can be reliably achieved by administration of sugammadex, provided a dose of 2.0 and 4.0 mg/kg, respectively, is used. Because neostigmine has neuromuscular effects when given alone, some spontaneous recovery of the TOF should be evident before it is given. In contrast, sugammadex has no neuromuscular effects when given alone. Accordingly, sugammadex can be given even if there is no response to TOF stimulation. Sugammadex allows a profound neuromuscular blockade to continue until the end of surgery.

In contrast to the anticholinesterase drugs (e.g., neostigmine), intense neuromuscular blockade (no response to TOF and PTC stimulation) can be reversed by sugammadex immediately after the administration of rocuronium. In a multicenter investigation, patients were randomized to receive 1.2 mg/kg of rocuronium followed 3 minutes later by 16 mg/kg of sugammadex or a dose of 1.0 mg/kg of succinylcholine.[146] The mean time to 90% recovery of the first twitch (T1) from the start of sugammadex administration was 2.9 minutes and to a recovery of the TOF ratio to 0.90 was 2.2 minutes.[146] In contrast, the spontaneous recovery time from a succinylcholine neuromuscular blockade to 90% recovery of T1 was 10.9 minutes. Thus, reversal of large doses of rocuronium with 16 mg/kg sugammadex was significantly faster than spontaneous recovery from succinylcholine (Fig. 35-19).[146]

*Recovery times (minutes) from the start of administration of sugammadex or placebo to recovery of the TOF ratio to 0.90.

These findings were confirmed in a randomized trial that assessed how rapidly spontaneous ventilation could be reestablished after rapid sequence induction of anesthesia and intubation of the trachea, using either the combination of rocuronium (1.0 mg/kg)–sugammadex (16 mg/kg) or succinylcholine (1.0 mg/kg).[147] The median time from tracheal intubation to spontaneous ventilation was 406 seconds with succinylcholine and 216 seconds with rocuronium-sugammadex (Table 35-8).[147] These data demonstrated that sugammadex reversal of a large-dose rocuronium neuromuscular blockade was not only significantly faster than spontaneous recovery from succinylcholine, but that spontaneous ventilation could be restored more rapidly (i.e., this dose can be used to replace succinylcholine for endotracheal intubation). In clinical practice and during an unexpected difficult airway (cannot intubate, cannot ventilate scenario), a rocuronium neuromuscular blockade may be reversed by sugammadex immediately in order to restore spontaneous ventilation.

When sugammadex was compared with neostigmine or edrophonium, the time course of neuromuscular recovery was markedly different.[148-150] In a clinical study, patients received 0.6 mg/kg of rocuronium after which neuromuscular blockade was sustained with supplemental boluses of rocuronium given at the reappearance of the second twitch (second response to TOF stimulation or T2).[148] Fifteen minutes after the last dose of rocuronium either 70 μg/kg of neostigmine, 1 mg/kg of edrophonium, or 4.0 mg/kg sugammadex was administered. The average time to achieve a TOF ratio of 0.90 was 10 times longer after the administration of neostigmine than it was after sugammadex (1044 seconds versus 107 seconds) and 3 times longer after the administration of edrophonium (331 seconds). In another study by Blobner and associates, similar differences were found when comparing reversal of rocuronium at the reappearance of the second twitch in the TOF response using 2 mg/kg sugammadex versus neostigmine 50 μg/kg.[149] This was also confirmed in an investigation that assessed the efficacy of sugammadex versus neostigmine for reversal of profound rocuronium-induced neuromuscular blockade.[150] More than 97% of patients reversed with sugammadex (4.0 mg/kg) at a PTC of 1 to 2 recovered to a TOF ratio of 0.90 within 5 minutes. In contrast, 73% of the patients administered neostigmine (70 μg/kg)

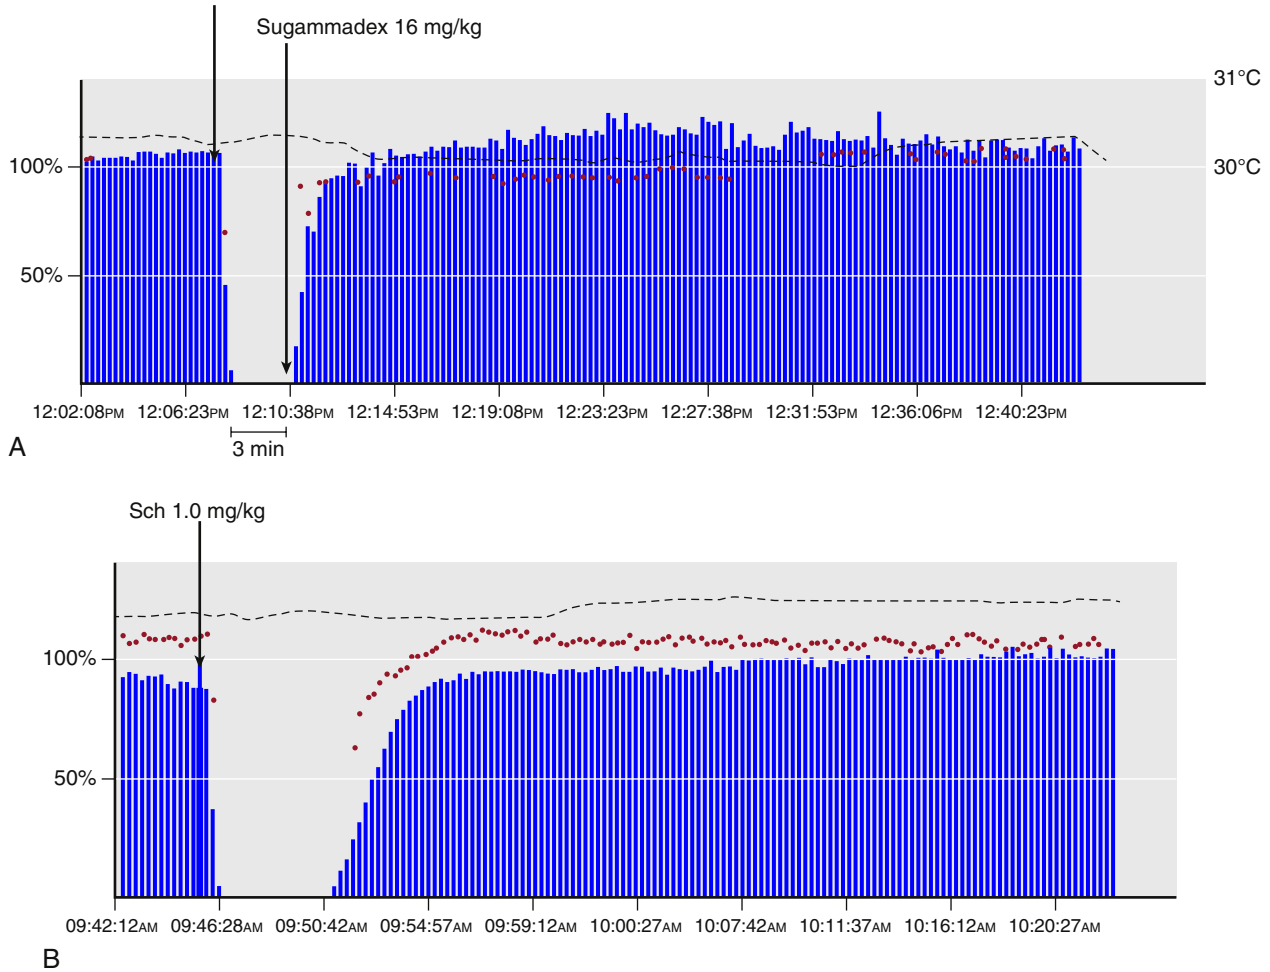

Figure 35-19. A, Recovery of T1 twitch height (*blue tracings*) and the train-of-four (TOF) ratio (*red dots*) after the administration of 1.2 mg/kg of rocuronium, followed 3 minutes later by 16 mg/kg of sugammadex, both given intravenously. Recovery to a first twitch height (T1) of 90% and a TOF ratio of 0.94 occurred 110 seconds later. The onset-offset time with this sequence (i.e., time from the end of the injection of rocuronium until T1 recovery to 90%) was 4 minutes, 47 seconds. **B,** Effects of administering 1.0 mg/kg of succinylcholine (Sch) with spontaneous recovery to a T1 recovery to 90% occurring after 9 minutes, 23 seconds. *Black dashed line* represents hand skin temperature (degrees Celcius). *(From Naguib M: Sugammadex: another milestone in clinical neuromuscular pharmacology,* Anesth Analg *104:575-581, 2007.)*

recovered between 30 and 60 minutes after administration, with 23% requiring more than 60 minutes to recover to a TOF ratio of 0.90 (Fig. 35-20).

A randomized trial compared the efficacy of sugammadex reversal of a rocuronium (0.6 mg/kg) neuromuscular blockade with that of neostigmine reversal of a cisatracurium (0.15 mg/kg) neuromuscular blockade.[151] Time from the start of administration of reversal agent sugammadex 2.0 mg/kg or neostigmine 50 μg/kg) to recovery of the TOF ratio to 0.90 was 4.7 times faster with sugammadex than with neostigmine, 1.9 versus 9.0 minutes, respectively.

Unlike with neostigmine or edrophonium, the choice of anesthetic (e.g., propofol versus sevoflurane) does not influence the ability of sugammadex to reverse rocuronium-induced neuromuscular blockade.[152,153] Provided that sugammadex is used in recommended dosages according to the level of neuromuscular blockade, a small risk exists of incomplete neuromuscular recovery or reoccurrence of neuromuscular blockade following surgery.

Clinical Use of Sugammadex in Pediatric and Older Adult Patients

Pediatrics. The use of sugammadex in pediatric patients (also see Chapter 93) was examined in a study enrolling 8 infants (28 days to 23 months), 24 children (2 to 11 years), and 31 adolescents (12 to 17 years).[154] Patients were anesthetized with propofol and opioids and received rocuronium 0.6 mg/kg. At the reappearance of T2 (second twitch), patients were given sugammadex 0.5, 1.0, 2.0 or 4.0 mg/kg or placebo. Recovery time to a TOF ratio of 0.90 decreased in a dose-dependent manner in all age groups. Residual neuromuscular blockade or recurarization was not observed, and no side effects were reported. In a more recent case report, sugammadex was used successfully in reversing a vecuronium-induced neuromuscular blockade in a 7-month-old infant.[155] Another case report described a 2-year-old patient who received readministration of rocuronium for reoperation after an initial successful reversal with sugammadex.[156] Sugammadex can be used safely in children and adolescents (2 to 17 years old). Information on the use of sugammadex in pediatric patients less than 2 years old is still limited.

Older Adult Patients. Reversal of neuromuscular blockade by sugammadex has been assessed in older patients (also see Chapter 80). One hundred and fifty patients were divided into three groups; an adult group (18 to 64 years old),

*One patient was excluded from the control group (normal renal function) because of unreliable TOF traces.

an older adult group (65 to 75 years old), and an oldest adult group (75 years or older).[157] Patients received an intubating dose of rocuronium 0.6 mg/kg with maintenance doses of 0.15 mg/kg as required. Sugammadex 2.0 mg/kg was administered after the last dose of rocuronium at the reappearance of T2. Recovery of neuromuscular blockade by sugammadex was slightly (0.7 minutes) faster in patients younger than 65 years of age. In general, a prolonged circulation time secondary to a reduced cardiac output in older patients was anticipated to result in a longer recovery time from neuromuscular blockade after administration of sugammadex.[158,159] However, based on these results, no dose adjustments are needed in older patients.[157]

Clinical Use of Sugammadex in Special Patient Populations

Cardiac Disease. Studies evaluating the safety and efficacy of sugammadex in patients with underlying cardiovascular disease have not demonstrated an effect of sugammadex on electrocardiogram (no indication of a possible prolongation effect on the QTc interval).[160,161] A study designed to evaluate the effects of sugammadex on QTc prolongation in healthy subjects (in doses up to 32 mg/kg, alone or in combination with rocuronium or vecuronium) revealed that the administration of sugammadex was not associated with QTc prolongation.[161] In a case report of a patient with long QT syndrome, a vecuronium neuromuscular blockade was reversed with sugammadex 2 mg/kg without adversely affecting the QT interval.[162] Based on current data, sugammadex reversal is not associated with cardiovascular side effects in healthy patients or in those with cardiovascular comorbidities (also see "Complications Associated With Inhibitors of Acetylcholinesterase").

Pulmonary Disease. Patients with a history of pulmonary disease have an increased risk of postoperative pulmonary complications such as pneumonia, respiratory failure, and exacerbation of the underlying pulmonary disease.[163] Sugammadex has been studied in patients with pulmonary disease.[163] Seventy-seven surgical patients with a diagnosis or known history of pulmonary disorders received sugammadex in doses up to 4 mg/kg in order to reverse a rocuronium neuromuscular blockade. As in other adult patient groups, reversal of a rocuronium-induced neuromuscular blockade was rapid, and there were no signs of residual neuromuscular blockade or recurarization.[164] Of the 77 patients treated with sugammadex, 2 patients developed bronchospasm, 1 minute and 55 minutes respectively, after the administration of sugammadex. Both patients were asthmatic, and there was no evidence that these symptoms were related to sugammadex. In other subsets of high-risk pulmonary patients (cystic fibrosis and end-stage lung disease), the successful use of sugammadex has been reported.[165] Reversal of a neuromuscular blockade with sugammadex has potential advantages compared with anticholinesterase drugs (e.g., neostigmine) in patients with pulmonary disease, because sugammadex lacks interactions with the muscarinic cholinergic system, and there is no need for coadministration of anticholinergic compounds (also see "Complications Associated With Inhibitors of Acetylcholinesterase").

Renal Failure. The use of sugammadex to reverse rocuronium neuromuscular blockade was investigated in 15 patients with severe renal impairment (creatinine clearance <30 mL/min) and compared with 15 patients with normal renal function (creatinine clearance >80 mL/min).[166] Sugammadex 2 mg/kg was administered at the reappearance of T2. There were no differences between groups in the recovery profile or the incidence of residual blockade after sugammadex (Table 35-9). Because complete elimination of the sugammadex-rocuronium complex remains poorly understood in renal impairment, sugammadex is at present not recommended for use in patients with severe renal failure. However, it can be used in patients with mild or moderate renal dysfunction.[166] Theoretically, because of the molecular mass of the rocuronium/vecuronium-sugammadex complex, it is possible to decrease the plasma levels of this complex by dialysis. Hemodialysis using a high-flux dialysis method has been demonstrated to be effective in removing sugammadex and the sugammadex-rocuronium complex in patients with severe renal impairment.[138]

Hepatobiliary Disease. Sugammadex has not been studied in animal models or in patients with hepatic impairment. However, it is known that the biliary route of excretion becomes unavailable for either sugammadex or the rocuronium/vecuronium-sugammadex complex, because the large size of this complex prohibits such excretion.[167] A population pharmacokinetic/pharmacodynamic (PK-PD)

model was used to simulate the scenario of an immediate reversal and reversal of a profound rocuronium-induced neuromuscular blockade in patients with hepatic impairment.[167] Under such study conditions, hepatic impairment had little effect on the reversal time when sugammadex (16 mg/kg) was administered 3 minutes after rocuronium (1.2 mg/kg). However, in other scenarios (sugammadex 2 mg/kg at reappearance of T2 and 4 mg/kg after 15 minutes), recovery from a rocuronium-induced (1.2 mg/kg) neuromuscular blockade was predicted to be longer than that seen in healthy patients.[167] In patients with hepatobiliary disease, the recovery of neuromuscular function after sugammadex administration will likely be faster than reversal with anticholinesterase drugs (but not be as rapid as patients without hepatobiliary disease). The explanation of the slower reversal is not yet fully understood and needs to be investigated in clinical studies. Based on limited available data, sugammadex should be used with caution in patients with hepatobiliary disease.

Obesity. Patients with obesity, particularly morbid obesity (body mass index [BMI] > 40 kg/m^2), are at risk for cardiovascular and respiratory complications perioperatively (also see Chapter 71).[168] These patients are susceptible to critical respiratory events in the postoperative period, including hypoventilation, hypoxia, airway obstruction, and acute respiratory failure.[38,67] The presence of postoperative residual neuromuscular blockade may further increase the risk for postoperative complications in these patients by producing impairment of the integrity of the upper airway and upper airway collapse.[33,34] Therefore, a rapid and complete reversal of neuromuscular blockade must be achieved before tracheal extubation is attempted. In this setting, sugammadex may have a more favorable recovery profile than traditional anticholinesterase drugs because it provides a more reliable recovery of neuromuscular functions and a less frequent risk of incomplete neuromuscular recovery.[168] A key issue is determining the appropriate dose of sugammadex to administer in a morbidly obese patient that is sufficient to capture remaining NMBD molecules. Whereas the dosing of NMBDs in obese patients should be based on lean/ideal body weight (because these drugs are hydrophilic and their volume of distribution is minimally affected by obesity), the dosing of sugammadex in obese patients is currently under debate. In order to ensure complete neuromuscular recovery, the dose of sugammadex must be sufficient to affect the gradient between the peripheral and central compartments and effectively encapsulate all rocuronium molecules. An inadequate dose of sugammadex may be incapable of sustaining this redistribution of rocuronium and lead to reoccurrence of the neuromuscular blockade.

The current product monograph recommends calculating the sugammadex dose based on the patient's actual body weight. However, because the low volume of distribution at steady state (estimated at 0.16 L/kg) restricts distribution to the intravascular space, it might be relevant to determine the dose of sugammadex based on the lean/ideal body weight and not on the actual body weight.[166] Several studies have investigated the dosage of sugammadex based on lean or variations on the lean/ideal body weight.[169-172] In one investigation, a sugammadex dose of 4 mg/kg based on a lean/ideal body weight calculation was administered to morbidly obese patients during a profound rocuronium neuromuscular blockade.[171] Approximately 40% of these patients were inadequately reversed with a lean/ideal body weight–based dose of sugammadex. In these patients, an additional dose of sugammadex 2 mg/kg based on lean/ideal body weight was required to achieve a TOF ratio 0.90. The conclusion of the authors was that a sugammadex dose calculated according to lean/ideal body weight was insufficient for reversing both profound and moderate blockade in a considerable number of morbidly obese patients.[171]

In another study in morbidly obese patients, investigators examined reversal of a moderate level of a rocuronium neuromuscular blockade (at T1-T2) using a dose of sugammadex of 2.0 mg/kg.[170] Four different weight corrections were used: lean/ideal body weight, lean/ideal body weight +20%, lean/ideal body weight +40%, and actual body weight. This study demonstrated that a moderate rocuronium neuromuscular blockade could be effectively reversed with sugammadex 2.0 mg/kg using the calculation lean/ideal body weight +40%.[170] However, longer and great interindividual variability of recovery times occur when dosing is based on lean/ideal body weight compared with dosing based on actual body weight.[170,171] Additionally, reoccurrence of neuromuscular blockade after suboptimal dosing of sugammadex has been reported in a morbidly obese patient.[172] Therefore, the dosing of sugammadex in obese patients is still under debate. Until more data are available, the dose of sugammadex should be based on the actual body weight.

Cesarean Section and Pregnant Patients. Induction of general anesthesia in late pregnancy and for patients undergoing cesarean section typically involves a rapid sequence induction of anesthesia with either thiopental or propofol and a rapid-onset neuromuscular blocking drug (also see Chapter 77). For decades, succinylcholine has been the prototypic NMBD used in these procedures to produce optimal endotracheal intubation conditions.[173] Rocuronium is an acceptable alternative to succinylcholine in rapid sequence induction of anesthesia procedures; rocuronium in doses larger than 1.0 mg/kg not only provides onset of action within 60 seconds, but also identical intubation conditions compared with succinylcholine.[174] However, the duration of action of rocuronium in dosages of 1.0 mg/kg or greater will result in a profound neuromuscular blockade of long duration (often more than 2 hours). Furthermore, the risk of failed intubation in the obstetric population is at least eight times higher compared with nonpregnant females.[175] In case of a failed endotracheal intubation scenario or a "cannot intubate, cannot ventilate" situation, rocuronium, even in dosages up to 1.2 mg/kg, can be immediately reversed with sugammadex 16 mg/kg.[146]

Preclinical animal data demonstrated that uteroplacental transfer of sugammadex is very small (<2% to 6%). Sugammadex does not have negative effects on pregnancy or on embryonic, fetal, or postnatal development.[173,176,177] Although no data are available about the excretion of sugammadex in human breast milk, excretion in breast milk is likely minimal, with insignificant clinical impact because oral absorption of cyclodextrins

in general is small. Therefore, sugammadex can be used in breastfeeding females. In two case series examining obstetric patients who received rocuronium and sugammadex (7 and 18 patients), no side effects were observed.[176,177] The efficacy and safety of sugammadex in obstetric anesthesia has not been determined; yet serious adverse events for the mother or the neonate have not been reported after sugammadex.

Neuromuscular Disorders. Neuromuscular disorders are frequently associated with an increased incidence of perioperative respiratory complications due to muscle weakness.[178,179] In these patient groups, administration of succinylcholine is often contraindicated and associated with potential life-threatening side effects. The use of nondepolarizing NMBDs can on occasion be associated with prolonged spontaneous neuromuscular recovery, even after a single dose. Consequently, these patients have an increased risk for postoperative muscle weakness of multifactorial origin, one being residual neuromuscular blockade.[178,179] Prompt recovery of neuromuscular function is essential in order to optimize patient safety and reduce the risk of pulmonary complications. However, reversal with anticholinesterase (e.g., neostigmine), especially in neuromuscular disorders, can be associated with postoperative complications.[179]

Multiple case reports describe the use of sugammadex in patients with various neuromuscular disorders such as myasthenia gravis, myotonic dystrophy, and spinal muscular atrophy (Fig. 35-21).[180-184] In general, dosing regimens for sugammadex were consistent with recommended doses adjusted to actual body weight and based on the level of neuromuscular blockade at the time of reversal. Sugammadex administration resulted in prompt reversal of neuromuscular blockade with a similar recovery profile as observed in normal patients. Although no studies have been performed in patients with neuromuscular disorders, the reported cases indicate that sugammadex should be considered as an alternative reversal drug (e.g., instead of neostigmine) in this patient population. These observations need to be confirmed in a larger series of patient studies.

Side Effects and Drug Interactions

Sugammadex is contraindicated in patients with known hypersensitivity to the drug. The potential for hypersensitivity is currently under investigation. At the time this chapter was written, sugammadex had been approved in many countries in the world, but not in the United States or Canada. Hypersensitivity was the major concern; however, this is difficult to study because hypersensitivity reactions occur rarely. Other reported side effects include coughing, movement, parosmia (abnormal sense of smell), and elevated levels of *N*-acetyl-glucosaminidase in the urine.[167] Coughing and movement after the administration of sugammadex may have been due to the unmasking of inadequate anesthesia rather than a direct side effect of sugammadex. These observations recall the old saying that patients are often "adequately paralyzed, but not anesthetized." This concern has existed for decades, well before the introduction of sugammadex. Cyclodextrins, such as sugammadex, are well known for their ability to form inclusion complexes with other compounds. Sugammadex forms a very tight complex with rocuronium or vecuronium in a 1:1 molecular ratio; however, because of its mechanism of action, it is possible that other relevant drug interactions may occur.[185] Theoretically, two important drug interactions can take place. First, sugammadex is capable of encapsulating endogenous or pharmaceutical molecules other than steroidal neuromuscular blocking drugs, resulting in reduced efficacy of the encapsulated molecules. However, the ability to form complexes with steroidal or nonsteroidal molecules such as cortisone, atropine, and verapamil is clinically insignificant, because the affinity for sugammadex is 120 to 700 times less than that of rocuronium.[185] In preclinical studies, an interaction of sugammadex with other steroidal compounds could be excluded up to a dose of sugammadex of 500 mg/kg/day.[186] Second, if the affinity of sugammadex for another molecule is very high, this molecule may displace rocuronium or vecuronium from the complex with sugammadex, resulting in reoccurrence of neuromuscular blockade. Both drug interactions may have potential clinical safety implications.[185] A modeling approach has been developed to evaluate 300 compounds (including the most commonly used drugs in the perioperative period) for possible displacement interactions with sugammadex.[185] In this screening, three compounds were identified as having possible displacement interactions: toremifene, fusidic acid, and flucloxacillin.[185] However, no clinically relevant reoccurrence of neuromuscular blockade was identified when sugammadex was used in combination with these drugs.[185] A clinical study reported that flucloxacillin did not cause reoccurrence of neuromuscular blockade after

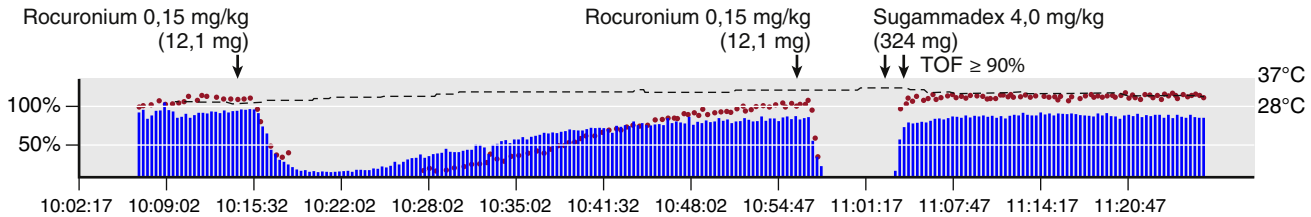

Figure 35-21. Original tracing of sugammadex reversal in a patient with myasthenia gravis. The time to spontaneous recovery from the first profound rocuronium-induced neuromuscular blockade to a TOF ratio was 36.5 minutes. The time from the start of the administration of sugammadex 4.0 mg/kg after the second dose of rocuronium to the recovery of the TOF ratio to 0.90 was 2.7 minutes. *Blue tracing* represent T1 recovery while *red dots* represent TOF ratio recovery. *Black dashed line* indicates hand skin temperature (degrees Celcius). *(From de Boer HD, van Egmond J, Driessen JJ, et al: A new approach to anesthesia management in myasthenia gravis: reversal of neuromuscular blockade by sugammadex,* Rev Esp Anesthesiol Reanim *57: 81-84, 2010.)*

reversal with sugammadex; no clinically important displacement interaction was observed.[187]

Special Considerations

Reintubation of the Trachea After Initial Reversal of Neuromuscular Blockade With Sugammadex. Patients receiving sugammadex before extubation of the trachea who need reintubation require special consideration because the remaining circulating sugammadex molecules may potentially interfere with readministration of rocuronium or vecuronium. In this setting, two alternate strategies can reestablish a neuromuscular blockade. Within 24 hours of sugammadex administration, it is currently recommended that a nonsteroidal NMBD be used instead of rocuronium or vecuronium. This conservative approach is based on the maximum clearance time for sugammadex. However, preclinical and clinical studies have shown that it is possible to safely reestablish neuromuscular blockade with rocuronium earlier than 24 hours.[188] A modeling-based study in healthy volunteers revealed that high-dose rocuronium given 5 to 60 minutes after sugammadex reversal produced a complete neuromuscular blockade (T1 = 0%).[189] Rocuronium (1.2 mg/kg) administrated 5 minutes after sugammadex reversal produced a rapid onset of neuromuscular blockade (T1 = 0%), with a mean onset time of approximately 3 minutes. Thirty minutes after administration of sugammadex, an onset time of 1.5 minutes can be achieved with rocuronium (1.2 mg/kg). Hence an inverse relationship exists between the onset time and the time interval between sugammadex and the repeat dose of rocuronium, and a direct relationship exists between the duration of neuromuscular blockade and the time interval between sugammadex and the repeat dose of rocuronium.

Based on dose calculations using a model in which the equilibrium is described in the common volume of distribution of rocuronium and sugammadex, even a second reversal is possible using sugammadex with large doses between 8 and 20 mg/kg.[188]

Incomplete Reversal of Neuromuscular Blockade. Although sugammadex encapsulates rocuronium and vecuronium to form a rigid complex, case reports have described incomplete reversal of neuromuscular blockade.[141,190] In a dose-finding study, a case was described in which a temporary decrease in the TOF response was observed in a healthy patient after reversal with 0.5 mg/kg sugammadex.[190] The TOF ratio initially reached 0.70 before decreasing to 0.30 and then gradually increasing to 0.90 (Fig. 35-22). The authors hypothesized that the decrease in TOF ratio occurred because of redistribution of unbound rocuronium from the peripheral compartments, with insufficient sugammadex available for additional encapsulation of rocuronium. Similarly, incomplete reversal was reported in two healthy patients given suboptimal doses of sugammadex (0.5 mg/kg) during profound rocuronium-induced neuromuscular blockade.[141] Therefore, the recommended dose adjusted to the depth of neuromuscular blockade should be administered.

Female Patients. Sugammadex may interact with hormonal contraceptive drugs. Possible capturing interactions, whereby unwanted encapsulation of a third drug by sugammadex reduces its clinical efficacy, have been investigated. In pharmacokinetic-pharmacodynamic simulations, it was predicted that 34% of (free) etonogestrel might be captured by 4 mg/kg sugammadex under very conservative modeling assumption conditions.[186] The interaction with this bolus dose of sugammadex resulted in a decrease in etonogestrel exposure, which was similar to the decrease seen after one missed daily dose of an oral contraceptive. Patients using hormonal contraceptives should be informed about the possible reduced effectiveness of hormonal contraceptive drugs after the administration of sugammadex. The use of an additional nonhormonal contraceptive method for the next 7 days should be considered in this patient population.

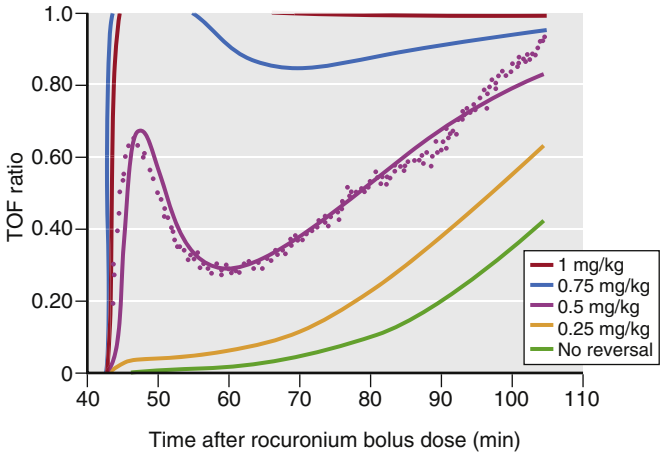

Figure 35-22. The train-of-four data *(dots)* and the results of simulations *(solid lines)* of various sugammadex dosing amounts. Muscle relaxation rebound only occurs for sugammadex doses in a limited range. The simulations indicate that for this patient, doses larger than about 1 mg/kg are sufficient to achieve rapid muscle relaxation reversal and avoid muscle relaxation rebound. *(From Eleveld DJ, Kuizenga K, Proost JH, et al: A temporary decrease in twitch response during reversal of rocuronium-induced muscle relaxation with a small dose of sugammadex,* Anesth Analg *104:582-584, 2007.)*

Electroconvulsive Therapy. Electroconvulsive therapy is the transcutaneous application of small electrical stimuli to the brain for treatment of selected psychiatric disorders like major depression. The tonic-clonic convulsions associated with electroconvulsive therapy can result in injuries such as limb fractures and compression fractures of vertebral bodies. The introduction of anesthesia, especially neuromuscular blockade, can mitigate tonic-clonic motor activity and reduce the physiologic trauma associated with uncontrolled tetanic muscle contractions.[191] Succinylcholine is commonly used as a neuromuscular blocking drug in these patients, and its use is associated with well-known unwanted side effects.[191] Rocuronium has similar efficacy as succinylcholine in electroconvulsive therapy, making it an appropriate alternative to succinylcholine.[192] However, the increased doses of rocuronium required to decrease the onset time are associated with a prolonged duration of neuromuscular blockade. Several reports have evaluated the use of sugammadex in electroconvulsive therapy. These investigations demonstrated that sugammadex produced a complete and rapid reversal of neuromuscular blockade

induced by rocuronium, without signs of residual blockade or other safety concerns.[192-195] Therefore, the combination of rocuronium and sugammadex may be an alternative to succinylcholine for electroconvulsive therapy. However, the required dose of sugammadex in this clinical situation is not well established.

Historically, an important strategy in anesthesia has been to ensure that neuromuscular blockade is sufficiently recovered to achieve adequate antagonism by neostigmine. Having an intense neuromuscular blockade at the end of surgery would more likely result in residual blockade. With the availability of sugammadex, a profound, or deep, neuromuscular blockade has been recommended for the entire duration of laparoscopy. A profound neuromuscular blockade increases surgical space with smaller pressures for the pneumoperitoneum.[196] It is even possible that reducing insufflation pressures may improve patient outcomes.[196] Furthermore, Staehr-Rye and associates[197] have postulated that a deep or profound neuromuscular blockade is associated with more optimal surgical conditions, which leads to less postoperative pain and nausea and vomiting. Sugammadex, at doses of 2 to 8 mg/kg, was given to reverse the blockade when the TOF ratio was less than 0.90.

In Japan, the use of sugammadex is widespread, and Japanese anesthesiologists have one of the largest clinical experiences with sugammadex in the world. A recently published report describes the clinical experience in Japan and provides a look at the role of sugammadex in clinical practice.[198] Notably, although neuromuscular blockade was not routinely monitored intraoperatively, the TOF ratio was determined after tracheal extubation. A total of 249 patients were studied in three separate groups: patients with spontaneous recovery (n = 23) were compared with patients being reversed with either neostigmine (n = 109) or sugammadex 2.7 mg/kg (n = 117). Although the sugammadex group had the least frequent incidence of residual neuromuscular blockade, all three groups had a surprisingly frequent incidence of residual neuromuscular blockade.[198]

A scholarly editorial written by Naguib and associates[199] placed prime emphasis on the dose of sugammadex used for reversal in combination with the lack of neuromuscular monitoring. Although proper monitoring is strongly advisable, an adequate dose of sugammadex is under current debate. Although the reversal effect of neostigmine is not improved by increasing the dose above the recommended dose interval, there are strong reasons to believe that sugammadex in doses larger than 2.7 mg/kg would be more effective for reversal. Others argue that a dose of sugammadex larger than 2.0 mg/kg would not be necessary if proper monitoring were used. Of course, another possibility exists. It would seem that a larger dose of sugammadex plus neuromuscular monitoring would be ideal.

In conclusion, sugammadex is an innovative addition to the armamentarium of reversal of neuromuscular blockade options. Although the expense of sugammadex continues to be an important factor that may limit its use, many institutions currently use sugammadex for routine reversal of neuromuscular blockade. We speculate whether, in the future, larger doses of sugammadex will likely be used and whether routine neuromuscular monitoring will finally be mandatory in anesthetic practice among countries worldwide.

CYSTEINE REVERSAL OF FUMARATE NEUROMUSCULAR BLOCKING DRUGS

A new class of nondepolarizing NMBDs called fumarates has been recently developed. These NMBDs are olefinic (double-bonded) isoquinolinium diester compounds that differ from symmetric benzylisoquinolines such as mivacurium in their unique method of inactivation. The developed drugs (gantacurium [GW280430A, AV430A], CW002, and CW011) bind to L-cysteine to form less active degradation products (Fig. 35-23). The administration of L-cysteine can rapidly inactivate fumarate compounds and reverse neuromuscular blockade.

Gantacurium is an asymmetric α-chlorofumarate that was developed to be a replacement for succinylcholine.[200] Gantacurium has a rapid onset and short duration of effect. The brief duration of gantacurium is primarily due to rapid reaction and subsequent inactivation of the drug with free cysteine in the plasma. The process of adduction of cysteine to gantacurium occurs at the central fumarate double bond. The adduction changes the stereochemistry of gantacurium so that it can no longer bind to the nAChR at the neuromuscular junction. Degradation also occurs through a slower secondary route (pH-sensitive ester hydrolysis) that yields two products without neuromuscular blocking properties.[200,201] CW 002 (a symmetrical fumarate) and CW 011 (an asymmetric maleate) are investigational NMBDs with no halogen (chlorine) substitution at the central double-bonded carbons. The absence of chlorine results in a slower adduction with cysteine; the inactivation of CW 002 and CW 011 is slower than gantacurium, resulting in a duration of action consistent with an intermediate-acting NMBD.

Cysteine is a nonessential endogenous amino acid derived from one molecule of serine and one molecule of methionine. It is composed of L- and D-enantiomers. L-cysteine is a normal building block of protein and is a conditionally essential amino acid in infants.[202] Several therapeutic applications of cysteine in medicine are common. It is often added to total parenteral nutrition solutions for pediatric patients in doses of approximately 80 mg/kg/day. An acetylated derivative of cysteine (*N*-acetyl L-cysteine) is approved for use in the treatment of acute acetaminophen toxicity. In the doses used clinically for these applications, there does not appear to be obvious toxicity. L-cysteine has also been studied for reversal of the neuromuscular blockade for fumarate NMBDs. Several laboratory investigations have attempted to define the L-cysteine dose necessary to effectively reverse gantacurium, CW 002, and CW 011 neuromuscular blockade.

The first of the fumarate NMBDs studied was gantacurium. In monkeys, the total duration of action was one half to one third that of mivacurium at equipotent doses; at three times the ED_{95} doses, the time until 95% twitch recovery was 8.5 ± 0.5 minutes versus 22.0 ± 2.6 minutes, respectively.[201] The administration of edrophonium 0.5 mg/kg accelerated the recovery of blockade. In a human volunteer trial, the time from administration of 0.40 mg/kg of gantacurium (2 × ED_{95}) until a TOF ratio

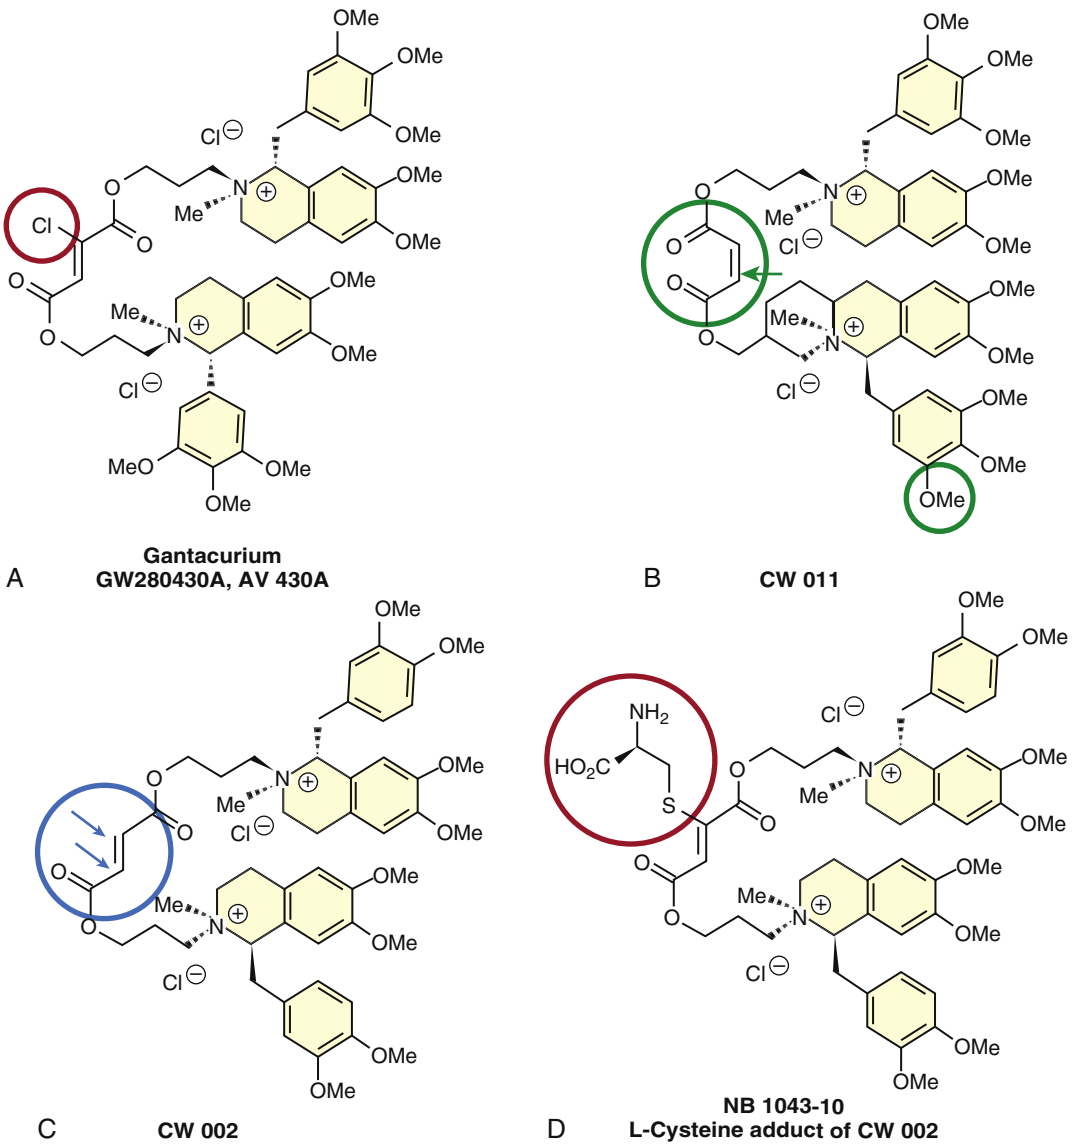

Figure 35-23. The chemical formulas of gantacurium (**A**), CW 011 (**B**), and CW 002 (**C**). Chemical features are as follows: chlorine substitution *(red circle)* on the olefinic double bond of gantacurium, a chlorofumarate, is designed to accelerate the L-cysteine adduction reaction. The fumarate CW 002 is symmetrical with no halogen (chlorine) substitutions and undergoes L-cysteine adduction more slowly than gantacurium, at either olefinic carbon *(blue arrows)*, enabled by the adjacent α-carboxyl (ester) groups. The maleate CW 011 is asymmetric in that one isoquinolinium group contains an extra methoxy substitution *(green circle)*. This may reduce access of L-cysteine to the olefin *(green arrow)* and may decrease the rate of the adduction reaction. The chemical formula of NB 1043-10, the L-cysteine adduct of CW 002, is also shown (**D**). The L-cysteine adduction is highlighted by the *red circle. (From Savarese JJ, McGilvra JD, Sunaga H, et al: Rapid chemical antagonism of neuromuscular blockade by L-cysteine adduction to and inactivation of the olefinic (double-bonded) isoquinolinium diester compounds gantacurium (AV430A), CW 002, and CW 011*, Anesthesiology *113:58-73, 2010.)*

0.90 or greater was achieved was studied during spontaneous recovery or reversal with edrophonium 0.5 mg/kg.[203] Mean recovery time was significantly more rapid in the reversal group (3.8 minutes) compared with the spontaneous recovery group (14.3 minutes). The reversal of gantacurium with cysteine was investigated in monkeys.[202] A bolus of L-cysteine (10 mg/kg) given 1 minute after gantacurium reduced duration from 10.4 ± 3.1 minutes (spontaneous recovery) to 3.0 ± 1.0 minutes ($P < .001$). Antagonism of gantacurium was significantly faster at 1 minute with L-cysteine than edrophonium. These studies suggest that although gantacurium is a short-acting NMBD, recovery can be further enhanced by the administration of L-cysteine.

In contrast to gantacurium, CW 002 and CW 011 have a duration of action between a short-acting and intermediate-acting NMBD. In monkeys given four to five times the ED_{95} of CW 002 and CW 011, the duration of blockade was three times longer than gantacurium (28.1 and 33.3 minutes versus 10.4 minutes), but only half the duration of cisatracurium.[202] The administration of neostigmine 1 minute after CW 002 did not accelerate neuromuscular recovery. Immediate reversal of CW 002 with cysteine (50 mg/kg), however, was highly effective in antagonizing

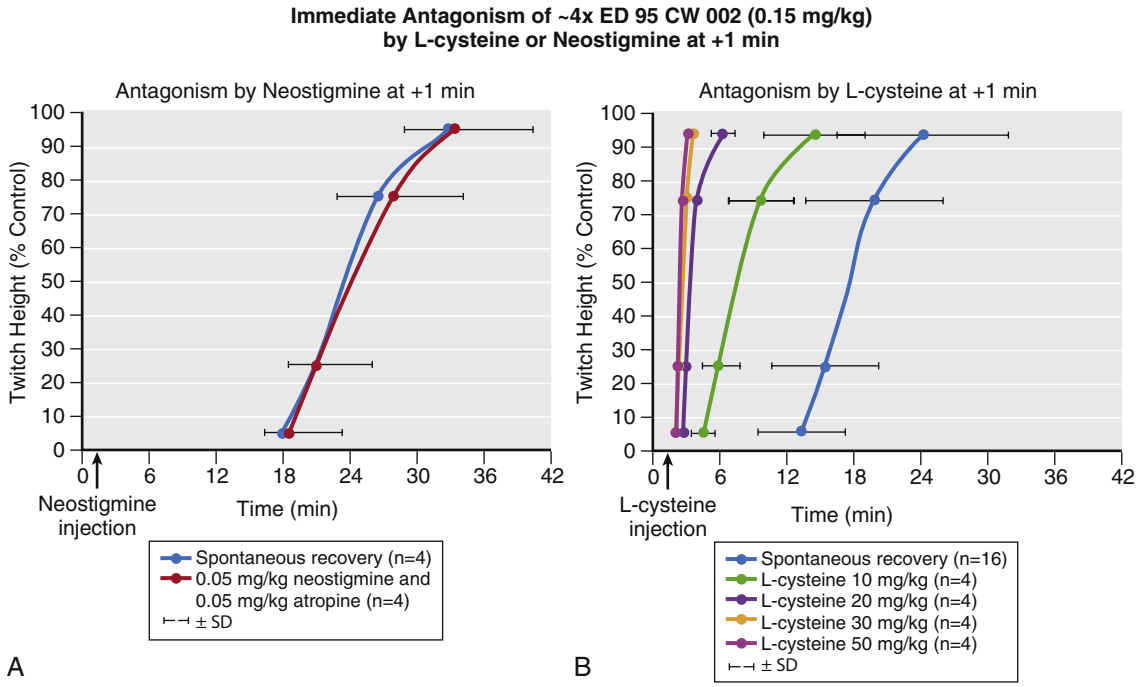

Figure 35-24. Immediate antagonism of CW 002 blockade 1 minute after CW 002 dosage of 0.15 mg/kg, or ≈4 × ED95, injected at $t = 0$. Neostigmine (0.05 mg/kg + atropine 0.05 mg/kg) or L-cysteine (10, 20, 30, or 50 mg/kg) was given at +1 min. Neostigmine did not shorten recovery (**A**), whereas L-cysteine produced a dose-related acceleration of recovery (**B**), peaking at 50 mg/kg. Data were taken from anesthetized rhesus monkeys. *(From Savarese JJ, McGilvra JD, Sunaga H, et al: Rapid chemical antagonism of neuromuscular blockade by L-cysteine adduction to and inactivation of the olefinic (double-bonded) isoquinolinium diester compounds gantacurium (AV430A), CW 002, and CW 011,* Anesthesiology *113:58-73, 2010.)*

neuromuscular blockade (95% of baseline twitch height within 2.2 ± 0.3 minutes and to a TOF ratio of 100% 1 to 2 minutes later)[202] (Fig. 35-24). Similar findings were observed with CW 011 using this model. Larger doses of L-cysteine were needed to optimally reverse CW 002 and CW 011 (50 mg/kg) compared with gantacurium (10 mg/kg); this is likely related to the slower rate of adduction of L-cysteine to these compounds, as well as the greater potency of CW 002 and CW 011. L-Cysteine reversal of CW 002 has also been investigated in a dog model given a dose of 9 × ED_{95}.[204] L-Cysteine (50 mg/kg) reduced the median duration of blockade from 70 minutes (spontaneous recovery) to less than 5 minutes. Doses of up to 200 mg/kg produced minimal hemodynamic changes and resulted in no anatomic, biochemical, or histologic evidence of organ toxicity.

In summary, fumarates are a new class of NMBDs that are inactivated primarily via adduction of cysteine to the double bond of the compounds, resulting in breakdown products that do not bind to the neuromuscular junction. Initial laboratory studies have shown that the administration of exogenous L-cysteine results in complete reversal of deep neuromuscular blockade within 2 to 3 minutes. These studies suggest that chemical antagonism of fumarate NMBDs will allow clinicians to rapidly and completely antagonize neuromuscular blockade, even when large doses of an NMBD have been recently administered. Early clinical trials in human volunteers have examined the pharmacology of gantacurium, and investigations of CW 002 in volunteers are currently ongoing. The optimal dose of L-cysteine is 50 mg/kg in an animal model. The dosing of L-cysteine needed to reverse the effects of gantacurium, CW 002, and CW 011 in humans has not been established. Additional investigations are also needed to determine whether large doses of cysteine produce adverse effects in humans. If future studies are consistent with these early findings, fumarate NMBDs may allow clinicians to maintain profound neuromuscular blockade throughout the surgical procedure with little risk of postoperative residual paralysis.

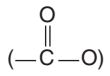
Chapter 36

Local Anesthetics

CHARLES B. BERDE • GARY R. STRICHARTZ

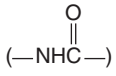
Key Points

- Local anesthetics block voltage-gated sodium channels thereby interrupting the initiation and propagation of nerve impulses in axons. Based on this mechanism of action, local anesthetics provide a wide variety of biologic actions, both desirable and unwanted, and have side effects through other mechanisms.
- Currently available local anesthetics are of two chemical classes: aminoesters and aminoamides.
- The low potency and lack of specificity of available local anesthetics are in part due to the weak structural constraints at their binding site on the sodium channel. Most of their features are derived from the requirement for high solubility and rapid diffusion in both aqueous environments and the lipid phases of biologic membranes.
- Reversible protonation of the tertiary amine group tends to make local anesthetics less charged at more basic pH values and more charged at neutral or acidic pH; the neutral base forms are more soluble in lipid environments, whereas the charged acid forms are more soluble in aqueous environments.
- Aminoesters are metabolized primarily by plasma esterases, and aminoamides are metabolized primarily by hepatic cytochrome P450–linked enzymes.
- The principal systemic toxicities of local anesthetics involve the heart (including atrioventricular conduction block, arrhythmias, myocardial depression, and cardiac arrest) and the brain (including agitation, lethargy, seizures, and generalized central nervous system depression). Hypoxemia and acidosis exacerbate these toxicities. Cardiopulmonary resuscitation (see Chapter 108) after bupivacaine overdose is particularly difficult. Therefore, prevention of intravascular injection or overdose is crucial, and major nerve blockade should involve incremental and fractionated delivery rather than bolus administration.
- Local anesthetics are directly toxic to nerve at the concentrations supplied in commercial solutions. Intraneural concentrations during regional anesthesia are generally (but not always) less than a threshold for toxicity because of local vascular removal, and dilutional effects due to spread of solutions through tissues and into nerve. Hence, injection into a constrained tissue space increases the risk for local toxicity.
- Optimal use of local anesthetics in regional anesthesia requires an understanding of (1) the individual patient's clinical situation, (2) the location, intensity, and duration of regional anesthesia and analgesia required, (3) anatomic factors affecting deposition of drug near nerves, (4) proper drug selection and dosing, and (5) repeated assessment of clinical effects after administration of a local anesthetic.
- There are several new formulations for topical anesthesia. Single-stereoisomer (as opposed to a racemic mixture) formulations can reduce systemic toxicity and improve sensory selectivity.
- Local anesthetics are increasingly being used as postoperative infusions and via both local and systemic administration for the management of chronic pain. Further research and development could lead to safe, more selective local anesthetics that will facilitate prolonged administration in the setting of acute or chronic pain.



Local anesthesia results from the blockade of nerve impulses to abolish sensation. All currently available, clinically useful anesthetics are either aminoesters or aminoamides. These drugs, when applied in sufficient concentration near the site of action, prevent conduction of electrical impulses by the membranes of nerve and muscle. In addition to blockade of impulses, local anesthetics can inhibit various receptors, enhance release of glutamate, and depress the activity of certain intracellular signaling pathways. When local anesthetics are given systemically, the functions of cardiac, skeletal, and smooth muscle, as well as transmission of impulses in the central and peripheral nervous systems and within the specialized conducting system of the heart, can all be altered. Local anesthetics can abolish sensation in various parts of the body by topical application, injection near peripheral nerve endings and major nerve trunks, or instillation within the epidural or subarachnoid space. Toxicity may be local or systemic. The central nervous and cardiovascular systems are most commonly the targets for acute clinical toxicity caused by local anesthetics.

BASIC PHARMACOLOGY



CHEMISTRY

Local Anesthetic Molecule

The typical local anesthetic molecule, exemplified by lidocaine and procaine (Fig. 36-1), contains a tertiary amine attached to a substituted aromatic ring by an intermediate chain that almost always contains either an ester

or an amide linkage.

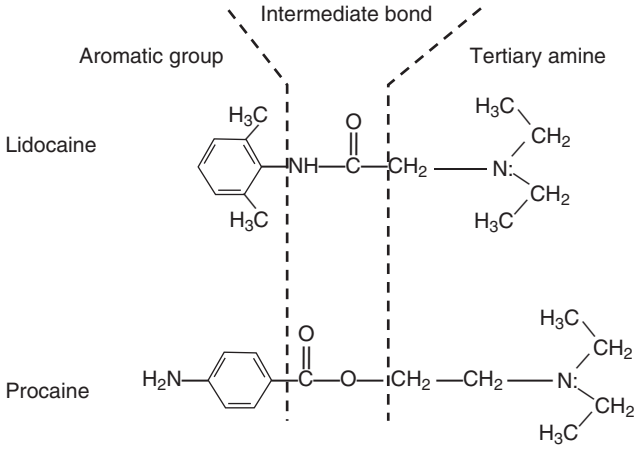


Figure 36-1. Structures of two local anesthetics: the aminoamide lidocaine and the aminoester procaine. In both drugs, a hydrophobic aromatic group is joined to a more hydrophilic base, the tertiary amine, by an intermediate amide or ester bond.

Local anesthetics can therefore be classified as aminoester or aminoamide compounds. The aromatic ring system gives a lipophilic (membrane-liking) character to its portion of the molecule, whereas the tertiary amine end is relatively hydrophilic, particularly since it is partially protonated and thus bears some positive charge in the physiologic pH range (Fig. 36-2). The structures of commonly administered local anesthetics are given in Table 36-1, and their physicochemical properties are given in Table 36-2.

STRUCTURE-ACTIVITY RELATIONSHIPS AND PHYSICOCHEMICAL PROPERTIES

The intrinsic potency and duration of action of local anesthetics are clearly dependent on certain features of the molecule.

Lipophilic-Hydrophilic Balance

The lipophilic versus hydrophilic character of a local anesthetic depends on the size of alkyl substituents on or near the tertiary amine and on the aromatic ring. *Lipophilicity* expresses the tendency of a compound to associate with lipids, and in this case membrane lipids in particular—a property usually approximated by equilibrium partitioning into a hydrophobic solvent such as octanol.[1] Although octanol/buffer partition coefficients are comparable to membrane/buffer partition coefficients for the uncharged species of local anesthetics, they severely underestimate membrane partitioning for the charged, protonated species—octanol being a poor model for the polar regions near the membrane surface where local anesthetics are concentrated.[2]

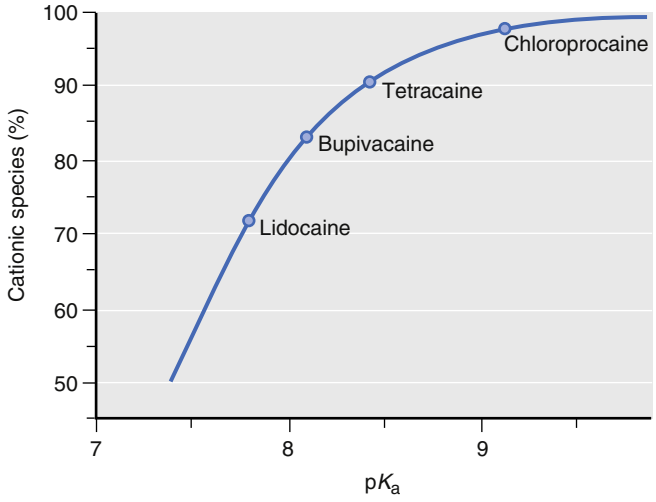

Figure 36-2. Fraction of local anesthetic in the protonated, cationic form of an aqueous solution at physiologic pH (7.4) as a function of the pK_a of the drug. Lidocaine, the drug with the lowest pK_a, has the smallest fraction of its molecules protonated, the largest in the neutral form, and vice versa for chloroprocaine, the local anesthetic with the highest pK_a. Individual drug molecules become protonated and deprotonated in thousandths of a second in solution.

From Strichartz GR, Sanchez V, Arthur GR, et al: Fundamental properties of local anesthetics. II. Measured octanol : buffer partition coefficients and pK_a values of clinically used drugs, Anesth Analg *71:158-170, 1990.*
*Data derived from C fibers of isolated rabbit vagus and sciatic nerve.
†pK_a and hydrophobicity at 36° C; hydrophobicity equals the octanol/buffer partition coefficient of the base. Values are ratios of concentrations.
‡Values at 25° C.

The term *hydrophobicity*, expressed as octanol/buffer partitioning, describes a physicochemical property of local anesthetics.

Compounds with a more hydrophobic nature are obtained by increasing the size of the alkyl substituents. These agents are more potent and produce longer-lasting blocks than their less hydrophobic congeners do.[3-5] For example, etidocaine, which has three more carbon atoms than lidocaine does in the amine end of the molecule, is fourfold as potent and fivefold as long lasting as lidocaine when compared using impulse blockade in the isolated sciatic nerve.

Hydrogen Ion Concentration

Local anesthetics in solution exist in a rapid chemical equilibrium between the base, uncharged form (B) and the charged cationic form (BH^+). At a certain hydrogen ion concentration ($\log_{10}^{-1}$ [−pH]) specific for each drug, the concentration of local anesthetic base in solution is equal to the concentration of charged cation. The logarithm of this hydrogen ion concentration is called pK_a. The relationship between the fraction of charged drug and the pH is defined by

$$\frac{[BH^+]}{[B]} = 10^{pK_a - pH}$$

The pK_a values of local anesthetic agents in aqueous solution are listed in Table 36-2. The tendency to be protonated also depends on environmental factors, such as temperature and ionic strength, and on the medium surrounding the drug. In the relatively apolar milieu of a membrane, the average pK_a of local anesthetics is lower than in solution.[6] This is chemically equivalent to saying that the membrane concentrates the base form of the local anesthetic more than it concentrates the protonated cation form.

The pH of the medium containing the local anesthetic influences drug activity by altering the relative percentage of the base and protonated forms. For example, in inflamed tissues the pH is lower than normal, and local anesthetics are more protonated than in normal tissue and consequently penetrate the tissue more slowly (discussed later).

The relationship between pK_a and the percentage of local anesthetic present in the cationic form is shown in Figure 36-2. As described later, there are dual effects of pH on clinical effectiveness, depending on where the local anesthetic is injected and the importance of the base form for tissue penetration.

ANATOMY OF THE PERIPHERAL NERVE

Each peripheral nerve axon possesses its own cell membrane—the axolemma. Nonmyelinated nerves, such as

autonomic postganglionic efferent and nociceptive afferent C fibers, contain many axons encased in a single Schwann cell sheath. In contrast, all large motor and sensory fibers are enclosed in many layers of myelin, which consists of the plasma membranes of specialized Schwann cells that wrap themselves around the axon during axonal outgrowth. Myelin markedly increases the speed of nerve conduction by insulating the axolemma from the surrounding conducting salt medium and forcing the "action current" generated by an impulse to flow through the axoplasm to the nodes of Ranvier, which are periodic interruptions in the myelin sheath where the active impulse is regenerated (Fig. 36-3). The Na^+ channels that serve to propagate impulses are highly concentrated at the nodes of Ranvier of myelinated fibers,[7] but are distributed all along the axon of nonmyelinated fibers (see Fig. 36-3). A classification of peripheral nerves according to fiber size and physiologic properties is presented in Table 36-3.

A typical peripheral nerve consists of several axon bundles, or fascicles. Each axon has its own connective tissue covering—the *endoneurium*. Each fascicle of many axons is encased by a second connective tissue layer—the epithelial-like *perineurium*—and the entire nerve is wrapped in a loose outer sheath called the *epineurium* (Fig. 36-4). To reach the nerve axon, a local anesthetic molecule must traverse four or five layers of connective tissue or lipid membranous barriers, or both.

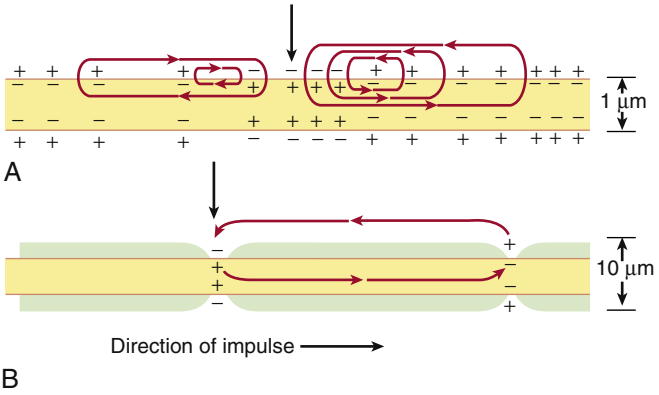

Figure 36-3. Pattern of local circuit currents flowing during propagation of an impulse in a nonmyelinated C fiber's axon (**A**) and a myelinated axon (**B**). During propagation of impulses, from left to right, current entering the axon at the initial rising phase of the impulse *(large vertical arrows)* passes through the axoplasm (local circuit current) and depolarizes the adjacent membrane. Plus and minus signs adjacent to the axon membrane indicate the polarization state of the axon membrane: negative inside at rest, positive inside during active depolarization under the action potential, and less negative in regions where local circuit currents flow. This ionic current passes relatively uniformly across the nonmyelinated axon, but it is restricted in the myelinated axon to entry at the nodes of Ranvier, several of which are simultaneously depolarized during a single action potential.

STRUCTURE OF THE AXONAL MEMBRANE

Biologic membranes consist of a molecular lipid bilayer containing proteins adsorbed on the surfaces, as well as embedded in or spanning the hydrocarbon core (Fig. 36-5). The character of the bilayer is determined by the phospholipids, which have long hydrophobic fatty acyl tails that lie in the center of the membrane, connected to polar hydrophilic head groups, which are usually composed of zwitterionic portions (containing both positive and negative charges) that project into the cytoplasm or the extracellular fluid. Within the membrane, there is both lateral and rotational diffusion, which allows lipids and certain proteins to migrate in a fluid mosaic, but most membrane proteins are fixed within specific regions of a membrane, anchored by connections to specific proteins of the cell's cytoskeleton.[6]

A dynamic interaction exists between cell membrane and cytoplasm. Although this chapter focuses on the channel-blocking actions of local anesthetics, it is noteworthy that many other cellular activities, including both metabolic and signal transduction pathways, are inhibited by these drugs.

PHYSIOLOGY OF NERVE CONDUCTION

The neural membrane constantly maintains a voltage difference at rest of –60 to –90 mV between the intracellular medium and the cell's outside, because during rest it is relatively impermeable to sodium ions but selectively permeable to potassium ions. The Na^+/K^+ pump, an active, energy-dependent mechanism, sustains the ion gradients that drive this potential difference by constant extrusion of sodium from within the cell in exchange for a net uptake of potassium, with adenosine triphosphate used as an energy source. Although the membrane is relatively permeable to potassium ions, an intracellular-to-extracellular potassium ratio of 150 to 5 mM, or 30:1, is maintained by active removal of potassium as it leaks passively across the plasma membrane.

The nerve at rest behaves largely as a potassium electrode, according to the Nernst equation:

$$E_m \approx E_K = \left(\frac{-RT}{F}\right) \ln \left(\frac{[K^+]_i}{[K^+]_o}\right)$$

where E_m is the membrane potential, E_K is the potassium equilibrium potential, R is the gas constant, T is temperature (Kelvin), F is Faraday's constant, and $[K^+]$ is the potassium ion concentration inside (i) and outside (o) the cell. For potassium, therefore,

$$E_K = -58 \log 30, \text{ or } -85.7 \text{ mV}$$

An opposite situation exists for Na^+, which is at higher concentration outside the cell and has a Nernst potential (E_{Na}) of approximately +60 mV. During an action potential, the nerve membrane transiently switches its higher permeability from K^+ to Na^+, thereby changing the membrane potential from negative to positive and back again.[7] The progress of this potential change and the underlying events are graphed in Figure 36-6. These events provide a basis for understanding local anesthetic conduction block.

Permeation of ions through membranes occurs via specialized proteins called *ion channels*.[8] The conformation of these channels is typically sensitive to the membrane potential; both Na^+ and K^+ channels in nerve membranes are activated to an "open" conformation by

TABLE 36-3 CLASSIFICATION OF PERIPHERAL NERVES ACCORDING TO ANATOMY, PHYSIOLOGY, AND FUNCTION

Fiber Class	Subclass	Myelin	Diameter (μm)	Conduction Velocity (m/sec)	Location	Function	Susceptibility to Local Anesthetic Block
A	alpha	+	6-22	30-120	Efferent to muscles	Motor	++
	beta	+	6-22	30-120	Afferent from skin and joints	Tactile, proprioception	++
	gamma	+	3-6	15-35	Efferent to muscle spindles	Muscle tone	++++
	delta	+	1-4	5-25	Afferent sensory nerves	Pain, cold temperature, touch	+++

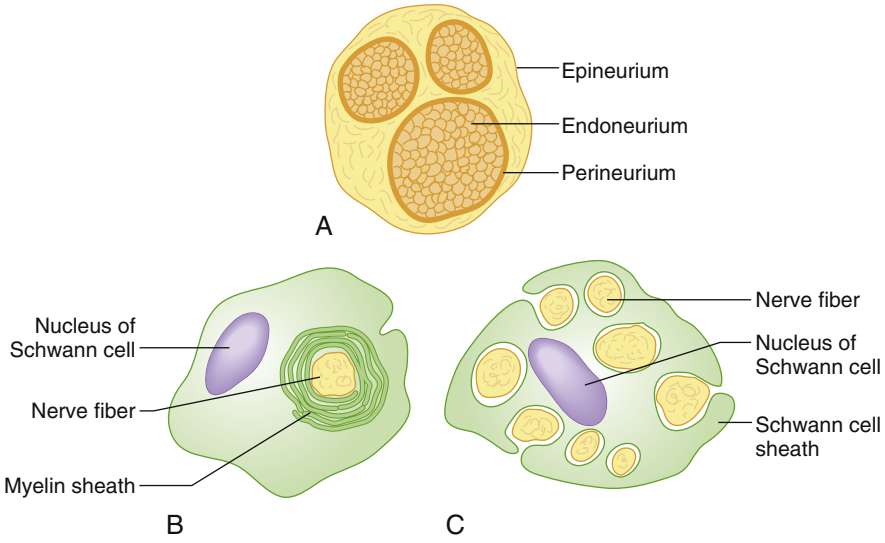

Figure 36-4. A, Transverse sections of a peripheral nerve showing the outermost epineurium; the inner perineurium, which collects nerve axons in fascicles; and the endoneurium, which surrounds each myelinated fiber. **B,** Each myelinated axon is encased in the multiple membranous wrappings of myelin formed by one Schwann cell, each of which stretches longitudinally more than approximately 100 times the diameter of the axon. The narrow span of axon between these myelinated segments, the node of Ranvier, contains the ion channels that support action potentials. **C,** Nonmyelinated fibers are enclosed in bundles of 5 to 10 axons by a chain of Schwann cells that tightly embrace each axon with but one layer of membrane.

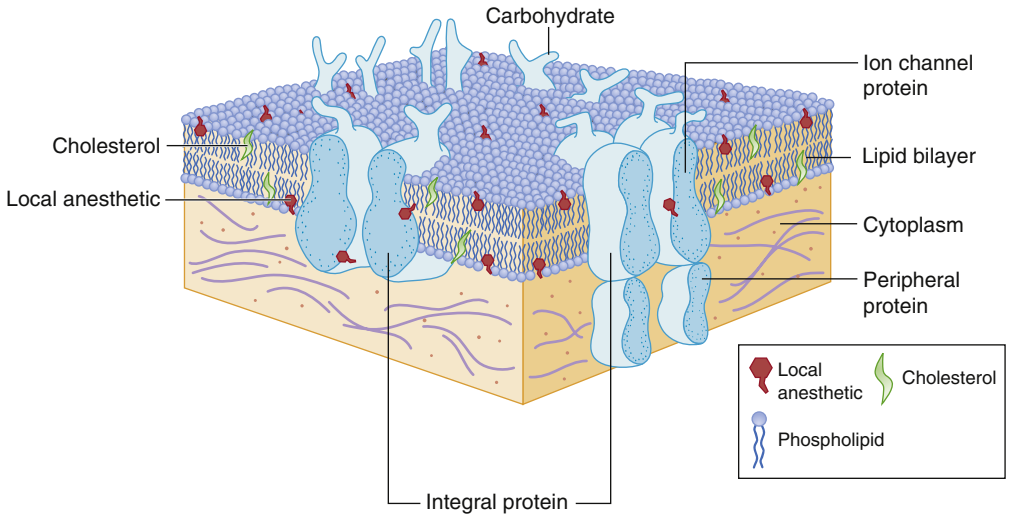

Figure 36-5. A typical plasma membrane has at its core the lipid bilayer, composed of phospholipids and cholesterol molecules (in an approximately 5:1 ratio) embedding the membrane integral proteins, which are most often glycosylated by extracellular carbohydrates and include receptors and ion channels essential for intercellular communication. "Peripheral proteins" regulate the functions of membrane proteins, chaperone them to the plasma membrane, and stabilize them in the cell through interactions with both the cytoskeleton and the extracellular matrix. Probable membrane locations and protein sites for local anesthetics are also shown.

membrane depolarization. Sodium channels, in addition, close to an "inactivated" conformation after their initial activation. A small membrane depolarization, extending along an axon from a region of excited membrane, for example, will begin to open both Na^+ and K^+ channels. The Na^+ channels open faster, however, and the inwardly directed Na^+ current (see Fig. 36-6) depolarizes the membrane further, thereby leading to opening of more Na^+ channels and increasing the inward Na^+ current even further (Fig. 36-7). This sequence of events continues during the depolarizing phase until some of the Na^+ channels have become inactivated and enough of the K^+ channels have opened to change the balance of current and result in a net outward current that produces membrane repolarization (see Fig. 36-7). After one action potential, the concentrations of Na^+ and K^+ have changed little for the large myelinated fibers, but by as much as 10% for the small, nonmyelinated axons. The Na^+ ions entering and K^+ ions leaving the cell because of this process are restored by the Na^+/K^+ pump.

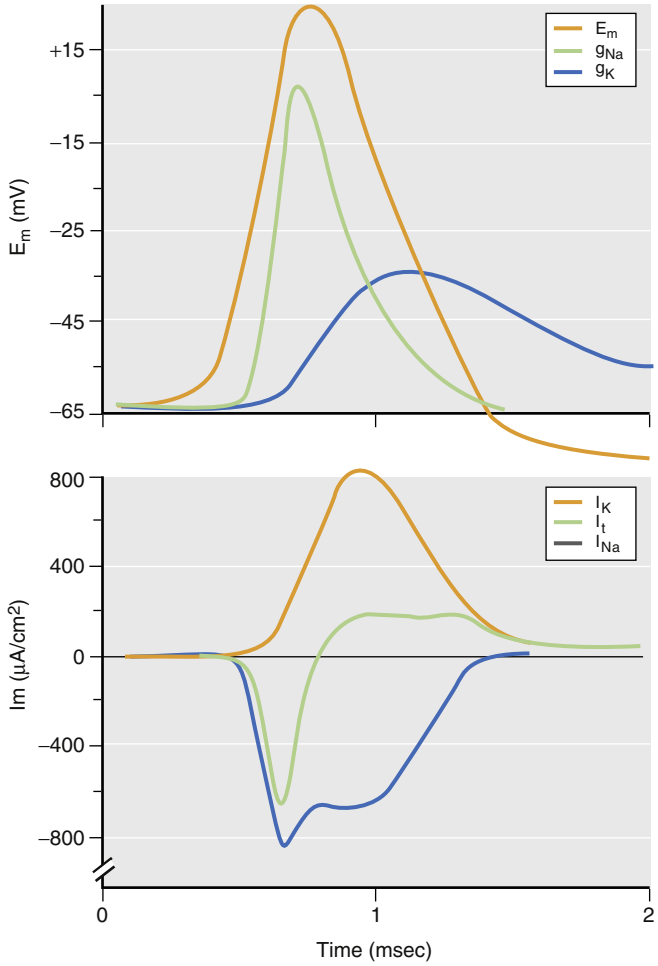

Figure 36-6. Membrane potential (E_m) and the voltage-gated ionic conductance of sodium (g_{Na}) and potassium (g_K), which determine the corresponding membrane currents Im (I_{Na} and I_K) during a propagated action potential. Modeled from the original studies of Hodgkin and Huxley on the squid giant axon (see Hodgkin[7]), these relationships hold for almost all invertebrate and vertebrate nerve fibers. The direction of the total ionic current (I_t), which is the sum of I_{Na} and I_K, is inward (negative values) for the depolarizing phase of the action potential and outward (positive values) for the repolarizing phase.

Depolarizations too weak to activate enough Na^+ channels to produce a net inward current are below the membrane's excitability threshold. The precise value of the threshold varies in different regions of the cell and changes with time. For example, directly after an impulse, when some Na^+ channels are still inactivated and some K^+ channels are still activated, the threshold is above its resting value and the membrane is refractory to stimulation. Over time, however, as Na^+ inactivation decays and K^+ channels return to their closed conformation, the original resting threshold value is restored.

The action potential is a wave of depolarization that is propagated along the axon by continuous coupling between excited and nonexcited regions of membrane. Ionic current (the action current) enters the axon in the excited, depolarized region and then flows down the axoplasm and exits through the surrounding membrane, thereby passively depolarizing this adjacent region (see Fig. 36-3). Although this local circuit current spreads away from the excited zone in both directions, the region behind the impulse, having just been depolarized, is absolutely refractory, and propagation of impulses is thus unidirectional.

The local circuit current spreads rapidly along a length of insulated internode in a myelinated axon (see Fig. 36-3), and many nodes of Ranvier in sequence are depolarized to threshold with little intervening delay. Single impulses do not jump from node to node as separate, discrete events; instead, active depolarization occurs simultaneously along several centimeters of the largest axons (see Fig. 36-3). Indeed, the local circuit current is so robust that it can skip past two completely nonexcitable nodes (e.g., blocked by local anesthetic) and successfully stimulate a third node. If excitability is partially reduced, such as by inhibition of some of the Na^+ channels, the amplitude of impulses in successive nodes falls decrementally in a process that can continue for many centimeters.[9] This situation most likely occurs during certain phases of local

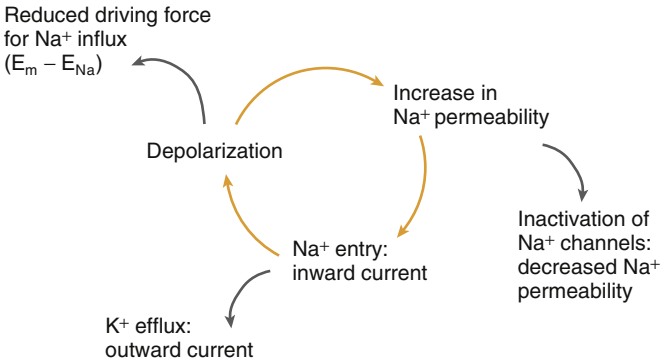

Figure 36-7. The action potential can be understood in terms of the cyclic relationships between factors contributing to the regenerative, depolarizing phase and the passive, repolarizing phase. Positive factors *(yellow arrows)* increase the rate of depolarization in a positive-feedback loop, with each element in the cycle favoring the subsequent one. Negative factors *(gray arrows)* decrease the depolarization rate by reducing or opposing the related positive factor, with efflux of K^+ eventually dominating the ionic flow and repolarizing the membrane.

anesthesia, as discussed later. However, when enough of the Na^+ channels are blocked, local circuit current fails to bring the adjacent resting region to threshold, and the impulse is fully extinguished.

MECHANISM OF ACTION OF LOCAL ANESTHETICS (PHARMACODYNAMICS)

ACTIVE FORM

Local anesthetic bases are poorly to sparingly soluble in water, but are soluble in relatively hydrophobic organic solvents. Therefore, as a matter of chemistry (and to optimize shelf life), most of these drugs are formulated as hydrochloride salts. The pK_a of the drug and tissue pH determine the amount of drug that exists in solution as free base or as positively charged cation when injected into living tissue (discussed earlier). Furthermore, uptake of the drug by tissue, largely via lipophilic adsorption, will also alter its activity, both by shifting the effective pK_a downward, thereby favoring the neutral base form, and by limiting diffusion of the anesthetic away from the site of injection. Moderately hydrophobic local anesthetics block faster than either hydrophilic or highly hydrophobic ones, delivered at the same concentration, for the following reasons. Moderately hydrophilic molecules, such as lidocaine, are less bound to tissues than highly hydrophobic drugs are (e.g., tetracaine) but are still more membrane permeant than highly hydrophilic ones (e.g., 2-chloroprocaine). The hydrophobic local anesthetics, having higher intrinsic potencies (see Table 36-2), are therefore used in lower concentrations and their diffusion-controlled rate of onset is correspondingly reduced.

Which form of the local anesthetic—charged cation or neutral base—is actually responsible for blockade of impulses? More alkaline solutions of local anesthetics block nerve conduction more effectively. On sheath-free nerves, the rate of inhibition by tertiary amine anesthetics is greater at alkaline than at neutral external pH because membrane permeation, favored by the base over the cationic species, determines the rate of access to the binding site.[10] Direct control of axoplasmic pH (or internal perfusion with permanently charged quaternary amine homologues) shows that the dominant potency derives from the cationic species acting from the cytoplasmic surface.[11,12] The uncharged base also has intrinsic pharmacologic activity, however, which explains the effectiveness of benzocaine as a topical local anesthetic.

ELECTROPHYSIOLOGIC EFFECT OF LOCAL ANESTHETICS

The nerve resting membrane potential is little affected by local anesthetics. As the concentration of local anesthetic applied to the nerve is increased, a decrease in the rate of depolarization and in the peak amplitude of the action potential occurs until the impulse is abolished. It is not possible, however, to derive data on the binding of local anesthetics to Na^+ channels from measurement of the changes in nerve impulses.

By using a "voltage-clamp" procedure, Na^+ currents and their inhibition by local anesthetics can be directly assayed (Fig. 36-8, *A*). When the membrane of isolated neurons is rapidly depolarized to a constant value, the time course of ionic currents is observed. Sodium currents during one initial depolarization are reduced by subclinical doses of local anesthetic (e.g., 0.2 mM lidocaine) and totally abolished by clinical doses (e.g., 1% lidocaine, ≈40 mM). If the test depolarization is applied repeatedly, for example, at frequencies higher than 5 Hz (five pulses per second), the partially depressed (tonically inhibited) Na^+ current is further reduced incrementally

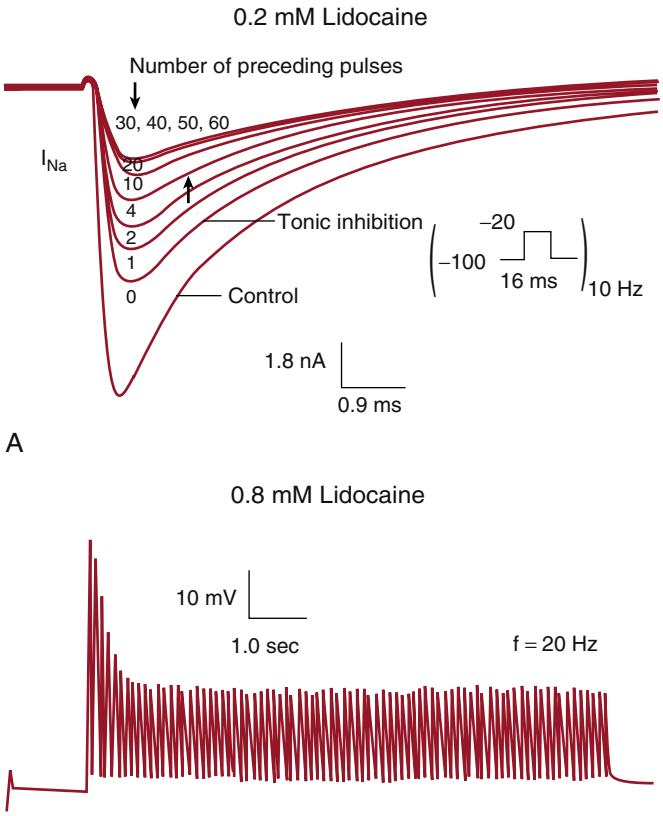

Figure 36-8. Use-dependent actions of local anesthetics on excitable membrane properties. **A,** Ionic Na^+ currents measured by a voltage-clamping technique are transiently activated by brief steps of depolarization applied infrequently (tonic test) or in a train at 10 times per second (phasic test, see E_m pattern in parentheses). After equilibration with 0.2 mM (0.005%) lidocaine, the currents measured tonically are reduced by approximately 30% from the control currents. Application of the phasic train of depolarizations results in a dynamic reduction of currents after each depolarization, with a steady-state value of phasic inhibition reached during the train of 75% of control currents. Recovery of currents to the tonic value occurs within a few seconds when phasic testing stops (not shown). **B,** Action potentials are also inhibited in a phasic manner by local anesthetics. After equilibration with 0.8 mM lidocaine (0.02%), the action potential is tonically reduced by approximately 20% from its amplitude in drug-free solution (not shown). Stimulation by a train at 20 stimuli per second induces a phasic inhibition that further reduces the amplitude by about 70% from the control value. As with the ionic currents (**A**), phasic inhibition of the action potential recovers rapidly when high-frequency stimulation stops.

for each pulse until a new steady-state level of inhibition is reached.[13,14] This frequency-dependent inhibition, also called *phasic inhibition,* is reversed when stimulation is slowed or stopped, and currents return to the level of tonic inhibition observed in the resting nerve. Paralleling the phasic inhibition of Na^+ currents in voltage-clamped membranes is a "use-dependent" blockade of action potentials during normal physiologic function (see Fig. 36-8, *B*).

The potency of local anesthetics to produce tonic and phasic inhibition is similarly dependent on their structure, hydrophobicity, and pK_a. At its simplest, there appears to be a single binding site for local anesthetics on the Na^+ channel, with a tonic affinity at rest and increased phasic affinity occurring because of depolarization. The phasic blocking phenomenon can thus be used to reveal the true kinetics of binding of local anesthetic to the functional receptor, the Na^+ channel itself.

Phasic actions are a manifestation of the selective affinity of local anesthetics for conformations of the Na^+ channel that result from depolarization. Both open and inactivated states of the channel bind local anesthetics more avidly than the resting state does. Repeated depolarization thus increases the fraction of drug-bound channels; dissociation of these bound drug molecules is usually a slower process than the normal recovery from inactivation (discussed earlier) and results in the use-dependent accumulation of channels in the blocked condition and the phenomenon of phasic block.

By its selective binding to a channel state, the local anesthetic stabilizes that state. During phasic block, therefore, more inactivated channels become drug bound, and reciprocally, less activation can occur. This relationship between state-dependent affinities and modification of transitions among states through drug binding is known as the *modulated receptor model*.[15] Overall binding of anesthetic is increased by membrane depolarization for two reasons: more binding sites become accessible during activation (the guarded receptor model) and drug *dissociation* from inactivated channels is slower than from resting channels (the modulated receptor model).

The specific binding rates and affinities for the different conformations of the sodium channel depend on the particular local anesthetic drug. When the details of this dependence are correlated with the physicochemical properties of the drug and with the experimental conditions, they provide insight into the molecular features of the local anesthetic binding site.

THE NATURE OF THE LOCAL ANESTHETIC BINDING SITE

Intentional mutation of specific amino acids of the Na^+ channel has allowed definition of regions that interact directly with local anesthetics. The major functional protein of the Na^+ channel (the α-subunit) is composed of four homologous domains (D-1 to D-4), each of which contains six helical regions (S1 to S6) that span the core of the membrane (Fig. 36-9, *A*). Each domain also has a loop, termed the *P region,* that links the extracellular ends of its S5 and S6 transmembrane segments. The P regions extend inward between the transmembrane regions such that when the α-subunit folds together, each P loop contributes a quarter of the cylindrical ion selectivity pore, the narrowest passage of an open channel (see Fig. 36-9, *B*). Voltage sensitivity derives from the positive charges located on S4 segments, which slide or swing outward in response to membrane depolarization. By linkages that are still unknown, this movement of S4 results in a conformational rearrangement of the S6 segments, which form the inner, cytoplasmic entry to the channel. Closed-to-open channel gating results from movement of the S6 segments, whereas inactivation gating results from binding of the cytoplasmic loop located between D-3 and D-4 to the cytoplasmic opening of the channel.

Local anesthetics bind in the inner vestibule of the closed Na^+ channel (see Fig. 36-9, *C*). Amino acid mutations in the S6 segments of D-1, D-3, and D-4 all modify local anesthetic action, thus suggesting either that these regions form a pharmacophore small enough to simultaneously contact the drug at three surfaces or that the local anesthetic molecule moves rapidly among these three segments.

The rate constant for binding of local anesthetic to the closed Na^+ channel is larger for the more hydrophobic molecules, which suggests that drug molecules can reach the binding site (and depart from it) through a hydrophobic pathway. This path could be movement from the membrane phase laterally, into the channel, or through hydrophobic amino acid residues that limit access through a pathway in the closed pore. The slow block of closed and inactivated channels appears to use such a hydrophobic access and thus accounts for tonic inhibition.

The charged species of local anesthetics dissociates much more slowly from closed and inactivated Na^+ channels than the neutral form does, which suggests that an ionic bond may be involved in drug binding or that the charged molecule moves only slowly along the hydrophobic pathway.

In brief, hydrophobicity delivers the drug to the receptor and charge keeps it there.

NEUROPHYSIOLOGIC ASPECTS OF PHASIC INHIBITION

Different fiber types in the nerve are affected differently during local anesthesia. At least part of this difference arises from pharmacokinetic factors. At the onset of and during recovery from clinical block, in particular, longitudinal and radial diffusion of drug will produce concentration variations within and along the nerve. This variation is superimposed on the dynamic use-dependent inhibition to provide variable propagation, which depends on a fiber's geometry, position within the nerve, and functional and electrophysiologic properties.

Different fiber types are also differentially sensitive to local anesthetic blockade. In vivo experiments in which continuous superperfusion of peripheral nerve allows equilibration with drug, and experiments in

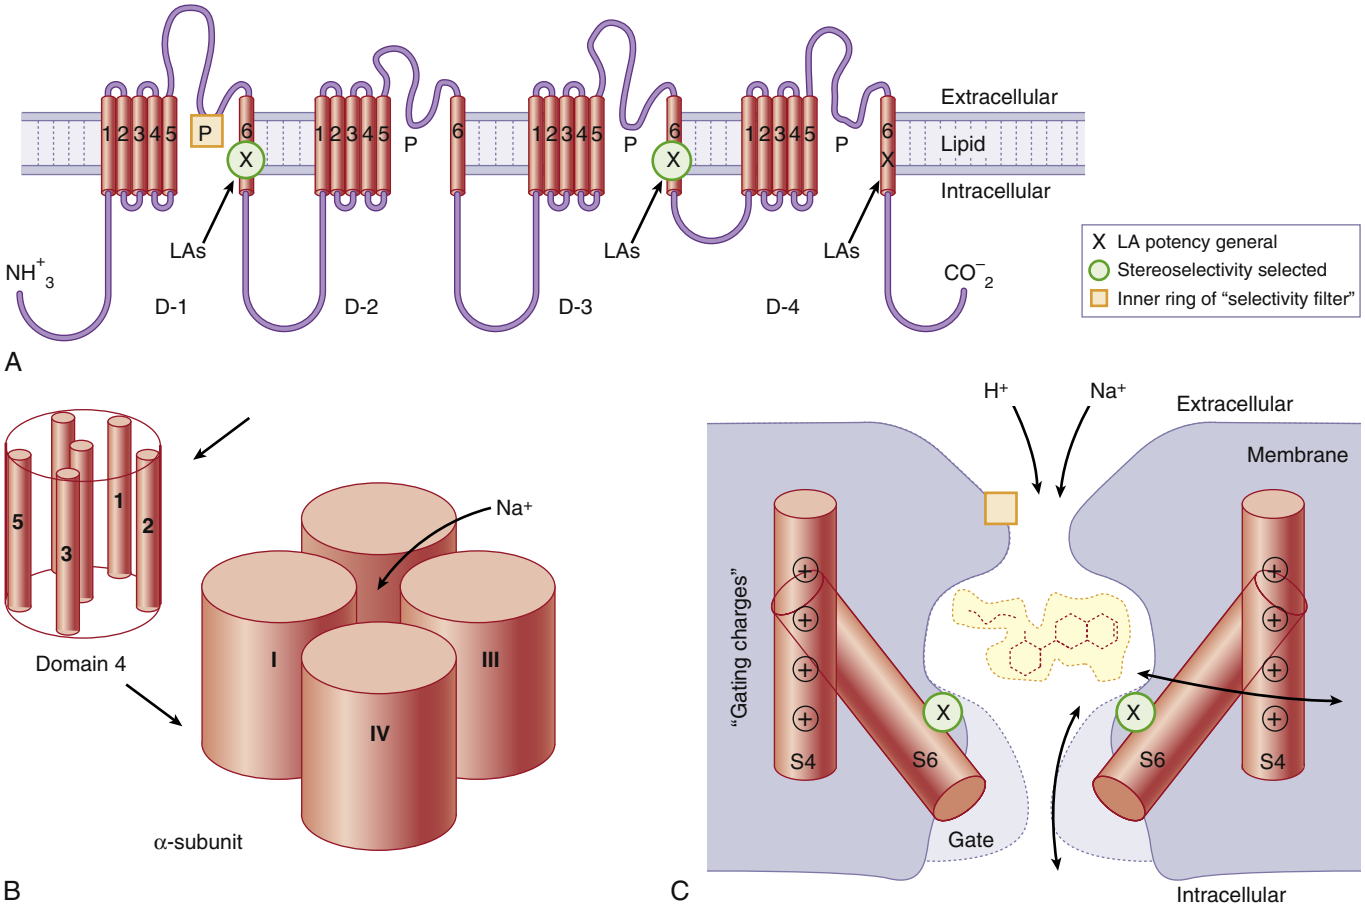

Figure 36-9. Structural features of the Na^+ channel that determine local anesthetic (LA) interactions. **A,** Consensus arrangement of the single peptide of the Na^+ channel α-subunit in a plasma membrane. Four domains with homologous sequences (D-1 through D-4) each contain six α-helical segments that span the membrane (S1 to S6). **B,** Each domain folds within itself to form one cylindrical bundle of segments, and these bundles converge to form the functional channel's quaternary structure. **C,** Activation gating leading to channel opening results from primary movement of the positively charged S4 segments in response to membrane depolarization. Fast inactivation of the channel follows binding to the cytoplasmic end of the channel of part of the small loop that connects D-3 to D-4. Ions travel through an open channel along a pore defined at its narrowest dimension by the P region formed by partial membrane penetration of the four extracellular loops of protein connecting S5 and S6 in each domain. Intentional, directed mutations of different amino acids on the channel indicate residues that are involved in LA binding in the inner vestibule of the channel (X on S6 segments), at the interior regions of the ion-discriminating selectivity filter (*square* on the P region), and also are known to influence stereoselectivity for phasic inhibition (*circle*, also on S6 segments). Schematic cross section of the channel speculating on the manner in which S6 segments, forming a "gate," may realign during activation to open the channel and allow entry and departure of a bupivacaine molecule by the hydrophilic pathway. The closed (inactivated) channel has a more intimate association with the LA molecule, whose favored pathway for dissociation is no longer between S6 segments (the former pore) but now, much more slowly, laterally between segments and then through the membrane, the hydrophobic pathway. Na^+ ions entering the pore will compete with the LA for a site in the channel, and H^+ ions, which pass slowly through the pore, can enter and leave from the extracellular opening, thereby protonating and deprotonating a bound LA molecule and thus regulating its rate of dissociation from the channel.

which a drug bolus is delivered by percutaneous injection,[16] analogous to clinical peripheral nerve block, show unequivocally that small myelinated axons (A gamma motor and A delta sensory fibers) are the most susceptible to impulse annihilation. Next in order of block are the large myelinated (A alpha and A beta) fibers, and the least susceptible are the small, nonmyelinated C fibers. In fact, in this last group, impulses in the slowest conducting population (conduction velocity of 0.5 to 0.8 m/sec) are the most resistant to local anesthetic.[16] The widespread notion that local anesthetics block the smallest fibers first or most is thus clearly wrong.

Selective Susceptibility of Na^+ Channel Isoforms

Ten different Na^+ channels have been physiologically identified and biochemically sequenced. At least four of them are found in peripheral neurons, and some are associated exclusively with nociceptive afferents. Obviously, it would be clinically advantageous to inhibit these channels selectively and thus prevent or reduce pain while sparing other functions. Although selective channel blockade has been attained with naturally occurring small peptide toxins,[17] relatively little selective blockade by local anesthetics occurs,[18] probably because the local anesthetic pharmacophore is too similar among the different channel isoforms

and the local anesthetic molecules themselves have several rotational axes, which makes them poor structural templates for selecting among static binding pockets.

Sodium Channel Isoforms in Human Diseases Characterized by Pain or Pain Insensitivity

Mutations in sodium channel isoform $Na_V1.7$ can produce disease states with either spontaneous pain[19,20] or profound and selective impairment of pain sensitivity.[21] Erythromelalgia is characterized by episodes of severe burning pain, predominantly in the feet and hands. In these subjects, pain is exacerbated by heat and relieved by cold. This disorder can occur as an isolated problem or can coexist with certain rheumatologic disorders. In a small subgroup of these patients, the disorder has a clear familial pattern with an autosomal dominant pattern of inheritance. A second autosomal dominant disorder characterized by spontaneous pain is known initially as *familial rectal pain disorder* or *paroxysmal extreme pain disorder*. Recent molecular studies have shown that these disorders involve several distinct types of mutations in $Na_V1.7$ sodium channels.[19,20] When these channels are inserted into cells that lack sodium channels, they generate spontaneous, temperature-sensitive, inward currents.

Perhaps even more remarkable is the recent report of several consanguineous families in Pakistan in which certain members exhibit profound insensitivity to pain while being neurologically normal in almost all other respects.[21] Genetic, biochemical, and electrophysiologic studies have demonstrated an autosomal recessive pattern of inheritance. Molecular studies have shown that these mutations are of the nonsense type and generate functionally impaired $Na_V1.7$ sodium channels; when placed into cell membranes in vitro, they fail to generate inward currents in response to depolarizing stimuli.

Aberrant impulses, which are often considered the hallmarks of various diseases of excitable membranes such as abnormal repetitive firing in neuropathic pain or in certain types of inherited skeletal myotonia, are abolished by systemic lidocaine in doses that do not block normal propagating impulses. Conditions for the sensitivity of such impulses to local anesthetics, such as lidocaine, appear to result from the patterns of impulse spikes superimposed on slow membrane depolarizations caused by abnormal expression of Na^+ channels rather than from selective sensitivity of certain subtypes of channels to these drugs.[22]

SUMMARY OF LOCAL ANESTHETIC MECHANISMS

Impulse blockade by local anesthetics may be summarized by the following chronology[4]:

1. Solutions of local anesthetic are deposited near the nerve. Removal of free drug molecules away from this locus is a function of tissue binding, removal by the circulation, and local hydrolysis of aminoester anesthetics. The net result is penetration of the nerve sheath by the remaining free drug molecules.
2. Local anesthetic molecules then permeate the nerve's axon membranes and accumulate within the axoplasm. The speed and extent of these processes depend on a particular drug's p*K*a and on the lipophilicity of its base and cation species.
3. Binding of local anesthetic to sites on voltage-gated Na^+ channels prevents opening of the channels by inhibiting the conformational changes that underlie channel activation. Local anesthetics primarily bind to the channel's pore and occlude the pore path for Na^+ ions.
4. During onset of and recovery from local anesthesia, impulse blockade is incomplete, and partially blocked fibers are further inhibited by repetitive stimulation, which produces an additional, use-dependent binding to Na^+ channels.
5. One local anesthetic binding site on the Na^+ channel may be sufficient to account for the drug's resting (tonic) and use-dependent (phasic) actions. Access to this site may potentially involve multiple pathways, but for clinical local anesthesia, resting block predominates and, the primary route is the hydrophobic approach from within the axon membrane.
6. The clinically observed rates of onset and recovery from blockade are governed by the relatively slow diffusion of local anesthetic molecules into and out of the whole nerve, not by their much faster binding and dissociation from ion channels. A clinically effective block that may last for hours can be accomplished with local anesthetic drugs that dissociate from Na^+ channels in a few seconds.

CLINICAL PHARMACOLOGY

The successful use of regional anesthesia requires knowledge of the pharmacologic properties of the various local anesthetic drugs, as well as technical skill in performing the nerve block. Local anesthetic requirements vary considerably, depending on factors such as the type of block, surgical procedure, and physiologic status of the patient.

Commonly used aminoester local anesthetics include procaine, chloroprocaine, tetracaine, and cocaine. The clinically used aminoamides include lidocaine, mepivacaine, prilocaine, bupivacaine (racemic and its levoenantiomer), ropivacaine, and etidocaine. The ester and amide local anesthetics differ in their chemical stability, locus of biotransformation, and allergic potential. Amides are extremely stable, whereas esters are relatively unstable in solution. Aminoesters are hydrolyzed in plasma by cholinesterase enzymes, but the amides undergo enzymatic degradation in the liver. Two exceptions to this trend include cocaine, an ester that is metabolized predominantly by hepatic carboxylesterase, and articaine, an amide local anesthetic widely used in dentistry that is inactivated by plasma carboxylesterase-induced cleavage of a methyl ester on the aromatic ring.

p-Aminobenzoic acid is one of the metabolites of ester-type compounds that can induce allergic-type reactions in a small percentage of patients. The aminoamides are not metabolized to *p*-aminobenzoic acid, and reports of allergic reactions to these agents are extremely rare.

GENERAL CONSIDERATIONS

Clinically important properties of the various local anesthetics include potency, speed of onset, duration of anesthetic action, and differential sensory vs motor blockade. As previously indicated, the profile of individual drugs is determined by their physicochemical characteristics (see Table 36-2).

Anesthetic Potency

Hydrophobicity is a primary determinant of intrinsic anesthetic potency[5] because the anesthetic molecule must penetrate into the nerve membrane and bind at a partially hydrophobic site on the Na^+ channel. Clinically, however, the correlation between hydrophobicity and anesthetic potency is not as precise as in an isolated nerve. Differences between in vitro and in vivo potency may be related to a number of factors, including local anesthetic charge and hydrophobicity (which influence partitioning into and transverse diffusion across biologic membranes) and vasodilator or vasoconstrictor properties (which influence the initial rate of vascular uptake from injection sites into the central circulation).

Onset of Action

The onset of conduction block in isolated nerves is related to the physicochemical properties of the individual agents. In vivo latency is also dependent on the dose or concentration of local anesthetic used. For example, 0.75% bupivacaine has more rapid onset than 0.25%. Chloroprocaine demonstrates a rapid onset of action in humans because its low systemic toxicity permits its use in high concentrations (i.e., 3%).

Duration of Action

The duration of action of the various local anesthetics differs markedly. Procaine and chloroprocaine have a short duration of action. Lidocaine, mepivacaine, and prilocaine produce a moderate duration of anesthesia, whereas tetracaine, bupivacaine, ropivacaine, and etidocaine have the longest durations.

In humans, the duration of anesthesia is markedly influenced by the peripheral vascular effects of the local anesthetic drugs. Many local anesthetics have a biphasic effect on vascular smooth muscle. These agents tend to cause vasoconstriction at low concentrations, whereas they cause vasodilation at higher, clinically administered concentrations.[23] There are, however, differences in the degree of vasodilator activity of the various drugs. The effects of local anesthetics on vascular tone and regional blood flow are complex and vary according to concentration, time, and the particular vascular bed near the site of application, among other factors. As a practical example, the topical local anesthetic formulation EMLA (a eutectic mixture of the local anesthetics lidocaine and prilocaine) vasoconstricts cutaneous vessels initially and through most of the first hour of application, but vasodilation is observed after 2 or more hours of application.

Differential Sensory and Motor Blockade

Another important clinical consideration is the ability of local anesthetic agents to cause differential inhibition of sensory and motor activity. Bupivacaine became popular in the 1980s for epidural blocks because it was better than the previously available long-acting agents were (e.g., etidocaine) in producing adequate antinociception without profound inhibition of motor activity, particularly when dilute solutions were used. Bupivacaine is widely used epidurally for obstetric analgesia and postoperative pain management because it can provide adequate analgesia or pain relief with only mild muscle weakness (see Chapters 56, 77, and 98). Additional observations on the sensory selectivity of newer local anesthetics are detailed later in the section on chiral local anesthetics.

Small-diameter axons, such as C fibers, are often stated to be more susceptible to local anesthetic block than larger-diameter fibers are. However, when careful measurements are made of single-impulse annihilation in individual nerve fibers, exactly the opposite differential susceptibility is noted (discussed earlier).[24,25] Repetitive stimulation, such as occurs during propagation of trains of impulses, produces further, phasic inhibition of excitability, but it is not clear how this will affect a functionally selective failure of impulses. The length of drug-exposed nerve in the intrathecal space, imposed by anatomic restrictions, can perhaps explain clinically documented differential spinal or epidural blockade, with longer drug-exposed regions yielding block by lower concentrations of local anesthetic.[26] However, this reasoning does not explain the functionally differential loss from peripheral nerve block. Other factors can include actual spread of the drug along the nerve or its selective ability to inhibit Na^+ channels over K^+ channels,[27] which in itself can produce a differential block because these channels are present in different proportions in different types of nerves. Because of these confounding factors, clinicians should be discouraged from making conclusions about fiber-type involvement in chronic pain syndromes based on the dose or concentration requirement for pain relief in diagnostic nerve blockade.[28]

FACTORS INFLUENCING ANESTHETIC ACTIVITY IN HUMANS

Dosage of Local Anesthetic

As the dose of local anesthetic is increased, the probability and duration of satisfactory anesthesia increase, and the time to onset of block is shortened. The dose of local anesthetic can be increased by administering either a larger volume or a more concentrated solution. For example, increasing the concentration of epidurally administered bupivacaine from 0.125% to 0.5%, while maintaining the same volume of injectate (10 mL), resulted in more rapid onset, an improved incidence of satisfactory analgesia, and a longer duration of sensory analgesia.[29] The volume of anesthetic solution probably influences the spread of anesthesia. For example, 30 mL of 1% lidocaine administered into the epidural space produces a level of anesthesia that is 4.3 dermatomes higher than that achieved when 10 mL of 3% lidocaine is given.

In selecting the volume and concentration for a specific block in a particular patient, clinicians must balance the risk of adverse effects from overdosing (e.g., systemic

toxicity, excessive motor or autonomic blockade) against the increased risk of block failure if an inadequate volume or concentration is chosen. The degree to which additional volume can compensate for imprecise needle placement varies among different blocks.

With the advent of extremely precise needle placement using ultrasound-guided blockade (see Chapter 58), the median effective volume for obtaining successful blockade can be achieved with smaller volumes than have been recommended previously as compared with techniques not using ultrasound. For example, in a recent dose-finding randomized trial for femoral nerve blockade, the median volumes for 50% or 95% success in obtaining dense sensory and motor block at 30 minutes under ultrasound guidance were 57% and 54% of the corresponding volumes with the use of nerve stimulation.[30] Confidence intervals (i.e., variability) were large in this study. Statistical design issues for dose-response studies involving all types of anesthetics are well described.[31] As limited by toxicity considerations, the aim in most clinical situations should be to choose doses that provide frequent and predictable success rates; that is, a dose effective in 95% of patients (ED_{95}) is generally a more relevant guide to dose selection than an ED_{50} dose. In other words, one should not aim for failure 50% of the time.[32]

Addition of Vasoconstrictors

Vasoconstrictors, usually epinephrine (5 μg/mL or 1:200,000), are frequently included in local anesthetic solutions to decrease the rate of vascular absorption, thereby allowing more anesthetic molecules to reach the nerve membrane and thus improve the depth and duration of anesthesia, as well as to provide a marker for inadvertent intravascular injection.[33] Test dosing with epinephrine can generate false negative and false positive results. Some of these sources of error have been described for specific patient groups, such as adults and children under general anesthesia, parturients in labor, and patients receiving β-adrenergic blockers. Despite these limitations, test dosing has utility in a wide range of clinical situations.[34]

Epinephrine in a concentration of 1:200,000 provides the optimal degree of vasoconstriction when used with lidocaine for epidural or intercostal blockade.[35] Other vasoconstrictor drugs, such as norepinephrine and phenylephrine, have been used but do not appear to be superior to epinephrine.

The extent to which epinephrine prolongs the duration of anesthesia depends on the specific local anesthetic used and the site of injection. Epinephrine will significantly extend the duration of both infiltration anesthesia and peripheral nerve blockade with shorter-duration agents (e.g., lidocaine); epinephrine produces mild intensification of blockade, but only most modest prolongation of epidural or peripheral blocks with bupivacaine.[36] α_2-Adrenergic receptors in the spinal cord are known to activate endogenous analgesic mechanisms, and the increased depth of analgesic action produced by epinephrine and the α_2-agonist clonidine[37] with both epidural and intrathecal local anesthetics may arise from this pharmacodynamic mechanism and from the pharmacokinetic (vasoconstrictive) action.

Site of Injection

The most rapid onset but the shortest duration of action occurs after intrathecal or subcutaneous administration of local anesthetics. The longest onset times and durations occur after brachial plexus blocks. For example, intrathecal bupivacaine will usually produce anesthesia with an onset time within 5 minutes that will persist for 3 to 4 hours. However, when bupivacaine is administered for brachial plexus blockade, the onset time is approximately 20 to 30 minutes, and the duration of anesthesia (or at least analgesia) averages 10 hours.[38] These differences in the onset and duration of anesthesia and analgesia are due in part to the particular anatomy of the area of injection, which will influence the rate of diffusion and vascular absorption and, in turn, affect the amount of local anesthetic used for various types of regional anesthesia. In the subarachnoid space, for example, the lack of a nerve sheath around the spinal cord and deposition of the local anesthetic solution in the immediate vicinity of the spinal cord are responsible for the rapid onset of action, whereas the relatively small amount of drug used for spinal anesthesia probably accounts for the short duration of conduction block.

In contrast, the onset of brachial plexus blockade is slow because the anesthetic is usually deposited at some distance from the nerve, and it must diffuse through various tissue barriers before reaching the nerve membrane. The prolonged block with brachial plexus blockade may be related to several factors, including comparatively slower rates of vascular absorption from the brachial plexus sheath, larger doses of drug required for this regional anesthetic technique, and comparatively long segments of nerves exposed to local anesthetic.

Carbonation and pH Adjustment of Local Anesthetics

The addition of sodium bicarbonate to a solution of local anesthetic applied to an isolated nerve accelerates the onset and decreases the minimum concentration required for conduction blockade.[39] Although the effect of carbon dioxide on local anesthetic activity is easily demonstrable in isolated nerve, controversy exists concerning the clinical utility of carbonated local anesthetic solutions.[40]

The addition of sodium bicarbonate to local anesthetic solutions decreases the onset time of conduction blockade.[40] An increase in the pH of the local anesthetic solution increases the amount of drug in the uncharged base form, which should enhance the rate of diffusion across the nerve sheath and nerve membrane and result in a more rapid onset of anesthesia. Alkalinization of solutions of bupivacaine or lidocaine accelerated the onset of brachial plexus and epidural blockade in some studies[40] but not others.[41]

Mixtures of Local Anesthetics

Mixtures of local anesthetics for regional anesthesia are sometimes used in an effort to compensate for the short duration of action of certain rapidly acting anesthetics such as chloroprocaine and lidocaine, and the long latency of longer-acting anesthetics such as tetracaine and bupivacaine. Mixtures of chloroprocaine and bupivacaine theoretically offer significant clinical advantages

because of the rapid onset and infrequent incidence of systemic toxicity of chloroprocaine and the long duration of action of bupivacaine; however, clinical results in studies of combinations have been mixed.[42] In addition, the use of catheter-based techniques for many forms of regional anesthesia makes it possible to begin with a rapid-onset local anesthetic such as lidocaine, mepivacaine, or chloroprocaine followed by an infusion of either a shorter-acting or longer-acting local anesthetic thereafter. Conversely and even more importantly, clinicians should be cautioned not to use maximum doses of two local anesthetics in combination in the mistaken belief that their toxicities are independent.[43] In the absence of additional data, the toxicities should be presumed to be additive.

Pregnancy

The spread and depth of epidural and spinal anesthesia are more in pregnant than in nonpregnant women (see Chapter 77). The effects of pregnancy on local anesthetic potency may reflect a combined effect of mechanical factors associated with pregnancy (i.e., dilated epidural veins decrease the volume of the epidural and subarachnoid spaces) and direct effects of hormones, especially progesterone, on the susceptibility of nerves to conduction blockade by local anesthetics.[44] Hormonal alterations are probably the more important of these two factors because greater spread of epidural anesthesia occurs during the first trimester of pregnancy,[45] before any gross change in vascular dimensions within the epidural or subarachnoid spaces. The dosage of local anesthetics probably should be decreased in patients in all stages of pregnancy.

CHOICE OF LOCAL ANESTHETIC FOR VARIOUS REGIONAL ANESTHETIC PROCEDURES

On the basis of anatomic considerations, regional anesthesia can be divided into infiltration anesthesia, intravenous regional anesthesia, peripheral nerve blockade (including plexus blockade), central neural blockade, and topical anesthesia (see Chapters 56, 57, 58, 77, 79, 92, and 98). An additional method of local anesthetic injection—tumescent anesthesia—is included because it is widely used in office plastic surgery practice.

INFILTRATION ANESTHESIA

Any local anesthetic can be used for infiltration anesthesia. Onset of action is almost immediate for all agents after intradermal or subcutaneous administration; however, the duration of anesthesia varies (Table 36-4). Epinephrine will prolong the duration of infiltration anesthesia by all local anesthetic drugs, although this effect is most pronounced when epinephrine is added to lidocaine. The choice of a specific drug for infiltration anesthesia largely depends on the desired duration of action.

The dose of local anesthetic required for adequate infiltration anesthesia depends on the extent of the area to be anesthetized and the expected duration of the surgical procedure. When large surface areas have to be anesthetized, large volumes of dilute anesthetic solutions should be used. These considerations are particularly important when performing infiltration anesthesia in infants and smaller children. For example, consider a 4-kg infant receiving infiltration anesthesia with the maximum safe dose of lidocaine of 5 mg/kg (see Chapter 92). Dosing to 5 mg/kg in a 4-kg infant permits 20 mg, which is 1 mL of a 2% solution or 4 mL of a 0.5% solution. Lidocaine is effective for infiltration in concentrations as dilute as 0.3% to 0.5%; therefore, the more dilute solution can be used more safely to anesthetize a larger area.

Patients frequently experience pain immediately after subcutaneous injection of local anesthetic solutions, in part because of the acidic nature of these solutions. For example, neutralization of lidocaine solutions by the addition of sodium bicarbonate immediately before injection reduces pain on skin infiltration[46] and can improve onset (discussed earlier).

Infiltration analgesia and indwelling wound catheters are used increasingly as components of multimodal postoperative analgesia.[47-49]

INTRAVENOUS REGIONAL ANESTHESIA

Intravenous regional anesthesia involves the intravenous administration of a local anesthetic into a tourniquet-occluded limb (i.e., Bier block; see Chapter 79). The local anesthetic diffuses from the peripheral vascular bed to nonvascular tissue such as axons and nerve endings. Both the safety and the efficacy of this regional anesthetic

TABLE 36-4 **INFILTRATION ANESTHESIA**

	Plain Solution			Epinephrine-Containing Solution	
Drug	**Concentration (%)**	**Maximum Dose (mg)**	**Duration (min)**	**Maximum Dose (mg)**	**Duration (min)**
Short Duration					
Procaine	1-2	500	20-30	600	30-45
Chloroprocaine	1-2	800	15-30	1000	30
Moderate Duration					
Lidocaine	0.5-1	300	30-60	500	120
Mepivacaine	0.5-1	300	45-90	500	120
Prilocaine	0.5-1	350	30-90	550	120
Long Duration					
Bupivacaine	0.25-0.5	175	120-240	200	180-240
Ropivacaine	0.2-0.5	200	120-240	250	180-240

procedure depend on interruption of blood flow to the involved limb and gradual release of the occluding tourniquet. Intravenous regional anesthesia has been used primarily for surgical procedures on the upper limbs. Shorter surgical procedures on the foot can also be performed successfully with intravenous regional anesthesia. If a lower-leg tourniquet is used, it should not be applied over the superficial peroneal nerve, which can cause nerve injury; in general, use of an upper-leg tourniquet is preferred over lower-leg tourniquets.[50]

Lidocaine has been the drug used most frequently for intravenous regional anesthesia. Prilocaine, mepivacaine, chloroprocaine, procaine, bupivacaine, and etidocaine have also been used successfully. One might suppose a safety advantage with the aminoester-linked compounds because of their hydrolysis in blood; however, thrombophlebitis has been reported with chloroprocaine. Cardiovascular collapse has occurred after the use of bupivacaine for intravenous regional anesthesia, and this use of bupivacaine is discouraged.[51]

In general, approximately 3 mg/kg (40 mL of a 0.5% solution) of preservative-free lidocaine without epinephrine is used for upper extremity procedures. For surgical procedures on the lower limbs, 50 to 100 mL of a 0.25% lidocaine solution can be used.

PERIPHERAL NERVE BLOCKADE

Regional anesthetic procedures that inhibit conduction in fibers of the peripheral nervous system can be classified together under the general category of peripheral nerve blockade (see Chapters 57 and 58). This form of regional anesthesia has been subdivided arbitrarily into minor and major nerve blocks. Minor nerve blocks are defined as procedures involving single nerve entities such as the ulnar or radial nerve, whereas major nerve blocks involve the blockade of two or more distinct nerves or a nerve plexus or the blockade of very large nerves at more proximal sites (i.e., the femoral and sciatic nerves).

Most local anesthetic drugs can be used for minor nerve blocks. The onset of blockade is rapid with most drugs, and the choice of drug is determined primarily by the required duration of anesthesia. A classification of the various drugs according to their duration of action is shown in Table 36-5. The duration of both sensory analgesia and motor blockade is prolonged significantly when epinephrine is added to the various local anesthetic solutions in some, but not all applications.[52]

In 1986, a technique of interpleural regional analgesia was described as an alternative to multiple intercostal nerve blocks.[53] This procedure involves the administration of local anesthetic solution into the pleural space, either by percutaneous placement or by placement through the open chest by the surgeon during thoracotomy. The risk of pneumothorax has varied in published case series. Although interpleural analgesia appeared to be useful for unilateral postoperative analgesia after open cholecystectomy, mastectomy, and nephrectomy, its efficacy for post-thoracotomy pain is doubtful.[54] This technique has been associated with extremely high plasma concentrations of anesthetic, and a subsequently associated risk of convulsions. Interpleural analgesia has also been used to provide analgesia for chronic pain conditions as diverse as upper extremity complex regional pain syndromes, pancreatitis, and cancer of the thorax and abdomen. In many centers, interpleural analgesia has largely been supplanted by thoracic epidural analgesia for the majority of thoracic and abdominal procedures.

Two related approaches for unilateral somatic blockade in the thorax are continuous extrapleural catheters[55] (placed by the surgeon through the chest dorsal to the parietal pleura) and continuous thoracic paravertebral somatic blockade.[56] One advantage of these two approaches over interpleural analgesia is that little of the administered solution leaks from the chest into chest tubes. The risk-benefit ratio of thoracic epidural analgesia versus thoracic paravertebral analgesia or extrapleural analgesia remains controversial.[57,58]

Brachial plexus blockade for upper limb surgery is the most common major peripheral nerve block technique. A significant difference exists between the onset times of various agents when these blocks are used (Table 36-6). In general, agents of intermediate potency exhibit a more rapid onset than the more potent compounds do. Onset times of approximately 14 minutes for lidocaine and mepivacaine have been reported, versus approximately 23 minutes for bupivacaine. A variety of approaches to the brachial plexus are available; the choice among these approaches is dictated by several factors, including the site of surgery and the ability of the patient to tolerate spillover to other nerves, including the phrenic nerve. These considerations are detailed in Chapters 57, 58, and 79.

TABLE 36-5 **MINOR NERVE BLOCKS***

Drug	Usual Concentration (%)	Usual Volume (mL)	Dose† (mg)	Average Duration (min)	
				Plain Solutions	Epinephrine-Containing Solutions
Procaine	2	5-20	100-400	15-30	30-60
Chloroprocaine	2	5-20	100-400	15-30	30-60
Lidocaine	1	5-20	50-200	60-120	120-180
Mepivacaine	1	5-20	50-200	60-120	120-180
Prilocaine	1	5-20	50-200	60-120	120-180
Bupivacaine	0.25-0.5	5-20	12.5-100	180-360	240-420
Ropivacaine	0.2-0.5	5-20	10-100	180-360	240-420

*See also Chapter 57.
†Doses are for a 70-kg adult. For pediatric doses, see Chapter 92.

Similarly, the lumbar plexus can be approached via several routes, including a posterior approach, an anterior perivascular "3 in 1" approach, and an anterior fascia iliaca compartment approach.[59]

The variation in duration of anesthesia after brachial plexus blockade is also considerably greater than that observed with other types of conduction block. For example, durations of anesthesia varying from 4 to 30 hours have been reported for bupivacaine. It is prudent to warn patients before a major nerve block about the possibility of prolonged sensory and motor block in the involved region, particularly when agents such as bupivacaine, levobupivacaine, and ropivacaine are used.

PERINEURAL AND PLEXUS INFUSIONS

Local anesthetics are increasingly being administered by continuous infusion for several days after surgery[48,60] or for periods of weeks to months for the treatment of chronic malignant and nonmalignant pain (see Chapters 64 and 98). With prolonged infusions, there is the potential for delayed systemic accumulation and toxicity. Continuous bupivacaine infusions of up to 30 mg/hr in adults for as long as 2 weeks produced no overt central nervous system (CNS) or cardiac toxicity despite total plasma bupivacaine concentrations in the range of 2 to 5 μg/mL in several patients.[61]

CENTRAL NEURAL BLOCKADE

Any of the local anesthetic drugs can be used for epidural anesthesia (Table 36-7), although procaine and tetracaine are rarely used because of their long onset times (see Chapter 56). Drugs of intermediate potency produce surgical anesthesia of 1 to 2 hours' duration, whereas long-acting drugs usually produce 3 to 4 hours of anesthesia. The duration of short- and intermediate-acting drugs is significantly prolonged by the addition of epinephrine (1:200,000), but the duration of long-acting drugs is only minimally affected by epinephrine. The onset of lumbar epidural anesthesia occurs within 5 to 15 minutes after the administration of chloroprocaine, lidocaine, mepivacaine, and prilocaine. Bupivacaine has a slower onset of action.

Bupivacaine epidural bolus doses at a concentration of 0.125% produce adequate analgesia in many clinical settings with only mild motor deficits.[62] Continuous epidural infusions of bupivacaine as dilute as 0.0625% to 0.1% are useful for labor epidural analgesia, especially when administered in combination with opioids and other additives. Bupivacaine 0.25% can be used for more intense analgesia (particularly during combined epidural–light general anesthesia cases) with moderate degrees of motor block. Bupivacaine at concentrations of 0.5% to 0.75% is associated with a more profound degree of motor block, which makes these solutions most suitable for major surgical procedures, particularly when epidural anesthesia is not combined with general anesthesia. It should be emphasized that although high concentrations of local anesthetics may be appropriate for episodic bolus dosing for surgery, these concentrations (i.e., >0.2% for bupivacaine) should generally be avoided for continuous epidural infusions. Bolus injections produce much more cephalocaudad spread than infusions do. When concentrated bupivacaine solutions are used for infusions, the potential exists for excessive local effect with an associated risk for unwanted and very prolonged motor blockade. Etidocaine produces adequate sensory analgesia and

TABLE 36-6 MAJOR NERVE BLOCKS*

Drug	Usual Concentration (%)	Usual Volume (mL)	Maximum Dose (mg) Without/With Epinephrine	Onset (min)	Duration (min)
Lidocaine	1-2	30-50	350/500	10-20	120-240
Mepivacaine	1-1.5	30-50	350/500	10-20	180-300
Prilocaine	1-2	30-50	400/600	10-20	180-300
Bupivacaine	0.25-0.5	30-50	175/225	20-30	360-720
Levobupivacaine	0.25-0.5	30-50	200/225	20-30	360-720
Ropivacaine	0.2-0.5	30-50	200/250	20-30	360-720

*See also Chapter 57. Doses are for a 70-kg adult receiving epinephrine-containing solutions. Doses should be reduced, as detailed in Chapter 92, for children, for patients with specific risk factors, and for blocks in specific locations (e.g., interscalene). When two or more blocks are performed together, the sum of the doses for each of the individual blocks should not exceed the max dose listed here.

TABLE 36-7 EPIDURAL ANESTHESIA*

Drug With Epinephrine (1:200,000)	Usual Concentration (%)	Usual Volume (mL)	Maximum Dose (mg) Without/ With Epinephrine	Usual Onset (min)	Usual Duration (min)
Chloroprocaine	2-3	15-30	700/900	5-15	30-90
Lidocaine	1-2	15-30	350/500	5-15

*Doses are for a 70-kg adult. Dosing may be reduced during pregnancy (see Chapter 77) and with advancing age (see Chapter 80). Pediatric dosing is detailed in Chapter 92.

profound, long-lasting motor block. Use of etidocaine has decreased in recent years, and currently it is primarily restricted to surgical procedures for which profound muscle relaxation is required.

Drugs available for subarachnoid administration are shown in Table 36-8.

Although lidocaine has long been used for spinal anesthesia as a 5% solution, recent studies of local anesthetic neurotoxicity have led some to question this practice. This issue is discussed later in the chapter in the section on the neurotoxicity of local anesthetics.

Tetracaine is available both as crystals and as a 1% solution, which may be diluted with 10% glucose to obtain a 0.5% hyperbaric solution. Hypobaric solutions of tetracaine (tetracaine in sterile water) can be used for specific operative situations, such as anorectal or hip surgery. Isobaric tetracaine obtained by mixing 1% tetracaine with cerebrospinal fluid or normal saline is useful for lower limb surgical procedures.

Bupivacaine is widely used as a spinal anesthetic, either as a hyperbaric solution at a concentration of 0.75% with 8.25% dextrose or by using the nearly isobaric 0.5% solution. Intrathecal bupivacaine possesses an anesthetic profile similar to that of tetracaine.[63]

The addition of vasoconstrictors can prolong the duration of spinal anesthesia. For example, the addition of 0.2 to 0.3 mg of epinephrine to lidocaine, tetracaine, or bupivacaine solutions will produce a 50% or greater increase in duration.[64,65] The duration of spinal anesthesia produced by tetracaine can also be increased to a similar extent by adding 1 to 5 mg of phenylephrine. The addition of epinephrine to bupivacaine or lidocaine may be more effective in prolonging the duration of spinal anesthesia in lumbosacral segments than in thoracic segments.

TOPICAL ANESTHESIA

A number of local anesthetic formulations are available for topical anesthesia (Table 36-9), with lidocaine, dibucaine, tetracaine, and benzocaine being the drugs used most commonly. In general, these preparations provide effective but relatively short durations of analgesia when applied to mucous membranes or abraded skin. Lidocaine and tetracaine sprays are commonly used for endotracheal anesthesia before endotracheal intubation or for mucosal analgesia for bronchoscopy or esophagoscopy.

Several topical local anesthetic formulations can penetrate intact skin. EMLA, which is a eutectic mixture of 2.5% lidocaine base and 2.5% prilocaine base, is widely used for venipuncture, intravenous cannulation, skin grafting, and a range of other uses, including circumcision.[66] This preparation must be applied under an occlusive bandage for 45 to 60 minutes to obtain effective cutaneous anesthesia. Longer application times increase the depth and reliability of skin analgesia. EMLA is safe in neonates, and methemoglobinemia with the use of prilocaine is exceedingly uncommon. EMLA is more effective for newborn circumcision than placebo is but less effective than dorsal penile nerve block.[66,67] Several alternative topical local anesthetic formulations also are in use, including tetracaine gel[68] and liposomal lidocaine.[69] Physical methods to accelerate local anesthetic transit across skin, including iontophoresis, local heating, electroporation, and a variety of forms of needleless pressure injection, can lead to more rapid onset of cutaneous analgesia.[70] Synera (originally studied as S-Caine) is a formulation of lidocaine and tetracaine that was developed with a heating element (activated by opening the package to initiate an oxygen-dependent exothermic reaction). This formulation has a rapid onset and evokes vasodilatation.[71]

Topical anesthesia through cut skin is commonly used in pediatric emergency departments for liquid application into lacerations that require suturing. Historically, this had been provided by a mixture of tetracaine, epinephrine (adrenaline), and cocaine, known as TAC. TAC is usually supplied as tetracaine 0.5%, epinephrine 1:2000, and cocaine 10% to 11.8%, although studies suggest that more dilute concentrations may be almost equally effective and less likely to cause toxicity. The generally

TABLE 36-9 **VARIOUS PREPARATIONS INTENDED FOR TOPICAL ANESTHESIA**

Anesthetic Ingredient	Concentration (%)	Pharmaceutical Application Form	Intended Area of Use
Benzocaine	1-5	Cream	Skin and mucous membrane
	20	Ointment	Skin and mucous membrane
	20	Aerosol	Skin and mucous membrane
Cocaine	4	Solution	Ear, nose, throat
Dibucaine	0.25-1	Cream	Skin
	0.25-1	Ointment	Skin
	0.25-1	Aerosol	Skin
	0.25	Solution	Ear
	2.5	Suppositories	Rectum
Cyclonine	0.5-1	Solution	Skin, oropharynx, tracheobronchial tree, urethra, rectum
Lidocaine	2-4	Solution	Oropharynx, tracheobronchial tree, nose
	2	Jelly	Urethra
	2.5-5	Ointment	Skin, mucous membrane, rectum
	2	Viscous	Oropharynx
	10	Suppositories	Rectum
	10	Aerosol	Gingival mucosa
Tetracaine	0.5-1	Ointment	Skin, rectum, mucous membrane
	0.5-1	Cream	Skin, rectum, mucous membrane
	0.25-1	Solution	Nose, tracheobronchial tree
EMLA	Lidocaine, 2.5 Prilocaine, 2.5	Cream	Intact skin
TAC	Tetracaine, 0.5 Epinephrine, 1:200,000 Cocaine, 11.8	Solution	Cut skin
LET	Lidocaine, 4% Epinephrine, 1:20,000 Tetracaine, 0.5%	Solution	Cut skin

Modified from Covino B, Vassallo H: Local anesthetics: mechanisms of action and clinical use. *Orlando, Fla, 1976, Grune and Stratton.*
EMLA, Eutectic mixture of lidocaine and prilocaine; *LET,* lidocaine-epinephrine-tetracaine; *TAC,* tetracaine-epinephrine-cocaine.

recommended safe maximum dose is 3 to 4 mL for adults or 0.05 mL/kg for children. TAC is ineffective through intact skin; in contrast, its rapid absorption from mucosal surfaces can lead to toxic, even fatal reactions.

Because of concerns regarding cocaine toxicity and the potential for diversion and abuse, several groups have investigated alternative cocaine-free topical preparations. Non–cocaine-containing formulations, especially lidocaine-epinephrine-tetracaine and tetracaine-phenylephrine, have largely supplanted TAC.[72] Similarly, otolaryngologists previously administered cocaine routinely as a solution or aerosol into the nasal passages to provide mucosal analgesia and vasoconstriction. In recent years, cocaine has increasingly been replaced for nasal application by the combined use of an α_1-adrenergic agonist (oxymetazoline or phenylephrine) and a local anesthetic such as 2% to 4% lidocaine, with more dilute solutions being recommended for infants and children (see Chapter 92). Systemic absorption of phenylephrine can cause severe hypertension and reflex bradycardia. Oxymetazoline is associated with much less systemic effect and has a wider margin of safety, although it can still produce peripheral vasoconstriction, hypertension, and reflex bradycardia. In the authors' view, there is no clinical setting for which the benefits of cocaine clearly outweigh the potential risks when compared with alternative approaches involving combined administration of a local anesthetic and a topical vasoconstrictor such as oxymetazoline.

TUMESCENT ANESTHESIA

A technique of local anesthesia most commonly used by plastic surgeons during liposuction procedures involves the subcutaneous injection of large volumes of dilute local anesthetic in combination with epinephrine and other drugs. Total doses of lidocaine ranging from 35 to 55 mg/kg produce safe plasma concentrations, which can peak more than 8 to 12 hours after infusion.[73] Despite these seemingly huge doses, good outcomes have been reported in several case series.[74] Conversely, there have been several case series of cardiac arrest and death during plastic surgery procedures in which multiple risk factors, including high local anesthetic concentrations and concomitant use of sedatives, may have contributed to the patients' instability and deterioration.[75] Factors governing uptake and clearance from this method of local anesthetic delivery deserve further study. Clinicians should exercise great caution when administering additional local anesthetics by infiltration or other routes for at least 12 to 18 hours after the use of this technique.

SYSTEMIC LOCAL ANESTHETICS FOR NEUROPATHIC PAIN

A broad variety of local anesthetics, antiarrhythmics, anticonvulsants, and other Na^+ channel blockers are administered intravenously, orally, or both to relieve a number of forms of neuropathic pain (see Chapter 64).[76] Clinical

results are unpredictable.[77] Although successful responses from intravenous lidocaine are often taken as a positive indication for oral mexiletine, some patients find mexiletine difficult to tolerate. When the signs of neuropathic pain are reversed by lidocaine infusion, normal nociception and other sensory modalities are unaffected, suggesting that the neurophysiologic correlate of the disease has an unusually high susceptibility to these drugs, present in plasma at concentrations 50- to 100-fold lower than that required to block normal impulses in peripheral fibers. Laboratory studies suggest that ectopic impulse activity arising at a site of injury or elsewhere, such as the dorsal root ganglion, contributes to the neuropathic pain and that such impulses are particularly sensitive to use-dependent Na^+ channel blockers. It is noteworthy that relief of preexisting neuropathic pain, both clinically and in animal models,[78] can in some cases persist for days, weeks, or months after a single intravenous infusion of drug (e.g., lidocaine), far beyond the lifetime of the drug in vivo or any nerve block that it might affect. The mechanism of this remarkable action remains a mystery.

PHARMACOKINETICS

The concentration of local anesthetics in blood is determined by the amount injected, the rate of absorption from the site of injection, the rate of tissue distribution, and the rate of biotransformation and excretion of the specific drug.[79,80] Patient-related factors such as age, cardiovascular status, and hepatic function influence the physiologic disposition and resultant blood concentration of local anesthetics.

ABSORPTION

The systemic absorption of local anesthetics is determined by the site of injection with its tissue blood perfusion, dosage and volume, addition of a vasoconstrictor agent, and the pharmacologic profile of the agent itself.[79,80] Comparison of the blood concentration of local anesthetics after various routes of administration reveals that the anesthetic drug concentration is highest after intercostal nerve blockade, followed in order of decreasing concentration by injection into the caudal epidural space, lumbar epidural space, brachial plexus, and subcutaneous tissue. When a local anesthetic solution is exposed to an area of greater vascularity, a greater rate and degree of absorption occur. This relationship is of clinical significance because use of a fixed dose of a local anesthetic agent can be potentially toxic in one area of administration but not in others. For example, the use of 400 mg of lidocaine without epinephrine for an intercostal nerve block results in an average peak venous plasma level of approximately 7 μg/mL, which is sufficiently high to cause symptoms of CNS toxicity in some patients. By comparison, this same dose of lidocaine used for a brachial plexus block yields a mean maximum blood level of approximately 3 μg/mL, which is rarely associated with signs of toxicity.

The maximum blood concentration of local anesthetic drugs is related to the total dose of drug administered for any particular site of administration. For most drugs, there is a proportionality between the amount of drug administered and the resultant peak anesthetic blood concentration. Epinephrine decreases the rate of vascular absorption of certain local anesthetics from various sites of administration and thus decreases their potential systemic toxicity. A 5-μg/mL concentration of epinephrine (1:200,000) significantly reduces the peak blood levels of lidocaine and mepivacaine irrespective of the site of administration. Peak blood levels of bupivacaine and etidocaine are minimally influenced by the addition of a vasoconstrictor after injection into the lumbar epidural space. However, epinephrine will significantly reduce the rate of vascular absorption of these drugs when they are used for peripheral nerve blocks such as brachial plexus blockade.

Differences also exist in the rate of absorption of various local anesthetics.

DISTRIBUTION

The systemic distribution of local anesthetics in many settings can be described sufficiently by a two-compartment model.[81,82] The rapid-disappearance phase is believed to be related to uptake by rapidly equilibrating tissues (i.e., tissues that have high vascular perfusion). The slower phase of disappearance from blood is mainly a function of the particular compound.[82]

Local anesthetic drugs are distributed throughout all body tissues, but the relative concentration in different tissues varies. In general, more highly perfused organs show higher concentrations of local anesthetic drug than less well-perfused organs do. Because local anesthetics are rapidly extracted by lung tissue, the whole blood concentration of local anesthetics decreases markedly as they pass through the pulmonary vasculature.[83]

BIOTRANSFORMATION AND EXCRETION

The pattern of metabolism of local anesthetic agents varies according to their chemical classification. The ester, or procainelike, drugs undergo hydrolysis in plasma by the pseudocholinesterase enzymes; clearance of chloroprocaine is especially rapid.[84,85]

The aminoamide drugs undergo enzymatic degradation primarily in the liver. Lidocaine is metabolized somewhat more rapidly than mepivacaine, which in turn is more rapidly metabolized than bupivacaine.[67,86,87]

Excretion of the metabolites of amide-type local anesthetics occurs via the kidney. Less than 5% of the unchanged drug is excreted via the kidney into urine.

PHARMACOKINETIC ALTERATIONS BY PATIENT STATUS

Patient age can influence the physiologic disposition of local anesthetics (see Chapters 80 and 92). In a report by Nation and colleagues,[88] the half-life of lidocaine after intravenous administration averaged 80 minutes in human volunteers varying in age from 22 to 26 years, whereas volunteers 61 to 71 years of age demonstrated a significantly prolonged lidocaine half-life that averaged 138 minutes.

Newborn infants have immature hepatic enzyme systems and hence prolonged elimination of lidocaine, bupivacaine, and ropivacaine.[89-91] Bupivacaine, for example, has a terminal elimination half-life in adults that averages 3.5 hours. In neonates and some younger infants, terminal elimination half-lives can be as long as 8 to 12 hours. Prolonged elimination is particularly an issue for continuous infusions of local anesthetics in infants, and seizures have been associated with high bupivacaine infusion rates.[92] Based on analysis of these cases, a maximum infusion rate of 0.4 mg/kg/hr for prolonged bupivacaine infusions has been proposed for children and adults, whereas prolonged infusion rates for neonates and young infants should not exceed 0.2 mg/kg/hr.[93] Even at 0.2 mg/kg/hr, plasma bupivacaine concentrations were found to be rising toward a toxic range in some younger infants after 48 hours.[94] Similarly, prolonged lidocaine infusions in neonates should not exceed 0.8 mg/kg/hr. The potential for toxicity with lidocaine infusions in neonates is also increased by the accumulation of its principal metabolite, monoethylglycinexylidide, which can cause seizures. Chloroprocaine may offer unique advantages for epidural infusion in neonates in that it is rapidly cleared from plasma, even in preterm neonates.[95]

Decreased hepatic blood flow or impaired hepatic enzyme function can produce a substantial elevation of blood levels of the aminoamide local anesthetics. An average lidocaine half-life of 1.5 hours was reported in volunteers with normal hepatic function, whereas patients with liver disease demonstrated an average half-life of 5.0 hours. The rate of disappearance of lidocaine from blood is markedly prolonged in patients with congestive heart failure.[96]

TOXICITY

Local anesthetic drugs are generally considered safe if administered in an appropriate dosage and in the correct anatomic location. However, systemic and localized toxic reactions can occur because of accidental intravascular or intrathecal injection or administration of an unwanted excessive dose. In addition, specific adverse effects are associated with the use of certain drugs, such as allergic reactions to the aminoester drugs and methemoglobinemia after the use of prilocaine.

SYSTEMIC TOXICITY

Systemic reactions to local anesthetics primarily involve the CNS and the cardiovascular system (see Chapters 56 to 58 and 92). In general, the CNS is more susceptible to the actions of systemic local anesthetics than the cardiovascular system is, and thus the dose or blood level of local anesthetic required to produce CNS toxicity is usually lower than that resulting in circulatory collapse.

Central Nervous System Toxicity

The initial symptoms of local anesthetic–induced CNS toxicity are feelings of lightheadedness and dizziness followed frequently by visual and auditory disturbances such as difficulty focusing and tinnitus. Other subjective CNS symptoms include disorientation and occasional feelings of drowsiness. Objective signs of CNS toxicity are usually excitatory in nature and include shivering, muscular twitching, and tremors initially involving muscles of the face and distal parts of the extremities. Ultimately, generalized convulsions of a tonic-clonic nature occur. If a sufficiently large dose or rapid intravenous injection of a local anesthetic is administered, the initial signs of CNS excitation are rapidly followed by a state of generalized CNS depression. Seizure activity ceases, and respiratory depression and ultimately respiratory arrest may occur. In some patients, CNS depression is seen without a preceding excitatory phase, particularly if other CNS depressant drugs have been administered.

CNS excitation may be the result of an initial blockade of inhibitory pathways in the cerebral cortex by local anesthetic drugs,[97] but it can also result from the net stimulation of release of glutamate, an excitatory amino acid neurotransmitter. Blockade of inhibitory pathways allows facilitatory neurons to function in an unopposed fashion, which results in an increase in excitatory activity leading to convulsions. Further increase in the dose of local anesthetic leads to inhibition of activity of both the inhibitory and facilitatory circuits, which results in a generalized state of CNS depression.

In general, the potency of the local anesthetic is correlated with intravenous CNS toxicity.[98] Convulsions caused by an inadvertent intravenous bolus of local anesthetic can generally be terminated by small intravenous doses of a benzodiazepine, such as midazolam, or by small intravenous doses of thiopental. Respiratory or metabolic acidosis increases the risks for CNS toxicity from local anesthetics.[99]

Increased $Paco_2$ enhances cerebral blood flow and thus the anesthetic is delivered more rapidly to the brain. In addition, diffusion of CO_2 into neuronal cells decreases intracellular pH, which facilitates conversion of the base form of the drugs to the cationic form. The cationic form does not diffuse well across the nerve membrane, so that ion trapping will occur, which will increase the apparent CNS toxicity of local anesthetics.

Hypercapnia and acidosis also decrease the plasma protein binding of local anesthetic agents.[100] Accordingly, an increase in $Paco_2$ or a decrease in pH will increase the proportion of free drug available for diffusion into the brain. On the other hand, acidosis increases the cationic form of the local anesthetic, which should decrease the rate of diffusion through lipid barriers.

The clinical implication of this effect of hypercapnia and acidosis on toxicity deserves emphasis. Seizures produce hypoventilation and a combined respiratory and metabolic acidosis, which further exacerbates the CNS toxicity. In the setting of local anesthetic toxic reactions, it is essential to provide prompt assisted ventilation and circulatory support as needed to prevent or correct hypercapnia and acidosis and to prevent or correct hypoxemia, which also exacerbates CNS toxicity.

Based on the preceding discussion and a number of national guidelines for safe perioperative care, it is generally agreed that clinicians performing major conduction blockade should make a routine practice of having the following ready at hand:

1. Routine vital sign monitoring equipment
2. An oxygen tank or wall oxygen outlet

3. Airway equipment, including a bag-mask circuit for delivery of positive-pressure ventilation
4. Drugs to terminate convulsions, should they occur, preferably midazolam, lorazepam, diazepam, or thiopental.

Cardiovascular System Toxicity

Local anesthetics can exert direct actions on both the heart and peripheral blood vessels, as well as indirect actions on the circulation by blockade of sympathetic or parasympathetic efferent activity.

Direct Cardiac Effects. The primary cardiac electrophysiologic effect of local anesthetics is a decrease in the rate of depolarization in the fast conducting tissues of Purkinje fibers and ventricular muscle.[101] This reduction in rate is believed to be due to a decrease in the availability of fast sodium channels in cardiac membranes. Action potential duration and the effective refractory period are also decreased by local anesthetics.

The electrophysiologic effects of various local anesthetics differ qualitatively. Bupivacaine depresses the rapid phase of depolarization (Vmax) in Purkinje fibers and ventricular muscle more than lidocaine does. In addition, the rate of recovery from a use-dependent block is slower in bupivacaine-treated papillary muscles than in lidocaine-treated muscles. This slow rate of recovery results in incomplete restoration of Na^+ channel availability between action potentials, particularly at high heart rates. These differential effects of lidocaine and bupivacaine have been advanced as explanations of the antiarrhythmic properties of lidocaine and the arrhythmogenic potential of bupivacaine.

Electrophysiologic studies have shown that high blood levels of local anesthetics will prolong conduction time through various parts of the heart, as indicated on the electrocardiogram (ECG) by an increase in the PR interval and duration of the QRS complex. Extremely high concentrations of local anesthetics depress spontaneous pacemaker activity in the sinus node, thereby resulting in sinus bradycardia and sinus arrest.

All local anesthetics exert dose-dependent negative inotropic action on cardiac muscle[102]; the depression of cardiac contractility is roughly proportional to conduction blocking potency. Thus, bupivacaine and tetracaine are more potent cardiodepressants than lidocaine is.

Local anesthetics may depress myocardial contractility by affecting calcium influx and triggered release from the sarcoplasmic reticulum,[97] as well as by inhibiting cardiac sarcolemmal Ca^{2+} currents and Na^+ currents.

Direct Peripheral Vascular Effects. Local anesthetics exert biphasic effects on peripheral vascular smooth muscle.[103] Low concentrations of lidocaine and bupivacaine produced vasoconstriction in the cremaster muscle of rats, whereas high concentrations produced vasodilation in both isolated tissue models and in vivo.

Cocaine is the only local anesthetic that consistently causes vasoconstriction at all concentrations because of its ability to inhibit the uptake of norepinephrine by premotor neurons and thus to potentiate neurogenic vasoconstriction.

COMPARATIVE CARDIOVASCULAR TOXICITY

All local anesthetics, but especially bupivacaine, can cause rapid and profound cardiovascular depression (see Chapters 56 to 58 and 92). The cardiotoxicity of bupivacaine appears to differ from that of lidocaine in the following manner:

1. The ratio of the dosage required for irreversible cardiovascular collapse (CC) and the dosage that will produce CNS toxicity (convulsions; i.e., the CC/CNS ratio) is lower for bupivacaine and etidocaine than for lidocaine.[104]
2. Ventricular arrhythmias and fatal ventricular fibrillation can occur more often after the rapid intravenous administration of a large dose of bupivacaine, but far less frequently with lidocaine. The CNS effects of local anesthetics may contribute to the generation of arrhythmias (see Chapter 68).
3. A pregnant animal or patient may be more sensitive to the cardiotoxic effects of bupivacaine than a nonpregnant animal or patient[105] (see Chapter 77). The 0.75% solution of bupivacaine is no longer recommended for use in obstetric anesthesia in the United States.
4. Cardiac resuscitation is more difficult after bupivacaine-induced cardiovascular collapse, and acidosis and hypoxia markedly potentiate the cardiotoxicity of bupivacaine.[106]

Many resuscitation drugs, including atropine, epinephrine, bretylium, lidocaine, amrinone, and phenytoin, have been used in animal studies, and occasionally in humans, for the treatment of bupivacaine overdose and cardiovascular collapse. As with other forms of cardiovascular collapse, basic CPR should be started immediately and defibrillation should be performed as indicated according to advanced cardiac life support (ACLS) algorithms.[107] In the authors' view—beyond the established uses of low-dose epinephrine and atropine in their designated steps in ACLS protocol[107] and beyond the use of lipid emulsions as detailed later—there is no established role for antiarrhythmic drugs or other traditional cardiac resuscitation drugs in the setting of bupivacaine-induced cardiac arrest. It is *not* recommended to treat bupivacaine-induced ventricular arrhythmias with lidocaine or amiodarone. Rapid institution of extracorporeal cardiopulmonary support has been lifesaving in a small number of cases of bupivacaine cardiotoxicity. There is a growing use of rapid-response extracorporeal membrane oxygenator and/or cardiopulmonary bypass teams in some tertiary hospitals. In selected cases, these teams should be activated even while initiating ACLS and infusing lipid emulsions.

The clinical implications for cardiac resuscitation after intravascular injection or overdose of local anesthetic are the following:

1. No medications are uniformly effective in facilitating resuscitation from bupivacaine-induced cardiac arrest or severe ventricular tachycardia (despite our recommendations regarding Intralipid later). Basic principles of cardiopulmonary resuscitation should be

emphasized first, including attention to securing the airway, providing oxygenation and ventilation, and performing chest compressions if needed.
2. Because resuscitation after local anesthetic-induced circulatory collapse is so difficult, prevention of massive intravascular injection or excessive dosing is crucial.
3. Negative aspiration of the syringe does not always exclude intravascular placement. Incremental, fractionated dosing should be the rule for all patients undergoing major conduction blockade. Although changes on the ECG are not always present before circulatory collapse, they often are, and continuous attention to the ECG (including changes in QRS morphology, rate, rhythm, or ectopy) may be lifesaving by terminating injection before a lethal dose is administered.
4. Based on animal studies[108] and a growing number of human case reports,[109-111] hospitals and clinics that perform major conduction blockade should keep available for emergency use a supply of lipid emulsion, such as Intralipid 20%.[111] If a patient experiences profound cardiovascular depression or circulatory arrest after the administration of bupivacaine, ropivacaine, or by extrapolation, other local anesthetics, then along with initiation of basic life support and the ACLS protocol we support the recommendation for a rapid bolus of Intralipid 20%, 1.5 mL/kg (or approximately 100 mL in adults), administering without delay, followed if necessary by an infusion of 0.25 mL/kg/min for the next 10 minutes.

Chiral Local Anesthetics: Ropivacaine and Levobupivacaine

Commercial bupivacaine is a racemic mixture of (*R*)- and (*S*)-stereoisomers. In response to the problem of cardiovascular toxicity resulting from accidental intravenous injection of bupivacaine, single enantiomers were developed in the hope that they would be potentially safer local anesthetics. Ropivacaine (Naropin)[112] and levo-(*S*)-bupivacaine (Chirocaine)[113] were formulated to exploit this stereoselectivity. Ropivacaine is a single (*S*)-stereoisomer that differs from levobupivacaine in the substitution of a propyl for the butyl group on the piperidine ring (see Table 36-1). With these designed changes in molecular structure, it was hoped that ropivacaine and levobupivacaine would be less intrinsically cardiotoxic. Conversely, it appears that the (*S*)-enantiomers of mepivacaine and bupivacaine are metabolized by the liver more slowly than the corresponding (*R*)-enantiomers, which would lead to somewhat greater systemic accumulation with prolonged infusions.

The slow reversal of Na^+ channel blockade after a cardiac action potential, which is a hallmark of bupivacaine, is considerably faster with ropivacaine. In addition to these electrical differences, the negative inotropic potency of ropivacaine on isolated cardiac tissue appears to be considerably less than that of bupivacaine. Both electrical and mechanical differences in the toxic profiles can arise from the selective inhibition of Ca^{2+} currents by bupivacaine.

Is there a greater therapeutic index for ropivacaine than bupivacaine, particularly regarding cardiotoxicity? In clinical studies comparing potencies of ropivacaine and bupivacaine administered for brachial plexus[114] or lumbar epidural block,[115] the anesthetic profiles of the drugs were almost identical. A third study comparing lumbar epidural 0.5% bupivacaine with 0.75% ropivacaine also found no significant differences in motor or sensory effects between the drugs at these different concentrations.[116] Overall, it appears that ropivacaine is slightly less potent than (1:1.3 to 1:1.5) bupivacaine for regional anesthesia. In some laboratory animal studies and in some human studies, ropivacaine also produced blocks of shorter duration than those induced by bupivacaine. Other studies in animals and humans have found equal durations of sensory and motor block for the two drugs.

At the projected equipotent doses for nerve block, are the drugs equally toxic? The overall impression is that ropivacaine is less cardiotoxic than bupivacaine. Studies in animals have generally found that bupivacaine more readily produces conduction disturbances, cardiac collapse, or ventricular fibrillation than ropivacaine does and that aggressive cardiac resuscitation after an intentional intravenous bolus in dogs leads to effective reversal of the toxic effects far more frequently with ropivacaine than with bupivacaine.[117]

The greater safety of ropivacaine than bupivacaine may be related both to the reduced toxicity of the single (*S*)-isomer and to the difference between the propyl- and butyl-*N*-piperidine substituent. In contrast to bupivacaine, the cardiotoxic profile of ropivacaine in pregnant ewes is the same as the corresponding profile in nonpregnant ewes.[118]

Levobupivacaine has been studied in a range of clinical settings and sites of administration.[119-121] Although many publications have compared levobupivacaine with racemic bupivacaine and ropivacaine,[120,121] conclusions differ among studies regarding the relative potency and duration of block of these three drugs at different sites of administration with respect to sensory and motor endpoints. Levobupivacaine is formulated as a weight percentage in regard to its free base content, whereas the weight percentage of most other local anesthetics is calculated on the basis of the hydrochloride salt.[122]

Acidosis and Hypoxia

As with CNS toxicity, hypercapnia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic actions of lidocaine and bupivacaine in isolated cardiac tissue, and the combination of hypoxia and acidosis markedly potentiates the cardiodepressant effects of bupivacaine.[123] Hypoxia and acidosis also increased the frequency of cardiac arrhythmias and the mortality rate in sheep after the intravenous administration of bupivacaine. Hypercapnia, acidosis, and hypoxia occur very rapidly in some patients after seizure activity caused by the rapid accidental intravascular injection of local anesthetic agents.[124] Thus, the cardiovascular depression observed in some patients after the accidental intravenous injection of bupivacaine may be related in part to the effect of seizures producing acidosis and hypoxia and thereby leading to an exacerbation of bupivacaine's intrinsic cardiotoxicity.

Indirect Cardiovascular Effects

High levels of spinal or epidural blockade can produce severe hypotension. A follow-up study of closed claims of patients who suffered perioperative cardiac arrest confirmed previous reports of a series of cardiac arrests involving generally healthy patients undergoing spinal or epidural anesthesia.[125] These events frequently occurred in conjunction with high dermatomal levels of blockade, liberal use of sedatives, and progression to cardiac arrest after a period of hypotension accompanied by bradycardia, often involving delays in recognition of the problem, delays in instituting airway support (particularly in sedated patients), and delays in administration of direct-acting combined α- and β-adrenergic agonists, such as epinephrine. Whereas mild to moderate degrees of hypotension generally respond well to indirect-acting sympathomimetics, such as ephedrine or incremental dosing of phenylephrine, the combination of severe hypotension and severe bradycardia under spinal anesthesia should in most clinical settings be treated promptly with incremental dosing of epinephrine, initially at doses of 0.1 to 1 μg/kg, or roughly 20- to 200-fold less than those used in the ACLS cardiac arrest algorithm (see Chapter 108).

METHEMOGLOBINEMIA

A unique systemic side effect associated with a specific local anesthetic is the development of methemoglobinemia after the administration of large doses of prilocaine.[126] In general, 600-mg doses are required for the development of clinically significant levels of methemoglobinemia in adults. Hepatic metabolism of prilocaine generates *O*-toluidine, which oxidizes hemoglobin to methemoglobin. Methemoglobinemia, if severe, can be treated with intravenous administration of methylene blue. Standard dosing of the topical local anesthetic EMLA (a mixture of lidocaine and prilocaine) in term newborns produces minimal amounts of methemoglobin, and EMLA when used in this manner should thus be regarded as safe in the great majority of newborns. It should be noted that risk is increased in newborns with rare metabolic disorders or after the concomitant administration of other drugs that impair reduction of methemoglobin.

ALLERGIES

Although patients receiving local anesthetics may experience a range of local and systemic symptoms, prospective studies indicate that few of these reactions are confirmed as allergic reactions.[127] Aminoester drugs such as procaine produce allergic-type reactions more commonly than the aminoamides do, although even with aminoesters, the vast majority of reactions are not allergic. Aminoesters, unlike aminoamides, are derivatives of *p*-aminobenzoic acid, which is known to be allergenic. Some aminoamide solutions contain a preservative, methylparaben, whose chemical structure is similar to that of *p*-aminobenzoic acid, but for most aminoamides, preservative-free solutions are available. Contamination of vials with latex antigen has been suspected in some allergic reactions, although it is difficult to confirm. In the rare patient for whom confirmed allergy to both aminoamides and aminoesters precludes their use for spinal anesthesia, meperidine can be considered as an alternative.[128]

LOCAL TISSUE TOXICITY

All the clinically used aminoamide and aminoester local anesthetics can produce direct toxicity to nerves if they achieve sufficiently high intraneural concentrations. Conversely, in most clinical applications, no damage to nerves occurs. Although local anesthetics are usually packaged and injected at concentrations well above their physiologically effective range, in the process of delivery they are generally diluted sufficiently so that no harm is done. If such dilution does not occur, however, long-term or permanent neural deficits do result. Thus, the application of 5% (200 mM) lidocaine in viscous, dense solutions through narrow intrathecal catheters has been associated with a high frequency of transient or longer-term radicular symptoms, or even cauda equina syndrome.[129] Laboratory investigations have shown that such high concentrations of local anesthetics alone applied directly to bare nerve fibers produce an irreversible conduction block in less than 5 minutes.[130] Clinicians should be aware that the concentrations of formulated local anesthetic solutions are neurotoxic and that their dilution, in situ or in tissue, is essential for safe use without local toxic reactions.

In the late 1970s and early 1980s, prolonged sensory and motor deficits were reported in some patients after the epidural or subarachnoid injection of large doses of chloroprocaine.[131] Studies in animals have proved somewhat contradictory regarding the potential neurotoxicity of chloroprocaine.[132,133] Some studies suggest that the combination of low pH, sodium bisulfite, and inadvertent intrathecal dosing is responsible in part for the neurotoxic reactions observed after the use of large amounts of chloroprocaine solution; other studies have disputed this claim and note that chloroprocaine itself at high concentrations can also be neurotoxic,[132,133] but these concentrations are probably rarely achieved during properly positioned epidural anesthesia, as opposed to inadvertent spinal anesthesia. The currently available commercial solutions of chloroprocaine do not contain sodium bisulfite. This was initially replaced by ethylene glycol-bis-(β-aminoethyl ether)-*N*,*N*-tetraacetic acid (EGTA), a preservative and high-affinity calcium chelator that occasionally causes local muscle spasms after epidural administration. More recently, chloroprocaine has become available in an entirely preservative-free preparation. Chloroprocaine has unique utility in situations in which rapid plasma clearance is required to prevent excessive systemic accumulation of local anesthetic. Chloroprocaine has been given by epidural infusion to neonates and young infants in settings in which lidocaine and bupivacaine do not provide an effective therapeutic index,[95] and it has also recently become popular as a short-duration spinal anesthetic.

Single-shot spinal anesthesia with commonly recommended doses and concentrations of many different local anesthetics can produce more limited and transient neurologic symptoms (back pain, paresthesias, radicular pain, or hypoesthesia).[134] Some studies and systematic

reviews have found that mepivacaine and lidocaine at a range of dilutions cause more frequent symptoms than bupivacaine and prilocaine do.[135] The risk of transient neurologic symptoms after spinal anesthesia was not diminished by dilution of lidocaine from 5% to 1% or 2%. Differences in study design, method of questioning, and criteria for inclusion may be partially responsible for differences in the prevalence of radicular sequelae in various studies. Despite these differences in study design, a meta-analysis concluded that the pooled relative risk for transient neurologic symptoms after spinal anesthesia with lidocaine was 6.7-fold higher than with bupivacaine and 5.5-fold higher than with prilocaine.[135] The addition of vasoconstrictors to local anesthetic solutions can also increase risk.[136] Neurotoxicity appears to be unrelated to conduction block, because saxitoxin, neosaxitoxin, and tetrodotoxin, which are highly potent blockers of sodium channels, can produce intense conduction blockade without histologic or behavioral signs of nerve injury.[137]

With the recent widespread use of ultrasound guidance of peripheral nerve blockade, there is an expectation, not yet fully demonstrated,[138] that this approach will reduce the frequency of neurologic sequelae from peripheral nerve blockade. This issue is discussed in detail in Chapter 58.

Intraoperative positioning in association with nerve blockade appears to be a risk factor (see Chapter 41). For example, patients undergoing surgery in the lithotomy position appear to be at increased risk for neurologic symptoms after either spinal or epidural anesthesia. It is unknown at present why this association produces increased risk; nerve compression or stretch or reduced perfusion pressure in the vasa nervorum may possibly exacerbate the toxicity from local anesthetics. The lithotomy position can produce neurologic sequelae and lower extremity compartment syndrome, particularly with prolonged surgery and use of the Trendelenburg position.[139]

Skeletal muscle changes occur after the intramuscular injection of local anesthetics such as lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine. In general, the more potent, longer-acting agents bupivacaine and etidocaine cause more localized skeletal muscle damage than the less potent, shorter-acting anesthetics lidocaine and prilocaine do. This effect on skeletal muscle is reversible, and muscle regeneration occurs rapidly and is complete within 2 weeks after the injection of local anesthetic agents. Local anesthetic-induced myotoxicity may involve actions on mitochondria.[140]

DEVELOPMENT OF PROLONGED-DURATION AND SENSORY- OR NOCICEPTIVE-SELECTIVE LOCAL ANESTHETICS

Several methods for producing long-duration nerve blockade are under investigation. Liposomal encapsulation can prolong nerve blockade, depending on the dose and the physical properties of the liposome (surface charge, size, lamellar structure).[141-143] Local anesthetics can be incorporated into biodegradable polymer microspheres for sustained release.[144] These preparations produce peripheral nerve blockade in animal models and human volunteers,[145] ranging from 2 to 8 days, depending on the dose, site, and species. Because of the intrinsic neurotoxicity of all aminoamide and aminoester local anesthetics, there is likely to be some irreducible potential for neurotoxicity with most of these approaches to controlled release of aminoamide and aminoester local anesthetics in proximity to major nerve trunks. Thus, these formulations will have the most favorable risk-benefit ratio when used in nonprotective locations, such as intercostal nerve blockade, where prolonged numbness may be a benefit rather than a complication of the intervention. This risk is also likely to be less clinically important for infiltration analgesia. Exparel is a lipid depot formulation that has recently been approved in the U.S. for infiltration analgesia, not for perineural administration.[146] Posidur is another lipid depot formulation currently in clinical trials.[147]

Prolonged-duration local anesthesia also appears to be feasible with the use of site 1 sodium channel blockers in combination with either local anesthetics or adrenergics.[148] The site 1 blocker neosaxitoxin has been used in humans in phase 1 and phase 2 clinical trials.[149-151] A combination of site 1 toxins with either local anesthetics or adrenergics results in prolongation of blockade and improvement in the therapeutic index.[149] Theoretically, attractive features of site 1 toxins include their apparent lack of local tissue toxicity on nerves[137] or muscles[152] and their minimal cardiotoxicity.[153]

Other drugs have been examined for use as local anesthetics, including tricyclic antidepressants,[154] although neurotoxicity may limit the clinical utility of this group of drugs.

Prolonged duration local anesthetics are expected to be useful for providing prolonged postoperative analgesia for a wide range of surgeries, both via wound infiltration and by peripheral nerve and plexus blockade. For peripheral nerve and plexus blocks for the extremities, clinical application will require careful consideration of the potential consequences of prolonged motor blockade. For thoracic and abdominal surgeries, prolonged-duration paravertebral and transversus abdominis plane blockades should be useful, and motor blockade should be a nonissue.

Sensory (or nociceptive) selectivity has been another long-sought goal for local anesthetics. A novel approach to targeting small sensory fibers involved routing a quaternary lidocaine derivative, QX-314, through transient receptor potential (TRP) channels, which are preferentially located in small sensory fibers.[155,156] These channels are involved in the transduction of heat pain and are activated by a vanilloid, such as capsaicin.

BIOLOGIC MECHANISMS OF LOCAL ANESTHETIC FAILURE: INFLAMMATION, HYPERALGESIA, TACHYPHYLAXIS, AND GENETIC VARIANTS

Failure of local anesthesia is commonly ascribed to technical failure of delivery, insufficient volume or concentration of drug, or erroneous clinical decisions in selection of techniques. However, there are many clinical situations in which biologic processes contribute to failed local anesthesia, even with proper technique and drug selection.

For example, in patients going to the dentist with infections such as a tooth abscess or severe pulpitis, failure rates of standard doses of local anesthetic have been reported to be as high as 70%. Local anesthetic failure at a site of inflammation appears to reflect a combination of pharmacokinetic and pharmacodynamic factors. Pharmacokinetic factors include (1) increased local blood flow leading to accelerated removal of drug from perineural injection compartments; (2) local tissue acidosis leading to a greater proportion of the drug in the hydrochloride form, which diffuses more poorly across biologic membranes; and (3) local tissue edema, which increases diffusion distances for drug into nerves and promotes further dilution. Pharmacodynamic factors include the effects of inflammation on both peripheral sensitization of nerves and central sensitization.[157,158] In the setting of an infected mandibular tooth, inferior alveolar nerve block (performed proximally at a site presumably remote from the infected area) also has an unexpectedly frequent failure rate.

Local anesthetics and regional anesthesia, in turn, can suppress components of inflammatory responses by a complex interplay of local, spinal, and systemic mechanisms.[159,160]

Apparent reductions in the effectiveness of local anesthetic infusions over time may be due to many causes unrelated to tolerance, including dislodgement of catheters and changes in the dermatomal origin or intensity of nociceptive input. In obstetric patients receiving epidural bolus injections, recurrence of pain before the next injection resulted in a reduction in the intensity and duration of blockade, whereas repeated injection before the return of pain prevented this rapidly occurring form of tolerance, or tachyphylaxis.[161] In postoperative patients, coadministration of systemic opioids prevented regression of segmental block in patients receiving thoracic epidural bupivacaine infusions.[162] Studies in rats suggest that both pharmacokinetic and pharmacodynamic mechanisms are involved. In a rat model, tachyphylaxis was linked to the development of hyperalgesia,[163] and drugs that inhibit hyperalgesia, including *N*-methyl-D-aspartate receptor antagonists and nitric oxide synthase inhibitors,[164] also prevented tachyphylaxis. Conversely, repeated sciatic injections of lidocaine resulted in reduced intraneural lidocaine content and reduced duration of block.[165]

Occasionally, patients report "local anesthetics don't work for me." Although this claim may reflect previous technical failures or a variety of other processes and patient- or procedure-specific factors, it is possible that these failures may involve genetic variation in local anesthetic responsiveness in some cases. For example, a subgroup of patients with the connective tissue disorder Ehlers-Danlos syndrome appears to have a diminished response to topical local anesthesia.[166]

Chapter 37

Risk of Anesthesia

MARK D. NEUMAN • LEE A. FLEISHER

Key Points

- Perioperative risk is multifactorial and may occur as a result of anesthesia-, surgery-, and/or patient-specific factors.
- Anesthesia-related (and surgery-related) risk is typically defined as morbidity and mortality occurring within 30 days of surgery, although events that occur at later points may still be related to anesthesia and/or surgery.
- The overall risk of anesthesia relates to both specific, organ-based complications and the rapidity with which they are managed (i.e., rescued).
- In the literature on anesthesia-related risk, the rates of morbidity and mortality reported across studies show a substantial variability in part attributable to the wide variety of definitions used in these studies.
- Historical studies of anesthesia-related risk identified anesthesia-related respiratory depression as the major cause of death and coma totally attributable to anesthesia. This finding prompted the creation of postanesthesia care units (PACUs).
- Research into anesthesia-related cardiac arrest has found it to be attributable to medication administration, airway management, and technical problems of central venous access.
- Multivariate modeling can be used to determine specific factors associated with an increased likelihood of adverse postoperative events, and it has been used to define a range of clinical risk indices to predict postoperative outcomes.
- Surveys of maternal mortality suggest that although the absolute rate of complications attributable to anesthesia has not decreased over time, the increased use of regional anesthesia may have led to improvements in outcome.
- Medication-related and cardiovascular events were the most common causes of cardiac arrest in the Pediatric Perioperative Cardiac Arrest (POCA) Registry.
- Growth in the number and variety of surgical procedures performed in hospital outpatient departments, ambulatory surgery centers, and physician offices creates novel challenges for assessing and managing perioperative risk.
- Initiatives established over time by the Anesthesia Patient Safety Foundation, the American Society of Anesthesiologists (ASA), and others have sought to decrease the potential risks of anesthesia through systems-level improvements, standardization of care processes, human-factors engineering, and simulation-based training.

INTRODUCTION

Since the beginning of its modern history, the administration of anesthesia has been recognized as a hazardous enterprise,[1] with distinct risks to the patient and occupational risks to anesthesia providers. From the perspective of public health, understanding both the nature and the magnitude of these risks is important on multiple levels. For individual patients, receiving accurate information on the probability of specific perioperative complications is a prerequisite for informed decision making related to anesthesia and surgery. More broadly, understanding the extent to which rates of perioperative morbidity and mortality vary across patients, physicians, and hospitals provides an important opportunity for assessing and improving quality in health care.

Efforts to determine the risks of anesthesia are complicated by many potential perspectives from which such risks can be defined. The use of alternate periods of observation for morbidity and mortality—the intraoperative period alone, the first 48 hours after surgery, the duration of the hospital stay, or the first 30 days or longer

TABLE 37-1 TIME PERSPECTIVE OF ANESTHETIC MORBIDITY AND MORTALITY STUDIES

Study	Study Year	Time Perspective
Beecher and Todd	1954	All deaths on the surgical services
Dornette and Orth	1956	Deaths in the surgical unit or after failure to regain consciousness
Clifton and Hotten	1963	Any death under or attributable to anesthesia or without return of consciousness after anesthesia
Harrison	1978	Death within 24 hours
Marx et al	1973	Death within 5 days
Hovi-Viander	1980	Death within 3 days
Lunn and Mushin	1982	Death within 6 days

TABLE 37-2 EXAMPLES OF COMMON OUTCOME MEASURES

Outcome	Example
Mortality	
Failure-to-rescue	Mortality after a postoperative complication
Morbidity	
Major	Myocardial infarction
	Pneumonia
	Pulmonary embolism
	Renal failure or insufficiency
	Postoperative cognitive dysfunction
Minor	Nausea
	Vomiting
	Readmission
Patient satisfaction	
Quality of life	

after surgery—complicate simple conclusions about the risks faced by any individual patient undergoing anesthesia and surgery and at what point after surgery the likelihood of further adverse events has returned to baseline (Table 37-1). For example, patients undergoing ambulatory surgery have the lowest risk of death the day of surgery as opposed to 1 month later.[2] At the opposite end of the spectrum, asymptomatic release of cardiac enzymes in the perioperative period can have implications for months to years.[3-5] Divergent conclusions would also be expected from studies that consider adverse events that are solely attributable to the administration of anesthesia versus those that examine the overall rates of morbidity and mortality after surgery, which anesthesia care may modify. Studies exclusively focusing on the intraoperative period have characterized contemporary anesthesia care as a patient safety "success story" as a result of the low rates of death directly attributable to anesthesia care. As a result, anesthesia has been hailed by the Institute of Medicine as "an area in which very impressive improvements have been made" in terms of patient safety.[6]

Nonetheless, a broader perspective on perioperative outcomes presents a more complicated story. For example, in the case of a patient with established coronary artery disease who sustains a myocardial infarction after experiencing tachycardia during high-risk surgery, the cause of the patient's adverse outcome could arguably be attributed to both the patient's underlying coronary artery disease and to the absence of intraoperative heart rate control. In this situation, the decision to view the perioperative infarction primarily as a consequence of patient disease or as an event that could be prevented by anesthesia care carries vastly different implications for efforts to define and reduce the risks of anesthesia.

Finally, the diverse array of outcomes considered as hazards of anesthesia complicate the interpretation of the literature on the risks of anesthesia. Traditionally, investigators have focused on issues of death and major morbidity such as myocardial infarction, pneumonia, and renal failure. More recently, however, this view has been broadened to include economic outcomes, as well as patient-centered outcomes such as functional independence, quality of life, and satisfaction (Table 37-2). For example, unanticipated rehospitalization after ambulatory surgery or a delay in discharge as a result of postoperative nausea and vomiting are both potentially important from the perspectives of the patient's quality of life, as well as economics (also see chapter 89).

In this chapter, current theories regarding the underlying causes of adverse events in the perioperative period are reviewed, and the historical and contemporary literature regarding the nature and magnitude of risk related to both intraoperative anesthesia care and perioperative care are more broadly examined in detail. Next, historical and recent efforts to characterize the patient-, provider-, and facility-level determinants of anesthetic and perioperative risk are reviewed through statistical risk indices and are clinically based approaches to patient classification, and available literature on the determinants of risk unique to the obstetric, pediatric, and geriatric populations are discussed. Finally, future directions in research and clinical care related to anesthetic risk are discussed, with a focus on the health policy implications of changing knowledge regarding the hazards of anesthesia.

FRAMEWORK OF PERIOPERATIVE RISK

Perioperative risk is multifactorial and depends on the interaction of anesthesia-, patient-, and surgery-specific factors (Fig. 37-1). With respect to anesthesia, the selection and effects of medications, including volatile and intravenous anesthetic agents, and the skills of the practitioner are important. Similarly, the surgeon's skills and the surgical procedure itself also affect perioperative risk. Further, practitioners may influence outcomes at multiple points in the postoperative course. Although the incidence of specific local or organ-based complications, such as perioperative myocardial infarction or central line–related bloodstream infection, may be modified by anesthetic or surgical care, variations in the adequacy of

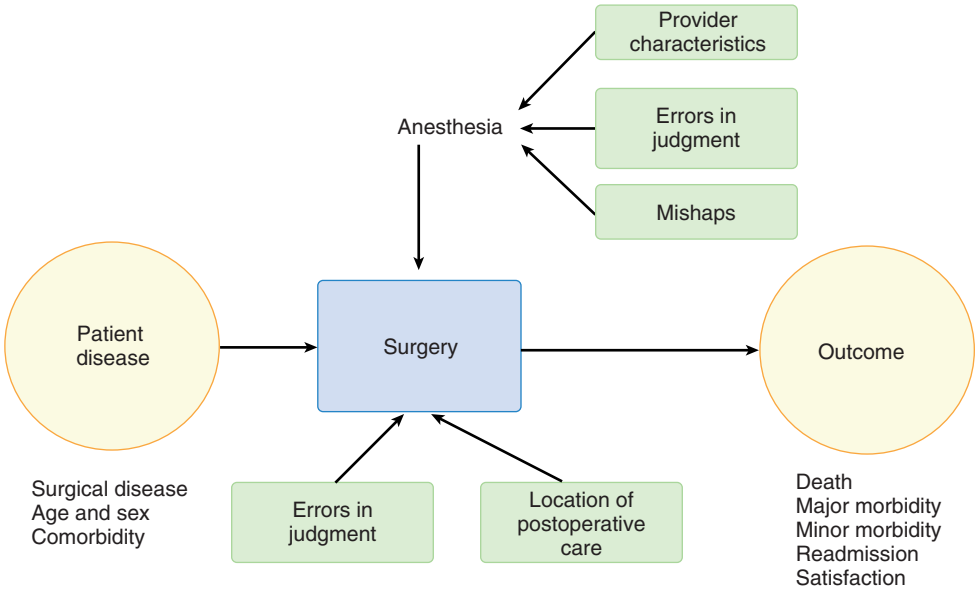

Figure 37-1. Representation of the influences of various components on poor perioperative outcomes. Surgical, anesthetic, and patient characteristics all contribute to outcome. Anesthesia-related contributions can include issues of judgment and mishaps, as well as characteristics of the provider. The surgical procedure itself affects outcome, as does the location of intraoperative and postoperative care.

care delivered to patients who have already experienced a complication (i.e., failure to rescue) may largely explain hospital-to-hospital differences in surgical outcomes.[7-9] Notably, although past investigators have pointed to volume-outcome relationships as potentially mitigating these hospital-to-hospital outcome differences,[10,11] more recent data have suggested that local quality-improvement efforts, rather than large-scale efforts, at regionalization of care for elective surgeries hold the greatest potential to yield meaningful improvements in operative outcomes.[12]

The potential for anesthetic care to influence the overall hazard of surgery at multiple time points highlights both the complexity of measuring the risks of anesthesia and surgery and the range of potential opportunities that may exist to reduce such risks. Given these challenges and opportunities, the goal of the next section is to summarize the current state of knowledge in this area, including the relative strengths and weaknesses of randomized and nonrandomized (i.e., observational) study designs used in efforts to understand patterns of outcomes after surgery and anesthesia.

ISSUES RELATED TO STUDY DESIGN

TYPES OF STUDIES

To interpret the literature related to anesthetic and perioperative risk, the strengths and limitations of various study designs must be understood. Prospective cohort studies involve the identification of a group of subjects who are monitored over time for the occurrence of an outcome of interest. The goal is to identify patients in whom the outcome develops. For studies of perioperative mortality, individual cases can be reviewed to determine the cause of mortality. Alternatively, data on all patients in the cohort study can be obtained, and discrete factors associated with the development of morbidity or mortality can be determined, often using multivariate regression techniques. An example of a prospective cohort study to identify factors associated with perioperative cardiac morbidity and mortality is that of Goldman and colleagues,[13] which led to development of the Cardiac Risk Index.

Although prospective cohort studies have important value in identifying risk factors for perioperative outcomes, they also have significant limitations. The range of patients enrolled in the cohort study, both in terms of baseline characteristics and the care they receive, may positively or negatively impact the generalizability of the study findings more broadly to the population. Additional biases may be introduced by loss of patients to follow-up for assessment of outcomes. Finally, failure to anticipate the potential impact of some variables and collect data on them may limit the insights gained from a cohort study. For example, if a cohort study focusing on predictors of postoperative myocardial infarction failed to collect data on preoperative angina, the study's findings could be limited by the investigators' inability to examine this factor as a potential predictor of postoperative outcomes. Similarly, the inability to collect data on all potential confounders of the relationship between a putative risk factor and a given outcome limits the extent to which cohort studies can support causal inferences.

Randomized clinical trials offer stronger evidence of causality than do observational cohort studies. In a randomized trial, subjects are assigned by random allocation to one of two or more treatments (potentially including a placebo) and are observed for the development of a particular outcome. In the context of perioperative risk, randomized trials may be used to determine the efficacy of an intervention or anesthetic regimen intended to improve postoperative outcomes. For example, hypothermia in the perioperative period has been associated with an increased incidence of perioperative ischemia, a surrogate marker for morbidity.[14] In a randomized clinical trial, the use of forced-air warming to maintain normothermia was associated with a significantly less frequent incidence of perioperative morbid cardiac events.[15] Randomized clinical trials often build on hypotheses generated in cohort studies regarding the determinants of outcomes by testing

interventions directed at a specific risk factor associated with adverse outcomes.

Randomized clinical trials derive their strength from their high degree of internal validity; the randomization scheme and the use of placebo (or accepted alternative treatments) provide strong evidence that the results are related to the intervention. Importantly, these trials may have a lower degree of external validity because the intervention tested in a particular trial may not work as well or in the same manner as when it is diffused into a more heterogeneous population. Further, as a result of sample size limitations, clinical trials may often be unable to detect subtle differences in outcomes among study groups or differences in rare events.

Retrospective studies involve the identification of patients who have sustained an outcome and definition of risk factors associated with the outcome. An example of a retrospective design is a case-control study. Case-control studies identify patients with the outcome of interest. Frequently, these patients are included as part of a prospective cohort study. The prevalence of a risk factor in patients with the outcome (i.e., cases) is compared with the prevalence of the risk factor in matched control participants to maximize the efficiency and power of the results. The ratio of cases to control participants can be varied to yield greater power with an increasing number of controls. An alternative retrospective design involves the systematic review of identifiable adverse events for patterns of error. For example, Cheney and colleagues[16] developed the American Society of Anesthesiologists' Closed Claims Project (ASA-CCP) to assess the risks associated with anesthesia care. By obtaining the records of major events that led to legal litigation, they were able to identify factors that contributed to bad outcomes. With this methodology, selected morbidities that led to litigation can be identified. The limitation of this methodology is that the actual rates of complications in the overall population are not known; only the number of closed legal claims is identified. Cases that do not result in litigation are not included in the database.

PROBLEMS INHERENT IN STUDYING ANESTHESIA-RELATED RISK

Studying anesthesia-related risk involves a range of methodologic challenges. On the most basic level, multiple definitions exist for key outcomes, such as perioperative mortality. In particular, the timeframe in which a death can be attributed to the surgery or the delivery of anesthesia or both varies. Notably, many events related to surgery may occur after discharge when monitoring of outcomes becomes more challenging. For this reason, the National Surgical Quality Improvement Program (NSQIP), a large, prospectively collected United States registry of surgical care and outcomes, requires 30-day follow-up on all patients to allow for consistent assessments of outcomes for all patients.

A second major challenge in any study of postoperative outcomes is the low observed rate of many key outcomes in the population of interest. Although some recent writers have called into question the safety of contemporary anesthesia care,[17] anesthesia-related death remains relatively uncommon in absolute terms. For example, the rate of anesthesia-related mortality described in the Confidential Enquiry into Perioperative Deaths (CEPOD) of 1987 was 1 in 185,000 patients as opposed to the 1 in 2680 cases reported by Beecher and Todd approximately 30 years earlier.[18,19] As a result, efforts to identify the range of factors that now contribute to anesthetic mortality are likely to require large patient cohort studies available either from administrative sources or collected over several years from multiple institutions. Several attempts have been made to establish large epidemiologic databases to address this challenge. One example of such an approach has been the work of Dennis Mangano and the Multicenter Study of Perioperative Ischemia Research Group with regard to cardiac surgery. This group used its database to evaluate issues such as the rate and importance of atrial fibrillation after cardiac surgery and the association of perioperative use of aspirin with cardiac surgical outcomes.[20,21] Other approaches include the development of cardiac surgery databases by the Society of Thoracic Surgeons, the U.S. Veterans Administration NSQIP, and the Northern New England Cardiovascular Disease Study Group.[22-25] These databases are used to define risk factors for poor outcome, to compare local with national complication rates, and as educational tools. In the United States, the Multicenter Perioperative Outcomes Group has undertaken such an enterprise by pooling electronically collected intraoperative and postoperative data.[26] Although these databases may provide extremely important information to improve care, the ability to generalize results to centers that do not have sufficient infrastructure to participate in such projects (e.g., smaller hospitals) is unknown.

Variations in care and outcomes across institutions may further complicate efforts to develop meaningful estimates of perioperative risk for use in clinical decision making by individual patients. Beyond the impact of patient illness, type of surgery, or anesthetic approach, hospital-level differences in postoperative care may have a profound impact on outcome. For example, the incidence of pulmonary embolism may be related to nursing care and the frequency of patient ambulation after surgery[27]; similarly, the presence of an intensivist who makes daily rounds and higher nurse staffing ratios may also affect outcome.[28]

Finally, issues of risk adjustment complicate efforts to determine changes in anesthesia risk over time. Common endpoints, such as mortality, are influenced by patient factors as well as by anesthesia and surgical care; as such, temporal trends in patient acuity may influence the apparent adverse outcomes associated with anesthesia and surgery in a given period. With appropriate risk adjustment, changes in mortality rates over short periods may provide some indication of changes in the quality of anesthesia or surgical care. When viewed over longer periods, however, it may be more difficult to reach firm conclusions regarding temporal changes in the safety of anesthesia or surgery based on differences in mortality rates over time. For example, if improvements in anesthetic technology have allowed for older and sicker patients to undergo surgery, then the safety of anesthesia may have improved without any apparent change in mortality rates because a sicker

patient population is now offered surgery that, in the past, would have been avoided. Similarly, the rapid adoption of new but relatively high-risk procedures, such as coronary artery bypass grafting or liver transplantation, complicates simple comparisons of anesthesia-related complications over time.

STUDIES OF ANESTHESIA-RELATED MORTALITY BEFORE 1980

Efforts to understand the specific risks imposed by anesthesia care, above and beyond the surgical procedure itself, have represented an important dimension of research in anesthesia since the early 20th century. Although more recent trends in anesthesia research have emphasized a broad view of perioperative outcomes not strictly limited to events primarily caused by anesthesia care,[30] the history of efforts to determine the safety of anesthesia management, per se, represents an important chapter in the development of modern perioperative medicine. This history also serves as important background for understanding current research and practice.

Research performed before 1980 demonstrated wide variation in reported rates of anesthesia-related mortality (Table 37-3). Beecher and Todd's 1954 report of anesthesia-related deaths at 10 institutions represents the earliest published major analysis of anesthesia outcomes.[18] Their study included 599,548 anesthesia procedures and found a rate of all-cause mortality of 1 per 75 cases (1.3%). In 1 out of every 2680 procedures, anesthesia represented the primary cause of mortality, and it was a primary or contributory cause of mortality in 1 of 1560 procedures. Surgical error in diagnosis, judgment, or technique was the primary cause of death in 1 in 420 cases, and patient disease was the primary cause in 1 in 95 cases.

Beecher and Todd's findings were confirmed by the work of Dornette and Orth,[31] who reported on deaths occurring in the surgical department at their institution over 12 years from 1943 through 1954. The rate of mortality totally attributable to anesthesia was 1 in 2427 cases, and the rate of mortality totally or partially attributable to anesthesia was 1 in 1343 cases. In contrast, Dripps and colleagues, working at the University of Pennsylvania, observed a higher rate of anesthetic mortality over a 10-year period from 1947 through 1957.[32] Whereas Beecher and Todd reported 1 incident of anesthesia-attributable mortality for every 2680 cases observed, Dripps and colleagues found the anesthesia-attributable mortality rate to be 1 in 852. Although definitive conclusions were not offered concerning the differences between the Dripps and Beecher studies, they may have been partially explained by Dripps' observation of 30-day, rather than intraoperative or 48-hour mortality, or differences in patient severity across studies.

Multiple additional studies on anesthetic risk appeared between 1960 and 1980.[33] In the United States, these included the Baltimore Anesthesia Study Committee,[34] which reviewed 1024 deaths occurring on the day of or the day after a surgical procedure; the study of Schapira and co-authors[35] who reported on mortality occurring within 24 hours after surgery between the years 1952 and 1956 at Montefiore Hospital in New York; and the study of Marx and colleagues[36] who evaluated the incidence of death within 7 days after surgery in 34,145 consecutive patients at the Bronx Municipal Hospital Center between 1965 and 1969. Overall, the rate of anesthesia-related mortality in these studies varied widely, ranging from 1 in 1232 cases in the Schapira study to 1 in 7692 cases in the Baltimore Anesthesia Study Committee report.

Internationally, Clifton and Hotten identified a total of 162 deaths associated with anesthesia in 205,640 surgical procedures performed at the Royal Prince Alfred Hospital in Sydney, Australia, between 1952 and 1962.[37] In 1964, Dinnick published a report, sponsored by the Association of Anaesthetists in London, on 600 deaths associated with anesthesia,[38] followed by a report on anesthesia-related mortality from Bodlander,[39] who observed a progressive decrease in the contribution of anesthesia to operative mortality at the Royal Prince Alfred Hospital for the years 1963 to 1972. Finally, Harrison[40] evaluated mortality associated with 240,483 anesthesia procedures performed between 1967 and

From Ross AF, Tinker JH: Anesthesia risk. In Miller RD, editor: Anesthesia, *ed 3. New York, 1990, Churchill Livingstone, p 722.*

1976 at Groote Schuur Hospital in Cape Town, South Africa. Data were prospectively collected, beginning in 1956. Anesthesia was the cause of death or a major contributory factor in 0.22 cases per 1000 procedures, as opposed to 0.33 per 1000 procedures in the previous 10 years.

In summary, studies of anesthetic risk published before 1980 varied widely in the definitions used for anesthesia-related mortality and in the mortality rates they reported. Nonetheless, these studies did offer several important insights for anesthesia care. First, they suggested that death related solely to anesthesia was a relatively uncommon event; moreover, an overall trend toward lower rates of anesthesia-related mortality across studies over time suggested potential improvements in anesthesia safety.

STUDIES OF ANESTHESIA-RELATED MORTALITY SINCE 1980

Whereas studies conducted before 1980 typically focused on one institution or a small number of institutions, studies since then have frequently been performed on a regional or national basis with a particular emphasis on documenting changes over time in anesthesia-related mortality. For example, Holland[41] reported deaths occurring within 24 hours after anesthesia in New South Wales, Australia. A committee of six anesthesiologists, three surgeons, an obstetrician, a general practitioner, and a medical administrator was established in 1960 and reviewed all such cases except those that occurred during a 3-year period between 1980 and 1983. Four categories were established to define the relationship of anesthesia to operative morbidity and mortality (Table 37-4). Between 1960 and 1985, information was available on 92% to 96% of all cases. The incidence of anesthesia-attributable deaths decreased from 1 in 5500 procedures performed in 1960 to 1 in 10,250 in 1970 and then to 1 in 26,000 in 1984. Based on these estimates, the investigators asserted that for all patients receiving surgery, it was more than five times safer to undergo anesthesia in 1984 than it was in 1960.[42]

Under the direction of the French Ministry of Health, Tiret and colleagues[43] carried out a prospective survey of complications associated with anesthesia in France between 1978 and 1982 from a representative sample of 198,103 anesthesia procedures chosen at random from hospitals throughout the country. The sample included a survey of 460 public and private hospitals. The investigators evaluated the occurrence of death or coma within 24 hours after surgery. In the group studied, 268 patients had major complications, 67 patients died, and 16 patients suffered persistent coma. Death was solely related to anesthesia in 1 in 13,207 procedures and partially related in 1 in 3810 (Table 37-5). The French survey confirmed previous findings that major complications occur more frequently in older patients, those undergoing emergency surgical procedures, and those with more extensive comorbid conditions as measured by ASA physical status classification.

A key finding of the French survey was that postanesthesia respiratory depression was the leading principal cause among cases of death and coma that were solely attributable to anesthesia. Moreover, almost all the patients who had had respiratory depression leading to a major complication had received narcotics, as well as neuromuscular blocking drugs, but they had not received anticholinesterase medications for reversal of the agents.

Despite these observations, the low rates of anesthesia-attributable mortality documented in the French study offered compelling evidence of improvements in anesthesia safety. Such findings were reinforced by the work of Tikkanen and Hovi-Viander,[44] who studied deaths associated with anesthesia and surgery in Finland and compared the results in 1986 with those collected in 1975. Mortality related to anesthesia decreased during the 9-year period; the incidence of anesthesia-related mortality was 0.15 per 10,000 procedures in 1986.

The next major step forward in efforts to understand the risks of anesthesia came through the pioneering work of Lunn[45] in the United Kingdom. Reporting on 197 fatalities occurring within 6 days after anesthesia during 1981, Lunn found 43% of the deaths to have been unrelated to anesthesia, 41% to be partly attributable to anesthesia, and 16% to be totally attributable to anesthesia. Of the

TABLE 37-4 EDWARDS CLASSIFICATION OF THE RELATIONSHIP OF ANESTHESIA TO OPERATIVE MORBIDITY AND MORTALITY

Category	Definition
I	Cases in which it is reasonably certain that the event or death was caused by the anesthetic agent or technique of administration or in other ways directly within the anesthetist's province
II	Similar to type I cases but ones in which some element of doubt exists concerning whether the agent or technique was entirely responsible for the result
III	Cases in which the patient's adverse event or death was caused by the anesthetic and the surgical technique
IV	Cases in which the events were entirely referable to the surgical technique

*Total number of anesthetics: 198,103.

32 cases for which death was totally attributable to anesthesia, most were caused by faulty anesthesia technique or postoperative respiratory failure.

One important result of Lunn's work was the development of the United Kingdom CEPOD, which assessed almost 1 million anesthetics during a 1-year period in 1987 in three large regions of the United Kingdom. Unique to this study was the establishment of "crown privilege" by the government to protect data submitted to the enquiry from further subpoena.[19]

Beyond confirming earlier work, CEPOD's findings suggested that anesthesia care may have been far safer than had been found in prior studies. Examining deaths within 30 days of surgery, CEPOD investigators observed 4034 deaths in an estimated 485,850 surgeries for a crude mortality rate of 0.7% to 0.8%. CEPOD reviewers concluded that surgery contributed totally or partially in 30% of all cases. Progression of the present disease contributed to death in 67.5% of the cases, and progression of an intercurrent disease was relevant in 44.3%. Anesthesia was considered the sole cause of death in only three individuals, for a rate of 1 in 185,000 cases, and anesthesia was contributory in 410 deaths, for a rate of 7 in 10,000 cases (Table 37-6).[19] The five most common causes of death in the CEPOD cohort study are shown in Table 37-7. Notably, of the 410 perioperative deaths, gastric aspiration was identified in 9 cases and cardiac arrest in 18 cases. Further, CEPOD identified potential health-system factors that conceivably contributed to the risk of surgery and anesthesia. Among patients with femoral neck fracture, for example, CEPOD researchers observed that the mortality rate was inversely related to the seniority of the surgeon and to preoperative preparation. The surgeon was a consultant in only 19% of the orthopedic cases, as compared with 47% overall. Ultimately, CEPOD researchers concluded that avoidable factors were present in approximately 20% of the perioperative deaths. Contributing factors for anesthesiologists and surgeons tended to be failure to act appropriately with existing knowledge (rather than a lack of knowledge), equipment malfunction, fatigue, and inadequate supervision of trainees, particularly in off-hours shifts (Table 37-8).

Large national studies performed since the 1987 CEPOD report vary in the extent to which their findings agree with those of the CEPOD investigators. Pedersen and colleagues[46] performed a series of studies in the late 1980s in Denmark to examine anesthesia-related factors contributing to serious morbidity or mortality. In a prospective study of 7306 anesthesia procedures, they found complications attributable to anesthesia in 43 patients (1 in 170) and 3 deaths (1 in 2500), an incidence far higher than that documented by the CEPOD investigators. Complications in the 43 patients, in order of incidence, included cardiovascular collapse in 16 (37%), severe postoperative headache after regional anesthesia in 9 (21%), and awareness under anesthesia in 8 (19%).

In the United States, Li and colleagues[47] conducted a population-level study to estimate epidemiologic patterns of anesthesia-related deaths, using International Classification of Diseases (ICD) codes listed in the United States multiple-cause-of-death data files for the years 1999 through 2005. Although the interpretation of Li's study is complicated by questions surrounding the sensitivity of ICD codes for anesthesia-related mortality,[48] their findings are in accord with those of the CEPOD report in presenting anesthesia-related mortality to be an extremely rare cause of death at the population level. In particular, the authors found anesthesia to be the underlying cause of death in 34 patients each year in the United States and a contributing factor in another 281 deaths annually, resulting in a 97% decrease in anesthesia-related death rates since the 1940s.

More recent studies conducted on the local and national level have sought to emphasize room for improvement in anesthesia-related mortality. Lagasse[17] reviewed perioperative deaths (i.e., deaths occurring within 2 days after surgery) at a suburban university hospital network between 1992 and 1994 and at an urban university hospital network between 1995 and 1999. A total of 347 deaths occurred in 184,472 cases. Anesthesia-related mortality (i.e., death to which error by an anesthesia practitioner

contributed) occurred in 1 in every 12,641 procedures in the suburban setting and in 1 in 13,322 procedures in the urban setting. Mortality increased with increasing ASA physical status (Fig. 37-2). In reviewing data over the previous decade, Lagasse estimated that anesthesia-related mortality had remained stable at approximately 1 death per 13,000 procedures.

Recent European studies, including those from the successor to CEPOD, Britain's National Confidential Enquiry into Patient Outcomes and Death (NCEPOD), have taken a broader focus beyond anesthesia-related events to examine perioperative outcomes more generally, particularly among high-risk patients who Lagasse and others previously observed to account for the majority of postoperative deaths. In a 2011 report, NCEPOD investigators prospectively collected data on all patients undergoing inpatient surgery, excluding obstetric, cardiac, transplant, or neurosurgery cases, in United Kingdom National Health Service facilities between March 1 and March 7, 2010.[49] In addition to prospectively collected patient-level data on clinical care and outcomes, which were available for 13,513 surgical patients, the authors conducted a detailed institution-level survey of resources and practices. Although the authors observed an overall 30-day mortality rate of 1.6%, a subset of high-risk patients—approximately 20% of the full cohort—experienced a disproportionate share of adverse outcomes, accounting for 79% of all perioperative deaths. Notably, the authors identified important gaps in the perioperative management of these patients. A minority of the high-risk patients were monitored using an arterial line, a central line, or cardiac output monitoring; still more concerning was their observation that 48% of all high-risk patients who died were never admitted to a critical care unit for postoperative management.

Similar findings were obtained in another study of surgical outcomes conducted across 28 European countries between April 4 and April 11, 2011.[50] Observing

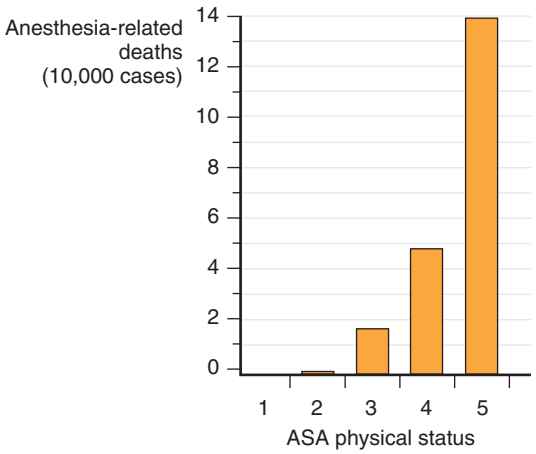

Figure 37-2. Relationship between the American Society of Anesthesiologists (ASA) physical status classification and perioperative mortality (within 2 days of surgery) related to anesthesia provided in urban and suburban institutions. *(Adapted from Lagasse RS: Anesthesia safety: model or myth? A review of the published literature and analysis of current original data,* Anesthesiology *97:1609, 2002.)*

perioperative care and outcomes for 46,539 adults undergoing inpatient noncardiac surgery, the authors noted an overall in-hospital mortality rate of 4%. Further, the investigators noted severity-adjusted operative mortality rates to differ significantly by country; for example, relative to the United Kingdom, the risk of death after surgery was highest in Poland (odds ratio [OR] 6.92, P = 0.0004) and lowest in Finland (OR 0.44, P = 0.06). Despite these national differences, the authors observed patterns of critical care use consistent with the 2011 NCEPOD report, noting that only 5% of all patients in the sample underwent a planned admission to critical care; still more concerning, of the patients who died, most (73%) were not admitted to critical care at any point. Such patterns, which the authors describe as a "systematic failure in the process of allocation of critical care resources" in Europe, highlight the potential importance of "rescue"—the prevention of mortality among patients who experience postoperative complications[8]—in determining the outcomes of surgical care. Further, to the extent that critical care use among patients who die after surgery is higher in the United States than in the United Kingdom,[51] such differences may offer insight into potential reasons for earlier observations of lower risk-adjusted postoperative mortality among American versus British surgical patients.[52]

In summary, research between 1980 and the present on anesthesia-related mortality offers a complex and still incomplete picture regarding the risks of anesthesia. Taken from the perspective of the 1987 CEPOD report or the findings of Li and colleagues, modern operative anesthesia could be characterized as an exceedingly safe enterprise with bad outcomes occurring as truly rare events. Nonetheless, subsequent research disputed the quantitative findings of CEPOD's 1987 study, making the argument that anesthesia-related mortality was common enough to represent an ongoing public health concern. Finally, more recent work has sought to go beyond efforts to quantify the contribution of anesthesia per se to overall operative risk to explore how anesthesia providers might be able to improve outcomes among high-risk patients; in essence asking not "how safe is anesthesia?" but instead "how can anesthesia providers help make surgery safer?" Ultimately, these studies' differing messages emphasize not only the dynamic nature of anesthesia risk over time, but they also highlight important changes in how anesthetic risk has been defined across different periods and how alternate approaches to evaluating, describing, and mitigating such risk may be more or less relevant at a given moment in time.

ANALYSIS OF INTRAOPERATIVE CARDIAC ARREST

In an alternative approach to evaluating perioperative mortality specific to anesthesia, several studies have evaluated intraoperative fatal and nonfatal cardiac arrest (Table 37-9). In contrast to efforts to estimate the mortality attributable to anesthesia per se, studies of intraoperative cardiac arrest may offer a broader picture of the potential hazards of anesthesia by examining an adverse outcome that is far more common than mortality yet remains highly consequential for long-term outcomes.

*Since pulse oximetry was introduced in 1984, no preventable respiratory cardiac arrests have occurred.

These studies offer a range of perspectives on the incidence of intraoperative cardiac arrest and the causes of such events. For example, Keenan and Boyan[53] studied the incidence and causes of cardiac arrest related to anesthesia at the Medical College of Virginia between 1969 and 1983. A total of 27 cardiac arrests occurred during 163,240 procedures, for an incidence of 1.7 per 10,000 cases. Fourteen patients died, for an incidence of 0.9 per 10,000 cases. Pediatric patients had a threefold higher risk of arrest than did adults, and emergency cases had a sixfold greater risk. Importantly, specific errors in anesthesia management could be identified in 75% of the cases; most common among these were inadequate ventilation and overdose of an inhaled anesthetic. Notably, the investigators identified progressive bradycardia preceding all but 1 arrest, suggesting that early identification and treatment may prevent complications.

Similar findings were reported by Olsson and Hallen[54] who studied the incidence of intraoperative cardiac arrest at the Karolinska Hospital in Stockholm, Sweden, from 1967 to 1984. A total of 170 arrests occurred in 250,543 anesthesia procedures performed. Sixty patients died, for a mortality rate of 2.4 per 10,000 procedures. After eliminating cases of inevitable death (e.g., rupture of a cerebral aneurysm, trauma), the rate of mortality caused by anesthesia was 0.3 per 10,000 procedures. The most common causes of anesthesia-related cardiac arrest were inadequate ventilation (27 patients), asystole after succinylcholine (23 patients), and postinduction hypotension (14 patients). The incidence of cardiac arrest was highest in the patients with significant comorbid disease, as assessed by the ASA physical status classification. Also of note is the finding that the incidence of cardiac arrest decreased over the study period.

Biboulet and colleagues[55] studied fatal and nonfatal cardiac arrests encountered during anesthesia and during the first 12 postoperative hours in the postanesthesia care unit (PACU) or intensive care unit (ICU) in a single hospital in France. Eleven cardiac arrests related to anesthesia were identified in 101,769 anesthesia procedures (1.1 per 10,000). The mortality rate related to anesthesia was 0.6 per 10,000 cases. The major causes of death were anesthetic overdose, hypovolemia, and hypoxemia; 10 of the 11 cases had at least one avoidable error.

Newland and associates[56] reported anesthesia-related cardiac arrests during 72,959 procedures between 1989 and 1999 in a teaching hospital in the United States. They judged that 15 of the 144 cardiac arrests were related to anesthesia (0.69 per 10,000 procedures); in an additional 10 cases, anesthesia was considered contributory, for a total rate of 1.37 per 10,000 procedures (95% confidence interval [CI], 0.52 to 2.22). The risk of death from perioperative cardiac arrest that was attributable to anesthesia was 0.55 per 10,000 procedures. Most of the arrests were related to medication administration, airway management, or technical problems of central venous access.

Kawashima and colleagues sent confidential questionnaires to all Japan Society of Anesthesiologists Certified Training Hospitals every year from 1994 through 1998.[57] A total of 2,363,038 cases were documented over a 5-year period. The average yearly incidence of cardiac arrest during surgery that was totally attributable to anesthesia was 1 per 10,000 cases (95% CI, 0.88 to 1.12). The average mortality per year in the surgical unit or within 7 postoperative days that was totally attributable to anesthesia was 0.21 (0.15 to 0.27) per 10,000 cases. The two principal causes of cardiac arrest solely attributable to anesthesia were drug overdose or selection error (15.3%) and serious arrhythmia (13.9%). Preventable human errors caused 53.2% of cardiac arrests and 22.2% of deaths in the surgical unit that were totally attributable to anesthesia. The outcomes of cardiac arrests totally attributable to anesthesia are shown in Table 37-10.

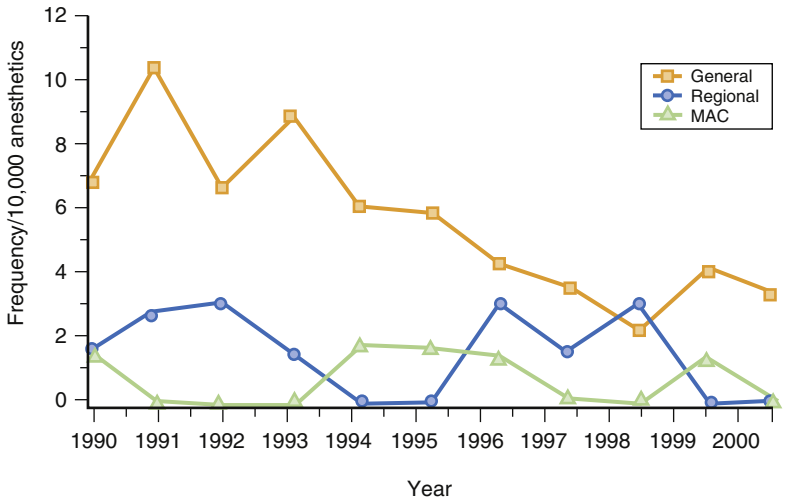

Figure 37-3. Frequency of cardiac arrest by calendar year and type of anesthesia. *MAC,* Monitored anesthesia care. *(From Sprung J, Warner ME, Contreras MG, et al: Predictors of survival following cardiac arrest in patients undergoing noncardiac surgery: a study of 518,294 patients at a tertiary referral center,* Anesthesiology *99:259-269, 2003.)*

Between 1990 and 2000, Sprung and colleagues studied patients who experienced cardiac arrest in the surgical unit, during transport to the PACU or ICU, or in the PACU after noncardiac surgery.[58] Cardiac arrest occurred in 223 of 518,294 anesthesia procedures (4.3 per 10,000) during the study period. The frequency of arrest in patients receiving general anesthesia decreased over time (7.8 per 10,000 during 1990 to 1992; 3.2 per 10,000 during 1998 to 2000). The frequency of arrest during regional anesthesia (1.5 per 10,000) and monitored anesthesia care (0.7 per 10,000) remained the same during the study period (Fig. 37-3). The hospital survival rate after cardiac arrest was 34.5%. Twenty-four patients (0.5 per 10,000) had cardiac arrest primarily related to anesthesia, 19 of whom (79.2%) survived to hospital discharge. The in-hospital mortality attributable to anesthetic-related cardiac arrest was 0.1 per 10,000 anesthetics.

Braz and co-workers[59] studied perioperative cardiac arrest that occurred during induction of anesthesia for 53,718 anesthetics between 1996 and 2005 in a Brazilian teaching hospital.[58] In this study, 186 cardiac arrests (34.6 per 10,000) and 118 deaths (21.97 per 10,000) were reported. Major risk factors for cardiac arrest were neonates, children younger than 1 year of age, and older adults; male patients with ASA III or poorer physical status; emergency surgery; and general anesthesia. There were 18 anesthesia-related cardiac arrests (3.35 per 10,000), 10 totally attributed to anesthesia (1.86 per 10,000) and 8 partially related to anesthesia (1.49 per 10,000). There were 6 anesthesia-related deaths (1.12 per 10,000), 3 totally attributable and 3 partially related to anesthesia (0.56 per 10,000 in both cases). The main causes of anesthesia-related cardiac arrest were respiratory events (55.5%) and medication-related events (44.5%).

More recently, Kheterpal and colleagues at the University of Michigan examined predictors of cardiac adverse events—including cardiac arrest, myocardial infarction, and clinically significant arrhythmia—among 7700 patients undergoing noncardiac surgery. Eighty-three patients (1.1%) experienced an adverse event. The authors identified nine independent predictors of an adverse event: (1) age 68 years or older, (2) body mass index of 30 or greater, (3) emergency surgery, (4) previous coronary intervention or cardiac surgery, (5) active congestive heart failure, (6) cerebrovascular disease, (7) hypertension, (8) operative time of 3.8 hours or longer, and (9) the intraoperative administration of one or more units of packed red blood cells.[60]

In summary, perioperative cardiac arrest is a relatively rare event whose incidence may be decreasing over time. Further, research in this area has highlighted the role of both patient factors and intraoperative care

as contributing to the risk of intraoperative and postoperative cardiac arrest and emphasized the management of ventilation and the selection and dosing of anesthetic medications as key areas of focus for the prevention of such events.

PERIOPERATIVE MORTALITY AND MORBIDITY IN OUTPATIENT SURGERY

At least in the United States, an estimated 60% of all surgical procedures are performed on an outpatient basis, and this percentage is increasing annually. The type and extent of surgical procedures performed in an outpatient setting are constantly changing, and more complicated procedures associated with greater perioperative risk are increasingly being performed on an outpatient basis (also see Chapter 89).

Notably, early research on the safety of two ambulatory surgical procedures—tonsillectomy and simple mastectomy—presented a negative view of the hazards of surgery in the outpatient setting. One of the first procedures advocated to be performed on an ambulatory basis was tonsillectomy (also see Chapter 85). Although a 1968 case series of 40,000 outpatient tonsillectomies reported no deaths,[61] details on patient selection and length of postoperative monitoring were vague. Based on insurance company and state mandates, performance of tonsillectomy on an outpatient basis became routine.[62] Beginning in the mid-1980s and continuing in the 1990s, a number of articles evaluated outcomes with early discharge after tonsillectomy. For example, Carithers and colleagues[63] in 1987 at Ohio State University reported on 3000 tonsillectomies and argued that early discharge might be hazardous and economically unwarranted. The rate of readmission for active bleeding between 5 and 24 hours after surgery was reported to be between 0.2% and 0.5%.[64-67] Notably, although these findings are important from a historical perspective, they may not reflect current practice; therefore they may or may not suggest the need for delayed discharge and prolonged postoperative monitoring for all patients undergoing tonsillectomy in the ambulatory setting.

Mastectomy represents a second important case study in the development of surgery as an outpatient procedure. An analysis of Medicare claims demonstrated that the rate of outpatient mastectomy increased from a negligible proportion of all mastectomies in 1986 to 10.8% of all mastectomies performed among Medicare beneficiaries in 1995.[68] Within this population, simple mastectomies performed on an outpatient basis had a significantly higher rate of readmission than did those undergoing a 1-day hospital stay, with an adjusted OR of 1.84. When compared with the group treated on an outpatient basis, rates of readmission after 1-day stays were significantly lower for infection (4.1 versus 1.8 per 1000 cases), nausea and vomiting (1.1 versus 0 per 1000 cases), and pulmonary embolism or deep venous thrombosis (1.1 versus 0 per 1000 cases).

In contrast to these earlier studies, the 1993 publication of Warner and colleagues[69] on major morbidity and mortality within 1 month of ambulatory surgery strongly argued for the safety and feasibility of surgery in the outpatient setting. Among the 38,598 patients included in Warner's study, 4 died. Of these 4 deaths, 2 were due to myocardial infarctions occurring more than 1 week after surgery; the other 2 deaths occurred in automobile accidents (Fig. 37-4).

In part, as a result of such findings, the use of ambulatory surgery has dramatically grown between the early 1990s and the present, with a concurrent increase in the number and type of sites for ambulatory surgery. Such sites now include not only freestanding ambulatory surgery centers (ASCs) and physician's offices, but they also include interventional radiology units and other diagnostic and therapeutic sites not affiliated with any other health care facility.

In the context of such growth, investigators have sought to examine the relative safety of similar procedures performed across different outpatient settings. For example, Fleisher and co-workers[2] performed a claims analysis of patients undergoing 16 different surgical procedures in a nationally representative (5%) sample of Medicare beneficiaries for the years 1994 through 1999. A total of 564,267 procedures were studied, with 360,780 in an outpatient hospital, 175,288 in an ASC, and 28,199 in a physician's office. On the day of surgery, no deaths occurred in the office, but four deaths occurred in the ASC (2.3 per 100,000) and nine deaths occurred in the outpatient hospital (2.5 per 100,000). The 7-day mortality rate was 35 per 100,000 in the office setting, 25 per 100,000 in the ASC, and 50 per 100,000 in the outpatient hospital. The rate of admission to an inpatient hospital within 7 days was 9.08 per 1000 in the office, 8.41 per 1000 in the ASC, and 21 per 1000 in the outpatient hospital. Notably, the inferences of this study are limited by an inability to distinguish fully whether these differences in outcomes are related to the differences in the types of patients selected to have surgery in each setting versus the differences in the care patients received in each setting.

In a related report, Fleisher's group analyzed data from surgical procedures performed in hospital-based and freestanding ASCs in New York during 1997 that were obtained from the Agency for Healthcare Research and Quality's Healthcare Cost and Utilization Project.[70] Of the 783,558 patients eligible for inclusion in this study, 4351 were discharged directly for short-term hospitalization (1 in 180), and 19 died (1 in 41,240).

Subsequent work by Chukmaitov and colleagues compared quality outcomes between ASCs and hospital-based outpatient departments in the state of Florida between the years 1997 and 2004.[71] They used 7- and 30-day mortality and unexpected hospitalization as the outcomes of interest in 12 surgical procedures. The importance of location of care varied by surgical procedure and the number of comorbid conditions included in the analysis. Although their conclusions were limited by differences in the data available for patients treated in each setting, they postulated that the difference in outcomes between the two locations may be related to variations in organizational structure, processes, and strategies.

In contrast to the growing literature on the safety of anesthesia and surgery in ASCs, limited information exists to quantify the incidence of complications in office-based settings. The American Association for Ambulatory Plastic

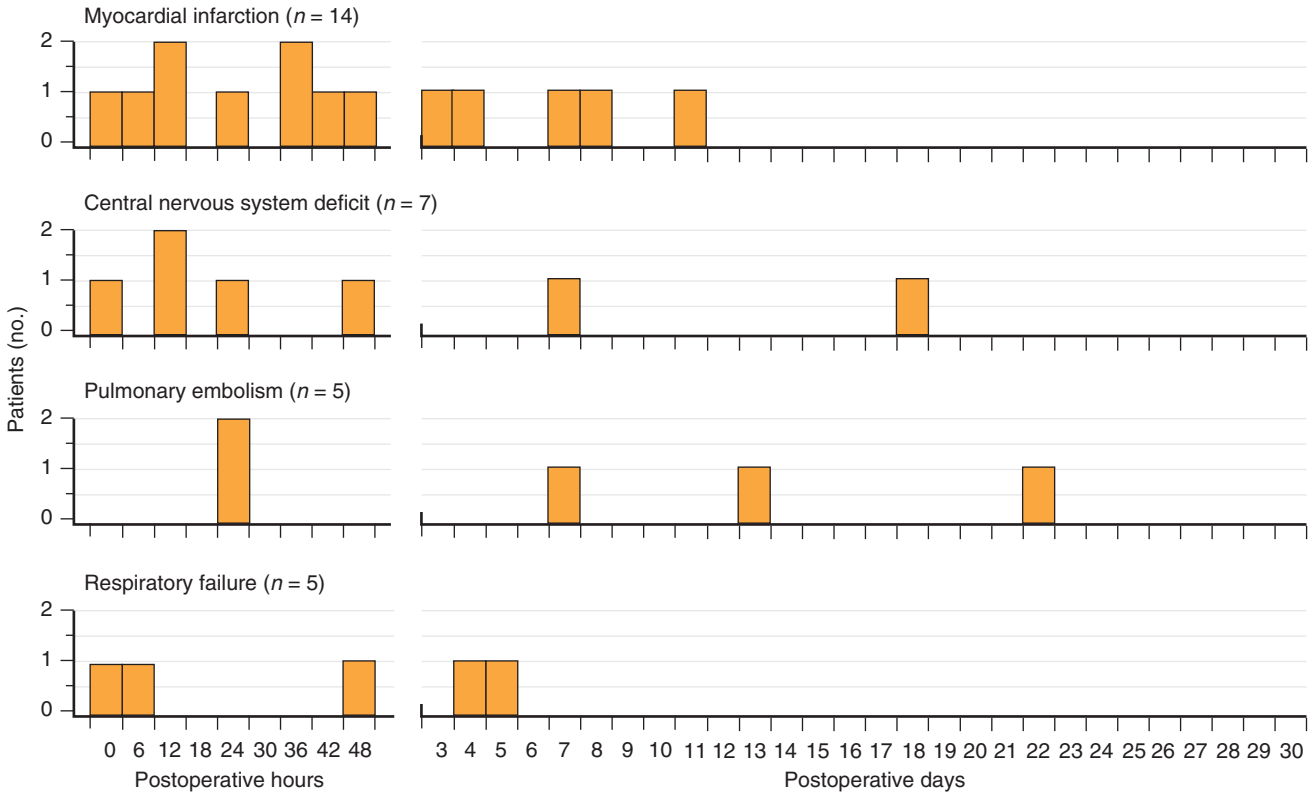

Figure 37-4. Timing of perioperative events in patients undergoing ambulatory surgery. Many of the events occurring within the first 48 hours are probably related to the stress of surgery. A subset of events occurring after this period may be related to background event rates. The overall rate of morbidity was lower than expected for a similar cohort of age-matched nonsurgical patients. *(From Warner MA, Shields SE, Chute CG: Major morbidity and mortality within 1 month of ambulatory surgery and anesthesia,* JAMA *270:1437, 1993.)*

Surgery Facilities mailed a survey to their members to determine the incidence of complications occurring in office facilities.[72] The overall response rate was 57%. The findings showed that 0.47% of patients had at least one complication, including bleeding, hypertension, infection, and hypotension, and 1 in 57,000 patients died. Although low in absolute terms, the observation of a rate of mortality after minor outpatient procedures that is three times the current estimate for anesthesia-related complications is concerning in this context.

Vila and colleagues reviewed all adverse incident reports to the Florida Board of Medicine for procedures dated April 1, 2000, to April 1, 2002.[73] The numbers of office procedures performed during a 4-month period were used to estimate the total number of procedures. Adverse incidents occurred at a rate of 66 and 5.3 per 100,000 procedures in offices and ASCs, respectively. The death rate per 100,000 procedures performed was 9.2 in offices and 0.78 in ASCs. The relative risk for injury and death for procedures performed in offices versus ASCs was 12.4 (95% CI, 9.5 to 16.2) and 11.8 (95% CI, 5.8 to 24.1), respectively. As a result, the authors concluded that if all office procedures had been performed in ASCs, approximately 43 injuries and 6 deaths per year could have been prevented. In contrast, Coldiron and colleagues studied office-based surgeries in Florida and showed that the greatest danger to patients lies not with the surgical procedures in office-based settings per se but with cosmetic procedures that are performed in office-based settings, particularly when under general anesthesia.[74] Several other groups have analyzed the Florida data and have been unable to document the increased risk in the office setting.[75,76]

In summary, although early research on ambulatory surgery placed an emphasis on the undue risks created by premature discharge, more recent analyses confirm that a range of surgeries can be safely performed in properly selected patients; moreover, although some variations in outcomes have been observed across settings (i.e., hospital outpatient department versus ASC), available literature suggests that, given proper patient selection, outpatient surgeries can be performed with a low rate of adverse events in multiple practice environments. Finally, given the gradual expansion of outpatient surgery over time to include patients with greater burdens of comorbid disease and more extensive procedures, ongoing evaluations will be essential to characterize the dynamic, evolving nature of anesthetic risk in the ambulatory setting.

USE OF ANESTHESIA INFORMATION MANAGEMENT SYSTEMS

Over the past 4 decades, the use of computerized databases has enhanced the ability to assess perioperative risk and complications (see also Chapter 5).

In one of the earliest computer analyses of postanesthesia deaths, Marx and associates[36] identified 645 individuals who died within 7 days after surgery out of a total cohort

of 34,145 consecutive surgical patients. More recently, the growth of electronic anesthesia record systems has allowed for better insights into the causes of anesthesia-related events within the surgical unit, and, when used in combination with other data sources, on postoperative outcomes. An early example of such an analysis was that of Sanborn and colleagues,[77] who used a computer anesthesia record to identify intraoperative incidents. They were able to demonstrate that perioperative deaths occurred more frequently in patients who sustained an intraoperative incident of any type than in those who did not.

Similarly, Reich and colleagues used computerized anesthesia records to evaluate hemodynamic variables and their relationship to risk.[78] Among 2149 patients, 50 deaths, 51 strokes, and 85 perioperative myocardial infarctions occurred. By multivariate analysis, they identified pulmonary hypertension, hypotension during cardiopulmonary bypass, and post–cardiopulmonary bypass pulmonary diastolic hypertension as independent predictors associated with mortality, stroke, and perioperative myocardial infarction over and above the effects of other preoperative risk factors.

More recently, data from the University of Michigan anesthesia information management system have been used to identify predictors of perioperative risk. For example, they evaluated factors related to adequacy of mask ventilation in 22,660 patients.[79] Limited or severely limited mandibular protrusion, abnormal neck anatomy, sleep apnea, snoring, and a body mass index of 30 kg/m^2 or greater were independent predictors of grade 3 or 4 mask ventilation and difficult intubation. In another publication, the same group examined a total of 15,102 patients who had a normal preoperative creatinine clearance and underwent noncardiac surgery.[80] Acute renal failure developed in 121 patients (0.8%), and 14 patients required renal replacement therapy (0.1%). Seven independent preoperative predictors were identified: age, emergency surgery, liver disease, body mass index, high-risk surgery, peripheral vascular occlusive disease, and chronic obstructive pulmonary disease necessitating chronic bronchodilator therapy. They found that acute renal failure was associated with increased mortality from any cause at 30 days, 60 days, and 1 year.

In an effort to expand upon the insights gained from single-institution studies, two major efforts have since been initiated to pool electronic data on anesthesia care from multiple sites as a means of more effectively comparing outcomes and defining risk factors related to outcomes after anesthesia. The first of these, the Multicenter Perioperative Outcomes Group, was initiated in 2008 under the leadership of investigators at the University of Michigan. This project currently collects electronic anesthesia data from over 30 participating anesthesia departments and has released initial data related to the incidence of epidural hematoma across member practices.[26] The second of these, the National Anesthesia Clinical Outcomes Registry, is maintained by the Anesthesia Quality Institute, a nonprofit organization established by the ASA. This large-scale data warehouse collects both paper and electronic anesthesia case data that will be used to assess anesthesia practices to optimize local efforts to assess both the risk and the quality of care and for research purposes for the specialty as a whole.

OTHER APPROACHES TO DISCERN THE ROOT CAUSE OF MORBIDITY AND MORTALITY

Although mortality directly attributable to anesthesia appears to have declined over time, the exact causes of this decline remain unclear. Numerous factors have been implicated in the improved outcome, including new monitoring modalities, new anesthetic drugs, and changes in the anesthesia workforce. However, relating the reduced risk to any one factor on the basis of available epidemiologic data is difficult. Further, although the use of newer monitoring modalities, particularly pulse oximetry, would be expected to improve outcomes, no randomized trial has been able to document such a conclusion. This limitation supports the need for continued monitoring of complications and their root cause through a number of approaches.

Initiated by the Professional Liability Committee of the ASA, the ASA-CCP represents one important approach to understanding the root causes of important complications of anesthesia care (also see Chapter 11). The ASA-CCP constitutes an ongoing, nationwide survey of closed insurance claims for major anesthesia-related adverse events. In an early publication based on data collected by the ASA-CCP, Caplan and colleagues reviewed both fatal and nonfatal outcomes resulting in claims against anesthesia providers. Among the fatal events, unexpected cardiac arrest during spinal anesthesia was observed in 14 healthy patients from the initial 900 claims.[81] These cases were analyzed in detail to identify patterns of care that might have led to the event. Two patterns were identified: oversedation leading to respiratory insufficiency and inappropriate resuscitation of high spinal sympathetic blockade.

Tinker and co-workers[82] queried the ASA-CCP to determine the role of monitoring devices in the prevention of anesthesia mishaps. They reviewed 1097 anesthesia-related claims and determined that 31.5% of the negative outcomes could have been prevented by the use of additional monitors, primarily pulse oximetry and capnography. Injuries that were deemed preventable with additional monitoring resulted in dramatically more severe injury and cost of settlement than did those judged to be nonpreventable with additional monitoring. In nearly 90% (305 of 346) of the preventable cases, at least one clinical sign of abnormality was identified by the existing monitors.

In a subsequent report, Caplan and colleagues[83] reviewed the ASA-CCP for respiratory events (Table 37-11). These claims represented the single largest class of injury (34%), with death or brain damage occurring in 85% of cases. They identified inadequate ventilation, esophageal intubation, and difficult tracheal intubation as the primary causes of respiratory events. The investigators believed most of the outcomes to be preventable with better monitoring, such as pulse oximetry or capnography (Fig. 37-5).

More recently, the ASA-CCP has focused on such topics as monitored anesthesia care.[84] More than 40% of 121 claims associated with monitored anesthesia care involved death or permanent brain damage. Respiratory

depression, after an absolute or relative overdose of sedative or opioid drugs, was the most common (21%, $n = 25$) of the complications.

A similar registry was developed by the Danish Patient Insurance Association.[85] For the years of 1996 through 2004, 1256 files were related to anesthesia, and 24 deaths were considered to be a result of the anesthetic procedure: 4 deaths were related to airway management, 2 to ventilation management, 4 to central venous catheter placement, 4 as a result of medication errors, 4 from infusion pump problems, and 4 after complications from regional blockade. Severe hemorrhage caused one death, and the cause was uncertain in one case.

Cooper and colleagues[86,87] took an alternate approach to examining perioperative mortality through the study of critical incidents, which were defined as those that were potentially preventable and could lead to undesirable outcomes. This definition included events that led to no harm or only transient effects. The investigation involved collecting data on anesthesia-related human errors and equipment failures from anesthesiologists, residents, and certified registered nurse anesthetists (CRNAs). In a series of reports, the authors identified frequent incidents, such as disconnections in breathing circuits, and causes of discovery of errors, such as intraoperative relief. They confirmed that equipment failure was a small cause of anesthesia mishaps (4%), whereas human error was a predominant factor. They suggested that future studies of anesthesia-related mortality and morbidity should classify events according to a strategy for prevention rather than outcome alone.

The Australian Incident Monitoring Study was developed by the Australian Patient Safety Foundation and has been in existence since the early 1990s. It is a method of reporting and analyzing critical incidents so that corrective strategies can be implemented. Similar to the ASA-CCP, there is no rate of occurrence, only an analysis of reported cases. Numerous reports have looked at the cause of critical incidents, including problems with ventilation, with vascular access, and in the postanesthesia care unit.[88,89]

Buffington and co-workers[90] studied the ability of attendees of an anesthesia meeting to identify five faults intentionally created in a standard anesthesia machine. A survey was distributed, and the answer sheets were scored with respect to the number of correct answers. Only 3.4% of the respondents found all five faults. The average number of faults detected was 2.2. The professional background of the participants did not influence the ability to find the faults; distributions were similar between physicians and CRNAs. A small improvement in fault-finding ability was found in those with more than 10 years of experience. Studies such as these highlight the problem of the practitioner's ability to identify conditions that may lead to anesthesia mishaps. Whether improved technology or education can reduce some basal level of mishaps is unknown.

TABLE 37-11 DISTRIBUTION OF ADVERSE RESPIRATORY EVENTS IN THE AMERICAN SOCIETY OF ANESTHESIOLOGISTS' ANESTHESIA CLOSED CLAIMS STUDY

Event	Number of Cases	Percent of 522 Respiratory Claims
Inadequate ventilation	196	38
Esophageal intubation	94	18
Difficult tracheal intubation	87	17
Inadequate inspired oxygen concentration	11	2

ISSUES ASSOCIATED WITH ANESTHESIA-RELATED MORTALITY

The studies detailed in the previous text focus on intraoperative or inhospital deaths directly attributable to anesthesia care; nonetheless, perioperative complications may contribute to the risk of mortality beyond the immediate postoperative period. For example, a perioperative stroke or myocardial infarction may lead to death after the period of analysis. Notably, recent research has suggested that even small myocardial infarctions or unstable

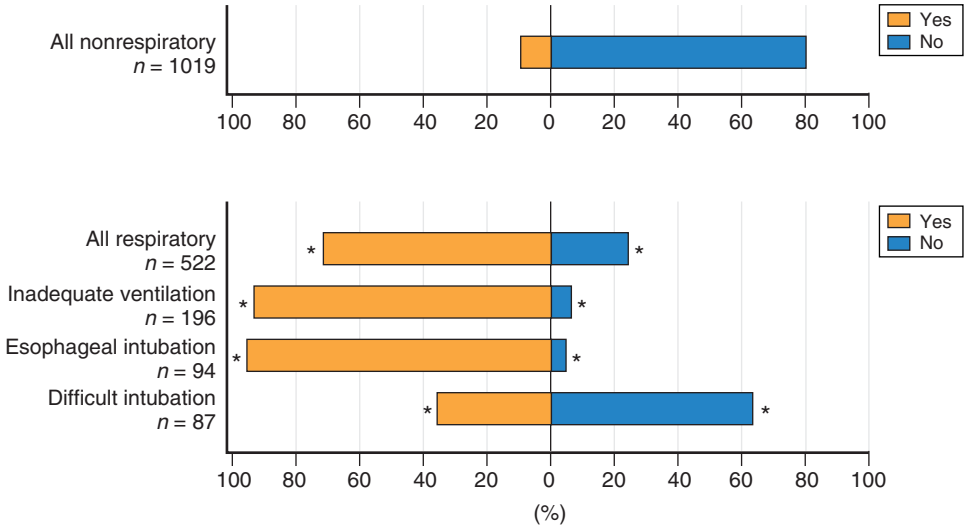

Figure 37-5. Relationship between adverse events in the American Society of Anesthesiologists' Anesthesia Closed Claims Study and preventable complications. Preventable events related to respiratory complications were significantly more common than those related to all nonrespiratory complications. Of the respiratory complications, difficult intubation had the least number of preventable complications (*$P < .05$ versus nonrespiratory claims). *(From Caplan RA, Posner KL, Ward RJ, et al: Adverse respiratory events in anesthesia: a closed claims analysis,* Anesthesiology *72:828, 1990.)*

angina during the perioperative period have been associated with worsened long-term survival.[91] Should these *late* deaths be attributed to anesthesia complications for the purpose of such analyses? The answer depends on the outcome and its relationship to anesthesia management.

The potential effects of anesthesia on long-term survival were suggested by Monk and colleagues.[92] Using multivariate Cox proportional hazards models, these investigators identified three variables as significant independent predictors of mortality: patient comorbidity (relative risk [RR], 16.116), cumulative deep hypnotic time (bispectral index < 45) (RR, 1.244/hr), and intraoperative systolic hypotension (RR, 1.036/min). They reported that cumulative deep hypnotic time and intraoperative hypotension were significant, independent predictors of increased mortality. Further work is required to determine whether these results reflect a true pathophysiologic link between perioperative (anesthesia) management and long-term outcome or a simple statistical association. This study and others, however, emphasize the importance of evaluating all aspects of anesthesia care and short- and long-term outcomes to try to optimize both long- and short-term patient outcomes.

RISKS RELATED TO PATIENT CHARACTERISTICS

Multiple past studies have demonstrated that perioperative morbidity and mortality are increased in the presence of coexisting medical diseases (also see Chapter 39). The ASA physical status classification system, originally proposed in 1941,[93] represents a widely used method of classifying the severity of coexisting disease among surgical patients. Since its introduction, this classification system has introduced a standardized terminology for anesthesia practice and has aided in developing valid statistical comparisons of outcomes among sites.[94]

The correlation between ASA physical status and mortality offers a simple illustration of the link between comorbidities and adverse operative outcomes. In 1961, Dripps and co-workers demonstrated that mortality increased as the severity of comorbid disease increased, as assessed by the ASA physical status classification.[32] Several investigators have reevaluated the relationship between operative mortality and ASA physical status. Studies by Pedersen[46] and Tiret[43] and their colleagues demonstrated such relationships. Vacanti and co-workers[95] also demonstrated the relationship between increasing mortality and decreasing physical status in 68,388 cases.

In Canada, Cohen and colleagues[96] analyzed 100,000 anesthesia procedures and determined mortality within 7 days of surgery by using governmental vital statistics mortality data between the years 1975 and 1984. They collected information for each patient on age, preoperative conditions, ASA physical status, anesthetic technique, monitors, and other factors. The overall 7-day mortality rate was 71.04 deaths per 10,000 procedures. The mortality rate increased with advanced age, and it showed a significant increase in those older than 80 years of age. Rates were low for normal, healthy individuals and for those undergoing minor procedures. The investigators developed a multiple logistic regression model to determine the independent predictors of mortality. Significant risk markers for increasing mortality were advanced age, male gender, increasing physical status score, major or intermediate surgery, emergency procedure, having a complication in the surgical unit, narcotic anesthetic techniques, and having received only one or two anesthetic drugs (Table 37-12).

One of the limitations of the ASA physical status classification system is that the ranking is determined by individual anesthesia providers; as such, it might differ from one practitioner to another. Owens and co-workers[97] evaluated this hypothesis by asking 255 anesthesiologists to classify 10 hypothetical patients. In six of the cases there was general agreement among the practitioners about classification of the patient; in the other four cases, opinion diverged.

TABLE 37-12 RISK FACTORS ASSOCIATED WITH INCREASED ODDS OF DYING WITHIN 7 DAYS FOR ALL CASES

Variable	All Procedures: Relative Odds of Dying Within 7 Days	95% Confidence Limits
Patient related		
Age (yr)		
60-79 vs <60	2.32	1.70-3.17
80+ vs <60	3.29	2.18-4.96
Sex (female vs male)	0.77	0.59-1.00
ASA physical status classification (3-5 vs 1-2)	10.65	7.59-14.85
Surgery related		
Major vs minor	3.82	2.50-5.93
Intermediate vs minor	1.76	1.24-2.5
Length of anesthesia (≤2 hr vs <2 hr)	1.08	0.77-1.50
Emergency vs elective	4.44	3.38-5.83
Other factors		
Year of surgery (1975-1979 vs 1980-1984)	1.75	1.32-2.31
Complication in the surgical or recovery unit (yes vs no)	1.42	1.06-1.89
Anesthesia related*		
Experience of the anesthetist (>600 procedures for ≥8 yr vs <600 procedures for <8 yr)	1.06	0.82-1.37
Inhalation with narcotic vs inhalation alone	0.76	0.51-1.15
Narcotic alone vs inhalation alone	1.41	1.01-2.00
Narcotic with inhalation vs inhalation alone	0.79	0.47-1.32
Spinal vs inhalation alone	0.53	0.29-0.98
Number of anesthetic drugs (1-2 vs 3)	2.94	2.20-3.84

Adapted from Cohen MM, Duncan PG, Tate RB: Does anesthesia contribute to operative mortality? JAMA *260:2861, 1988.*

**All cases performed with the five most frequently used anesthetic techniques.*

In contrast to the ASA physical status classification, which offers a general assessment of the severity and extent of a patient's coexisting illnesses, other studies have attempted to define the specific patient characteristics that are most strongly associated with perioperative adverse events related to a particular organ system. In evaluating the risk directly related to the patient's condition, the limitations of the methodology must be understood. All such studies evaluate the predictive value of a clinical or laboratory risk factor for a defined perioperative complication. In this approach, a cohort of individuals of interest is defined. In the optimal state the study is performed prospectively, and the outcome of interest is assessed in a rigorous, blinded fashion. Despite this, many available studies of perioperative risk factors focus on selected patients and include a retrospective design, methods that greatly limit their generalizability and validity.

Many studies have identified a cohort of individuals, determining their clinical and laboratory risk factors and using multivariate modeling to determine the factors associated with increased risk. A major limitation in the use of multivariate modeling for this purpose is the assumption that the intraoperative period is a *black box* and that care is not modified by the knowledge of the risk factor (Fig. 37-6). However, anesthesiologists modify intraoperative care of high-risk patients in an attempt to minimize the likelihood of complications. Changes in medical care over time and better knowledge about high-risk patients should result in a reduction of the risk related to specified clinical factors. For this reason, many of the indices defined in previously published studies may no longer be valid because of changes in clinical practice. Such considerations make it difficult to design and complete formal investigations to validate individual management strategies in the context of current practice.

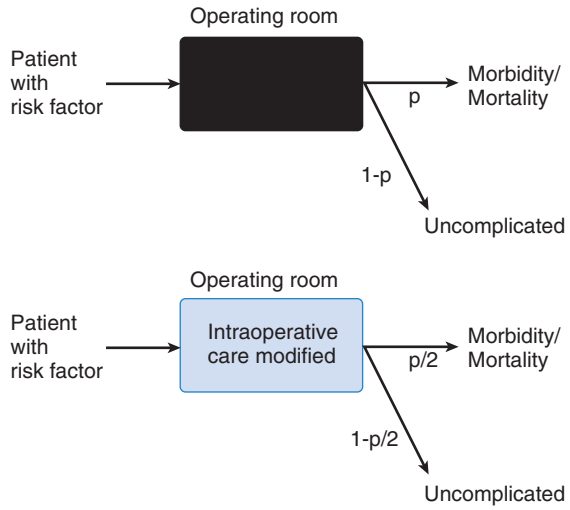

Figure 37-6. The concept of the black box for risk indices. In developing a risk index, patients with a specific risk factor enter the operating room and have a complication at a rate *p*. If the anesthesiologist is aware of the importance of the risk factor and can modify care to reduce such risk (*p/2*), then the risk factor may no longer be significant. If the risk factor is ignored, then complications may again occur in such patients.

One common approach taken in past efforts to quantify operative risk has been to examine the relationship between a single risk factor and a broad range of adverse perioperative outcomes (also see Chapter 39). For example, numerous studies have evaluated the importance of hypertension on perioperative risk. Goldman and Caldera[98] evaluated a cohort of patients undergoing noncardiac surgery under general anesthesia. Hypertension was not associated with increased perioperative risk, although the number of patients with diastolic blood pressure greater than 110 mm Hg was too small to draw any statistically significant conclusions. In contrast, Hollenberg and co-workers[99] identified hypertension and the presence of left ventricular hypertrophy as predictors of perioperative ischemia, but they did not consider their independent relationship to perioperative major morbidity.

An alternative to examining the impact of a single risk factor on perioperative outcomes involves a more general effort to identify multiple risk factors for one or more adverse perioperative outcomes. As such, multiple researchers have undertaken prospective and retrospective cohort studies with the goal of identifying patients at greatest risk for fatal and nonfatal myocardial infarction. One of the earliest attempts to define cardiac risk was performed by Goldman and colleagues at the Massachusetts General Hospital.[13] They studied 1001 patients older than 45 years of age who were undergoing noncardiac surgery, excluding those who underwent transurethral resection of the prostate under spinal anesthesia. Using multivariate logistic regression, they demonstrated nine clinical factors associated with increased morbidity and mortality. Each risk factor was weighted in the logistic regression equation and converted into points in the index. An increasing number of points was associated with increasing perioperative cardiac morbidity or mortality.

Several attempts have been made to validate the Goldman Cardiac Risk Index. Zeldin[100] prospectively determined the Cardiac Risk Index for 1140 surgical patients and reported that the overall accuracy of the index was as high as in the original study, although the rate of complications in the highest risk group was less than originally reported. Larsen and co-workers[101] also found that the Cardiac Risk Index demonstrated good accuracy in 2609 consecutive unselected patients older than 40 years of age. The validity of the Cardiac Risk Index is more controversial for patients undergoing vascular surgery. Domaingue and colleagues[102] studied patients undergoing various vascular surgery procedures and reported a higher probability of major cardiac complications than that reported by Goldman and associates; however, they also demonstrated a higher rate of complications with increasing cardiac risk class. Jeffrey and colleagues[103] evaluated the rate of cardiac complications in 99 patients undergoing elective abdominal aortic surgery and demonstrated a similar pattern of increased overall complication rates with increasing cardiac risk. A higher percentage (7%) of patients in the lowest category in their study sustained a cardiac complication. White and associates[104] demonstrated the value of the Goldman Cardiac Risk Index for long-term survival after vascular surgery. Several other studies, however, were unable to

demonstrate any relationship between the Cardiac Risk Index and perioperative cardiac complications, with a high incidence of complications found in patients with a Cardiac Risk Index of I or II.[105,106] When the ASA physical status classification system was compared with the Goldman Cardiac Risk Index in a cohort of 16,277 patients undergoing noncardiac surgery,[106] both indices demonstrated predictive value, although the objective Goldman Cardiac Risk Index provided little additional value over the more subjective ASA physical status classification.

Since the introduction of the Goldman Cardiac Risk Index, other investigators have put forward alternative risk indices for cardiac events after noncardiac surgery. Detsky and co-workers[107] studied a cohort of individuals who were referred to an internal medicine service for preoperative evaluation. Many of the factors identified by Goldman were confirmed or slightly modified in the Detsky Modified Risk Index, and angina was added to the risk factors. The researchers advocated the calculation of a pretest probability of complications based on the type of surgery, after which the Detsky Modified Risk Index is applied with the use of a nomogram. In this manner, the overall probability of complications can be determined as a function of the surgical procedure and patient disease. The Detsky Modified Risk Index was advocated as the starting point for risk stratification in the American College of Physicians guidelines on preoperative evaluation.[108] In an attempt to update Goldman's original index, Lee and colleagues[109] at the Brigham and Women's Hospital studied 4315 patients 50 years of age or older who were undergoing elective major noncardiac procedures in a tertiary care teaching hospital. Six independent predictors of complications were identified and included in a Revised Cardiac Risk Index (RCRI): high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine level higher than 2.0 mg/dL. The rate of major cardiac complications increased with the number of risk factors. The performance of the RCRI was examined in a meta-analysis conducted by Ford and colleagues.[110] In a review of 24 studies including over 700,000 patients, they found that although the RCRI showed moderate discrimination for patients at low versus high risk for cardiac events after noncardiac surgery, it did not perform well at predicting death or at predicting cardiac events after vascular surgery.

More recently, Gupta and colleagues[111] used data collected by the NSQIP to develop the risk for cardiovascular events after noncardiac surgery. They developed a risk-prediction model using all 211,410 patients recorded in the 2007 version of the NSQIP database and subsequently validated this model on the 257,385 patients in the 2008 dataset. This model, which included five variables—type of surgery, dependent functional status, abnormal creatinine level, ASA physical status, and increasing age—demonstrated improved discrimination over the RCRI, which did not improve with the addition of the RCRI score to the model.

Beyond the efforts at identifying those patients most at risk of postoperative cardiovascular events, recent research has sought to develop statistical models for a range of other organ-based preoperative outcomes. These have included risk models for acute kidney injury in cardiac[112] and noncardiac surgery patients,[60] postoperative respiratory failure,[113,114] and stroke after cardiac surgery[115] and carotid endarterectomy.[116]

In contrast to the efforts to determine risk factors for specific organ-based complications, other investigators have sought to develop risk-prediction models to identify those patients at risk of death from any cause in the immediate postoperative period. For example, Glance and colleagues from the University of Rochester used data from the NSQIP to derive and validate a predictive score for 30-day all-cause mortality for noncardiac surgery. Studying 298,772 patients undergoing surgery between 2005 and 2007, Glance and colleagues identified three factors that were highly predictive of death at 30 days after surgery: (1) ASA physical status, (2) emergency status, and (3) surgery type. Patients with ASA physical status I, II, III, IV or V were assigned 0, 2, 4, 5, or 6 points, respectively; intermediate- or high-risk procedures were assigned 1 or 2 points, respectively; and emergency procedures were assigned 1 point. Patients with risk scores less than 5 had a predicted risk of mortality less than 0.5%, whereas patients with a risk score of 5 to 6 had a risk of mortality between 1.5% and 4%. Patients with a risk score greater than 6 had risk of mortality more than 10%.[117]

Beyond their clinical applicability, such risk indices have become important in the context of health policy by allowing for comparisons of risk-adjusted mortality rates across hospitals and physicians providing cardiac surgery. For example, the state of New York annually publishes data on mortality rates associated with coronary bypass grafting by surgeon and by hospital.[118-120] For comparison of rates across institutions, institutional mortality rates are typically risk-adjusted so that high-performing institutions that treat a high percentage of medically complex patients are not spuriously categorized as *poor performers* simply because of the features of their patient mix.

Beyond identifying clinical indicators of perioperative risk, historic and current research has focused on the role of genetics and genomics on the outcomes of major surgical procedures. Notably, the impact of genotype on perioperative risk has been well known since elucidation of the inheritance pattern of malignant hyperthermia. With malignant hyperthermia, a clear link exists between the autosomal dominant disease and an adverse outcome after administration of an anesthetic.[121] Interest in evaluating the impact of genetic polymorphism on overall perioperative outcome is increasing, even if the link to anesthesia is less well defined. For example, apolipoprotein E4 has been shown to modulate neurologic injury and recovery after a variety of acute ischemic insults, including coronary artery bypass grafting.[122] Polymorphism of the glycoprotein IIIa constituent of the platelet integrin receptor has also been correlated with postoperative cognitive decline.[123,124] Further research will be required to determine specific genetic profiles that will impact anesthetic management strategies, drug selection, and other aspects of care.

SPECIAL PATIENT GROUPS

OBSTETRICS

Anesthesia for the obstetric patient carries unique challenges, since both the mother and the fetus are potentially at risk for complications. Fortunately, maternal mortality is rare, and the anesthesia-related component of maternal delivery represents only a small fraction of all maternal deaths. As a result, studies of peripartum complications require a large number of patients from a diversity of clinical settings (also see Chapter 77).

In parallel to the early efforts to determine the overall risk of anesthesia for surgery, a series of studies were performed between 1974 and 1985 that sought to determine the rate of obstetric complications in the United States and England and to assess the contribution of anesthesia per se to the risk of adverse events in this group. One of the first reports included the period of 1974 through 1978. Kaunitz and coauthors[125] reported an anesthesia-related death rate of 0.6 per 100,000 births with data from all 50 states. Endler and co-workers[126] studied births in Michigan between 1972 and 1984 and reported 15 maternal deaths in which anesthesia was the primary cause and 4 deaths in which anesthesia was contributory. This resulted in a rate of 0.82 anesthesia-related deaths per 100,000 live births. Eleven of the 15 deaths were associated with cesarean section. Obesity and emergency surgery were risk factors in many patients. Complications related to regional anesthesia were identified as a problem in the earlier years of the study, whereas failure to secure a patent airway was the primary cause of mortality in the later years. No anesthesia-related maternal deaths occurred in the final 2 years of the study. Rochat and colleagues[127] studied 19 areas of the United States between 1980 and 1985 and reported 0.98 anesthesia-related deaths per 100,000 live births. They observed that maternal mortality did not decrease over the time of the study.

The Confidential Enquiry into Maternal Deaths in England and Wales has been assessing maternal deaths since 1952.[128] Records of all maternal deaths are sent to a district medical officer, who sends an inquiry form to all health practitioners involved in the care of these patients. These forms are evaluated by a senior obstetrician and an anesthesia assessor. Morgan[128] reported the maternal deaths from anesthesia between 1952 and 1981 (Table 37-13). The total maternal mortality rate decreased over time, but the percentage of deaths related to anesthesia increased, although the absolute number of deaths associated with anesthesia decreased. During the early years of the study, endotracheal intubation was rarely performed during obstetric anesthesia. Later reports advocated the use of endotracheal intubation after the induction of thiopental and suxamethonium, and technical difficulties with intubation were identified. The other major finding of this study was that the experience of the anesthesia provider in obstetric anesthesia was the most important factor in anesthesia-related maternal mortality.

More recent investigations have confirmed ongoing decreases over time in the hazards of obstetric anesthesia. Hawkins and associates[129] obtained data from the ongoing National Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention on births and fetal deaths from 1979 through 1990 to determine the possible risk related to anesthesia for obstetrics. They identified a total of 129 women who died of anesthesia-related causes during the study period, most (82%) of the deaths occurred during cesarean section, and the incidence of anesthesia-related maternal mortality decreased over time (Table 37-14), possibly the result of a trend toward a greater use of neuraxial techniques. Importantly, among maternal deaths that occurred in the context of general anesthesia for cesarean delivery, 73% were related to airway problems.

In a subsequent study, Panchal and colleagues[130] conducted a retrospective case-control study using patients' records from a state-maintained anonymous database of all nonfederal Maryland hospitals that performed deliveries between 1984 and 1997. Variables studied included patient demographics and the International Classification of Diseases, Clinical Modification (ICD-9 CM) diagnosis and procedure codes. Of the 822,591 hospital admissions for delivery during the 14-year study period, 135 maternal deaths occurred. The most common diagnoses associated with mortality during hospital admission for delivery were preeclampsia or eclampsia (22.2%), postpartum hemorrhage or obstetric shock (22.2%), pulmonary complications (14%), blood clot or amniotic embolism

TABLE 37-13 **MATERNAL MORTALITY FIGURES OBTAINED FROM THE CONFIDENTIAL ENQUIRY INTO MATERNAL DEATHS IN ENGLAND AND WALES**

Years	Maternal Mortality per 1000 Total Births	Number of Deaths From Anesthesia	Percent of True Maternal Deaths From Anesthesia	Percent With Avoidable Factors
1952-1954	0.53	49	4.5	—
1955-1957	0.43	31	3.6	77
1958-1960	0.33	30	4.0	80
1961-1963	0.26	28	4.0	50
1964-1966	0.20	50	8.7	48
1967-1969	0.16	50	10.9	68
1970-1972	0.13	37	10.4	76
1973-1975	0.11	31	13.2	90

or both (8.1%), and anesthesia-related complications (5.2%). Notably, Panchal's study noted differences by race in the rate of maternal death per 100,000 live births per year (Fig. 37-7). Although the potential causes of this difference remain to be elucidated, Panchal's findings also suggested potential improvements over time in both the overall risk of maternal mortality, as well as the degree to which such risk differed by race.

More recent studies have continued to portray maternal mortality related to anesthesia as an important, although exceedingly rare event. Importantly, contemporary analyses of adverse maternal outcomes of anesthesia emphasize the particular risks associated with airway management in this population. For example, Mhyre and colleagues reviewed maternal mortality in Michigan between 1985 and 2003.[131] Of 855 pregnancy-associated deaths, 8 were related to anesthesia, and anesthesia was considered to be contributory in 7. All anesthesia-related deaths from airway obstruction or hypoventilation took place during emergence and recovery, not during induction of general anesthesia. Lapses in postoperative monitoring and inadequate supervision by an anesthesiologist seemed to contribute to more than one half of the deaths. In a similar study, Bloom and associates studied anesthesia-related morbidity and mortality as part of a prospective observational study conducted in women (N = 37,142) with singleton gestations undergoing cesarean delivery in the clinical centers comprising the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network.[132] One maternal death was caused by failed intubation in which the anesthetic procedure was directly implicated.

In summary, extensive past research has indicated that the risks of major morbidity and mortality attributable to obstetric anesthesia care have decreased over time; nonetheless, recent research indicates that adverse outcomes continue to occur and may be of particular concern for patients receiving general anesthesia for cesarean delivery. Looking forward, further research is needed, potentially using national and international databases, to define more clearly the current risks of anesthesia for obstetrics, as well as the variability in the care delivered (including the use of differing anesthetic techniques) and the maternal outcomes across institutions and practice environments.

PEDIATRICS

There are few studies of anesthesia-related risk in the pediatric population (also see Chapters 92 to 95). Two themes emerge from these studies: very young infants are at increased risk, and anesthesia-related risk is reduced in centers with specialized pediatric anesthesia facilities.

TABLE 37-14 NUMBERS, CASE FATALITY RATES, AND RISK RATIOS OF ANESTHESIA-RELATED DEATHS DURING CESAREAN SECTION DELIVERY BY TYPE OF ANESTHESIA IN THE UNITED STATES, 1979-1984 AND 1985-1990

In Beecher and Todd's classic 1954 study on anesthesia outcomes,[18] a "disproportionate number" of anesthesia-related deaths occurred in children younger than 10 years of age. Similarly, Graff and colleagues[133] from the Baltimore Anesthesia Study Committee reported 335 operative deaths in the pediatric age group. Of these, 58 were thought to be primarily or partially attributable to anesthesia. The percentage of operative deaths attributable to anesthesia was relatively constant among age groups at 16.6% to 21.7%. The estimated anesthesia-associated mortality rate was 3.3 deaths per 10,000 surgeries for those younger than 15 years of age versus 0.6 for those between 15 and 24 years of age and 11.7 for those older than 64 years. Notably, the majority of pediatric anesthetic deaths occurred in children with low anesthesia risk and among those undergoing tonsillectomy, a common surgical procedure in this age group. In an effort to understand the causes of pediatric anesthetic mortality, the authors noted errors in anesthesia management as accounting for approximately one half of the cases. Respiratory complications (e.g., underventilation, aspiration of vomitus or blood) were apparent in 82% of the anesthesia-related deaths. Notably, since this study was completed at a time when anesthetic management and monitoring techniques were quite different, its applicability to modern practice remains limited.

The studies that followed those of Beecher and Todd and the Baltimore Anesthesia Study Committee provided further detail on the risks associated with pediatric anesthesia over time. Tiret and coauthors[134] prospectively studied major anesthesia-related complications in pediatric patients in 440 hospitals in France between 1978 and 1982. There were 27 major complications in 40,240 cases, which included 12 cardiac arrests and 1 death. The incidence of major complications and cardiac arrest was significantly higher in infants than in older children. The rate of cardiac arrest related to anesthesia was highest in infants (19 per 10,000) and lowest in children (2.1 per 10,000). Most complications in infants involved the respiratory system and predominantly consisted of airway problems and aspiration. Older children experienced respiratory and cardiac complications, which occurred most frequently during induction and recovery.

Cohen and colleagues[135] studied 29,220 anesthesia procedures at the Winnipeg Children's Hospital. Data were collected from mid-1982 through 1987 and stored in a databank. Data on patients' coexisting medical conditions and postoperative follow-up were obtained within 72 hours. Complications included death, cardiac arrest, drug reactions, airway obstruction, and minor complications such as nausea and vomiting, arrhythmias, and sore throat. Neonates underwent a higher percentage of major vascular or cardiac and intraabdominal procedures, and older children had a higher incidence of extremity procedures. Intraoperative cardiac arrest occurred most frequently in patients younger than 1 year of age (4 in 2901 procedures). Postoperatively, minor events such as nausea and vomiting were more common in older children, whereas respiratory events were more common in infants and younger children (Table 37-15). When compared with adult patients, children experienced different complications, which frequently extended well into the postoperative period. In a comparison of 2-year periods between 1982 and 1987, rates of intraoperative events were found to be stable, and the rate of postoperative complications decreased.

More recently, van der Griend and colleagues reported on 24-hour and 30-day mortality associated with 101,885 anesthetics administered to 56,263 children at the Royal Children's Hospital in Melbourne, Australia. They noted a rate of all-cause 24-hour mortality of 13.4 per 10,000 anesthetics and a 30-day all-cause mortality of 34.5 per 10,000 anesthetics. The incidence of deaths related to anesthesia was far lower, occurring at a rate of 1 in 10,188 or 0.98 cases per 10,000 anesthetics performed. In all of the 10 anesthetic-related deaths that the authors observed, preexisting medical conditions were assessed to have been a significant contributing factor.[136]

In contrast to efforts to determine the incidence and predictors of mortality among pediatric surgical patients, a number of investigators have focused on cardiac arrest in the context of pediatric anesthesia. For example, Flick and associates[137] studied patients younger than 18 years of age who underwent surgery at the Mayo Clinic and

TABLE 37-15 SUMMARY OF PERIOPERATIVE EVENTS BY AGE GROUP*

§Percentage of total anesthetics in which at least one event occurred in the intraoperative unit, recovery unit, or later during the postoperative period.

experienced perioperative cardiac arrest between November 1, 1988, and June 30, 2005. A total of 92,881 anesthetics were administered during the study period, 4242 (5%) of which were for the repair of congenital heart malformations. The incidence of perioperative cardiac arrest during noncardiac procedures was 2.9 per 10,000, and the incidence during cardiac procedures was 127 per 10,000. The incidence of perioperative cardiac arrest attributable to anesthesia was 0.65 per 10,000 anesthetics. The incidence of cardiac arrest and mortality was highest in neonates (0 to 30 days of life) undergoing cardiac procedures (incidence, 435 per 10,000; mortality, 389 per 10,000).

Investigators at the Children's Hospital of Boston used an established data registry that included all cardiac arrests from January 2000 through December 2005 related to surgery for congenital heart disease.[138] Over this time period, 41 cardiac arrests occurred in 40 patients during 5213 anesthetics for an overall frequency of 0.79%. Eleven cardiac arrests (26.8%) were classified as either likely ($n = 6$) or possibly related ($n = 5$) to anesthesia (21.1 per 10,000 anesthetics) but with no mortality; 30 cardiac arrests were categorized as being related to the procedure.

Efforts to understand the causes and outcomes of cardiac arrest in pediatric anesthesia patients have been aided by the development of large-scale clinical registries for research and quality improvement. In 1994, the Pediatric Perioperative Cardiac Arrest (POCA) Registry[139] was formed to determine the clinical factors and outcomes associated with cardiac arrest in anesthetized children. Institutions included in the registry submitted standardized data from each cardiac arrest occurring in an anesthetized child 18 years of age or younger. A total of 289 cardiac arrests occurred in the 63 institutions in the database during the first 4 years of the registry, 150 of which were judged to be related to anesthesia (1.4 per 10,000 anesthesia procedures), with a 26% mortality rate. Medication-related causes and cardiovascular causes of cardiac arrest were most common. Anesthesia-related cardiac arrest occurred most often in patients younger than age 1 year and in patients with severe underlying disease. The goal of the registry is similar to that of the closed claims studies—to identify the causes in this unique population and thereby formulate preventive strategies.

An update from the POCA Registry was published in 2007.[140] From 1998 through 2004, 193 arrests (49%) were related to anesthesia. Medication-related arrests accounted for 18% of all arrests. Cardiovascular causes of cardiac arrest (41%) were the most common, with hypovolemia from blood loss and hyperkalemia from transfusion of stored blood being the most common identifiable cardiovascular causes (Fig. 37-8). Among respiratory causes of arrest (27%), airway obstruction from laryngospasm was the most common. Vascular injury incurred during placement of central venous catheters was the most frequent equipment-related cause of arrest. Cardiovascular and respiratory causes occurred most commonly in the surgical and postsurgical phases, respectively.

In 2010, POCA investigators reported on anesthesia-related cardiac arrest in children with preexisting cardiac disease, comparing 245 cardiac arrests in children without heart disease with 127 cardiac arrests in children with cardiac conditions. Compared with children without cardiac disease, children with cardiac conditions were more often ASA physical status III, IV, or V and more often arrested from cardiovascular causes. Mortality was higher in children with heart disease than among children without heart disease (33% vs 23%) but did not differ when adjusted for ASA physical status classification.[141]

GERIATRICS

The relationship of age to operative risk has been a subject of scientific and clinical debate since the early days of modern surgery (also see Chapter 80). As the proportion of United States adults aged 65 years and older is anticipated to increase rapidly over the next 3 decades as a result of the aging of the post–World War II *baby boomer* generation, the nature of operative and anesthetic risk in older patients remains a vital area of inquiry.

A key issue in research on the safety of surgery and anesthesia among older adults is the determination of what constitutes *old age* from the perspective of perioperative risk. Multiple definitions have been used for advanced age, including age older than 65, 70, 80, or 90 years. For example, Denney and Denson[142] evaluated risk associated with surgery in patients older than 90 years of age. They reported 272 patients undergoing 301 operations at the University of Southern California Medical Center, finding a high perioperative mortality rate among older patients with serious bowel obstruction (63%). Taking a slightly different approach, Djokovic and Hedley-Whyte[143] studied outcome after surgery in 500 patients older than 80 years of age. They found that mortality was predicted by ASA physical status classification, with greater comorbid conditions associated with increasing risk. Myocardial infarction was the leading cause of postoperative death. Patients without significant comorbid diseases (ASA I classification) had a mortality rate of less than 1%.

Del Guercio and Cohn[144] investigated the value of preoperative invasive monitoring in obtaining hemodynamic and cardiopulmonary variables for predicting operative risk in the older adult. Among 148 consecutive

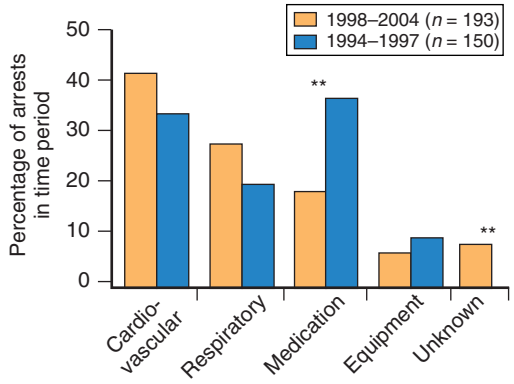

Figure 37-8. Causes of anesthesia-related cardiac arrest in the Pediatric Perioperative Cardiac Arrest (POCA) Registry from 1998 to 2004 versus 1994 to 1997. (**$P < .01$ 1998-2004 vs 1994-1997 by Z test). *(From Bhananker SM, Ramamoorthy C, Geiduschek JM, et al: Anesthesia-related cardiac arrest in children: update from the Pediatric Perioperative Cardiac Arrest Registry,* Anesth Analg *105:344-350, 2007.)*

patients older than 65 years of age who were treated in a surgical ICU, only 13.5% had normal physiologic measurements. Advanced and uncorrectable functional deficits were found in 63% of patients, and all in this group who underwent the planned surgery died.

Del Guerico and Cohn's work represented one of several studies that emphasized coexisting diseases, rather than aging itself, as the cause of apparently increased perioperative mortality among older adults. More recently, a growing body of literature has focused on the importance of functional disability and chronic geriatric syndromes, such as frailty and dementia, as determinants of postoperative outcomes among older individuals. Robinson and colleagues examined a cohort of 110 surgical patients with a mean age of 74 years, finding a 15% 6-month rate of mortality. Statistically significant predictors of 6-month mortality included impaired cognition, a recent fall, hypoalbuminemia, anemia, functional dependence, and comorbidity. Notably, functional dependence was the strongest predictor of 6-month mortality. Four or more markers in any one patient effectively predicted 6-month mortality (sensitivity, 81%; specificity, 86%).[145] Similarly, Finlayson and colleagues observed high rates of mortality after major gastrointestinal surgery among older nursing home residents versus the overall Medicare population; the high rates of mortality were likely attributable to high rates of comorbidity and functional disability within this population.[146]

In this context, research on the risks of surgery and anesthesia in the older adult now focuses on broader definitions of *risk* that include functional outcomes and quality of life, in addition to traditional morbidity and mortality outcomes. Most recently, Finlayson and colleagues examined 6822 older nursing home residents undergoing intestinal resections for colon cancer, noting a 53% 1-year mortality rate and a 24% rate of sustained decline in functional independence in activities of daily living among survivors. In multivariate regression, age older than 80 years, hospital readmission after surgical discharge, surgical complications, and functional decline before surgery all predicted functional decline at 1 year.[147] As this population continues to grow, these measures of outcome relative to patient goals of care will become increasingly important in determining optimal strategies for perioperative management.

RISKS DIRECTLY RELATED TO THE ANESTHETIC DRUG

Numerous studies have evaluated the influence of the choice of anesthetic on outcome, a question that is discussed throughout this book. From a global perspective, there does not appear to be a single best anesthesia technique for a particular surgery or group of surgeries. In a multivariate analysis by Cohen and co-workers[96] of 100,000 anesthesia procedures performed in Canada, the choice of drug did not provide any additional prognostic information for predicting mortality beyond that of patient disease and the surgical procedure. In univariate analysis, monitored anesthesia care appeared to be associated with worse outcomes; however, this association was attributable to the use of monitored anesthesia in sicker patients (see Table 37-12).

One question that has persisted within the anesthesia literature is the issue of whether anesthetic medications carry inherent toxicity (also see Chapter 26). For example, numerous recent discussions have focused on the potential toxicity of halothane and sevoflurane. In the case of halothane, concern focused on the potential for fulminant, potentially fatal, hepatic necrosis with this medication. After several case reports of hepatic necrosis after halothane anesthesia, a large retrospective study of 856,500 anesthesia procedures at 34 institutions was undertaken.[148-150] In all but nine cases, hepatic necrosis could be explained by other causes. Of the remaining nine cases, only seven received halothane. Halothane could be associated with hepatitis and hepatic failure, but the incidence was very low.

In the case of sevoflurane, concern has centered on the potential nephrotoxicity of its metabolite compound A. Although some laboratory studies have supported the contention that sevoflurane reacts with soda lime to form compound A and that this metabolite can lead to renal toxicity,[151,152] clinical studies have been unable to confirm this potentially detrimental effect[153,154] in the United States (also see Chapter 26) .

Numerous studies have attempted to define the *safest* anesthetic for high-risk patients. In the late 1980s, there was particular concern that isoflurane caused coronary steal in patients with coronary stenosis and collaterals and that this could result in myocardial ischemia.[155,156] A series of studies were conducted to evaluate the rate of perioperative cardiac morbidity and mortality in patients undergoing coronary artery bypass grafting to determine the importance of the agent used for general anesthesia.[157-160] Taken together, these studies demonstrated negligible differences in outcome, thus supporting the contention that multiple safe approaches to general anesthesia may exist for an individual context. Other studies have focused on the relative safety of general anesthesia versus neuraxial or regional techniques. Notably, multiple randomized trials and observational studies demonstrated improved outcome with regional rather than general anesthesia.[161,162] For lower extremity and pelvic surgery, regional anesthesia was associated with a lower incidence of graft thrombosis and deep venous thrombosis, as well as decreased bleeding. For patients undergoing vascular surgery, the primary finding was a lower incidence of graft thrombosis and the need for reoperation in patients undergoing infrainguinal bypass surgery; however, the largest of these studies was unable to demonstrate any difference in outcome based on anesthesia technique.[163-165] The rate of this complication was low in the total cohort in the largest trial, which made it impossible to detect any difference based on technique. Summarizing findings from several of these studies, Rodgers and co-workers[162] published an influential meta-analysis of regional versus general anesthesia. Neuraxial blockade was found to reduce postoperative mortality and other serious complications. The magnitude of some of these benefits remained uncertain. Discussion of regional versus general anesthesia is presented in Chapters 56 and 57.

RISKS RELATED TO SURGERY

The surgical procedure itself significantly influences perioperative risk. In virtually every study performed, emergency surgery is associated with additional risk. For example, in the study of Goldman and Caldera,[98] emergency surgery was associated with the second highest weight (i.e., number of points) after active signs of congestive heart failure. In this same study, intrathoracic and abdominal procedures were determined to have higher risk.

In some cases, the risk related to surgery is a function of the underlying disease processes and the stress related to the surgical procedure. As a category of surgical procedures, cardiovascular surgery has historically been associated with the highest risk of mortality and major morbidity. (The risks related to cardiac surgery are reviewed in Chapter 67.) Vascular surgery is among the highest-risk group of noncardiac procedures. Although aortic reconstructive surgery has traditionally been considered the procedure with the highest risk, infrainguinal procedures have shown a similar rate of cardiac morbidity in several studies.[166,167] In an attempt to analyze the cause of the high complication rate with a relatively peripheral procedure, L'Italien and associates[167] demonstrated that the extent of coronary artery disease is higher in patients undergoing infrainguinal procedures and most likely accounts for the excess morbidity and mortality.

Ashton and colleagues[168] evaluated perioperative morbidity and mortality in a cohort of patients at a Veterans hospital. Although vascular surgery was among the highest risk procedures, amputation was associated with the highest inhospital cardiac complication rate within this subgroup. This finding most likely represents the more severe nature of the cardiovascular disease in these patients and the prolonged hospitalization needed to facilitate recuperation. As in the study by Goldman and co-workers,[13] intraabdominal, thoracic, and orthopedic procedures were associated with increased risk. In another report, Ashton and colleagues[169] evaluated the rate of perioperative myocardial infarction in patients undergoing transurethral resection of the prostate. Despite the high frequency of coronary artery disease in this population, the incidence of perioperative myocardial infarction was only 1%.

Numerous studies have evaluated the perioperative complication rate related to superficial procedures. Backer and associates[170] evaluated the rate of perioperative myocardial reinfarction in patients who had histories of preexisting coronary artery disease and who underwent ophthalmologic surgery. They demonstrated that the rate of perioperative cardiac morbidity after ophthalmologic surgery was extremely low, even in patients with a recent myocardial infarction. Similar findings of the safety of ophthalmologic surgery have been reported by multiple other investigators.[69,171]

Eagle and associates[172] evaluated perioperative cardiac morbidity and mortality among patients who had been treated for coronary artery disease and subsequently underwent major noncardiac surgery. Among these patients, major vascular surgery was associated with the highest risk of myocardial infarction or death, with a combined incidence of morbidity and mortality greater than 5%. Procedures associated with a combined complication rate of 1% to 5% included intraabdominal, thoracic, and head and neck surgical procedures. Low-risk procedures included breast, skin, urologic, and orthopedic surgeries. Ultimately, these groupings of surgical procedures came to form the basis for the definitions of surgical risk published in the American College of Cardiology/American Heart Association joint guidelines on perioperative cardiovascular evaluation for noncardiac surgery.[173]

More recent statistical modeling efforts aimed at predicting postoperative outcomes have recognized the important contribution of the type of surgical procedure to the overall operative risk. Gupta and colleagues,[111] who reported on efforts to model the risk of cardiac events after noncardiac surgery, identified the type of surgical procedure as one of five key predictors of postoperative cardiac events. Glance and colleagues[117]developed a risk-prediction model for 30-day mortality after noncardiac surgery incorporating three key risk factors, one of which was an indicator of the risk associated specifically with the surgical procedure. Although these groups each used different methods of grouping procedures into categories of higher and lower risks, their common incorporation of information on procedure type into risk models to predict operative outcomes highlights the important contribution of the surgical procedure itself to overall operative risk.

RISKS RELATED TO THE LOCATION OF SURGERY AND POSTOPERATIVE MONITORING

Perioperative risk varies among hospitals for major procedures such as coronary artery bypass grafting and abdominal aortic aneurysm repair[9,10,174] (also see Chapters 67 and 69). Multiple studies have documented a relationship between surgical volume and mortality. Although surgical skill most certainly plays a role in the rate of complications and mortality, local factors may also play an important role. For example, low surgical volume may lead to less skilled anesthesia and postoperative care. The influence of each of these factors on overall morbidity and mortality is unknown.

Although the value of postoperative monitoring and care in an ICU has never been documented in a randomized clinical trial, many investigators have suggested that such care is one of the primary reasons for the improved morbidity and mortality in recent years. For patients undergoing major vascular surgery, several investigators have suggested that more intense postoperative monitoring could obviate the need for preoperative cardiac testing and revascularization.[173] One potential value of risk assessment is the identification of patients who could benefit from referral to clinical centers with more extensive perioperative resources. Patients with a low probability of perioperative morbidity and mortality could have surgery performed locally, and individuals at higher risk could receive benefit from transfer to a center with high surgical volume.

RISKS RELATED TO THE ANESTHESIA PROVIDER

Over the past decade a great deal of attention has been paid to the role and skill of the anesthesia provider on patient outcome. Since the initial introduction of ether, anesthesia has been administered by a diverse group of providers with variable levels of supervision including anesthesiologists, general medical officers, residents, CRNAs, and anesthesia assistants. The extent to which the skills and training of the individual anesthesia provider may affect outcomes has been assessed in a number of studies. In a now-classic paper, Slogoff and Keats[175] studied the association of perioperative myocardial ischemia and cardiac morbidity in patients undergoing coronary artery bypass grafting across multiple anesthesiologists working in a single practice. Notably, the rate of perioperative ischemia and infarction varied by anesthesiologist; for example, the care delivered by the seventh anesthesiologist in their sample was associated with a significantly higher rate of complications than the average for the rest of the group. The authors concluded that operator technique and experience may affect risk. Subsequent work has moved beyond efforts to demonstrate variability in anesthesia outcomes at the level of the individual practitioner to examine whether outcomes might vary across different models of anesthesia care. Arbous and coauthors reported a case-control study of major morbidity (coma) and mortality affecting a total of 869,463 procedures over a 1-year period in the Netherlands.[176] In this study, 807 cases of coma or death within 24 hours of anesthesia were identified and matched by age and sex to randomly selected control participants who underwent anesthesia temporally in close proximity to the matched case. The Hospital Characteristics Questionnaire, Procedure Questionnaire, and anesthesia and recovery records were used to examine the intraoperative and postoperative characteristics of cases and controls. Anesthesia practice in the Netherlands is described as a *flexible* system with one-on-one anesthesiologist coverage of induction and emergence, assisted by a nurse anesthetist or resident, and a two-on-one system during maintenance anesthesia, with a nurse or resident present in the room and an anesthesiologist in the vicinity. The authors elected to use multivariate analysis on data sets rather than match cases and controls for the anesthesia and physical risk categories or the type of surgical procedure (or both).

Included in the analysis were 807 cases and 883 control participants. Cases and controls, however, were not comparable for ASA classification, and controls were more likely than cases to have undergone minor elective procedures during regular working hours. Cases more frequently underwent cardiac and major vascular procedures, and controls more often underwent orthopedic, urologic, and ophthalmologic procedures. Of the 807 cases, 95% died within 24 hours, and 5% remained comatose, all of whom eventually died in the hospital. Postoperative mortality was 8.8% per 10,000 anesthetics, and postoperative coma occurred in 0.5% of 10,000 anesthetics. Confounding factors were, expectedly, ASA physical status, type of procedure, anesthetic technique, and hospital. Practice-level independent variables that were associated with a decreased risk for coma and death in 24 hours were (1) anesthesia equipment check performed with a checklist; (2) direct availability of an anesthesiologist during maintenance anesthesia by telephone, beeper, or walkie-talkie; (3) no change of anesthesiologist during the case (OR, 0.46); (4) presence of a full-time nurse anesthetist versus a part-time anesthetist during maintenance anesthesia; and (5) presence of two persons (anesthesiologist plus resident or nurse anesthetist) versus one person during emergence.

This study is one of very few that attempts to identify practice characteristics rather than specific drugs or techniques that have an impact on anesthesia outcomes. The size of this study and the nonambiguity of outcomes followed are important characteristics. The study suffers from several significant problems, however. Study groups were not comparable in important ways. The estimated incidence of underreporting of coma and death was 13% to 47%, and selective underreporting could have occurred. The finding that a change of anesthesiologist during maintenance anesthesia adversely affected patient outcomes contradicts findings in previous studies and requires further explanation. Confounding variables associated with a change of anesthesiologist during maintenance anesthesia could include case length and the time of day in which cases are performed. An intriguing finding is that practitioner characteristics affect outcomes; for example outcomes are better with more availability of an anesthesiologist and when nurse anesthetists practice full time rather than part time. This finding warrants further follow-up.

Several studies have attempted to evaluate the complication rates and risks associated with various care provider models. Bechtoldt,[177] as a member of the North Carolina Anesthesia Study Committee, evaluated 900 perioperative deaths that occurred in an estimated 2 million anesthesia procedures performed in North Carolina between 1969 and 1976. Data were obtained from the medical examiner's report, routine death certificates, and a questionnaire completed by the person who administered the anesthetic. The committee concluded that 90 of these deaths were related to anesthesia. Approximately one half of the anesthesia-related deaths took place in the surgical unit, including 19 that occurred on induction. With information obtained from a survey of hospitals, the committee then determined the relationship between mortality and anesthesia provider, based on the total number of procedures administered by each group. The lowest rate of anesthesia-related deaths (1 per 28,166 procedures) occurred in patients who received anesthesia from an anesthesia care team (physician anesthesiologist and CRNA), and the highest rate (1 per 11,432 procedures) was associated with anesthesia administered by a dentist; the rate for the nurse anesthetist–only cohort was intermediate (1 per 20,723). The large number of cases in which the care provider was unknown and reliance on hospital estimates of the number of cases performed by each group made interpretation of this study difficult.

The Stanford Center for Health Care Research[178] also evaluated the impact of the provider on the outcome of care. This group prospectively collected data

from 8593 patients undergoing 15 surgical procedures over a 10-month period (May 1973 through February 1974). Using a risk adjustment methodology, the actual patient outcome was compared with that predicted by the patient's health status and surgical procedure. The investigators reported that death plus severe morbidity was 11% higher than predicted in patients who received their care in a nurse anesthetist–only setting, 3% lower than predicted for physician-only care, and 20% lower than predicted for an anesthesia care team environment. Because of the small sample size, these findings did not reach statistical significance between groups.

The differences in outcome among anesthesia providers are extremely difficult to study from a methodologic standpoint. The impact of specific provider types may be greatest in specific situations. For example, there may be no difference in outcome for healthy individuals, particularly if no complications occur. In contrast, patients with significant comorbid diseases and those who sustain perioperative complications may benefit from having providers with specific skill sets. One way to study such issues is to evaluate the rate of survival after complications. Silber and colleagues[7] at the University of Pennsylvania studied the medical records of 5972 surgical patients randomly selected from 531 hospitals. They evaluated patient and hospital characteristics, including the number and type of physicians, board certification status, and ratio of care providers. The 30-day mortality rate correlated with patient characteristics. Failure to rescue (i.e., failure to prevent death) after an adverse event was inversely associated with the proportion of board-certified anesthesiologists on staff in each facility. Improved perioperative survival was significantly associated with the presence of an increased number of board-certified anesthesiologists.

As a follow-up to this study, Silber[179] used an administrative data set to compare the outcomes of surgical patients for whom anesthesia care was or was not personally performed or medically directed by an anesthesiologist. All older patients in Pennsylvania who underwent general surgical or orthopedic procedures between 1991 and 1994 were analyzed. The 30-day mortality rate and the mortality rate after complications (e.g., failure to rescue) were lower when anesthesiologists directed anesthesia care, even after adjustment for patient and hospital characteristics. Interpretation of the study was limited because the undirected group was small and included a large percentage of procedures in which no bill was submitted for anesthesia services. Administrative data sets, such as Medicare claims, allow the investigator to study a large number of patients, but significant limitations exist, related to the robustness of the data and the potential uncontrolled confounding factors. Therefore most investigators suggest that such studies are best at generating hypotheses rather than defining best practices.[180]

Silber and colleagues[181] used similar methodology to determine the importance of board certification on perioperative risk. Adjusted ORs for death (1.13; 95% CI, 1.00 to 1.26; $P < .04$) and for failure to rescue (1.13; 95% CI, 1.01 to 1.27; $P < .04$) were greater when care was delivered by noncertified, midcareer anesthesiologists.

Pine and co-workers evaluated mortality after eight specific surgical procedures.[182] Procedure-specific risk adjustment models (including institutional and geographic factors) were derived by stepwise logistic regression. Observed and predicted values by type of provider were not statistically significantly different. Hospitals without anesthesiologists had results similar to those facilities in which anesthesiologists provided or directed anesthesia care. The authors did not evaluate failure to rescue or cause of mortality.

More recently, work by Needleman and Minnick has appeared in the health services research literature comparing obstetric outcomes in facilities with different obstetric anesthesia staffing patterns[183]; although the authors observed consistent differences in maternal mortality or other quality indicators at facilities where nurse anesthetists practiced with minimal or no supervision by anesthesiologists versus anesthesiologist-only facilities, questions regarding risk adjustment and study design limit definitive interpretations of this work for policy making.[184] Similarly, a 2010 study by Dulisse and Cromwell suggested no changes in overall surgical patient outcomes in states that had enacted laws allowing nurse anesthetists to practice independently versus states that required anesthesiologist supervision.[185] However, as such new legislation was not associated with major changes in the number or types of surgery conducted without anesthesiologist supervision, Dulisse and Cromwell's work does not speak directly to the question of the gains or losses in safety associated with any specific provider type for a given type of surgery.

Ultimately, as concluded by Smith and associates[186] in a review of available published studies through 2004 on the influence of anesthesia providers, the relationship of patient outcomes to the type of anesthesia provider has not yet been conclusively demonstrated. Nurse anesthetists and other nonphysician providers are vital to the delivery of anesthesia care in the United States and elsewhere, and determining the optimal scope of practice for such providers remains an ongoing area of academic research and political debate.

RISKS TO THE ANESTHESIOLOGIST

Several potential risks to the anesthesiologist are related to the provision of care (also see Chapter 110), including medicolegal risk, the risk of an allergic reaction, and the risk of a needlestick injury and transmission of disease from the patient to the practitioner. (Medicolegal risks are described in Chapter 11.)

The risk for latex allergy, which can lead to a life-threatening reaction, is becoming increasingly apparent for anesthesiologists. Many anesthesiologists are sensitized to latex and need to apply appropriate precautions. The problem is that many sensitized individuals are asymptomatic. Brown and co-workers[187] studied 168 eligible anesthesiologists and nurse anesthetists working in the anesthesia department of The Johns Hopkins Hospital. The prevalence of latex allergy with clinical symptoms was 2.4% and that of latex sensitization without clinical symptoms was 10.1%. The prevalence of irritant or contact dermatitis was 24%. These data suggest that latex is an important problem to the anesthesiologist and that

transforming the hospital to a latex-free environment is needed.

The fact that anesthesiologists are at risk for contracting a disease from a patient has always been a concern. In a review of the literature, Berry and Greene[188] reported that at least 20 different pathogens have been transmitted through accidental needlestick injuries. In the past the risk was primarily hepatitis, but human immunodeficiency virus (HIV) is now also a great concern. Among anesthesia personnel in several studies conducted in the United States, hepatitis B seropositivity ranged from 12.7% to 48.6%, a rate at least four times greater than that in the general population.[189-191] The development of the hepatitis B vaccine has substantially reduced this risk. Hepatitis C virus has been identified as a major cause of posttransfusion hepatitis. Several cases of occupationally acquired hepatitis in health care workers have been reported.[192] Because signs of chronic liver infection develop in up to 50% of infected individuals, this represents a potentially serious problem.

Among the greatest fears of health care workers is the HIV infection. The risk of acquiring HIV is approximately 0.4% from a single percutaneous exposure to blood or bloody fluid from an HIV-infected patient.[193] At least one case of an anesthesiologist who was infected with HIV from a needlestick injury during the insertion of a central venous catheter into an HIV-positive patient has been reported.[194]

Several strategies have been developed to reduce the transmission of communicable diseases (also see Chapter 110). Although anesthesiologists traditionally think of the risk to the patient, they must now be aware of the risk to themselves. Widespread adoption of Universal Precautions should reduce the rate of infection; however, anesthesiologists have not widely accepted these recommendations. In a study of nine hospitals, 59% of the contaminated percutaneous injuries were preventable.[195] In a theoretic model of the risk for HIV infection, the 30-year occupational risk was estimated at 0.10% to 0.22% in low-prevalence areas and 8.26% to 13% in high-prevalence areas.[196] The researchers suggested that double-gloving practices may lead to reduced risk.

IMPROVING ANESTHESIA SAFETY

Over the past several decades, major improvements to the safety of anesthesia have been initiated. In 1984, Cooper, Kitz, and Pierce hosted a landmark International Symposium on Preventable Anesthesia Mortality and Morbidity in Boston. Approximately 50 anesthesiologists from around the world attended the meeting and, after much debate, established a series of definitions of outcome, morbidity, and mortality (Box 37-1). Beyond its specific conclusions, however, the symposium remains an event of major historical importance as a seminal early event in the movement to improve patient safety and as the context out of which the Anesthesia Patient Safety Foundation (APSF) was established. After its formal incorporation in October 1985, the APSF has since actively promoted a range of initiatives focused on fulfilling its mission to improve continually the safety of patients during anesthesia care by encouraging and conducting: (1) safety research and education, (2) patient safety programs and campaigns, and (3) national and international exchange of information and ideas. To this end, the APSF has focused on promoting research, practice improvement, and knowledge dissemination across a range of priority areas (Box 37-2). Overall, these efforts have stressed the potential for systems-level improvements, standardization of care processes, human-factors engineering, and simulation-based training to limit harms caused by preventable adverse events and errors in crisis management in the context of anesthesia care. Through this work, the APSF has come to serve as a leader in patient safety, not only in the context of anesthesia and perioperative care, but also more generally within medicine by establishing *patient safety* as a formal concept and discipline in medical care and serving as a model for other organizations such as the U.S. National Patient Safety Foundation.[197]

Alongside the efforts of the APSF, other prominent organizations, such as the ASA, have sought to improve the safety of anesthesia care through the creation and dissemination of standards and guidelines for clinical practice. In general, both standards and guidelines represent summations by clinicians of the available evidence about the benefits and risks of particular approaches to treatment. Typically, a practice standard implies that a therapy or practice should be performed for patients with a particular condition. Standards are approved only if an assessment of the probabilities and utilities of the group indicate that the decision to choose the treatment or a strategy would be virtually unanimous. At present, the ASA has established one set of practice standards for anesthesia care, which outline basic requirements for intraoperative monitoring.[198]

In contrast to practice standards, guidelines are intended to be more flexible than standards, but they should be followed in most cases. Depending on the patient, setting, and other factors, guidelines can and should be tailored to fit individual needs. Similar to standards, guidelines should be cost-effective methods. Specific guidelines have been created by the ASA for diverse

BOX 37-1 ***Proposed Definitions From the 1984 International Symposium on Preventable Anesthesia Morbidity and Mortality***

Outcome
- Normal
- Abandoned procedure
- Morbidity
- Death

Morbidity
- Unplanned, unwanted, undesirable consequence of anesthesia

Mortality
- Death that occurs before recovery from the effects of a drug or drugs given to facilitate a procedure
- Death that occurs during an attempt to relieve the pain of a condition
- Death that results from an incident that occurs while the drugs are effective

Adapted from Pierce EC Jr: The 34th Rovenstine Lecture. 40 years behind the mask: safety revisited, Anesthesiology *84:965, 1996.*

BOX 37-2 ***Selected Areas of Focus of the Anesthesia Patient Safety Foundation, 1985-2012***

- Use of anesthesia simulators for training and evaluation
- Improvement of standards for intraoperative monitoring
- Application of patient safety checklists to intraoperative care
- Promotion of standardized approaches to difficult airway management
- Prevention of medication-related adverse events
- Reuse and attempted resterilization of disposable anesthesia equipment
- Risks of outdated anesthesia machines without modern safety features
- Aiding the development of practice standards by the World Federated Societies of Anesthesiologists
- Surgery department crisis management, including teamwork, team training, and resource management
- *Production pressure*, causing dangerous omissions and cutting corners
- Intravenous procedural sedation by nonanesthesia personnel
- Contamination of medical gases and disruption of pipeline flow
- Contamination of intravenous medications
- Special risks of office-based anesthesia
- Patients with obstructive sleep apnea and their postoperative care
- Postoperative cognitive dysfunction (particularly in older adults)
- Possible long-term increase in morbidity and mortality after extensive general anesthesia
- Postoperative vision loss, especially in extensive prone spine surgery
- Wrong-site surgery
- Residual neuromuscular blockade and postoperative complications
- Protocols for assessing and managing adverse events
- Persistence of deaths from malignant hyperthermia
- Dangers and challenges in patients with coronary artery stents
- Maintenance of current protocols for the anesthesia machine checkout
- Possible impact of anesthesia management on cancer recurrence
- Persistence of surgical unit fires

Adapted from Eichhorn JH: The Anesthesia Patient Safety Foundation at 25: a pioneering success in safety, 25th anniversary provokes reflection, anticipation, Anesth Analg *114: 791-800, 2012.*

issues such as a difficult airway,[199] the use of the pulmonary artery catheter,[200] and the use of blood components[201] with the goal of defining the evidence on which optimal practice can be based. In a similar vein, the World Health Organization has recently placed an emphasis on the potential for a simple preoperative checklist, modeled on the processes used in other high-risk industries such as aviation, to reduce the rates of adverse events in the perioperative period.[202] Driven in part by the findings of improved outcomes with checklist use in a multicenter, international study by Haynes and co-authors,[203] such expanding interest in the use of standardized safety checks offers new potential opportunities to decrease the risk of anesthesia further.

Applying further insights gained from the aviation industry to anesthesia care, the APSF and other organizations have focused on developing simulation-based approaches to train anesthesia providers and to evaluate their decision-making capabilities in crisis situations.[204-208] To date, an extensive array of standardized scenarios have been developed for making comparisons among individuals, and research is ongoing to examine how best to use this technology in anesthesia training and recertification. Ultimately, such efforts, combined with improved monitoring of adverse outcomes through large outcomes databases and those now being assembled by the Multicenter Perioperative Outcomes Group and the Anesthesia Quality Institute, hold potential to improve the safety of anesthesia care continually on both a national and an international level.

SUMMARY

The risks related to anesthesia appear to have dramatically decreased over the past several decades. Clearly, death solely attributable to anesthesia is rare; rather, underlying patient disease and the nature and extent of surgery have a greater effect on overall outcome than do risks attributable to the anesthetic per se. Although these changes in the risk attributable to anesthesia could justifiably be considered a major achievement on the part of anesthesia providers over time, they also present a novel challenge to anesthesia providers to identify new opportunities to aid in more broadly decreasing both the morbidity and the mortality of surgical procedures and to aid in aligning the results of surgical interventions with individual patients' goals of care. At the same time, vigilance must be continued to maintain high standards of basic anesthesia care across both hospital- and nonhospital-based settings. Finally, anesthesia providers should play a role in systems-based thinking to improve perioperative care and the short- and long-term outcomes of patients undergoing surgery and anesthesia.

Chapter 38

Preoperative Evaluation

DUMINDA N. WIJEYSUNDERA • BOBBIE-JEAN SWEITZER

Acknowledgment: The editors and publisher would like to thank Drs. Stephen P. Fischer, and Angela M. Bader for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The anesthesia preoperative evaluation, which is the clinical foundation for guiding perioperative patient management, reduces perioperative morbidity and enhances patient outcome.
- The fundamental purpose of preoperative evaluation is to obtain pertinent information regarding the patient's medical history, formulate an assessment of the patient's perioperative risk, and develop a plan for any requisite clinical optimization.
- The preanesthesia evaluation should include a focused clinical examination, documentation of comorbid illness, reduction of patients' anxiety through education, assurance that preexisting medical conditions are optimally managed, selective referrals to medical specialists, ordering of preoperative investigations, initiation of interventions intended to decrease risk, discussion of aspects of perioperative care, arrangements for appropriate postoperative care, and recommendations to delay or cancel the surgical procedure, if deemed appropriate.
- Basic and complex medical diseases and syndromes that can influence anesthetic perioperative management require the anesthesiologist to be clinically knowledgeable and current in many aspects of internal medicine.
- Patients require appropriate preoperative diagnostic and laboratory studies consistent with their medical history, the proposed surgical procedure, and possible intraoperative blood loss. Routine preoperative testing is costly, is often clinically inappropriate, and cannot be justified.
- The anesthetic preoperative evaluation clinic can enhance operating room efficiency, decrease day-of-surgery cancellations or delays, reduce hospital costs, and enhance the quality of patient care.
- New and updated preoperative evaluation consensus and evidence-based guidelines published by multiple medical specialties have important influences on the preparation of patients for anesthesia and surgery.
- Anesthesiologists must be aware of, and be compliant with, increasing regulatory and reporting requirements involving preoperative issues by agencies such as The Joint Commission.
- The anesthesiologist is the perioperative medical specialist and thus is uniquely positioned to evaluate the risks associated with anesthesia or surgery, discuss these risks with the patient, and manage them perioperatively in collaboration with the surgical team and sometimes the referring physician.

Preoperative evaluation is a requisite component to administering any anesthetic. The practice and scope of preanesthesia evaluation have changed dramatically, largely because of a rapid transformation in hospital practice from admission of patients to the hospital the night before surgical procedures to admission on the morning of surgery. This practice led to a new approach to preoperative evaluation, which is a vital role of the perioperative physician. Accordingly, many anesthesiologists have expanded their responsibilities from providers of intraoperative anesthesia care to *perioperative medical specialists* who use their unique knowledge and experience to

manage medical complexities related to surgery.[1] Within the context of preoperative evaluation, this expanded role entails that anesthesiologists assume the leadership role in the assessment and optimization of patients who are being prepared for surgery.[2] This chapter provides a comprehensive discussion of the fundamental practice of preoperative assessment, as well as a review of related concepts, regulatory requirements, consensus-based guidelines, and clinical options.

EVOLUTION OF PREANESTHESIA EVALUATION

All patients requiring anesthesia for surgery undergo a preoperative evaluation by their anesthesia provider. Clinical practice with regard to this evaluation has changed substantially. Historically, anesthesiologists assessed their patients for the first time either just before the surgical procedure or on the day before it, whereas the remainder of preoperative evaluation and preparation was the responsibility of surgeons, primary care providers, or other medical specialists. In some countries, this approach remains the standard model of preanesthesia evaluation. Once the surgical procedure has been contemplated or actually decided, the trend has been for anesthesiologists increasingly to take on a leadership role in preoperative evaluation and preparation, well in advance of the scheduled surgical procedure.

Several factors have contributed to this change. First, few patients are admitted to the hospital before surgical procedures. Currently, most surgical procedures in the United States are performed on an outpatient or same-day admission basis, including major neurosurgical, cardiac, and radical cancer procedures. Little financial justification exists for the previous model of admitting patients to the hospital at least 1 day before surgery. Second, the increasing burden of medical comorbidity among surgical patients entails sufficient time between the preanesthesia evaluation and the planned surgical procedure to facilitate required testing, interventions, and medical optimization. Third, anesthesia care is no longer limited to the operating room. Indeed, many departments of anesthesiology have changed their official departmental titles to include anesthesia and perioperative care. The leadership role of anesthesiologists in preoperative evaluation is a logical extension of their role in perioperative medicine, especially given their unique expertise in the management of medical complexities related to anesthesia and surgery.

The development of the outpatient preoperative assessment clinic has been instrumental in facilitating increasing involvement of anesthesiologists in preoperative evaluation. These clinics also impose new clinical and organizational challenges. In an institution where most surgical patients are evaluated in the preoperative assessment clinic, anesthesiologists may have less time to evaluate often medically complex patients. Consequently, anesthesiologists must achieve a high level of efficiency and accuracy in the assessment of a patient's history, physical examination, and differential diagnosis, as well as in the planning of perioperative management. Conversely, in a hospital where only the highest-risk patients are referred for consultation at a preoperative assessment clinic, the anesthesia department must interact with surgical departments to establish general protocols that ensure capture of the information needed to perform anesthesia safely, as well as the appropriate selection of individuals who require preoperative anesthesia consultation.

In addition to changes in the scope and timing of the preanesthesia evaluation, this assessment has increasingly been influenced and governed by practice guidelines. For example, The Joint Commission mandates documentation of a history and physical examination for any surgical patient within 30 days before the planned procedure, as well as reassessment within the 48-hour period immediately preceding the surgical procedure. The American Society of Anesthesiologists (ASA) published specific standards for the conduct of preoperative anesthesia evaluation.[3] In addition, several other specialty societies published practice guidelines specifically relating to the preoperative management of medical issues in surgical patients.[4-7]

GOALS AND BENEFITS OF PREANESTHESIA EVALUATION

The preoperative evaluation can help influence and thereby improve perioperative care (Fig. 38-1). Conversely, *inadequate* preoperative evaluation was identified as a clear contributing factor for 3% of perioperative adverse events captured by the Australian Incident Monitoring Study (AIMS) database.[8]

The goals of the preanesthesia evaluation are twofold: first, to ensure that patients can safely tolerate anesthesia for planned surgical procedures; and second, to mitigate risks associated with the overall perioperative period, such as postoperative pulmonary or cardiac complications. In pursuit of these goals, the preanesthesia evaluation offers opportunities to perform focused clinical examinations, better document comorbid illness, reduce the patient's (and family's) anxiety through education, optimize preexisting medical conditions, make selective referrals to medical specialists (e.g., pulmonologists, cardiologists), order specialized preoperative investigations (e.g., cardiac stress tests), initiate interventions intended to decrease perioperative risk (e.g., β-adrenergic blockers), discuss aspects of perioperative care (e.g., anticipated risks, fasting guidelines, regional anesthesia), and arrange appropriate levels of postoperative care (e.g., admission to a critical care unit). When the patient is at very high risk for adverse perioperative outcomes, the anesthesiologist may recommend an alternative nonoperative or less invasive treatment. The preanesthesia evaluation may sometimes identify previously unrecognized medical conditions (e.g., hypertension) that may not significantly affect immediate perioperative risks, but that warrant subsequent follow-up by appropriate health care professionals.[5]

Preanesthesia evaluation has measurable benefits. Anesthesiologist-led preoperative evaluation is associated with more selective ordering of laboratory tests and

specialist referrals than is evaluation led by surgeons or primary care physicians, thereby leading to reduced health care costs.[9-12] Additional benefits have been shown when patients are assessed in an outpatient preoperative assessment clinic, including reduced levels of patients' anxiety,[13] improved acceptance by patients of regional anesthesia,[14] fewer case cancellations on the day of surgery,[9,15-17] shorter duration of hospitalization,[14,16,17] and lower hospital costs.[16]

ROLE OF THE MEDICAL CONSULTANT IN PREOPERATIVE EVALUATION

The use of preoperative medical consultation for surgical patients varies across institutions, likely depending on the expertise in perioperative medicine among clinicians performing preanesthesia assessments. Given the inadequate degree of exposure to preoperative assessment at many anesthesia residency programs,[18] some anesthesiology departments may prefer that medical specialists and hospitalists take primary responsibility for most preoperative evaluations at their centers. When anesthesiologists who perform preoperative evaluations do have improved comfort levels with respect to the ordering and interpretation of electrocardiograms (ECGs), special tests, or stress ECGs, rates of preoperative medical consultations are substantially reduced.[12]

Medical consultants have a clear role in the preoperative care of selected surgical patients. Potential reasons for medical consultations include management of unstable medical conditions before elective surgery (e.g., unstable angina), preoperative optimization of poorly controlled medical diseases (e.g., treatment of asthma exacerbation), facilitation of clinically relevant preoperative diagnostic workups (e.g., coronary angiography following high-risk stress test results), or guidance regarding the perioperative management of an uncommon medical disorder (e.g., severe hyponatremia). Preoperative consultation by medical specialists or hospitalists can also help facilitate postoperative comanagement by these same individuals.[19] The comanagement model for postoperative care of surgical patients is increasingly common,[20] although its benefits for patients' outcomes and costs remains unclear.[21-24]

The effects of preoperative medical consultation on patients' outcomes are also mixed. A randomized trial of outpatient preoperative evaluation demonstrated fewer last-minute cancellations of surgical procedures but no difference in hospital length of stay, as well as an increase in consultations.[25] In addition, medical consultation was associated with increases in specialized testing,[26] costs,[27] hospital length of stay,[26,27] and mortality.[26] Conversely, a transition from an anesthesiologist-led to a hospitalist-led preoperative assessment clinic reduced hospital length of stay in high-risk patients.[28] Potential reasons

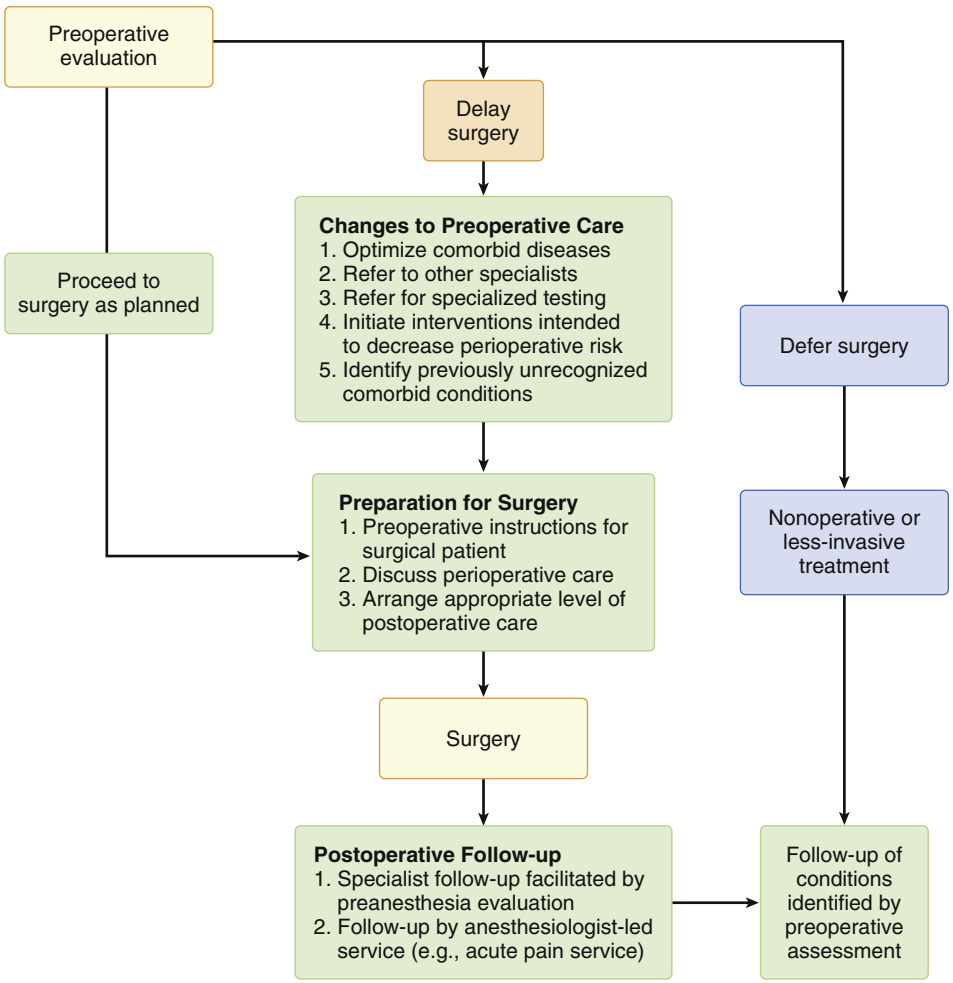

Figure 38-1. Mechanisms by which preoperative evaluation can help influence and improve perioperative care.

for this variable effect may be the absence of actual recommendations in many medical consultations,[29] as well as disagreements among medical specialists, anesthesiologists, and surgeons on the intended purpose of these consultations.[30] In addition, increased burden of comorbidity is a very small determinant of whether patients are referred for preoperative medical consultations,[31] a finding suggesting that most consultations are not sought for higher-risk patients who most warrant the involvement of medical specialists.

DETECTING DISEASE IN PREOPERATIVE EVALUATION

The *clinical examination*, consisting of the history and physical examination, is often all that is required to make a diagnosis or eliminate alternative hypotheses. In a study of patients in a general medical clinic, 56% of correct diagnoses were made on the basis of the history alone; this percentage increased to 73% with the physical examination. In patients with cardiovascular disease, the history established the diagnosis two thirds of the time, with physical examination contributing to one fourth of diagnoses.[32] Diagnostic tests, such as chest radiographs (x-ray studies) and ECGs, helped with only 3% of diagnoses, whereas special tests (e.g., cardiac stress tests) assisted with 6%. In respiratory, urinary, and neurologic conditions, history taking is the most important diagnostic method. The skill of performing a clinical examination derives from pattern recognition acquired by seeing patients and assimilating their stories and outcomes. The diagnostic acumen of physicians reflects their ability to integrate and develop an overall impression, rather than just reviewing a compilation of facts.

IMPORTANCE OF THE MEDICAL HISTORY

The variability in the words that patients and physicians use to describe symptoms is a common problem. The use of lay language and the recording of symptoms in ordinary words lead to greater interobserver agreement among practitioners and can prevent communication errors that are common in medical care. Common errors occur when diagnostic labels such as "angina" are written in the medical record when the patient actually complained of "chest pain." Conversely, patients rarely describe true angina or myocardial infarction (MI) as chest *pain*. More likely, they present with complaints of tightness or squeezing, often in their upper abdomen, shoulder, or neck. Medical interviewers should therefore not be surprised that patients may deny ever having chest *pain* when this is the only noun used when inquiring about symptoms of angina. Obtaining the patient's history is not simply asking questions but asking the right questions, often in a variety of ways, and interpreting and carefully recording the answers. Thorough histories assist in planning appropriate safe anesthesia care and are more accurate and cost effective in establishing diagnoses than are screening laboratory tests.

COMPONENTS OF THE MEDICAL HISTORY

The important components of the anesthesia history are shown in Figure 38-2. The form can be completed by anesthesia staff during an in-person or telephone interview with the patient. Alternatively, the patient can complete the form, either in person (paper or electronic version) or remotely through a Web-based program.

The classic history of present illness, or HPI, as it relates to preanesthesia evaluation starts with the indication for surgery and the planned procedure. The development of the surgical condition and any prior related therapies need to be clear. Current and past medical problems, previous surgical procedures, types of anesthesia, and any anesthesia-related complications must be noted. A simple notation of diseases or symptoms such as hypertension, diabetes mellitus, coronary artery disease (CAD), shortness of breath, or chest pain is rarely sufficient. Rather, the severity, stability, exacerbations (current or recent), prior treatments, and planned interventions should be clear. The extent, degree of control, and the activity-limiting nature of the problems are equally of interest. The patient's responses to these initial questions elicit further inquiry to establish a complete history.

Prescription and over-the-counter medications (including supplements and herbal medications) should be carefully recorded, along with their dosages and schedules. This includes any recent but currently interrupted medications because this could lead to the recognition of important issues (e.g., recent corticosteroid therapy). It is necessary to inquire about allergies to medications and other substances (e.g., latex, radiographic dye), with special emphasis on the patient's response to the exposure. Patients often claim an "allergy" to a substance when, in reality, the reaction was an expected side effect (e.g., nausea or vomiting with narcotics). The patient's use of tobacco, alcohol, or illicit drugs must be documented. Quantitative documentation of tobacco exposure using pack-years (number of packs of cigarettes smoked per day, multiplied by the number of years of smoking) is best. For example, if an individual has smoked 2 packs of cigarettes daily for the last 10 years, this is recorded as 20 pack-years of tobacco use.

A personal or family history of pseudocholinesterase deficiency, malignant hyperthermia (MH), or a suggestion of MH (hyperthermia or rigidity during anesthesia) in a patient or family member must be clearly documented to allow appropriate arrangements to be made before the day of surgery (see also Chapter 43). Records from previous anesthetic experiences may clarify an uncertain history.

A screening review of systems may identify symptoms that could lead to the establishment of previously undiagnosed conditions. Prime emphasis is on airway abnormalities; a personal or family history of adverse events related to anesthesia; and symptoms of cardiovascular, pulmonary, hepatic, renal, endocrine, or neurologic disease. A report of a patient who has experienced excessive sore throat, dental injuries, or "the need to have a small tube" with previous anesthetic cases may be an indication of previous difficulty with airway management. Questioning the patient about snoring and daytime

somnolence may suggest undiagnosed sleep apnea, which has implications for anesthesia management (see the later section on obstructive sleep apnea [OSA] and also Chapter 14). The presence of any two of the following findings increases the chance that a patient has sleep apnea: snoring, daytime somnolence, sleepiness, hypertension, and obesity. The presence of chest discomfort (pain, pressure, tightness), as well as its duration, precipitating factors, associated symptoms, and relieving factors, could be important. All diagnoses, diagnostic tests, therapies, and names of treating physicians should be documented. Any history of shortness of breath, both with exertion or when lying flat (i.e., orthopnea), and peripheral edema could signal potential postoperative problems. Does the patient have a history of heart murmurs? Were diagnostic studies performed to evaluate the murmur? The cardinal symptoms of severe aortic stenosis are angina, heart failure, and syncope, although decreased exercise tolerance and exertional dyspnea are more likely. A history of significant heartburn or reflux, especially after a fasting duration comparable to preoperative fasting, is important. Women of childbearing age need to recall their last menstrual period and their likelihood of being pregnant. This history is more reliable if the female patient, especially if a minor child, is questioned in privacy.

Patient's name_____Age_____Sex_____Date of surgery_____

Planned operation _____Surgeon_____

Figure 38-2, cont'd

The status of the patient's cardiorespiratory fitness or functional capacity helps determine whether additional preanesthetic evaluation should be performed and may predict perioperative outcomes. Exercise or work activity can be quantified in metabolic equivalents of the task (METs), which is a measure of the volume of oxygen consumed during an activity. A proposed scheme for estimating METs is presented in Table 38-1. Poor exercise capacity may be the cause or result of cardiopulmonary disease. Although lack of exercise may increase the risk of developing cardiac disease, preexisting cardiopulmonary disease can also prevent an individual from exercising. For example, patients with peripheral arterial disease (PAD) are limited by intermittent claudication, and patients with ischemic heart disease may complain of chest discomfort with exertion. Patients may not volunteer this information until asked why they cannot walk more than a certain distance or climb stairs. A patient's self-reported inability to perform average levels of exercise (i.e., 4 to 5 METs) increases the risk of perioperative complications.[33,34] Nonetheless, the magnitude of the association is relatively weak.

A general review of all organ systems should also be done. For example, asking patients whether they ever had problems with their heart, lungs, kidneys, liver, nervous system or whether they have had cancer, anemia, bleeding problems or have ever been hospitalized for any reason often prompts recall of medical problems.

Similarly, obtaining a complete list of previous surgical procedures can help complete the medical history. Finally, a review of records from primary care physicians, specialists, or the hospital can reveal any issues the patient may not recall.

PHYSICAL EXAMINATION

At a minimum, the preanesthetic examination includes vital signs (i.e., arterial blood pressure [BP], heart rate [HR], respiratory rate, oxygen saturation), height, and weight. Body mass index (BMI) is calculated from the height and weight and is more accurate than weight in establishing obesity. Online BMI calculators are found at http://www.cdc.gov/nccdphp/dnpa/bmi/index.htm or http://www.nhlbi.nih.gov/guidelines/obesity/BMI/bmicalc.htm. The formulas for calculating the BMI are as follows:

English formula:

$$\text{BMI} = \left(\frac{\text{Weight in pounds}}{(\text{Height in inches}) \times (\text{Height in inches})} \right) \times 703$$

Metric formula:

$$\text{BMI} = \left(\frac{\text{Weight in kilograms}}{(\text{Height in meters}) \times (\text{Height in meters})} \right)$$

or:

$$\text{BMI} = \left(\frac{\text{Weight in kilograms}}{(\text{Height in centimeters}) \times (\text{Height in centimeters})} \right) \times 10^4$$

A BMI of 40 or more defines extreme obesity, a BMI of 30 to less than 40 defines obesity, and a BMI of 25 to less than 30 defines an overweight person. A scheme for classifying children and adults based on BMI is presented in Table 38-2. An increased BMI is predictive of difficulties with airway management, both bag-mask ventilation and endotracheal intubation. In addition, obesity is associated with development of chronic diseases such as heart disease, cancer, or diabetes[35] (see also Chapter 71).

Patients often have increased arterial BP during the preoperative visit, even without a prior history of hypertension. This finding may be caused by anxiety, or the patient may have forgotten to take his or her usual dose of antihypertensive medication before an appointment or procedure. Thus, this single reading may not reflect the patient's usual BP control. Repeating the BP measurement or obtaining previous readings, either from medical records or asking the patient what his or her "usual" BP measurements are, can be informative.

From the anesthesiologist's perspective, inspection of the airway may be the single most important component of the physical examination (see Chapter 55). Without specialized training in airway evaluation and management, it is challenging for nonanesthesiologists to perform an adequate assessment. The components of the airway examination are presented in Box 38-1. Documentation of an airway examination includes the Mallampati score (Fig. 38-3), status of teeth, degree of neck mobility (especially extension), neck circumference (increased size predicts difficulty with laryngoscopy), thyromental distance, body habitus, and pertinent deformities.[36] Because of the potential for occasional dental injuries during anesthesia, a thorough documentation of preexisting tooth abnormalities is useful (Fig. 38-4). Patients with the following characteristics have potential difficulty with ventilation through a bag-mask apparatus.

- Age of 55 years or more
- BMI exceeding 26
- Lack of teeth
- Beard
- History of snoring

Patients with the following characteristics may pose a challenge to ventilate by any mechanism:

- OSA (see also Chapter 14)
- History of snoring
- Obesity (see also Chapter 71)

TABLE 38-1 METABOLIC EQUIVALENTS OF FUNCTIONAL CAPACITY

METs	Equivalent Level of Exercise
1	Eating, working at computer, or dressing
2	Walking down stairs, walking in your house, or cooking
3	Walking one or two blocks on level ground
4	Raking leaves or gardening
5	Climbing one flight of stairs, dancing, or bicycling
6	Playing golf or carrying clubs
7	Playing singles tennis
8	Rapidly climbing stairs or slowly jogging
9	Jumping rope slowly or cycling moderately
10	Swimming quickly, running, or jogging briskly
11	Skiing cross country or playing full court basketball
12	Running rapidly for moderate to long distances

Modified from Jette M, Sidney K, Blumchen G: Metabolic equivalents (METS) in exercise testing, exercise prescription, and evaluation of functional capacity, Clin Cardiol *13:555-565, 1990.*

MET, Metabolic equivalent (1 MET is equivalent to oxygen consumption of 3.5 mL/minute/kg body weight).

TABLE 38-2 CLASSIFICATION SCHEME FOR BODY MASS INDEX

Body Mass Index	Weight Status
Adults >20 Yr Old	
BMI <18.5	Underweight
BMI 18.5-24.9	Normal
BMI 25.0-29.9	Overweight
BMI ≥30.0	Obese
For Children and Teens	
BMI for age <5th percentile	Underweight
BMI for age 5th-<85th percentile	Normal
BMI for age 85th-<95th percentile	At risk of overweight
BMI-for-age ≥95th percentile	Overweight

From Centers for Disease Control and Prevention: <http://www.cdc.gov/> (Accessed 26.02.14.)

BMI, Body mass index.

- Increased neck circumference (>17 inches in men or >16 inches in women)
- Thyromental distance less than 7 cm with head in maximum extension
- Higher Mallampati scores (see Fig. 38-3)
- Large tongue
- Inability to protrude the mandible or lower teeth in front of the upper teeth
- Facial and neck deformities from previous surgery
- Previous head and neck radiation
- Head and neck trauma
- Congenital abnormalities of the head and neck
- Rheumatoid arthritis
- Down syndrome
- Scleroderma
- Cervical spine disease or previous cervical spine surgery

Examination of previous anesthetic records is critical, and extensive effort should be expended to obtain these records. Patients with documented difficult airways should be urged to obtain proper medical alert identification. When challenging airways are identified, advance planning ensures that necessary equipment and skilled personnel are available on the day of surgery.

An evaluation of the heart, lungs, and skin is necessary, as well as further focus on the organ systems involved with disease as reported by the patient. Auscultation of the heart and inspection of arterial pulses, veins (peripheral and central), and any edema in the extremities help establish diagnoses and predict perioperative risk. In addition, inspection of peripheral veins can help assess the ease of intravenous access. If intravenous access sites are limited, possible central line placement can be discussed with the patient, or arrangements can be made for assistance from the interventional radiology department. The auscultatory examination should assess for murmurs, rhythm disturbances, and evidence of volume overload. Important physical findings include third or fourth heart sounds, rales, jugular venous distention, ascites, hepatomegaly, and dependent edema. As opposed to patients' self-reporting of exercise tolerance, direct observation of a patient climbing flights of stairs can provide very useful prognostic information. The observed inability to climb one to two flights of stairs predicts a significantly increased risk of postoperative morbidity or mortality,[37] and it may help guide the need for further specialized testing, such as pulmonary function tests (PFTs) or cardiac stress testing. Examination of the pulmonary system should include auscultation for wheezing and for decreased or abnormal breath sounds, as well as inspection for cyanosis, clubbing, accessory muscle use, and respiratory effort. Obesity, hypertension, and large neck circumference are associated with an increased risk of OSA.[38]

A basic neurologic examination includes documenting deficits in mental status, speech, cranial nerves, gait, and motor and sensory function. For selected patients (e.g., those with deficits or disease or patients undergoing neurosurgery), a more extensive or focused neurologic examination should document specific preexisting abnormalities that may aid in diagnosis or interfere with positioning. In addition, definition of a baseline state can be compared with the postoperative state for identification of new deficits and to aid in defense of any future legal claims. Auscultation for carotid bruits is also important, especially in patients with a history of head or neck irradiation, strokes, or transient ischemic attacks.

BOX 38-1 ***Components of the Airway Examination***

Length of the upper incisors
Condition of the teeth
Relationship of the upper (maxillary) incisors to the lower (mandibular) incisors
Ability to advance the lower (mandibular) incisors in front of the upper (maxillary) incisors
Interincisor or intergum (if edentulous) distance
Visibility of the uvula
Presence of heavy facial hair
Compliance of the mandibular space
Thyromental distance
Length of the neck
Thickness or circumference of the neck
Range of motion of the head and neck

PREOPERATIVE EVALUATION OF PATIENTS WITH COEXISTING DISEASE

For some conditions commonly seen in the preanesthetic assessment clinic, preoperative intervention may be important (see also Chapter 39). Identification of these comorbid conditions often presents an opportunity for the anesthesiologist to intervene to decrease risk. These conditions are best managed before the day of surgery,

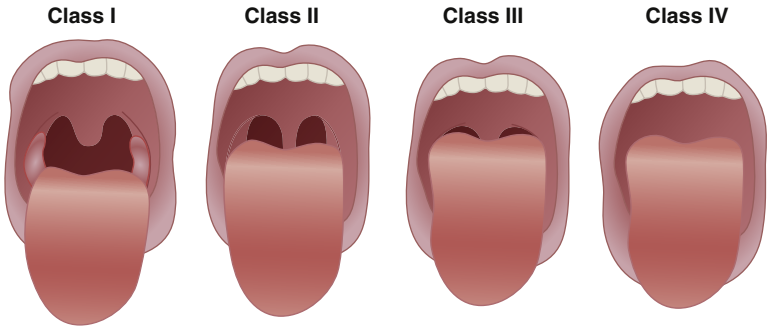

Figure 38-3. Mallampati classification: class I, soft palate, fauces, entire uvula, pillars; class II, soft palate, fauces, portion of uvula; class III, soft palate, base of uvula; class IV, hard palate only. *(Redrawn from Bair AE, Caravelli R, Tyler K, et al: Feasibility of the preoperative Mallampati airway assessment in emergency department patients,* J Emerg Med *38:677-680, 2010.)*

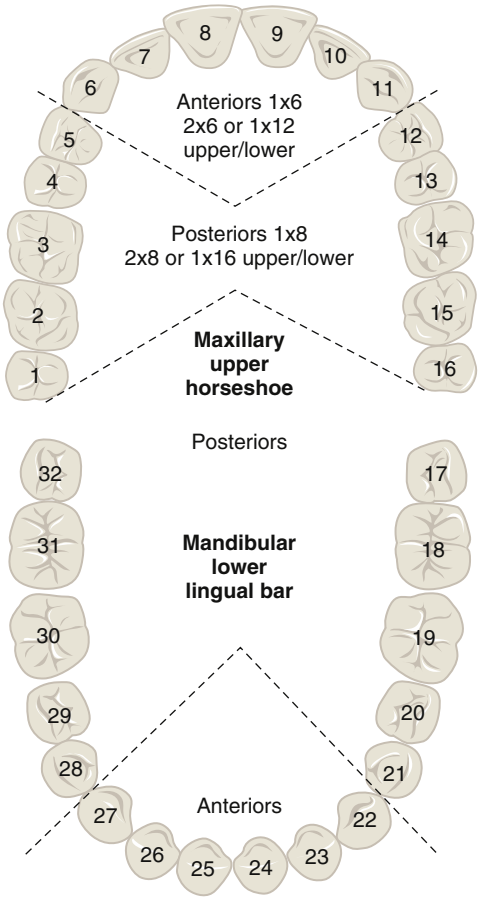

Figure 38-4. Tooth numbering.

thus allowing ample time for thoughtful evaluation, consultation, and planning.

CARDIOVASCULAR DISEASE

Cardiovascular complications are very common serious perioperative adverse events (see Chapter 37), and they account for almost half of all perioperative deaths.[39] In addition, serious myocardial injury occurs in approximately 8% of patients who undergo major surgery.[39] Some perioperative interventions may modify risks for cardiovascular morbidity and mortality.[5,40,41]

Hypertension

Hypertension, which is defined by two or more arterial BP measurements greater than 140/90 mm Hg, affects 1 billion individuals worldwide and increases with age. In the United States, 25% of adults and 70% of patients more than 70 years old have hypertension; of these individuals, less than 30% are adequately treated. The duration and severity of hypertension are highly correlated with subsequent end-organ damage, morbidity, and mortality. Ischemic heart disease is the most common form of organ damage associated with hypertension. Each incremental increase of systolic BP of 20 mm Hg or diastolic BP of 10 mm Hg above 115/75 doubles the lifetime risk for cardiovascular disease in individuals 40 to 70 years of age. Although the degree of preoperative hypertension is associated with increased risks of postoperative death and MI,[42] hypertension is associated only with a relatively small 1.3-fold increase in perioperative cardiac risk.[43] Other end-organ manifestations of hypertension are heart failure, renal insufficiency, and cerebrovascular disease.

Preoperative evaluation can help identify causes of hypertension, other cardiovascular risk factors, and end-organ damage. Paroxysmal hypertension or hypertension in young individuals should prompt a search for coarctation, hyperthyroidism, pheochromocytoma, or illicit drug use (e.g., cocaine, anabolic steroids). The physical examination focuses on the cardiovascular system, pulses, vital signs (BP measurement must be repeated and previous records obtained to establish long-term values), thyroid gland, and signs of excessive intravascular volume. Other than essential hypertension, the patient should be asked about episodic tachycardia, palpitations, and syncope. In addition, the physical examination should include BP measurements in both arms, auscultation of bruits, and examination of pulses in both upper and lower extremities. Additional testing should be directed by history and physical examination. Patients with long-standing, severe, or poorly controlled hypertension need an ECG and determinations of blood urea nitrogen (BUN) and creatinine, depending on the surgical procedure. Individuals receiving diuretics may require evaluation of electrolytes. Patients with significant left ventricular hypertrophy (LVH) on their ECG, especially with strain pattern, should be assessed for associated CAD. Patients suspected of hyperthyroidism require thyroid function tests (see also Chapter 39).

Elective surgery should be delayed for severe hypertension (diastolic BP >115 mm Hg or systolic BP >200 mm Hg) until BP is less than 180/110 mm Hg. Nonetheless, current guidelines from the American College of Cardiology Foundation (ACCF) and American Heart Association (AHA) instead suggest that the potential benefits of delaying surgery to optimize antihypertensive treatment should be weighed against the risks of delaying the surgical procedure.[5] Specifically, the literature is generally unclear on whether such delays help improve perioperative outcomes.[43] For example, a randomized trial of 898 patients with inadequately treated chronic hypertension without acute symptoms demonstrated no advantage of delaying surgery to optimize long-term BP control, when compared with simply proceeding to surgery with short-term BP treatment.[44]

The perioperative period should also be viewed as an excellent opportunity to alter both long-term and short-term consequences of diseases.[5] Thus, although surgery may not have to be delayed to optimize BP control, appropriate referrals should be made so that patients will have future appropriate postoperative management of inadequately managed hypertension. In general, all long-term antihypertensive treatment should be continued preoperatively. The only potential exceptions are angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs). Preoperative administration of these medications is associated with increased risks for intraoperative hypotension.[45]

Figure 38-5. Ischemic Heart Disease

The goals in the preanesthetic evaluation of patients with ischemic heart disease are as follows:

- Identify the risk of heart disease based on risk factors (Fig. 38-5 and Table 38-3).
- Identify the presence and severity of heart disease based on symptoms, physical findings, or diagnostic tests.
- Determine the need for preoperative interventions.
- Modify the risk of perioperative adverse events.

The primary basis of cardiac assessment comprises the history, physical examination, and ECG. Evaluation of risk factors for CAD is important because 40% of men and 65% of women are not diagnosed before their first acute coronary syndrome (unstable angina, acute MI, or sudden death). The traditional risk factors for CAD (i.e., smoking, hypertension, increased age, male sex, hypercholesterolemia, family history) are not the same risk factors that increase perioperative cardiac events (see Fig. 38-5 and Table 38-3). However, traditional risk factors are important in assessing the significance of chest pain, dyspnea, or an abnormal ECG identified during the preoperative evaluation. The Revised Cardiac Risk Index (RCRI) has been extensively validated for predicting perioperative cardiac risk in noncardiac surgery (see Table 38-3).[46,47]

TABLE 38-3 REVISED CARDIAC RISK INDEX COMPONENTS AND EXPECTED CARDIAC RISK

Components of Revised Cardiac Risk Index*	Points Assigned
High-risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular procedure)	1
Ischemic heart disease (by any diagnostic criteria)	1
History of congestive heart failure	1
History of cerebrovascular disease	1
Diabetes mellitus requiring insulin	1
Creatinine >2.0 mg/dL (176 μmol/L)	1
Revised Cardiac Risk Index Score	Risk of Major Cardiac Events†‡
0	0.4%
1	1.0%
2	2.4%
≥3	5.4%

*Data from Lee TH, Marcantonio ER, Mangione CM, et al: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery, *Circulation* 100:1043-1049, 1999.
†Data from Devereaux OJ, Goldman L, Cook DJ, et al: Perioperative cardiac events in patients undergoing noncardiac surgery: a review of the magnitude of the problem, the pathophysiology of the events and methods to estimate and communicate risk, *CMAJ* 173:627-634, 2005.
‡Defined as cardiac death, nonfatal myocardial infarction, or nonfatal cardiac arrest.

The components of the RCRI, all of which are assigned equal weights, are a history of ischemic heart disease, heart failure, diabetes, cerebrovascular disease, renal insufficiency (creatinine concentration >2.0 mg/dL), and high-risk surgery (intraperitoneal, intrathoracic, and suprainguinal vascular procedures).

The presence of chest discomfort (pain, pressure, tightness) and its duration, precipitating factors, associated symptoms, and relieving factors should be determined. The reporting of shortness of breath with exertion may represent an angina equivalent; nonetheless, dyspnea with exertion is nonspecific and can be the result of physical deconditioning, pulmonary disease, or heart failure. Even in the absence of angina symptoms, patients should be assessed for known risk factors for clinically silent ischemic heart disease. Thus, dyspnea in patients with risk factors for CAD may necessitate an investigation for ischemic heart disease. Women are particularly likely to have atypical symptoms of ischemic heart disease.

Preoperative laboratory tests for patients with known or suspected CAD include determination of the blood creatinine and hemoglobin concentrations. Renal insufficiency is a component of the RCRI and a risk factor for perioperative cardiac complications.[47] Preoperative anemia is associated with increased perioperative cardiac risk.[48,49] Anemia can decrease the effects of β-adrenergic blocker therapy in patients undergoing noncardiac surgery, with evidence of increased harm when this therapy is used in patients with perioperative anemia or significant bleeding.[50,51] However, increasing the blood transfusion rate in anemic surgical patients does not decrease perioperative cardiac risk.[52]

Patients with risk factors for CAD or symptoms (typical or atypical) suggestive of ischemia may require an ECG, especially for intermediate- to high-risk surgical procedures. Routine preoperative ECGs are not indicated (Box 38-2), particularly in patients without known cardiovascular disease or risk factors.[53] Specific abnormalities that are associated with increased perioperative cardiac risk include Q waves, right bundle branch blocks (RBBBs), and left bundle branch blocks (LBBBs).[47,54] Nonetheless, when considered *in combination* with known clinical risk factors, such as the components of the RCRI, these ECG abnormalities do not enable clinicians to identify patients with increased perioperative cardiac risk more accurately.[54] A preoperative ECG should not be ordered simply because of a patient's advanced age. Although ECG abnormalities are more common with advanced age, such as a 34% prevalence of Q waves in surgical patients 70 years old or older,[55] these abnormalities themselves provide minimal additional prognostic information (see also Chapter 80). Establishing a baseline for postoperative comparison is often the most important reason to obtain a preoperative ECG; however, this decision should be based on the patient's likely risk of postoperative adverse effects. Specifically, a baseline ECG is unlikely to be helpful in an individual who is already at very low risk for postoperative cardiac events. In addition, if a previous ECG is available and no intervening change in clinical status has occurred, a repeat ECG is unlikely to be useful.

BOX 38-2 ***Recommendations for Preoperative Resting 12-Lead Electrocardiogram***

Class I Recommendation: Procedure *Should* Be Performed

Preoperative resting 12-lead ECG is recommended for patients with one or more clinical risk factors* who are undergoing vascular surgical procedures.

Preoperative resting 12-lead ECG is recommended for patients with known CAD, PAD, or CVD who are undergoing intermediate-risk surgical procedures.

Class IIa Recommendation: It Is Reasonable to Perform the Procedure

Preoperative resting 12-lead ECG is reasonable in persons with no clinical risk factors who are undergoing vascular surgical procedures.

Class IIb Recommendation: The Procedure May Be Considered

Preoperative resting 12-lead ECG may be reasonable in patients with one or more clinical risk factors who are undergoing intermediate-risk operative procedures.

Class III Recommendation: The Procedure Should Not Be Performed Because It Is Not Helpful

Preoperative and postoperative resting 12-lead ECGs are not indicated in asymptomatic persons undergoing low-risk surgical procedures.

From Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, Circulation *120:e169-e276, 2009.*

CAD, Coronary artery disease; CVD, cerebrovascular disease; ECG, electrocardiogram; PAD, peripheral arterial disease.

*Risk factors are history of ischemic heart disease, a history of heart failure, a history of cerebrovascular disease, diabetes mellitus, and renal insufficiency.

The preoperative evaluation should include a review of medical records and previous diagnostic studies, especially stress tests and coronary angiography results. It is important not to rely on a patient's history of a "normal" test result because many patients are unaware of mild abnormalities not requiring revascularization. In many cases, a phone call to the primary care physician or cardiologist yields important information and obviates the need for further testing or consultation. Any further consultation initiated by the preoperative physician should seek specific advice regarding the diagnosis and status of the patient's condition. Asking specific questions such as "Does this patient have CAD?" or "Is this patient optimized for planned radical nephrectomy?" is the first step. Specialist consultations that simply state that a patient is "cleared for surgery" are not sufficient to design a safe anesthetic plan. The specialist's consultation report should summarize the medical problems, therapies, and results of any necessary diagnostic tests.

The goal of the preoperative evaluation is to identify patients who have a high perioperative cardiac risk or those who have *modifiable* risk. The ACCF/AHA practice guidelines for cardiac evaluation before noncardiac surgery have become the national standard of care.[5] In general, the guidelines emphasize the use of functional capacity, surgical risk, and clinical predictors for

preoperative diagnostic and therapeutic interventions. At the time of this writing, new guidelines are in development and should be published after mid 2014.

The 2009 guidelines propose an algorithm for preoperative cardiac risk evaluation that is followed in stepwise fashion and stops at the first point that applies to the patient (see Fig. 38-5).

Step 1 in this guideline algorithm considers the urgency of surgery. For emergency surgery, the focus is on perioperative surveillance (e.g., serial ECGs, cardiac enzymes, monitoring) and risk reduction (e.g., β-adrenergic blockers, statins, pain management).

Step 2 focuses on active cardiac conditions such as acute MI, unstable or severe angina, decompensated heart failure, severe valvular disease (e.g., critical aortic stenosis), or significant arrhythmias (e.g., atrial fibrillation with rapid ventricular rate, sustained ventricular tachycardia). Active cardiac conditions warrant postponement of surgery for all except lifesaving emergency procedures. After identification and treatment of these conditions, surgery can be reconsidered if the benefit is substantial and the risk acceptable. Traditionally, patients who experienced an MI within the previous 3 to 6 months were considered high risk and necessitated delay of surgery in step 2. Instead, the ACCF/AHA guidelines now suggest postponement of surgery if a patient had an *acute MI*, defined as occurring within the past 7 days. Patients who had a *recent MI*, defined as occurring within 7 to 30 days before surgery, are also considered at high risk if they have *evidence of myocardium at risk*, based on persistent symptoms or stress testing results. Such individuals should also delay any nonemergency surgery.

Step 3 considers the surgical risk or severity (Table 38-4). Patients without active cardiac conditions who undergo low-risk surgery can proceed without further cardiac testing. All ambulatory surgery is in the low-risk category.

Step 4 assesses the patient's functional capacity based on METs (see Table 38-1). Asymptomatic patients with average functional capacity, defined as the ability to walk one to two flights of stairs or four blocks on a level surface, can proceed directly to surgery.

Step 5 considers patients who have poor or indeterminate functional capacity and need intermediate-risk or vascular surgery (see Table 38-4). The number of patient-level clinical predictors from the RCRI (CAD, heart failure, cerebrovascular disease, diabetes, renal insufficiency) determines the likely benefit of further cardiac testing among individuals who reach step 5. Patients with no clinical predictors proceed to surgery. Those with risk predictors may benefit from further testing, but only if the results *alter management*. Selective testing in individuals with risk factors may also help improve postoperative survival. Data suggest that preoperative stress testing in patients with RCRI scores of 3 or more is associated with a moderate reduction in 1-year mortality.[267]

Preoperative cardiac stress testing can help identify the presence and severity of preexisting CAD. These tests also provide some prognostic information with respect to predicting risks of perioperative cardiac complications. Given the relatively infrequent incidence of postoperative cardiac events, the prognostic performance of these tests should not be evaluated on the basis of positive or negative predictive values. Rather, the prognostic performance of these tests is better assessed based on positive likelihood ratio, negative likelihood ratio, sensitivity, or specificity. For context, positive test results must have likelihood ratios exceeding 2 to provide clinically meaningful information, whereas negative test results should have associated likelihood ratios of 0.5 or less.[56] Exercise ECG testing has a sensitivity of 74% and a specificity of 69% for predicting postoperative cardiac events.[57] These values correspond to a positive likelihood ratio of 2.4 and a negative likelihood ratio of 0.4. In contrast, dobutamine stress echocardiography has a positive likelihood ratio of 4.1 and a negative likelihood ratio of 0.2, whereas myocardial perfusion scintigraphy has a positive likelihood ratio of 1.8 and a negative likelihood ratio of 0.4.[58] Thus, overall, dobutamine stress echocardiography provides the most accurate prognostic information (for both positive and negative test results), whereas myocardial perfusion scintigraphy may be predisposed to more false-positive results. The prognostic value of myocardial perfusion scintigraphy may be improved by considering the extent of reversible ischemia found on these tests. Significant increases in perioperative cardiac risk are associated with reversibility affecting more than 20% of the myocardium.[59] The presence of fixed defects alone on perfusion imaging is not associated with increased perioperative cardiac risk. Coronary angiography, which is considered the gold standard for diagnosing CAD, may not absolutely risk stratify patients either. Specifically, many perioperative cardiac events may be related to noncritical coronary lesions rupturing within the context of the hypercoagulable perioperative state.[60] Nonetheless, a randomized trial

TABLE 38-4 STRATIFICATION OF PERIOPERATIVE CARDIAC RISK FOR NONCARDIAC SURGICAL PROCEDURES

Risk Stratification	Estimated Risk of Cardiac Death or Nonfatal MI	Examples of Procedures
Vascular	>5%	Aortic and other major vascular surgery Peripheral vascular surgery
Intermediate	1-5%	Intraperitoneal and intrathoracic surgery Carotid endarterectomy Head and neck surgery Orthopedic surgery Prostate surgery
Low*	<1%	Endoscopic procedures Superficial procedure Cataract surgery Breast surgery Ambulatory surgery

From Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, Circulation *120:e169-e276, 2009.*

MI, Myocardial infarction.

*These procedures do not require further preoperative cardiac testing unless the patient has an unstable cardiac condition.

of 208 intermediate- to high-risk patients undergoing vascular surgery found that a strategy of routine preoperative coronary angiography led to superior long-term survival when compared with the selective use of angiography in individuals with high-risk stress test results.[61]

When considering the choice of cardiac stress test, exercise ECG testing can be ordered for patients with normal ECGs who can exercise and are likely to achieve an adequate HR response (see also Chapter 47). An adequate test result is obtained when patients can exercise to at least 85% of their target HR (target HR is defined as 220 minus age). Pharmacologic stress tests, such as dobutamine echocardiography or dipyridamole myocardial perfusion scintigraphy, are indicated for individuals who cannot exercise, have pacemakers or significant bradycardia, or receive high-dose β-adrenergic blockers. A combination of exercise and imaging (e.g., exercise stress echocardiography) can be used in patients who can exercise but have significant ECG abnormalities (e.g., LVH with a strain pattern or LBBB) that may interfere with ECG interpretation for ischemia. Exercise echocardiography can lead to many false-positive results in patients with LBBB because of associated septal abnormalities[5] (see also Chapter 46). For most patients, the choice of pharmacologic stress test is immaterial. Because dobutamine uncovers ischemia by increasing contractility, HR, and BP, it may not be the best choice in patients with pacemakers, significant bradycardia, aortic or cerebral aneurysms, or poorly controlled hypertension. Adenosine or dipyridamole myocardial scintigraphy relies on the vasodilatory properties of adenosine or dipyridamole (stenotic vessels are maximally vasodilated at rest) and uptake of the radioisotope by viable myocardium. Although these tests do not depend on HR response, they may exacerbate bronchospasm in patients taking theophylline or may cause dangerous reductions in preload for patients with severe aortic valve disease or hypertrophic cardiomyopathy (HCM).

Echocardiography, combined with exercise or a pharmacologic agent, is used to look for wall motion abnormalities (see also Chapter 46). Abnormalities present at rest (baseline) indicate scar tissue from previous infarction. Areas of myocardium that are normal at rest but show abnormalities with increased inotropy and chronotropy (i.e., inducible wall motion abnormalities) indicate stenotic coronary lesions and limited blood flow. Similarly, nuclear imaging perfusion abnormalities at rest are consistent with prior infarction. Normal coronary arteries vasodilate with adenosine or exercise, and uptake of isotope is normal. Myocardium with flow limiting lesions is normal at rest, but it shows decreased uptake of isotope with exercise or adenosine administration. If a patient had a specific test in the past, it is most useful to obtain the same test for comparison. The ACCF/AHA guidelines also state that a patient who had a favorable stress test result within the previous 2 years does not require repeat testing if no subsequent change in symptoms has occurred.

By applying the ACCF/AHA recommendations and using the predictive value of the RCRI, practitioners in preanesthetic clinics are well positioned to initiate preoperative cardiac evaluation with stress tests. Results may obviate the need for subsequent cardiology consultation or ensure that relevant test results will be available at the time of the consultation. The preoperative period is also an opportunity to identify patients with CAD who will benefit from long-term risk modification with statins, aspirin, exercise, and diet adjustment. Patients with symptoms consistent with ischemia or significant risk factors without medical management may benefit from evaluation by a cardiologist, regardless of whether they are having surgery. Preoperative evaluation should therefore not simply focus on the immediate perioperative risk.

However, concerns exist over the predictive value, costs, risks, and benefits of the ACC/AHA guidelines for cardiac evaluation for noncardiac surgery. An important controversy pertains to the benefits versus risks of coronary revascularization before noncardiac surgery. Two randomized trials of preoperative coronary revascularization versus medical management in intermediate- to high-risk patients undergoing vascular surgery found no benefit to a strategy of revascularization.[62,63] The revascularization strategies employed in these studies included both coronary artery bypass grafting and percutaneous coronary intervention (PCI) with stenting. The larger of the two trials excluded individuals found to have left main coronary artery stenosis on preoperative coronary angiography, a finding present in 5% to 15% of intermediate- to high-risk patients undergoing vascular surgery.[61,62,64] Such patients with unprotected left main coronary artery stenosis may be the only subgroup of patients deriving a perioperative benefit from preoperative coronary revascularization.[64] These patients would usually require revascularization by coronary artery bypass graft.[65]

Patients already receiving statins and β-adrenergic blockers must continue taking these drugs without interruption throughout the perioperative period (Boxes 38-3 and 38-4). Patients already taking β-adrenergic blockers need their dosages adjusted to achieve an HR of less than 70 beats/minute, if at all possible. The role of initiating β-adrenergic blockers de novo in patients at increased perioperative cardiac risk is unclear, especially given the results of the Perioperative Ischemic Evaluation Study-1 (POISE-1) trial.[40] The patients most likely to benefit are individuals undergoing vascular surgery with evidence of inducible ischemia on preoperative testing.[5,41] β-Adrenergic blockers should be initiated at least several days before surgery,[66,67] and they should be titrated to achieve HR control without precipitating hypotension. Caution should be exercised in individuals with known cerebrovascular disease because of the potential for β-adrenergic blockers to increase rates of perioperative acute stroke.[40,68] In intermediate- to high-risk surgical patients, consideration should also be given to initiating statins, which reduce perioperative cardiac risk with few safety concerns.[69,70] Randomized trials to date have not clearly shown benefits from routinely continuing aspirin before noncardiac surgery.[71-73] The largest trial to-date, the Perioperative Ischemic Evaluation Study-2 (POISE-2), found that continuing low-dose aspirin (100 mg/day) did not prevent cardiac events but also increased rates of major bleeding.[71] Since only one-third of these participants had known vascular disease, it may

BOX 38-3 *Preoperative Management of Medications*

Instruct patients to take these medications with a small sip of water, even if fasting.

1. **Antihypertensive medications**
   Continue on the day of surgery.
   - **Possible exception:** For patients undergoing procedures with major fluid shifts, or for patients who have medical conditions in which hypotension is particularly dangerous, it may be prudent to discontinue ACEIs or ARBs before surgery.
2. **Cardiac medications (e.g., β-blockers, digoxin)**
   Continue on the day of surgery.
3. **Antidepressants, anxiolytics, and other psychiatric medications**
   Continue on the day of surgery.
4. **Thyroid medications**
   Continue on the day of surgery.
5. **Birth control pills**
   Continue on the day of surgery.
6. **Eye drops**
   Continue on the day of surgery.
7. **Heartburn or reflux medications**
   Continue on the day of surgery.
8. **Narcotic medications**
   Continue on the day of surgery.
9. **Anticonvulsant medications**
   Continue on the day of surgery.
10. **Asthma medications**
    Continue on the day of surgery.
11. **Steroids (oral and inhaled)**
    Continue on the day of surgery.
12. **Statins**
    Continue on the day of surgery.
13. **Aspirin**
    Consider selectively continuing aspirin in patients where the risks of cardiac events is felt to exceed the risk of major bleeding. Examples would be patients high-grade CAD or CVD. If reversal of platelet inhibition is necessary, aspirin must be stopped at least 3 days before surgery. Do not discontinue aspirin in patients who have drug-eluting coronary stents until they have completed 12 months of dual antiplatelet therapy, unless patients, surgeons, and cardiologists have discussed the risks of discontinuation. The same applies to patients with bare metal stents until they have completed 1 month of dual antiplatelet therapy. In general, aspirin should be continued in any patient with a coronary stent, regardless of the time since stent implantation.
14. **Thienopyridines (e.g., clopidogrel, ticlopidine)**
    Patients having cataract surgery with topical or general anesthesia do not need to stop taking thienopyridines. If reversal of platelet inhibition is necessary, then clopidogrel must be stopped 7 days before surgery (14 days for ticlopidine). Do not discontinue thienopyridines in patients who have drug-eluting stents until they have completed 12 months of dual antiplatelet therapy, unless patients, surgeons, and cardiologists have discussed the risks of discontinuation. The same applies to patients with bare metal stents until they have completed 1 month of dual antiplatelet therapy.
15. **Insulin**
    For all patients, discontinue all short-acting (e.g., regular) insulin on the day of surgery (unless insulin is administered by continuous pump). Patients with type 2 diabetes should take none, or up to one half of their dose of long-acting or combination (e.g., 70/30 preparations) insulin, on the day of surgery. Patients with type 1 diabetes should take a small amount (usually one third) of their usual morning long-acting insulin dose on the day of surgery. Patients with an insulin pump should continue their basal rate only.
16. **Topical medications (e.g., creams and ointments)**
    Discontinue on the day of surgery.
17. **Oral hypoglycemic agents**
    Discontinue on the day of surgery.
18. **Diuretics**
    Discontinue on the day of surgery (exception: thiazide diuretics taken for hypertension, which should be continued on the day of surgery).
19. **Sildenafil (Viagra) or similar drugs**
    Discontinue 24 hours before surgery.
20. **COX-2 inhibitors**
    Continue on the day of surgery unless the surgeon is concerned about bone healing.
21. **Nonsteroidal antiinflammatory drugs**
    Discontinue 48 hours before the day of surgery.
22. **Warfarin (Coumadin)**
    Discontinue 4 days before surgery, except for patients having cataract surgery without a bulbar block.
23. **Monoamine oxidase inhibitors**
    Continue these medications and adjust the anesthesia plan accordingly.

ACEI, angiotensin converting enzyme inhibitors; ARB, angiotensin receptor blocker; CAD, coronary artery disease; *COX-2,* Cyclooxygenase-2; CVD, cerebrovascular disease.

still be reasonable to continue aspirin in select patients where the risk of cardiac events is felt to exceed the risk of major bleeding. Examples would be patients with high-grade CAD (including coronary stents) or cerebrovascular disease. (see Box 38-3).

Coronary Stents

Patients who have undergone PCI, especially those with drug-eluting stents, require several months, if not a lifetime, of antiplatelet therapy to avoid restenosis or acute in-stent thrombosis. The presence and type (drug-eluting or bare metal) of any coronary stent must be identified in the preanesthetic clinic, and subsequent management must be performed in collaboration with a cardiologist. A scientific advisory from major national medical and dental associations, including the ACCF and the AHA, provides recommendations for managing patients with coronary stents.[74] Patients with a recent bare metal stent implantation, defined as occurring within the previous 30 days, should absolutely *not* undergo elective surgery. If urgent surgery is needed, strong consideration is given to continuing dual antiplatelet therapy (i.e., thienopyridine and aspirin) throughout the perioperative period (see Box 38-3),[5] as well as close monitoring for postoperative myocardial injury (i.e., serial troponin measurement).

Current guidelines also clearly recommend against elective surgery within 1 year after drug-eluting stent implantation.[74] Conversely, perioperative cardiac risk is

BOX 38-4 ***Recommendations for Use of Perioperative β-Blockers From the American College of Cardiology Foundation and American Heart Association***

Class I Indications*

- β-Blockers should be continued in patients undergoing surgery who are already receiving β-blockers for treatment of conditions with ACCF/AHA class I guideline indications for the drugs.

Class IIa Indications†

- β-Blockers titrated to heart rate and blood pressure are probably recommended for patients undergoing vascular surgery who are at high cardiac risk as a result of coronary artery disease or the finding of cardiac ischemia on preoperative stress testing.
- β-Blockers titrated to heart rate and blood pressure are reasonable for patients in whom preoperative assessment for vascular surgery identifies high cardiac risk, as defined by the presence of more than one clinical risk factor.
- β-Blockers titrated to heart rate and blood pressure are reasonable for patients in whom preoperative assessment identifies coronary artery disease or high cardiac risk, as defined by the presence of two or more clinical risk factors, who are undergoing intermediate-risk surgery.

Modified from Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, Circulation *120:e169-e276, 2009.*

ACCF/AHA, American College of Cardiology Foundation and American Heart Association.

*Class I indication: Conditions for evidence and general agreement indicate that a given procedure or treatment is beneficial, useful, and effective.

†Class IIa indication: Conditions for conflicting evidence and a divergence of opinion exist about the usefulness and efficacy of a procedure or treatment, but the weight of evidence or opinion is in favor of usefulness and efficacy

relatively low if elective surgery is performed more than 6 months after drug-eluting stent implantation.[75-78] Nonetheless, surgery within 1 year must involve consultation with a cardiologist who is familiar with the implanted stent type and the details of the patient's coronary artery anatomy. In general, elective surgery should *not* be performed until at least 1 year following drug-eluting stent implantation. If urgent surgery is needed, strong consideration is given to continuing dual antiplatelet drug therapy throughout the perioperative period (see Box 38-3).

Antiplatelet drugs should not be interrupted in patients with coronary stents without consultation with a cardiologist familiar with coronary stents, as well as an in-depth discussion with the surgeon and the patient regarding the risks of stopping these drugs. The major concern with premature discontinuation of dual antiplatelet therapy, especially during critical time windows following bare metal stent implantation (30 days) or drug-eluting stent implantation (1 year), is the risk of precipitating catastrophic stent thrombosis, MI, or death. Every effort should be made to ensure that surgical procedures are performed following these critical time windows, aspirin is continued throughout the perioperative period, and thienopyridine (typically clopidogrel) therapy is restarted as soon as possible postoperatively. Unfractionated heparin and low-molecular-weight heparin (LMWH) are not appropriate for "bridging" patients with coronary stents who have been withdrawn from all antiplatelet therapy. Specifically, heparin administration can paradoxically *increase* platelet aggregation and thereby may actually increase risk.[79] Stent thrombosis is best treated with PCI, which can be performed safely even in the immediate postoperative period.[80] High-risk patients are thus likely best managed in facilities with immediate access to interventional cardiology.

Heart Failure

Heart failure affects 4 to 5 million people in the United States and is a significant risk factor for postoperative mortality and adverse events.[39,81,82] Decompensated heart failure is also a high-risk characteristic that warrants postponement of surgery for all except lifesaving emergency procedures.[5] Heart failure may result from systolic dysfunction (decreased ejection fraction from abnormal contractility), diastolic dysfunction (increased filling pressures from abnormal relaxation but normal contractility and ejection fraction), or a combination. Diastolic failure accounts for almost half of all cases, but little science guides the perioperative care of these individuals. Hypertension is a cause of diastolic dysfunction, and LVH on an ECG raises suspicion. Ischemic heart disease is the most common cause of systolic dysfunction in developed countries (50% to 75% of cases). Cardiomyopathies have a variety of causes including infections (human immunodeficiency virus [HIV], coxsackievirus, influenza virus, adenovirus, Chagas or Lyme disease), toxins, alcohol, sarcoidosis, peripartum cardiomyopathy, drugs (e.g., doxorubicin [Adriamycin], cocaine), muscular dystrophy, and idiopathic causes. Cardiac magnetic resonance imaging (MRI) or endomyocardial biopsy may be used to establish a diagnosis.

The goal in the preoperative evaluation is to identify and minimize the effects of heart failure. Recent weight gain, complaints of shortness of breath, fatigue, orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, peripheral edema, hospitalizations, and recent changes in management are all significant. Patients with decompensated heart failure feel like they are "suffocating" or have "air hunger."

The physical examination focuses on finding third or fourth heart sounds, tachycardia, a laterally displaced apical pulse, rales, jugular venous distention, ascites, hepatomegaly, and peripheral edema. Classifying the patient's medical status according to the New York Heart Association (NYHA) categories is also useful:

- NYHA class I: no limitation of physical activity; ordinary activity not a cause of fatigue, palpitations, or syncope
- NYHA class II: slight limitation of physical activity; ordinary activity resulting in fatigue, palpitations, or syncope
- NYHA class III: marked limitation of physical activity; less than ordinary activity resulting in fatigue, palpitations, or syncope; comfort at rest
- NYHA class IV: inability to do any physical activity without discomfort; symptoms at rest

Brain natriuretic peptide (BNP), which is released from the atria and ventricles in response to ischemia or strain, is useful in evaluating patients suspected of having decompensated heart failure. [83] The plasma concentration of BNP is a powerful marker of cardiovascular risk in nonsurgical patients, including individuals who are at risk for CAD, have CAD, or have heart failure.[83] In patients undergoing noncardiac surgery, preoperative BNP levels predict risk for cardiac complications and death.[84,85] A particular use for BNP is screening individuals whose functional capacity is difficult to estimate.[86,87] Specifically, a low BNP concentration is very reassuring with respect to predicting a low perioperative cardiac risk. Among patients undergoing vascular surgery, a BNP level less than 30 pg/mL has a negative likelihood ratio of 0.11 with respect to predicting postoperative MI or death; the negative likelihood ratio associated with a level less than 116 pg/mL is 0.41.[87]

An ECG and determination of electrolytes, BUN, creatinine, and possibly BNP are indicated in patients with or suspected of having heart failure. Digoxin levels are not routinely determined unless toxicity, undertreatment, or noncompliance is suspected. One must determine trough levels of digoxin, and this is not always possible in a preoperative evaluation setting. Paroxysmal atrial tachycardia with a 2:1 atrioventricular (AV) block is pathognomonic of digoxin toxicity. Junctional tachycardia, ventricular ectopic beats, bigeminy, second-degree AV block, nausea, lethargy, altered color perception, and mental status changes or agitation are symptoms of digoxin toxicity. Chest radiography is useful in patients suspected of having pulmonary edema. The use of echocardiography to obtain objective measures of left ventricular ejection fraction, ventricular performance, and diastolic function may be helpful, especially in patients with NYHA class III or IV heart failure (Box 38-5). Normal left ventricular ejection fraction is greater than 50%; mildly diminished is 41% to 49%, moderately diminished is 26% to 40%, and severely diminished is 25% or less. The current ACCF/AHA guidelines recommend preoperative echocardiography (or other noninvasive measure of ventricular function) to assess dyspnea of unknown origin or recent altered clinical status in an individual with known heart failure.[5] Conversely, routine preoperative assessment of ventricular function is discouraged. Patients with class III or IV heart failure should be evaluated in conjunction with a cardiologist before they undergo general anesthesia or any intermediate- or high-risk procedure. In addition, severely affected individuals or those with decompensated heart failure may need the help of a heart failure specialist. Very minor procedures performed using monitored anesthesia care may proceed as long as the patient's condition is stable.

Medical therapy, including β-adrenergic blockers, hydralazine, nitrates, and digoxin, must be optimized and continued preoperatively. ACEIs, ARBs, and diuretics (including aldosterone antagonists such as spironolactone) may be beneficial, even on the day of surgery. Continuation of loop diuretics on the day of surgery does not increase the risk of intraoperative hypotension or adverse cardiac events.[88] Conversely, preoperative administration of ACEIs or ARBs is a risk for intraoperative hypotension.[45] Thus, selective continuation or discontinuation of these drugs depends on the intravascular volume and hemodynamic status of the patient, the degree of cardiac dysfunction, and the anticipated surgical procedure and intravascular volume challenges (see Box 38-3). Continuing all medications for patients with severe dysfunction who are scheduled for minor procedures is probably best. The other extreme occurs when patients with well-compensated NYHA class I heart failure are scheduled for lengthy high-risk procedures with projected significant blood loss or fluid requirements. In these cases, potent diuretics should be discontinued on the morning of surgery. Patients with pacemakers or implantable cardioverter-defibrillators (ICDs) have their own special perioperative considerations (see the later section on cardiovascular implantable electronic devices [CIEDs]: pacemakers, and ICDs; see also Chapter 48).

As indicated previously, surgery should be postponed in patients with decompensated or untreated heart failure, unless the situation is truly an emergency. No consensus exists on how long such patients remain at risk after resolution of an acute exacerbation of heart failure.

BOX 38-5 ***Recommendations for Preoperative Noninvasive Evaluation of Left Ventricular Function***

Class IIa: Reasonable to Perform

- It is reasonable for patients with dyspnea of unknown origin to undergo preoperative evaluation of LV function.
- It is reasonable for patients with current or prior heart failure with worsening dyspnea or other change in clinical status to undergo preoperative evaluation of LV function if such evaluation was not performed within 12 months.

Class IIb: May Be Considered

- Reassessment of LV function in clinically stable patients with previously documented cardiomyopathy is not well established.

Class III: Should Not Be Performed Because It Is Not Helpful

- Routine perioperative evaluation of LV function in patients is not recommended.

Modified from Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, Circulation *120:e169-e276, 2009.*

LV, Left ventricle.

Murmurs and Valvular Abnormalities

Clinical goals in preoperative assessment include determining the cause of cardiac murmurs and distinguishing between significant murmurs and those that are clinically unimportant[89] (see Chapter 67). Functional murmurs occur from turbulent flow across the aortic or pulmonic outflow tracts. These benign murmurs occur with high-flow states such as hyperthyroidism, pregnancy, or anemia. It is often not easy for noncardiologists to distinguish benign from pathologic murmurs. Indications for echocardiography to assess a murmur include increased

BOX 38-6 ***American College of Cardiology and American Heart Association Guidelines Recommendations for Echocardiography in Asymptomatic Patients With Cardiac Murmurs***

Class I: Evidence and general agreement indicate that echocardiography is useful in asymptomatic patients with the following cardiac murmurs:

- Diastolic murmurs
- Continuous murmurs
- Late systolic murmurs
- Murmurs associated with ejection clicks
- Murmurs that radiate to the neck or back
- Grade 3 or louder systolic murmurs

Class IIa: The weight of evidence or opinion is in favor of usefulness of echocardiography in asymptomatic patients with the following cardiac murmurs:

- Murmurs associated with other abnormal physical findings on cardiac examination
- Murmurs associated with an abnormal electrocardiogram or chest radiograph

Class III: Evidence and general agreement indicate that echocardiography is not useful in asymptomatic patients with the following murmurs:

- Grade 2 or softer midsystolic murmurs considered innocent or functional by an experienced observer

Modified from Bonow, RO, Carabello, BA, Chatterjee, K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, Circulation *114:e84-e231, 2006.*

age, risk factors for heart disease, other abnormal heart sounds, history of rheumatic fever, anorectic drug use, evidence of excessive intravascular volume, pulmonary disease, cardiomegaly, or abnormal ECG (Box 38-6). Diastolic murmurs are always pathologic and require further evaluation. In general, regurgitant valvular lesions are better tolerated perioperatively than is stenotic disease. Murmurs can be graded according to loudness, as shown in Table 38-5. Nonetheless, the usefulness of this approach is debatable because severe lesions can be associated with soft murmurs and vice versa. The location of the murmur, as well as changes in intensity associated with maneuvers, can guide diagnosis (Table 38-6). A Valsalva maneuver decreases filling of the right and left heart chambers and reduces the intensity of most murmurs, except those associated with mitral valve prolapse (MVP) and HCM. Standing also decreases preload and thereby increases the intensity of murmurs of MVP and HCM. Conversely, squatting increases venous return and afterload and therefore increases most murmurs, except those of MVP and HCM. Having the patient repeatedly perform a hand grip increases HR and arterial BP and thereby augments murmurs of mitral regurgitation, mitral stenosis, and aortic insufficiency; however, this maneuver decreases murmurs of aortic stenosis and HCM. Significant abnormalities found by history, physical examination, or ECG may require a preoperative echocardiogram or cardiology consultation.

TABLE 38-5 **GRADING THE INTENSITY OF CARDIAC MURMURS**

Grade	Description
I	Faintest that can be heard with difficulty
II	Faint but easily heard
III	Moderately loud without a thrill
IV	Loud with a palpable thrill
V	Very loud but still need stethoscope (thrill present)
VI	Heard without a stethoscope

Aortic Stenosis. Severe aortic stenosis is associated with increased perioperative cardiac risk, especially in combination with other risk factors for perioperative cardiac complications.[90] Patients with bicuspid valves typically develop stenosis at a younger age (fourth and fifth decades of life), whereas patients with stenosis of nonbicuspid valves are usually 60 years old or older. Aortic *sclerosis,* which also causes a systolic ejection murmur similar to that of aortic stenosis, is present in 25% of people 65 to 74 years old and in almost half of those 84 years old or older. Aortic sclerosis is associated with a 40% increase in the risk of MI and a 50% increase in the risk of cardiovascular death in patients without a prior history of CAD.[91] No hemodynamic compromise occurs in aortic sclerosis.

The cardinal symptoms of severe aortic stenosis are angina, heart failure, and syncope, although patients are much more likely to complain of a decrease in exercise tolerance and exertional dyspnea. Aortic stenosis causes a systolic ejection murmur, best heard in the right upper sternal border and often radiating to the neck. A delayed carotid upstroke and a paradoxically split S_2 (second heart sound) are noted. Exercise increases HR and decreases an aortic stenosis murmur. The pattern of radiation of the murmur can help rule out aortic stenosis; specifically, the absence of murmur radiation to the right clavicle is associated with a negative likelihood ratio of 0.1 for aortic stenosis.[92] Any patient with a previously undiagnosed suspicious murmur needs an ECG, and any ECG abnormality warrants an echocardiogram (see Box 38-6). ECG abnormalities may consist of LVH, often with a strain pattern, left axis deviation, or LBBB. Because of the difficulties noncardiologists have in distinguishing murmurs of aortic stenosis from those of aortic sclerosis, an echocardiogram is often useful, even without ECG abnormalities. This is especially true if general anesthesia or an intermediate- or high-risk procedure is planned.

Aortic stenosis severity is based on the valve area and mean transvalvular pressure gradient (Table 38-7). A limitation of using the pressure gradient alone to assess severity is that the gradient may decrease if the left ventricle begins to fail. Echocardiography is recommended annually for patients with severe aortic stenosis, every 2 years for moderate stenosis, and every 5 years for mild stenosis. Patients with aortic stenosis are at risk for sudden death, arrhythmias, heart failure, ischemia, and MI; ischemia may result from concomitant CAD or a supply-demand mismatch. Aortic sclerosis or stenosis is an indicator of CAD, regardless of other risk factors. Severe or critical stenosis should preclude noncardiac surgery (unless it is an

TABLE 38-6 DESCRIPTIONS OF MURMURS ASSOCIATED WITH CARDIAC ABNORMALITIES

Lesion	Location	Timing	Description
Aortic stenosis	Second parasternal interspace	Midsystolic	Crescendo-decrescendo, radiates to the carotid arteries; with or without S_3, S_4; Valsalva maneuver and sustained hand grip exercise decrease intensity
Aortic insufficiency	Third and fourth parasternal interspaces	Holodiastolic	Decrescendo, blowing, high pitched, radiates to the carotid arteries; Austin-Flint rumble at the apex; squatting, hand grip exercise, and leaning forward increase intensity
Mitral stenosis	Apex	Middiastolic	Opening snap; low-pitched rumble radiates to the axilla; squatting and hand grip exercise increase intensity
Mitral regurgitation	Apex	Holosystolic	High pitched, blowing, radiates to the axilla; loud S_3; standing decreases intensity; squatting and hand grip exercise increase intensity
Mitral valve prolapse	Apex	Late systolic	Crescendo, midsystolic click; Valsalva maneuver and standing increase intensity; squatting decreases intensity
Hypertrophic cardiomyopathy	Apex, lower left sternal border	Midsystolic	S_4, single S_2; Valsalva maneuver and standing increase intensity; squatting, passive leg raising, and hand grip exercise decrease intensity

TABLE 38-7 GRADING SEVERITY OF AORTIC STENOSIS

Grade	Velocity of Aortic Jet (m/sec)	Mean Pressure Gradient (mm Hg)	Valve Area (cm^2)
Mild	<3	<25	≥1.5
Moderate	3-4	2-40	1.0-1.5
Severe	4-4.5	40-50	0.7-1.0
Critical	>4.5	50	<0.7

emergency and lifesaving procedure) without cardiology evaluation, careful consideration of risks, or valve replacement. Patients with moderate to severe aortic stenosis have an increased risk of bleeding. The cause appears to be *acquired* von Willebrand syndrome, resulting from mechanical disruption of von Willebrand multimers during turbulent blood flow through a narrowed valve.[93] An activated partial thromboplastin time (aPTT) is indicated. Prophylaxis for infective endocarditis in patients with aortic stenosis is no longer recommended.[94]

Aortic Insufficiency. Insufficiency of the aortic valve occurs with true valvular disease affecting the leaflets, aortic root dilation, or both. Rheumatic heart disease, bicuspid valves, collagen vascular diseases, and endocarditis can all lead to valvular disease. Aortic root dilation can complicate ankylosing spondylitis, osteogenesis imperfecta, syphilis, hypertension, age-related degeneration, Marfan syndrome, and collagen vascular diseases. Acute aortic insufficiency can also result from trauma, infections, or aortic dissection; this is an emergency. The murmur of aortic insufficiency is described in Table 38-6. The intensity of the murmur does not correlate with the severity of regurgitation.[95] Patients typically have a widened pulse pressure, which manifests as Corrigan or water-hammer pulses (bounding carotid pulse with a rapid downstroke). Other signs include de Musset sign (head bob with each heart beat), Duroziez sign (systolic and diastolic bruit heard over the femoral artery when it is partially compressed), Quincke pulses (capillary pulsations in the fingertips or lips), and Mueller sign (systolic pulsations of the uvula).

An ECG is needed and an echocardiogram may be useful (see Box 38-6). LVH with ST-segment and T-wave changes as a result of excessive intravascular volume, or underlying chronic ischemia, may be present. Left atrial hypertrophy and left axis deviation along with premature atrial and ventricular contractions are not uncommon. Generally, chronic aortic insufficiency is well tolerated in the perioperative period. Patients with good functional status and preserved left ventricular systolic function have a low risk of complications of anesthesia. Prophylaxis for infective endocarditis is no longer recommended.[94]

Mitral Stenosis. Mitral stenosis is much less common than aortic stenosis and is usually associated with a history of rheumatic heart disease. Mitral stenosis causes a diastolic murmur and is always evaluated with an ECG and an echocardiogram (see Box 38-6). This disorder can occur with aortic valvular disease or mitral regurgitation. A normal mitral valve has an area of 4 to 6 cm^2; stenosis is mild when the area is 1.5 to 2.5 cm^2, moderate with an area of 1.1 to 1.5 cm^2, and critical when the area is 0.6 to 1.0 cm^2. A resting mean transvalvular gradient of 10 mm Hg or more also denotes severe stenosis. Symptoms typically occur 10 to 20 years after acute rheumatic fever and often are precipitated by pregnancy or illness. Unrecognized mitral stenosis should be included in the differential diagnosis of pulmonary edema.

Dyspnea, fatigue, orthopnea, pulmonary edema, and hemoptysis result from increased left atrial pressures and decreased cardiac output. Atrial fibrillation can result from a dilated left atrium, which can precipitate heart failure in the short term and cause thrombosis in the long term. Patients with atrial fibrillation also require anticoagulation to avoid a left atrial thrombus. Pulmonary

hypertension (suggested by a loud S_2 heart sound) and right-sided heart failure may occur in patients with significant stenosis. The characteristics of the murmur are described in Table 38-6. Sustained hand grip exercise increases HR and arterial BP, thereby increasing the intensity of the murmur. Physical examination involves looking for rales and for signs of right-sided heart failure such as jugular venous distention, peripheral edema, hepatomegaly, right ventricular heave, and ascites.

An ECG and an echocardiogram are necessary (see Box 38-6). β-Adrenergic blockers are used to control HR, and antiarrhythmic agents prevent or control atrial fibrillation. These medications should be continued preoperatively. HR must be controlled preoperatively. Anticoagulation is managed in conjunction with the treating cardiologist and surgeon. Prophylaxis for infective endocarditis is no longer recommended.[94]

Mitral Regurgitation. Mitral regurgitation can be acute in the setting of ischemia and infarction or chronic and associated with mitral stenosis, MVP, collagen vascular diseases, and cardiomyopathies. The course is typically very gradual, with symptoms developing late and only after left ventricular dysfunction occurs. The symptoms are vague and are often attributed to other causes. Fatigue, dyspnea, and atrial fibrillation can be present. A description of the murmur is presented in Table 38-6. A loud murmur associated with a thrill (grade 4 murmur or higher) has a specificity of 91% for severe regurgitation, but a sensitivity of 24%.[95] Severe regurgitation is rarely present with a grade 1 to 2 murmur; however, the range of severity is wide with a grade 3 murmur. An ECG and an echocardiogram may be necessary (see Box 38-6). Chronic mitral regurgitation is generally well tolerated perioperatively, unless other valvular lesions (e.g., mitral or aortic stenosis) or left ventricular dysfunction coexist. Prophylaxis for infective endocarditis is no longer recommended.[94]

Mitral Valve Prolapse. Also known as click-murmur or floppy valve syndrome, MVP is commonly diagnosed in young women during evaluation for atypical chest pain, palpitations, or syncope. Whether these symptoms are truly related is questionable. Men who are more than 55 years old and who have MVP are more likely to have regurgitation and complications, and they are at greatest risk for infective endocarditis. The important preoperative issue is to differentiate patients with clinically significant mitral valve degeneration and regurgitation from those with an incidental finding of prolapse that does not warrant further evaluation or management. Patients taking β-adrenergic blockers for control of palpitations or atypical chest pain should continue taking these drugs perioperatively. Prophylaxis for infective endocarditis is no longer recommended.[94]

Tricuspid Regurgitation. Tricuspid regurgitation is a relatively common abnormality; however, because it is usually asymptomatic and not audible on physical examination, it is most commonly noted by echocardiography performed for other reasons. A small degree of tricuspid regurgitation is present in approximately 70% of normal adults. Tricuspid regurgitation is most commonly caused by dilatation of the right ventricle and the tricuspid annulus. Right ventricular dilatation results from conditions that directly involve the right ventricle (ischemia, cardiomyopathy) or from pulmonary hypertension and resulting elevations in right ventricular systolic pressure. Tricuspid regurgitation and mitral regurgitation often occur together. Tricuspid regurgitation is less often caused by processes that directly affect the tricuspid valve, such as Ebstein anomaly (congenital malformation), infective endocarditis (typically in intravenous drug users), rheumatic fever, carcinoid syndrome, connective tissue disorders (Marfan syndrome), myxomatous degeneration, or injury (e.g., pacemaker lead, central venous line, ICD lead). Drugs such as anorectics (i.e., fenfluramine, phentermine) and pergolide (dopamine agonist) may cause tricuspid regurgitation by a mechanism similar to carcinoid syndrome. These drugs are no longer available in the United States.

Tricuspid regurgitation is classically associated with a holosystolic murmur that is best heard at the right or left midsternal border or at the subxiphoid area. When the right ventricle is greatly enlarged, the murmur may even be appreciated at the apex. Usually, little radiation of the murmur occurs, and a thrill is not palpable. The murmur of tricuspid insufficiency is often soft or absent, even when regurgitation is severe. Interventions that result in an increase in venous return (e.g., leg raising, exercise, hepatic compression) augment the murmur of tricuspid regurgitation. The murmur may also become louder after a premature beat and prolonged diastole (secondary to augmented preload). In contrast, reducing venous return (e.g., standing, amyl nitrate) diminishes the intensity of the murmur. In patients with pulmonary hypertension, the intensity of the murmur may change with changes in pressure in the pulmonary artery and therefore the right ventricle. Patients with, or suspected of having, pulmonary hypertension must be managed by a pulmonary hypertension specialist (see the later section on pulmonary hypertension). An ECG, echocardiogram, and often a chest radiograph may be indicated. Prophylaxis for infective endocarditis is no longer recommended.[94]

Hypertrophic Cardiomyopathy. Previously known as hypertrophic obstructive cardiomyopathy or idiopathic hypertrophic subaortic stenosis, HCM can have either a familial or a nonfamilial basis. Patients with HCM are often young male patients who may be asymptomatic and without murmurs. An ECG and an echocardiogram should be obtained if the patient has a personal or family history of syncope with exertion or sudden death or when a murmur consistent with this disorder is detected. Characteristics of the murmur are described in Table 38-6. A maneuver that decreases diastolic volume or increases contractility increases the intensity of the murmur. Thus, passive leg raising and squatting decrease the intensity, whereas the Valsalva maneuver increases it. Other indicators may be LVH and ST-segment and T-wave abnormalities on an ECG in an otherwise healthy nonhypertensive patient, and further evaluation with echocardiography is warranted. These patients are at risk for sudden cardiac

death, likely from arrhythmias. An ECG and an echocardiogram are indicated (see Box 38-6). Holter monitoring may be useful in some patients. Many patients are treated with β-adrenergic blockers to decrease contractility; these medications should be continued perioperatively. An ICD may be in place to prevent sudden death. Prophylaxis for infective endocarditis is no longer recommended.[94]

Prosthetic Heart Valves. The most important preoperative issues in patients with prosthetic heart valves are determinations of the underlying condition requiring replacement, the type of prosthesis, the need for anticoagulation, and the planned anticoagulation management of such patients in the perioperative period. Patients may also have valve-related hemolysis. In descending order of risk, the risk of thrombosis is greatest with multiple valves, mitral valve replacements, and aortic valve replacements. Caged-ball valves (e.g., Starr-Edwards) have the highest risk, single tilting-disk valves (e.g., Björk-Shiley, Medtronic-Hall, Omnicarbon) have an intermediate risk, and the lowest risk is with bileaflet tilting-disk prostheses (e.g., St. Jude, CarboMedics, Edwards Duromedics). Bioprosthetic valves such as Carpentier-Edwards or Hancock brands generally do not require long-term anticoagulation. Decisions about stopping anticoagulants, the duration of anticoagulant discontinuance, the use of "bridging" with a shorter-acting drug, and the type of bridging agent (intravenous heparin or LMWH) are made in conjunction with the treating cardiologist and surgeon. Prophylaxis for infective endocarditis is recommended for specific procedures and is discussed in the next section.[94]

Infective Endocarditis Prophylaxis

Patients at risk for infective endocarditis (e.g., valve replacements, complex congenital heart disease, previous endocarditis) and scheduled for procedures with the potential for transient bacteremia must be identified preoperatively. Current guidelines have dramatically scaled back the range of conditions and procedures warranting prophylaxis.[94] Prophylaxis is now recommended only for patients with cardiac conditions with the highest risk of major adverse outcomes (Box 38-7), not necessarily the highest risk of acquiring endocarditis. For example, MVP is the most common underlying condition predisposing to endocarditis in industrialized countries, yet infection in the setting of MVP is rarely associated with severe complications. The absolute risk rate for infective endocarditis with MVP is thought to be 1 in 1.1 million procedures. Prophylaxis to prevent endocarditis is also no longer recommended for patients with valvular abnormalities (other than transplant recipients). Prophylaxis is recommended only for a limited number of "dirty" procedures. Patients who are having procedures on infected skin or musculoskeletal tissues and who also have one of the conditions listed in Box 38-7 receive prophylaxis. Many procedures involving the gastrointestinal and genitourinary tracts may cause transient bacteremia; however, reports of endocarditis associated with these procedures are anecdotal. The current guidelines recommend prophylaxis only for at-risk patients (see Box 38-7) undergoing urinary tract procedural manipulation (e.g., cystoscopy) in the presence of enterococcal urinary infection or colonization. If the procedure is elective, infection should be eradicated before the procedure is performed. No prophylaxis is recommended for upper and lower gastrointestinal diagnostic endoscopic procedures.

BOX 38-7 ***Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis, for Which Prophylaxis Is Recommended***

- Previous infective endocarditis
- Congenital heart disease*
  - Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
  - Completely repaired congenital heart defects with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure†
  - Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibited endothelialization)
- Cardiac valvulopathy that develops in cardiac transplantation recipients

Modified from Wilson W, Taubert K, Gewitz M, et al: Prevention of infective endocarditis: guidelines from the American Heart Association. A Guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group, Circulation *16:1736-1754, 2007.*

*Antibiotic prophylaxis is no longer recommended for forms of congenital heart disease not listed in this table.

†Prophylaxis is recommended because prosthetic material is endothelialized within 6 months after the procedure.

Rhythm Disturbances on the Preoperative Electrocardiogram

Arrhythmias and conduction disturbances are common in the perioperative period. Supraventricular and ventricular arrhythmias are associated with a higher risk of perioperative adverse events, both because of the arrhythmias themselves and because they are markers for cardiopulmonary disease. Uncontrolled atrial fibrillation and ventricular tachycardia are high-risk clinical predictors, and elective surgery is postponed until evaluation and stabilization are complete. New-onset atrial fibrillation, uncontrolled atrial fibrillation (rates >100 beats/minute), symptomatic bradycardia, or high-grade heart block (second- or third-degree heart block), warrants postponement of elective procedures and referral to cardiology for further evaluation.

First-degree AV block is defined as a PR interval exceeding 0.20 msec with an HR of 50 to 100 beats/minute, and it is generally benign. Second-degree heart block occurs when the PR interval exceeds 0.20 msec and some atrial beats are blocked, resulting in a dropped or missing QRS complex after a P wave. Two types of second-degree block exist. Mobitz type I, or Wenckebach block, is more benign, rarely progresses to complete heart block, and is easily responsive to atropine. Because of AV nodal delay, it is characterized by progressive lengthening of the PR interval until the dropped beat occurs. Mobitz type II block results

from an infranodal block, can progress to complete heart block, and is generally treated with a pacemaker unless the condition is secondary to a reversible cause such as ischemia or drugs. Mobitz type II block is characterized by a fixed, prolonged PR interval that does not change before the dropped QRS complex. Third-degree or complete heart block is complete dissociation between the atrial and ventricular beats and requires a pacemaker unless a reversible source is identified. Two general factors are considered when determining the need for a pacemaker: an arrhythmia associated with symptoms and the location of the conduction abnormality. Syncope or near syncope associated with bradycardia or conduction delays is generally an indication for pacemaker placement. Disease below the AV node, in the His-Purkinje system, is also ominous. Such conduction disease is suggested by a normal or minimally prolonged PR interval, Mobitz type II block, and QRS abnormalities (BBB, fascicular block, or both). Disease in the His-Purkinje system is generally less stable and likely benefits from permanent pacemaker placement. Indications for perioperative pacemaker placement are the same as those in nonsurgical patients (Box 38-8).[96]

BBBs are complete or incomplete, and they manifest as either RBBB or LBBB. They can be normal variants, or they can result from aging or fibrosis of the conducting system, ischemia, pulmonary disease, radiation, and cardiomyopathies. A recent onset (or no previous evaluation) of BBB prompts a more extensive consideration of cardiac risk. A previous ECG for comparison helps differentiate a long-standing abnormality from a new development. Nonetheless, even if the LBBB was present in a previous ECG, the patient should be appropriately assessed if no prior cardiac evaluation was performed. An LBBB on an ECG necessitates a detailed history and examination to ascertain the presence of cardiac disease and associated risk factors. Traditionally, LBBB has been considered more ominous and is associated with CAD and heart failure.[97,98] RBBB is more likely than LBBB to be related to congenital causes, pulmonary disease, or degeneration of the conduction system. Brugada syndrome is a congenital disease characterized by RBBB with ST-segment elevation in the right precordial leads and is associated with sudden death and lethal arrhythmias. If the history and physical examination do not suggest significant pulmonary, congenital, or ischemic heart disease or Brugada syndrome, no further evaluation of an isolated RBBB is warranted. An RBBB in a patient with pulmonary symptoms (including pulmonary hypertension) may suggest severe respiratory or vascular compromise; consideration should be given to pulmonary evaluation and echocardiography if intermediate- or high-risk surgery is planned. If congenital heart disease, pulmonary hypertension, or Brugada syndrome is suspected, a cardiology consultation is indicated.

A prolonged QT interval should prompt an evaluation of electrolytes, magnesium, and calcium, as well as a search for potentiating drugs. Syncope, presyncope, or a family history of sudden death in a patient with a prolonged QT interval mandates cardiology consultation.

Atrial Fibrillation. Atrial fibrillation can occur in the setting of increased age, thyrotoxicosis, and valvular heart disease. It also occurs in the perioperative setting. Atrial fibrillation can be intermittent (i.e., paroxysmal), persistent (i.e., capable of being cardioverted), or permanent (i.e., cannot be converted). In general, HR control is more important than rhythm control.[99,100] Patients with rapid ventricular rates, exceeding 100 beats/minute, require rate control before elective surgical procedures.[5] Patients with slow ventricular rates without any rate-controlling medications may have sick sinus syndrome; these individuals should be questioned carefully regarding any previous syncopal or presyncopal episodes. In addition, Holter monitor testing may be warranted. Most patients with atrial fibrillation require long-term anticoagulation, which entails perioperative management. The requirement for bridging anticoagulation therapy during the perioperative period is based on a patient's expected risk for stroke related to the atrial fibrillation. Patients with atrial or ventricular thrombi, mechanical heart valves, or a history of previous thromboembolic events are at higher risk for stroke. In addition, the $CHADS_2$ (congestive heart failure, hypertension, age, diabetes, stroke) index can more accurately estimate the risk of stroke in individuals with nonrheumatic atrial fibrillation.[101] This index consists of five components: congestive heart failure, hypertension (BP >140/90 mm Hg), age 75 years or older, diabetes, and prior thromboembolism (including stroke or transient ischemic attack). Each risk factor is assigned

BOX 38-8 *Indications for a Pacemaker*

Class I Indications*

- Sinus bradycardia with symptoms clearly related to the bradycardia (usually with a heart rate <40 beats/minute or frequent sinus pauses)
- Symptomatic chronotropic incompetence
- Complete (third-degree) AV block†
- Advanced second-degree AV block (block of >2 consecutive P waves)
- Symptomatic Mobitz I or II second-degree AV block
- Mobitz II second-degree AV block with a widened QRS complex or chronic bifascicular block, regardless of symptoms

Class 2 Indications‡

- Sinus bradycardia (heart rate <40 beats/minute) with symptoms suggestive of bradycardia but without a clear association between bradycardia and symptoms
- Sinus node dysfunction with unexplained syncope
- Chronic heart rates <30 beats/minute in an awake patient

Modified from Gregoratos, G, Abrams, J, Epstein, AE, et al: ACC/AHA/NASPE 2002 Guideline update for implantation of cardiac pacemakers and antiarrhythmia devices: summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/NASPE Committee to Update the 1998 Pacemaker Guidelines), Circulation *106:2145-2161, 2002.*

AV, Atrioventricular.

*Class I indications: Conditions in which permanent pacing is definitely beneficial and effective, provided the condition does not have a transient cause.

†Controversy exists concerning complete AV block without symptoms. The current American College of Cardiology Foundation and American Heart Association guidelines classify asymptomatic third-degree AV block with average awake ventricular rates ≥40 beats/minute as a class 2a indication, although others recommend definite pacemaker placement.

‡Class II indications: Conditions in which permanent pacing may be indicated but conflicting evidence and a divergence of opinon exist.

one point except for prior thromboembolism, which is assigned two points. Guidelines from the American College of Chest Physicians recommend consideration of bridging therapy for patients who have $CHADS_2$ scores of 3 or more.[102] In general, the perioperative management of a patient's long-term anticoagulant therapy is made in concert with the treating physician. Any β-adrenergic blockers, digoxin, calcium channel blockers, or antiarrhythmic medications used for atrial fibrillation should be continued perioperatively.

Supraventricular Arrhythmias. Supraventricular tachycardia results from rapidly firing ectopic atrial foci with rapid conduction through the AV node or from a reentry mechanism through accessory pathways. In a reentry mechanism, the cycle self-perpetuates because conduction occurs down one pathway and up the other, involving both the AV node-Purkinje system and the accessory pathway. Various degrees of AV block may slow the ventricular rate. Wolff-Parkinson-White (WPW) syndrome is characterized by the presence of an accessory pathway (called bundle of Kent) that permits both retrograde and antegrade conduction. Antegrade conduction over the accessory pathway results in a short PR interval (<0.12 msec) and a slurring of the upstroke of the QRS complex (termed a delta wave). Individuals with WPW syndrome are predisposed to supraventricular tachycardia. In individuals with WPW syndrome, treatment of supraventricular tachycardia with AV nodal blocking drugs (e.g., β-adrenergic blockers, calcium channel blockers, digoxin) can paradoxically increase conduction over the accessory pathway, thus potentially causing ventricular fibrillation. Lidocaine and procainamide are the preferred drugs for treating supraventricular tachycardia in patients with WPW syndrome. Patients with WPW syndrome typically undergo ablation for long-term management of their conduction before any elective surgery.

Ventricular Arrhythmias. Ventricular ectopic beats can be differentiated from atrial ectopic beats by a wide QRS complex (>0.12 msec) and lack of a P wave. Classifying ventricular arrhythmias according to the type of rhythm disturbance and the presence of coexisting heart disease helps predict the risk of sudden death, as follows:

- Benign: isolated ventricular premature beats (VPBs) without associated heart disease
  - No need for further evaluation
  - No risk of sudden cardiac arrest
- Potentially lethal: more than 30 VPBs/hour or nonsustained ventricular tachycardia with underlying heart disease
  - Requires cardiology evaluation with echocardiography, as well as possible stress testing, coronary angiography, and electrophysiology testing
  - Moderately high risk of sudden cardiac arrest; possible benefit from an ICD
- Lethal: sustained ventricular tachycardia, ventricular fibrillation, syncope, or hemodynamic compromise associated with VPBs with underlying heart disease and depressed cardiac function
  - Requires cardiology evaluation with echocardiography, as well as possible stress testing, coronary angiography, and electrophysiology testing
  - High risk of sudden cardiac arrest; likelihood of benefiting from an ICD

Reversible causes such as hypokalemia, ischemia, acidosis, hypomagnesemia, drug toxicity, and endocrine dysfunction must be sought out and treated. Antiarrhythmic medication must be continued perioperatively.

Prolonged QT Syndrome. The long QT syndrome (LQTS) is a disorder of myocardial repolarization that can be either genetic or acquired. It is associated with *torsades de pointes*, a polymorphic ventricular tachycardia with frequent variations of the QRS axis or morphology. Symptoms include palpitations, syncope, seizures, and sudden cardiac death. The ECG in individuals with LQTS shows a prolonged QT interval. The QT interval is measured in lead II of a 12-lead ECG from the onset of the QRS complex to the end of the T wave. Because the QT interval varies inversely with HR, the QT_c (corrected for HR) can be calculated (QT_c = QT interval + square root of the RR interval). In children 1 to 15 years old, a QT_c exceeding 0.46 seconds is considered prolonged. Otherwise, a QT_c is prolonged if exceeding 0.47 seconds in women and 0.45 seconds in men.

Acquired LQTS results from hypokalemia, hypomagnesemia, and eating disorders, as well as specific drugs such as antiarrhythmic drugs (quinidine) and psychotropic drugs (haloperidol, droperidol, methadone). Concerns over methadone prompted a safety alert by the U.S. Food and Drug Administration in 2006, and reports of adverse events with droperidol resulted in a black box warning and subsequent removal of the drug from the U.S. market. Amiodarone markedly prolongs the QT interval but is rarely associated with *torsades de pointes*, except in association with hypokalemia. The ACCF/AHA scientific statement on the prevention of *torsades de pointes* suggests that QT_c be documented before initiation of QT-prolonging drugs and thereafter at least every 8 to 12 hours.[103] Other components of treating individuals with LQTS include β-adrenergic blockers (congenital LQTS), ICD implantation, and correction of underlying metabolic disorders.

Brugada Syndrome. Brugada syndrome is a rare cause of sudden cardiac arrest that occurs without structural heart disease. Most affected individuals are of Asian ethnicity. Brugada syndrome is an autosomal dominant disorder that is much more common in men and rarely diagnosed in children. It is associated with a peculiar ECG consisting of a pseudo-RBBB and persistent ST-segment elevation in V_1 to V_3 (Fig. 38-6). The widened S wave in the left lateral leads, as is typical of usual RBBB, is absent in most patients with Brugada syndrome. In some patients, these ECG changes are transient and provoked by medications. The website www.brugadadrugs.org lists drugs that are associated with adverse events in Brugada syndrome. Some are commonly used anesthetic drugs, including propofol and bupivacaine. Findings on echocardiography, stress testing, and cardiac MRI in these individuals

From Bernstein AD, Daubert JC, Fletcher RD, et al: The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing: North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group, Pacing Clin Electrophysiol *25:260-264, 2002.*

are usually normal. The most significant clinical manifestations are ventricular arrhythmias, syncope, and sudden death. These patients may also be at increased risk of atrial arrhythmias, especially atrial fibrillation. The syndrome has no proven pharmacologic treatment; indeed, class I antiarrhythmic medications (e.g., flecainide, procainamide) and β-adrenergic blockers can worsen the risk of lethal arrhythmias. ICD implantation is the standard of care.

Cardiovascular Implantable Electronic Device: Pacemakers and Implantable Cardioverter-Defibrillators

More than 100,000 new CIEDs are implanted yearly in the United States (see also Chapters 48 and 68). The preoperative evaluation should determine the type of device, as well as features (e.g., rate modulation) likely to malfunction with perioperative electromagnetic interference. Patients frequently carry a wallet card with important designations and phone numbers. Equally important is the need to evaluate the coexisting cardiac disease because these patients invariably have conditions such as heart failure, ischemic heart disease, valvular heart disease, or potentially lethal arrhythmias.

Pacemakers are designated with a five-letter code (Table 38-8),[104] and consultation with the device manufacturer, cardiologist, or the electrophysiology or CIED service may be needed (Box 38-9). Ideally, patients with CIEDs have these devices interrogated preoperatively. Special features such as rate-adaptive mechanisms and antitachyarrhythmia functions must be disabled, or the device must be reprogrammed to an asynchronous pacing mode before surgical procedures where interference may occur.[105] Electromagnetic interference is likely to occur with electrocautery, radiofrequency ablation, MRI, and radiation therapy; it can result in malfunction or adverse events.[105] Patient monitors, ventilators, vibrations, or chest preparation can be misinterpreted by the sensors such that the pacing rate is increased, with the possibility of tachycardia, ischemia, or inappropriate shocks. An ICD can also misinterpret electrocautery as an arrhythmia and can inappropriately shock a patient. During delicate surgical procedures (e.g., intracranial, spinal, ocular), an unexpected discharge with movement of the patient can have catastrophic results. Central line placement can also trigger cardioversion.

Given the complexity of newer-generation CIEDs, reliance on a magnet without specific information about the CIED is not recommended, except in emergency situations. In fact, some CIEDs from certain manufacturers are programmed to ignore magnet placement or have antitachyarrhythmia therapy *permanently* disabled by magnet placement. Depending on the available resources, it may

BOX 38-9 ***Proposed Principles for Cardiovascular Implantable Electronic Device Management***

The perioperative management of CIEDs must be individualized to the patient, the type of CIED, and the procedure being performed. A single recommendation for all patients with CIEDs is not appropriate.

The CIED team is defined as the physicians and physician extenders who monitor the CIED function of the patient.

The surgical or procedural team should communicate with the CIED team to identify the type of procedure and the likely risk of EMI.

The CIED team should communicate with the procedure team to deliver a prescription for the perioperative management of patients with CIEDs.

For most patients, the prescription can be made from a review of the records of the CIED clinic. A few patients may require consultation with CIED specialists if the information is not available.

It is inappropriate to have industry-employed allied health professionals independently develop this prescription.

From Crossley GH, Poole JE, Rozner MA, et al: The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers and implantable monitors: facilities and patient management: executive summary, Heart Rhythm *8:e1-e18, 2011.*

CIED, Cardiovascular implantable electronic device; *EMI,* electromagnetic interference.

not be appropriate to care for these patients in some facilities. These individuals require a preoperative ECG, while a chest radiograph can reveal the manufacturer's code. Communication and guidance with an electrophysiology specialist comprise the preferred approach for managing these patients. Preoperative recommendations for CIEDs are presented in Box 38-10.

Peripheral Arterial Disease

Formerly called peripheral vascular disease, PAD refers to aneurysmal or occlusive arterial disease of the extremities, visceral organs, head, neck, and brain. In many patients, PAD is secondary to tobacco use, diabetes, hyperlipidemia, and hypertension. Patients with Marfan syndrome or Ehlers-Danlos syndrome may have aneurysmal disease without other risk factors. Renal insufficiency and cerebrovascular disease are also common in these patients. Patients with PAD frequently have concomitant CAD. For example, in a study of 1000 consecutive patients scheduled for major vascular surgery, almost 60% had critical stenosis in at least one major coronary vessel.[106] Although the high perioperative cardiac risk of vascular surgery is well appreciated, patients with PAD have a high cardiac risk even when undergoing nonvascular surgery. For example, a reduced ankle-to-arm BP index, which indicates PAD, is independently associated with an increased perioperative cardiac risk following noncardiac surgery.[107] In addition, claudication related to PAD generally limits functional capacity and thereby masks the symptoms of underlying ischemic heart disease. If significant vascular disease is diagnosed during an examination for nonvascular surgery, referral to a vascular specialist is needed.

BOX 38-10 ***Preoperative Recommendations for Cardiovascular Implantable Electronic Devices***

- Inactivation of ICDs is not absolutely necessary for all procedures.
- Not all pacemakers need to be altered to pace asynchronously in all patients or for all procedures.
- Pacemakers can be reprogrammed or magnets can be used to force pacemakers to pace asynchronously to prevent inhibition.
- ICDs can be reprogrammed or magnets can be used to inhibit ICD arrhythmia detection and tachyarrhythmia functions.
- Magnets *cannot* or *will not* force pacemakers in ICDs to pace asynchronously.
- Inactivation of ICDs is recommended for all procedures above the umbilicus involving electrocautery or radiofrequency ablation.
- It is preferable to change to asynchronous pacing in pacemaker-dependent patients for procedures involving electrocautery or radiofrequency ablation above the umbilicus.

The procedure team provides the following information to the CIED team:

- Type of procedure
- Anatomic site of the procedure
- Patient position during the procedure
- Whether electrocautery will be used (and if so, type of cautery)
- Whether other sources of EMI are present
- Other issues such as likelihood of damage to leads (e.g., chest procedures), anticipated large blood loss, and surgery in close proximity to the CIED

The CIED team provides the following information to the procedure team:

- Type of device (e.g., pacemaker, ICD)
- Indication for the device (e.g., sick sinus syndrome, primary or secondary prevention of lethal arrhythmias)
- Programming (e.g., pacing mode, rate, rate responsive, heart rates for shock delivery)
- Whether the patient is pacemaker dependent and the patient's underlying heart rate and rhythm
- Magnet response
  - Pacing rate
  - Whether the device is responsive to a magnet
  - Whether ICD functions will resume automatically after magnet removal
  - Whether the magnet must be placed off-center

Modified from Crossley GH, Poole JE, Rozner MA, et al: The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers and implantable monitors: facilities and patient management: executive summary, Heart Rhythm *8:e1-e18, 2011.*

CIED, Cardiovascular implantable electronic device; *EMI,* electromagnetic interference; *ICD,* implantable cardioverter-defibrillator.

Arterial BPs should be measured in both upper extremities, and the presence of peripheral pulses in these patients should be assessed. Auscultation for bruits over the abdomen and femoral arteries, as well as palpation for abdominal masses, should be part of the vascular examination. A creatinine concentration should be determined before procedures involving injection of radiocontrast dye. These dyes can damage an already compromised kidney. Many patients take aspirin or dipyridamole,

a vasodilator with antiplatelet effects that are reversible on discontinuation. Dipyridamole's elimination half-life is approximately 10 hours, and its discontinuation for 48 hours is sufficient to eliminate its antiplatelet effect. Nonetheless, the risks of stopping antiplatelet drugs must be also considered. Continuation of antiplatelet drugs is preferable for almost all vascular procedures.

PULMONARY DISORDERS

See also Chapters 19 and 66.

Asthma

Asthma is a chronic inflammatory disease characterized by obstruction of the airways that is partially or completely reversible with treatment or spontaneously.[108] Bronchoconstriction is precipitated by irritants (e.g., smoke), allergens, infections, medications, or airway instrumentation. Asthma is classified as intermittent, persistent mild, persistent moderate, and persistent severe, based on the degree of impairment and on whether symptoms are intermittent or constant. Patients with mild, well-controlled asthma have no greater perioperative risk than do individuals without asthma.

A history of asthma should be associated with further questioning about shortness of breath, chest tightness, cough (especially nocturnal), recent exacerbations, therapy (especially steroids), prior hospitalizations or emergency department visits, critical care unit admissions, and endotracheal intubations. The patient's best exercise level is important information for risk assessment. Previous exacerbations with anesthesia must be explored. Patients with asthma can estimate their breathing capacity based on their estimated percentage at which they are currently functioning. Medical therapy must be determined. The quality of breath sounds, quantity of air movement, and degree of wheezing are important. The degree of wheezing does not always correlate with the severity of bronchoconstriction. With severe obstruction, airflow is dangerously restricted, and wheezing diminishes. Wheezing is common in asthmatic patients, but it is not specific for this disease. Patients with chronic obstructive pulmonary disease (COPD), gastroesophageal reflux disease, vocal cord dysfunction, tracheal stenosis, bronchial stenosis, cystic fibrosis, allergic bronchopulmonary aspergillosis, and heart failure may also wheeze. Observing the degree of accessory muscle use helps gauge severity of the bronchoconstriction. Determining oxygen saturation by pulse oximetry is needed.

Analysis of arterial blood gases is *not* necessary unless the patient is having a severe acute exacerbation. Patients taking oral steroids must have their blood glucose checked. Chest radiography is necessary only to evaluate infections or pneumothorax. Spirometry is the preferred diagnostic test for asthma, but a normal result does not exclude asthma. A methacholine challenge test or a trial of bronchodilator therapy is indicated if results of spirometry are normal but a strong suspicion of asthma still exists. PFTs have no perioperative predictive value for asthmatic patients. Typical findings on PFTs include reduced forced expiratory volume in 1 second (FEV_1) and normal to slightly reduced forced vital capacity (FRC). Bronchodilators, inhaled and oral steroids, and antibiotics (if taken) must be continued on the day of surgery. The use of β-adrenergic agonists is the most useful prophylactic intervention to lower the risk of bronchospasm on induction of anesthesia. A short course of steroids (20 to 60 mg of prednisone daily for 3 to 5 days) preoperatively may be considered in any patient who is not "as good as they can be." Specifically, a 5-day course of 40 mg oral methylprednisolone daily before surgery decreases posttracheal intubation wheezing in a newly diagnosed or poorly compliant asthmatic patient.[109] Inhalers and any long-term medications for asthma should be continued on the day of surgery.

Chronic Obstructive Pulmonary Disease

COPD is characterized by persistent (sometimes partially reversible) airflow obstruction (see also Chapters 19 and 39). It is often the result of smoking, environmental pollutants (e.g., air pollution, dust), α_1-antitrypsin deficiency, chronic infections, and long-standing asthma. Historically, COPD was characterized as "chronic bronchitis" and "emphysema." Chronic bronchitis is a persistent productive cough for at least 3 months per year in 2 consecutive years. The *contemporary* definition of COPD, based on the Global Initiative for Chronic Obstructive Lung Disease (GOLD), is a preventable and treatable disease with a pulmonary airflow limitation that is progressive, not fully reversible, and associated with an abnormal inflammatory response of the lung to noxious particles or gases (see http://www.goldcopd.org). This definition is largely consistent with that proposed by the American Thoracic Society and the European Respiratory Society.[110] Dyspnea, cough, wheezing, and sputum production are common features. The severity of COPD is classified based on spirometry findings, specifically forced vital capacity (FVC) and FEV_1. In patients with an FEV_1/FVC ratio of 0.7 or less, COPD is *mild* if FEV_1 is at or greater than 80% of predicted, *moderate* if FEV_1 is between 50% and 80% of predicted, *severe* if FEV_1 is between 30% and 50% of predicted, and *very severe* if less than 30% of predicted. An acute exacerbation is defined as an "acute event characterized by a worsening of the patient's respiratory symptoms that is beyond normal day-to-day variations and leads to a change in medication" (see http://www.goldcopd.org).

The history and physical examination for patients with COPD are similar to those for patients with asthma, with an additional emphasis on changes in sputum amount, color, or other signs of infection. A barrel chest and pursed-lip breathing suggest advanced disease. Typically, the FEV_1 is reduced secondary to obstruction of airflow, whereas the FRC is increased because of reduced airflow, loss of elasticity, and overexpansion. Diffusing capacity of the lung for carbon monoxide (D_{LCO}) is often decreased, with the severity of decrease often correlating with the degree of hypoxia and hypercarbia. PFT results are generally not predictive of perioperative outcomes in patients with COPD.[111] A preoperative determination of oxygen saturation by pulse oximetry is important to establish a baseline. Patients found to be hypoxic, or requiring supplemental oxygen, benefit from further testing, including arterial blood gas determinations. A chest

radiograph is useful only when infection or bullous disease is suspected. Right axis deviation, RBBB, or peaked P waves on an ECG suggest right ventricular changes and pulmonary hypertension. Inhalers and other long-term medications for COPD should be continued on the day of surgery.

Restrictive Pulmonary Disorders

Restrictive lung disease is characterized by a reduction in total lung capacity. Both pulmonary and extrapulmonary conditions can cause restrictive disease. Pulmonary causes include idiopathic interstitial pneumonia, prior lung resection, pulmonary fibrosis, and interstitial lung disease secondary to connective tissue disease. Extrapulmonary disorders may be related to chest wall limitations (e.g., kyphoscoliosis, obesity, ankylosing spondylitis), muscle dysfunction (e.g., muscular dystrophies, myasthenia gravis, paralyzed diaphragm), and pleural disease (e.g., mesothelioma, effusion, pneumothorax). The medical history of associated diseases or symptoms prompts the directed evaluation. Chest radiograph and PFTs may be indicated to establish a diagnosis or evaluate acute or progressive worsening; however, preoperative PFTs are not routinely necessary. Typically, the FEV_1 and the FVC are reduced proportionally such that the FEV_1/FVC ratio is normal (i.e., >0.7). These patients are at risk of pulmonary hypertension, which may not be recognized because of overlapping symptoms with restrictive lung disease.

Dyspnea

Dyspnea is a subjective experience of breathing discomfort. It is a symptom of deconditioning, obesity, and disorders of ventilation, cardiac function, perfusion, and oxygen delivery. Dyspnea is also associated with cardiac, pulmonary, hematologic, and neuromuscular diseases (Fig. 38-7). Patients with an insidious onset may not seek attention until quite late; often, they and their caregivers assume that the dyspnea results from being "out of shape." Dyspnea should not simply be attributed to deconditioning without a thorough investigation to rule out other causes. Most patients with chronic dyspnea of unclear etiology have one of four diagnoses: asthma, COPD, interstitial lung disease, or cardiac dysfunction.[112] The severity of dyspnea symptoms is classified using the NYHA functional class categories (see the section on heart failure).

The important facts to determine in the preoperative evaluation of dyspnea are its onset, progression, precipitating factors, associated symptoms (e.g., chest pain, leg edema, fatigue, syncope, or near syncope), associated conditions (e.g., arthritis, connective tissue disease, cardiac disease, smoking), and drug (or toxin) exposure. Asking about the quality of dyspnea can differentiate causes. Dyspnea secondary to deconditioning is usually described as "heavy breathing." Bronchoconstriction in asthma exacerbations is more commonly described as "tightness" or "air hunger," whereas patients with COPD complain of "not being able to take a deep breath" or an "increased effort to breathe." Patients with heart failure feel like they are "suffocating" or have "air hunger."[113] Orthopnea (dyspnea while recumbent) suggests heart failure. Coughing can be a symptom of heart failure, asthma, or COPD. Concomitant angina or a history of CAD in a dyspneic patient may indicate heart failure. Prior anorectic drug exposure

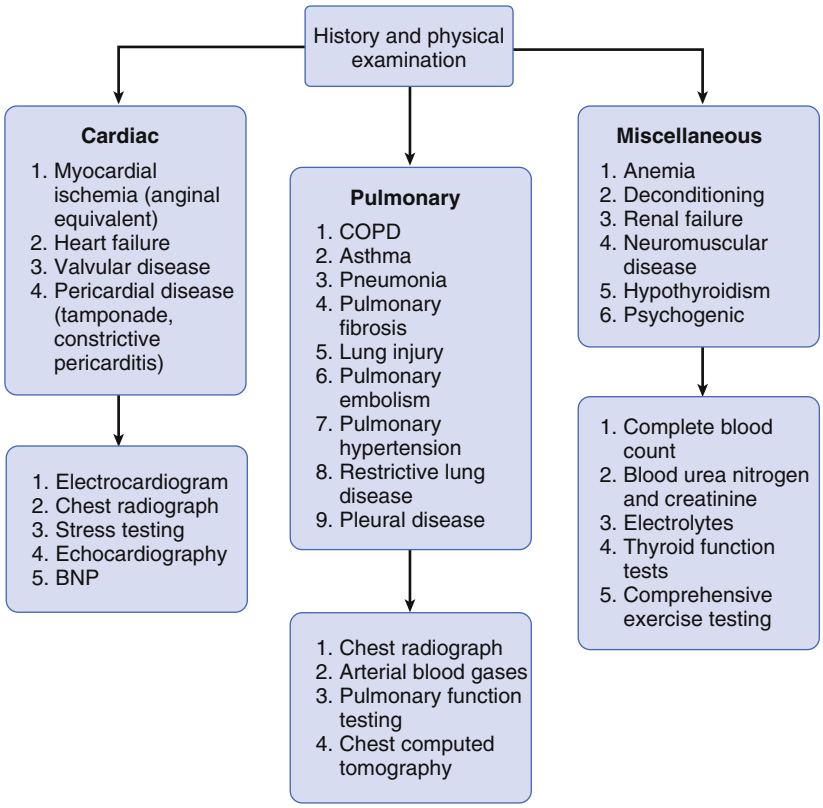

Figure 38-7. Classification scheme for causes of dyspnea. *BNP,* Brain natriuretic protein; *COPD,* chronic obstructive pulmonary disease.

may suggest pulmonary hypertension or valvular abnormalities as causes of dyspnea. Dyspnea in an individual with connective tissue disease may suggest secondary interstitial lung disease. Physical examination should assess for pallor, cyanosis, barrel chest, rales, wheezing, crackles, murmurs, abnormal heart sounds or rhythms, cardiomegaly, tachycardia, jugular venous distention, joint involvement, clubbing, fibrotic skin changes, and peripheral edema. Patients with severe airflow obstruction may have pursed lips and a slow deep breathing pattern, whereas patients with interstitial fibrosis or kyphoscoliosis typically have rapid shallow breathing.

The preoperative history and physical examination lead to accurate diagnoses in two thirds of cases. Initial testing includes an ECG, hematocrit (to exclude anemia), arterial blood gas analysis, thyroid function tests, chest radiograph, spirometry, and oximetry (at rest and after walking several feet). BNP levels may be useful. Most dyspneic patients with heart failure have BNP values exceeding 400 pg/mL, although plasma BNP concentrations between 100 and 400 pg/mL in a dyspneic patient should raise suspicions about compensated left ventricular dysfunction, pulmonary embolism, and cor pulmonale. Other specialized testing should be directed by the history, physical examination, and initial test results. Computed tomography (CT) scans and cardiopulmonary exercise testing (CPET) are rarely necessary, but they can be useful if the aforementioned tests are not diagnostic.

Patients Scheduled for Lung Resection

Most patients scheduled for lung resection operations have underlying lung disease, and PFTs may be useful in predicting risk or in excluding patients who lack adequate pulmonary reserve after resection (see also Chapter 66). The amount of residual lung function after resection can be estimated by using a combination of spirometry and radionuclide quantitative lung scanning. The estimated residual FEV_1 is predicted by multiplying the baseline FEV_1 by the percentage of radioactive counts from the nonoperative lung or lung region, as presented here[114]:

$$\text{Predicted postoperative } FEV_1 = FEV_1 \times \frac{\text{Radioactive counts in nonoperative lung}}{\text{Radioactive counts from both lungs}}$$

A predicted postoperative FEV_1 exceeding 0.8 L, or greater than 40% of predicted, indicates that sufficient lung tissue and ventilatory capacity will remain.[115] A postoperative FEV_1 or D_{LCO} less than 40% of predicted indicates increased perioperative risk. In patients undergoing pneumonectomy, a preoperative FEV_1 less than 2 L or 50% of predicted, maximal voluntary ventilation less than 50% of predicted, or D_{LCO} less than 60% indicates increased risk.[116]

If preoperative PFTs and ventilation-perfusion $\dot{V}/\dot{Q}$ scanning suggest that the patient is at great risk or may not be an operative candidate, additional information can be obtained with CPET and determinations of peak oxygen consumption (VO_{2peak}). Patients with preoperative VO_{2peak} greater than 20 mL/kg/minute have a low risk of complications or death, those with VO_{2peak} less than 15 mL/kg/minute have an increased risk; and those with VO_{2peak} less than 10 mL/kg/minute are at very high risk of postoperative complications. Stair climbing can also help predict VO_{2peak}. Patients who can climb five flights of stairs likely have a VO_{2peak} exceeding 20 mL/kg/minute. Conversely, patients who cannot climb one flight of stairs likely have a VO_{2peak} less than 10 mL/kg/minute.[117] Hypoxia with exertion or hypercarbia at rest is also associated with increased postoperative complications in patients having lung resection procedures.[117] This topic is covered in more detail in Chapter 66.

Obstructive Sleep Apnea

Sleep-disordered breathing affects up to 9% of middle-aged women and 24% of middle-aged men; less than 15% of these cases have been diagnosed (see also Chapters 19 and 39). OSA, which is the most common serious manifestation of sleep-disordered breathing, is caused by intermittent airway obstruction. It is characterized by total collapse of the airway with complete obstruction for more than 10 seconds. Obstructive hypopnea is partial collapse (30% to 99%) associated with at least a 4% arterial oxygen desaturation. Snoring, daytime sleepiness, hypertension, obesity, and a family history are risk factors for OSA.[118] The severity of OSA is measured based on the apnea-hypopnea index (AHI), which is the number of apneic and hypopneic episodes per hour of sleep. Patients with severe OSA have 30 or more episodes per hour.

Cardiovascular disease is common in patients with OSA. Patients have an increased prevalence of hypertension, atrial fibrillation, bradyarrhythmias, ventricular ectopy, stroke, heart failure, pulmonary hypertension, dilated cardiomyopathy, and CAD.[119] Mask ventilation, direct laryngoscopy, endotracheal intubation, and fiberoptic visualization of the airway are more difficult in patients with OSA (see Chapters 55 and 71). Such patients are likely to have perioperative airway obstruction, hypoxemia, atelectasis, ischemia, pneumonia, and prolonged hospitalizations.[120] Patients with OSA are more sensitive to the respiratory depressant effects of opioids. Once their coexisting comorbidities are accounted for, patients with OSA are *not* at increased risk for postoperative mortality.[39]

Preoperative evaluation focuses on identifying patients at risk for OSA and optimizing associated comorbid conditions. The STOP-Bang questionnaire, which was developed and validated in an anesthesia preoperative clinic, screens for OSA (Fig. 38-8).[38] Echocardiography may be indicated if heart failure or pulmonary hypertension is suspected. Patients should be instructed to bring their continuous positive airway pressure (CPAP) devices to the hospital on the day of operation.

Pulmonary Hypertension

Pulmonary hypertension may occur in isolation or with associated medical conditions and is defined as a persistent increase of mean pulmonary artery pressure of 25 mm Hg or more with a pulmonary artery occlusion pressure less than 15 mm Hg. According to the World Health Organization, pulmonary hypertension is classified into five groups (Box 38-11). Idiopathic pulmonary arterial hypertension, formerly called primary pulmonary hypertension, is relatively

STOP-Bang
Screening for Sleep Apnea

Have you been diagnosed with sleep apnea by a sleep study? Yes ☐ No ☐

Have you received treatment for sleep apnea, such as CPAP or Bi-PAP? Yes ☐ No ☐

Please answer the following four questions with a *yes* or *no* answer:

1) Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
Yes ☐ No ☐

2) Do you often feel tired, fatigued, or sleepy during daytime?
Yes ☐ No ☐

3) Has anyone observed you stop breathing during your sleep?
Yes ☐ No ☐

4) Do you have or are you being treated for high blood pressure?
Yes ☐ No ☐

FOR STAFF USE ONLY, DO NOT WRITE BELOW THIS LINE

---

5) Is the BMI ≥35 kg/m^2?
Yes ☐ No ☐

6) Is the patient ≥50 years of age?
Yes ☐ No ☐

7) Is the neck circumference greater than 15.7 inches (40 cm)?
Yes ☐ No ☐

8) Is the patient male?
Yes ☐ No ☐

Total number of questions answered YES: _____ Is the patient at high risk for OSA? Yes ☐ No ☐

High risk of OSA: Yes to >3 items

Figure 38-8. STOP-Bang questionnaire to screen patients for obstructive sleep apnea (OSA). *BMI,* Body mass index. *(From Chung F, Yegneswaran B, Liao P, et al: STOP questionnaire: a tool to screen patients for obstructive sleep apnea,* Anesthesiology *108:812-821, 2008.)*

rare. Other more common forms occur with a variety of diseases including cardiac, pulmonary, liver, thromboembolic, and collagen vascular diseases. Pulmonary hypertension is associated with HIV infection, anorectic drug exposure (e.g., fenfluramine), sleep apnea, chronic liver disease (especially with portal hypertension), and collagen vascular diseases (e.g., scleroderma, systemic lupus erythematosus [SLE]). Occult pulmonary hypertension is more problematic than fully recognized disease because symptoms may be attributed to other diseases, and perioperative decompensation may occur unexpectedly. The onset of pulmonary hypertension is usually nonspecific, insidious, and associated with delayed diagnosis. Dyspnea is the initial symptom in 60% of patients, but it is present in 98% by the time of diagnosis. Presyncopal or syncopal episodes portend severe disease.

Patients with pulmonary arterial hypertension have a high rate of perioperative morbidity and mortality.[121] Hypoxia, hypercarbia, vasoconstrictors, and increased sympathetic tone (even from anxiety) increase pulmonary vascular resistance, with the potential for acute decompensation with right-sided heart failure. Mild pulmonary hypertension rarely affects anesthetic management, but moderate to severe disease increases the risk of right-sided heart failure. Signs and symptoms of disease severity include dyspnea at rest, metabolic acidosis, hypoxemia, right-sided heart failure (peripheral edema, hepatomegaly, jugular venous distention), and syncope.[122] Physical examination may reveal a split S_2 with a loud second component, right ventricular heave, tricuspid regurgitation murmur, ascites, hepatomegaly, jugular venous distention, and peripheral edema. An ECG and a chest radiograph are useful in patients with more than mild disease. Typical ECG findings include right axis deviation, RBBB, right ventricular hypertrophy, and tall R waves in leads V_1 and V_2. Right atrial hypertrophy and "P-pulmonale" may be present in severe pulmonary hypertension, with peaked P waves, usually in leads II, III, aVF, and V_1. Enlargement of the main pulmonary artery and a globular heart shape with a loss of the retrosternal airspace from right ventricular dilation can be seen on a chest radiograph. In addition, testing for complete blood count (CBC); determination of electrolyte, BUN, and creatinine levels; and liver function tests (LFTs; may be elevated from congestion or bosentan) are needed. An echocardiogram is the initial screening test of choice and can assess the pulmonary artery pressure and right ventricular function, identify left-sided heart failure, and valvular or congenital heart disease[122] (see also Chapter 46). Patients with significant findings usually require right and left cardiac catheterizations, especially

BOX 38-11 *Classification Scheme for Pulmonary Hypertension*

Pulmonary Arterial Hypertension
- Primary pulmonary hypertension
  - Sporadic
  - Familial
- Associated with other conditions
  - Collagen vascular disease
  - Congenital shunts
  - Portal hypertension
  - Human immunodeficiency virus infection
  - Drugs or toxins
  - Persistent pulmonary hypertension of the newborn

Pulmonary Venous Hypertension
- Left-sided heart disease
- Extrinsic compression of the central pulmonary veins
- Pulmonary venoocclusive disease

Pulmonary Hypertension Related to Lung Disease or Hypoxemia
- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Sleep-disordered breathing
- Neonatal lung disease
- Chronic exposure to high altitude

Pulmonary Hypertension Caused by Chronic Thromboembolic Disease
- Pulmonary thrombosis or embolism
- Sickle cell disease

Pulmonary Hypertension From Disorders Directly Affecting the Pulmonary Vasculature
- Schistosomiasis
- Sarcoidosis

given the potential inaccuracy of estimating right-sided pressures by echocardiography alone.

Patients may be treated with diuretics, anticoagulation, calcium channel blockers, supplemental oxygen, sildenafil (phosphodiesterase inhibitor), endothelin receptor antagonists (e.g., bosentan), and prostanoids (e.g., iloprost, epoprostenol). Some of these drugs are given by continuous intravenous infusions, and even momentary interruption of therapy can be catastrophic. All drugs must be continued preoperatively. Management of these patients in conjunction with a pulmonary hypertension specialist is advised.

Smokers and Patients Exposed to Second-Hand Smoke

Exposure to tobacco, directly or through "second-hand" smoke, increases the risk of many perioperative complications. Smokers are more likely to experience wound infections, respiratory complications (including oxygen desaturation), and severe coughing.[123] Patients without ischemic heart disease who smoked shortly before operation have significantly more episodes of ST-segment depression than do nonsmokers, former smokers, or chronic smokers who do not smoke in the immediate preoperative period.[124] Smoking decreases macrophage function; negatively affects coronary flow reserve; and causes vascular endothelial dysfunction, hypertension, and ischemia. Smokers require longer hospital stays and often need more postoperative intensive care than do nonsmokers.

The greatest benefit of smoking abstinence is probably realized only after several months of cessation. In addition, the perioperative clinical benefits of preoperative smoking cessation demonstrated in systematic reviews are evident only when cessation occurred at least 3 to 4 weeks before the surgical procedure.[125] These benefits include reduced respiratory and wound healing complications. Despite an early study reporting an increased perioperative risk (this association was not statistically significant) in recent quitters,[126] a systematic review found no increased risk of adverse events with quitting smoking soon before surgical procedures (i.e., within 8 weeks).[127] Thus, motivated patients should quit smoking at any point before surgery. Quitting has many potential benefits, even within a few days before operation. Soon after a patient quits smoking, carbon monoxide levels decrease, thereby improving oxygen delivery and use. Cyanide levels decrease, and this benefits mitochondrial oxidative metabolism. Lower nicotine levels improve vasodilatation, and many toxic substances that impair wound healing decrease.

The U.S. Public Health Service recommends that "*all* physicians should strongly advise every patient who smokes to quit because evidence shows that physician advice to quit smoking increases abstinence rates."[128] Nearly 70% of smokers want to quit. Effective interventions include medical advice and pharmacotherapy, such as nicotine replacement therapy, which is safe in the perioperative period. Nicotine patches, gum, and lozenges are available without a prescription; nasal spray, bupropion (i.e., Zyban), and varenicline (i.e., Chantix) require prescriptions. Clonidine is also effective. Bupropion, varenicline, or clonidine is started 1 to 2 weeks before a quit attempt; nicotine replacement therapy is effective immediately. Individual and group counseling may increase rates of long-term abstinence. Many hospitals, insurance companies, and communities offer smoking cessation programs. Excellent resources are available on the Internet and from the U.S. government. Advice and guidelines are available at 1-800-QUITNOW and http://www.cdc.gov/TOBACCO/quit_smoking/index.htm. Tobacco intervention training during medical school and residency can significantly improve the quality of physician counseling and rates of abstinence.

Interventions in the preoperative clinic can cause significantly higher rates of short-term cessation of smoking (i.e., within 3 to 6 months after surgery).[129] The long-term benefits are less clear, although a randomized trial demonstrated reduced nicotine dependence of up to 1 year postoperatively with the institution of a perioperative smoking cessation intervention using varenicline.[130]

Upper Respiratory Tract Infections

Traditionally, elective surgical procedures were cancelled when patients, especially children, presented with current or recent upper respiratory tract infections (see also Chapter 93). With modern anesthetic practices, cancellation is not routine. In patients with severe symptoms, especially those with underlying conditions (e.g., significant asthma, heart disease, immunosuppression) that may further compromise a safe anesthetic regimen, elective surgical procedures are postponed for at least 4 weeks.[131]

When an infection is mild or uncomplicated in healthy patients, the risk in proceeding with a procedure to avoid the inconvenience of a cancellation is low. The dilemma lies with the patients between these two extremes. Decisions regarding suitability to proceed are made on an individual basis.

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive disease caused by altered chloride and water transport across epithelial cells. It can result in a progressive chronic airway disease with airway obstruction, destruction, and frequent infections. Exocrine pancreatic insufficiency (i.e., malnutrition, diabetes, pancreatitis), bowel obstruction, sinusitis, and liver disease (biliary cirrhosis, portal hypertension) can also be present. The diagnosis is established on the basis of a sweat chloride concentration exceeding 60 mEq/L (sweat chloride test), in addition to one of the following: chronic airway disease, exocrine pancreatic insufficiency, or cystic fibrosis in a first-degree relative. A history and physical examination similar to those for patients with asthma and nutritional and hepatic assessments are necessary. Optimization of pulmonary status (treatment of secretions, infections, bronchospasm) is key. Electrolytes, LFTs, and chest radiographs are useful. Continuation of most medications is recommended. Management of these patients with a pulmonologist or a cystic fibrosis specialist is best.

Postoperative Pulmonary Complications

Postoperative pulmonary complications develop in 5% to 10% of patients undergoing nonthoracic surgery and in 22% of high-risk patients. Established risk factors for pulmonary complications include the following[132]:

- History of cigarette use (current or exceeding 40 pack-years)
- ASA-PS scores of 2 or more
- Age 70 years or more
- COPD
- Neck, thoracic, upper abdominal, aortic, or neurologic surgical procedures
- Anticipated prolonged procedures (≥2 hours)
- Planned general anesthesia (especially with endotracheal intubation)
- Albumin concentration less than 35 g/dL
- Inability to walk two blocks on the level or to climb one flight of stairs
- BMI of 30 or more

Surprisingly absent in the foregoing list are asthma, analysis of arterial blood gases, or PFT results. The risk of complications is surprisingly low in patients with well-controlled asthma or in those treated preoperatively with corticosteroids.[133] The risk is higher in asthmatic patients with recent exacerbations, prior postoperative pulmonary complications, recent hospitalizations, or endotracheal intubations for asthma. Analysis of arterial blood gases is useful in predicting pulmonary function after lung resection operations, but it does not predict the risk of complications. The degree of airway obstruction, measured by the FEV_1, is not predictive of pulmonary complications.[111] The role of PFTs may be for diagnosis ("Is dyspnea caused by lung disease or heart failure?") or to assess management ("Can dyspnea or wheezing be improved further?"), but PFTs should *not* be used as a risk assessment tool or to deny a beneficial procedure.[111]

BOX 38-12 ***Risk Factors for Postoperative Pulmonary Complications***

PATIENT-RELATED

- Age ≥60 yr
- ASA-PS class ≥2
- Heart failure
- Partial or total functional dependence
- Chronic obstructive pulmonary disease
- Weight loss
- Delirium
- Cigarette smoking
- Alcohol use
- Abnormal chest examination findings

PROCEDURE-RELATED

- Thoracic surgery
- Abdominal surgery
- Neurosurgery
- Head and neck surgery
- Emergency surgery
- Vascular surgery
- Use of general anesthesia
- Blood product transfusion

LABORATORY TEST–RELATED

- Albumin level <35 g/L
- Abnormal chest radiograph
- BUN level >7.5 mmol/L (>21 mg/dL)

From Smetana GW, Lawrence VA, Cornell JE, et al: Preoperative pulmonary risk stratification for noncardiothoracic surgery: systematic review for the American College of Physicians, Ann Intern Med *144:581-595, 2006.*
ASA-PS, American Society of Anesthesiologists physical status; *BUN,* blood urea nitrogen.

Box 38-12 lists the laboratory results and the patient-related, procedure-related, and laboratory test–related determinants of perioperative pulmonary complications.[111] Some of these factors can be modified to alter risk. The pulmonary status of patients with recent exacerbations or infections must be improved whenever possible. Patients at high risk may require prescriptions for antibiotics, bronchodilators, and steroids; referrals to pulmonologists or internists; or delayed surgical procedures. Effective measures to decrease pulmonary complications include the following: a change in perioperative management, including altering the planned surgical procedure, if possible; discussing alternatives to general anesthesia, especially when a regional technique (see also Chapters 56 and 57) is an option; and educating the patient about the benefits of epidural pain management (see also Chapter 98).

ENDOCRINE DISORDERS

See also Chapter 39.

Diabetes Mellitus

Type 1 diabetes is an autoimmune disease resulting in destruction of pancreatic insulin-producing (β) cells. These patients, who have an absolute deficiency of insulin but normal sensitivity to insulin, are at risk of ketoacidosis and generally have an onset of disease at a younger

age. Because of the often difficult nature of control of type 1 diabetes and its long duration, by the time these individuals reach adulthood they are at increased risk of premature vascular disease, especially myocardial ischemia, even in the second decade of life. Type 2 diabetes is initially a result of insulin resistance, which can eventually result in pancreatic "burnout." It is usually found in older, overweight adults. Classifying diabetes with terms such as "insulin dependent," "non–insulin dependent," or "adult onset" is confusing and not recommended.

In the United States, 25.8 million persons (8.3% of the population) have diabetes, and 2 million new cases occur each year. Up to one third of patients are diagnosed only after developing significant diabetes-related complications. Unfortunately, the symptoms of diabetes are nonspecific, so the history, other than a family history of the disease, does not reliably screen for disease. Patients who are overweight, have excessive abdominal fat (even if BMI is normal), take steroids, or have polycystic ovarian syndrome are at increased risk. Certain ethnic groups (Native American, non-Hispanic black, Hispanic, South Asian) are also at higher risk.

Diabetic patients are at risk for multiorgan dysfunction, including renal insufficiency, stroke, peripheral neuropathy, autonomic dysfunction, and cardiovascular disease. Delayed gastric emptying, retinopathy, and reduced joint mobility occur in these patients. Diabetes is considered a CAD equivalent,[134] and it is a risk factor for perioperative cardiac complications on a par with previous MI.[47] Autonomic neuropathy and erectile dysfunction are strong predictors of silent ischemia in these patients. Poorly controlled blood glucose concentrations and longer duration of disease also correlate with cardiac risk.

Heart failure is twice as common in men and five times as common in women with diabetes as in persons without diabetes. Poor glycemic control is associated with an increased risk for heart failure, with both systolic and diastolic dysfunction. Diabetic patients are at increased risk for renal failure perioperatively and for postoperative infections. Chronic kidney disease (CKD) is usually asymptomatic until quite advanced. Diabetes is responsible for almost half of the patients requiring dialysis in the United States. "Screening" for kidney disease is accepted practice in patients with diabetes, likely using serum creatinine measurement and an estimated glomerular filtration rate (eGFR).[135] Patients with poorly controlled diabetes develop stiff joint syndrome with reduced cervical mobility that may affect airway management.

The preoperative evaluation should assess organ damage and blood glucose control. The history and physical examination focus on the cardiovascular, renal, and neurologic systems. Ischemic heart disease is often asymptomatic in the diabetic patient. Inquiring about early satiety, erectile dysfunction, numbness in extremities, and postprandial vomiting is important. Documenting pulses, skin breakdown, sensory examination, and orthostatic vital signs is important in most diabetic patients, particularly in those with long-standing disease or poor diabetes control. Patients with autonomic dysfunction (or hypovolemia) have more than a 20-mm Hg decrease in systolic BP, or more than a 10-mm Hg decrease in diastolic BP when changing from a supine to standing position. An ECG, in addition to determinations of electrolytes, BUN, creatinine, and blood glucose, is needed. Frequently, patients are not fasting when they are evaluated in a preoperative clinic, and relying on reported glucose values is problematic. If patients bring a diary of multiple glucose values at varying times of the day (preprandial and postprandial), one can estimate the adequacy of therapy. The glycosylated hemoglobin (HbA_{1c}) level is not influenced by fasting and can identify patients with poor diabetes control.[136] The American Diabetes Association recommends a target HbA_{1c} of less than 7%. Suggestions for hypoglycemic medication management on the day of surgery are shown in Box 38-3 and are discussed in Chapter 39. Poor long-term control of the disease is associated with infections and worse outcomes, especially for certain procedures such as joint replacements. Optimization of glucose control is a goal even before these patients proceed with surgery. The goals of perioperative diabetic management include avoidance of hypoglycemia and marked hyperglycemia. Tight perioperative glucose control in the immediate perioperative period is controversial. Patients with poor preoperative management of glucose are more likely to have diabetes that is out of control intraoperatively and postoperatively.[136] Thus, aggressive management of hyperglycemia may theoretically help decrease postoperative complications. However, these theoretical clinical benefits of intraoperative intensive glucose control have not been observed in randomized trials of surgical patients.[137]

Thyroid Disease

Thyroid hormones are important for metabolism and its regulation (see also Chapter 39). Mild to moderate thyroid dysfunction probably has minimal impact perioperatively.[138] Significant hyperthyroidism or hypothyroidism appears to increase perioperative risk. Hyperthyroid patients may have tachycardia, arrhythmias, palpitations, tremors, weight loss, and diarrhea. Hypothyroid patients may be hypotensive, bradycardic, and lethargic and may demonstrate weight gain, depressed cardiac function, pericardial effusions, and impaired ventilatory response to hypoxia and hypercarbia. Symptoms and findings of both hypothyroidism and hyperthyroidism can be subtle and nonspecific, particularly in older adults. Patients may have goiters with related symptoms such as dysphagia, dyspnea, wheezing, and orthopnea. Graves ophthalmopathy (or proptosis) is more common in smokers. Patients taking amiodarone are at risk of hypothyroidism and need evaluation of thyroid function before surgery.

Determination of medical therapy is important. Patients with a history of chronic thyroid disease need preoperative thyroid function tests. If symptoms and therapy have not changed, tests within the 6 months before the surgical procedure are generally adequate. Thyroid-stimulating hormone (TSH) assays are best to evaluate for hypothyroidism. Measuring free triiodothyronine (T_3), free thyroxine (T_4), and TSH levels is useful in hyperthyroid patients and avoids the confusion of protein-binding effects seen with total hormone levels. Elective surgical procedures should be postponed until patients are euthyroid. Surgery, stress, or illness can precipitate myxedema

or thyroid storm in patients with untreated or severe thyroid dysfunction. Consultation with an endocrinologist is necessary if surgery is urgent in patients with thyroid dysfunction. Hyperthyroid patients can be treated with β-adrenergic blockers, antithyroid medications, and steroids if surgery is urgent. Chest radiography or CT is useful to evaluate tracheal or mediastinal involvement by a goiter. Continuation of medications, such as thyroid replacement and antithyroid drugs (e.g., propylthiouracil), on the day of the surgical procedure is important.

Parathyroid Disease

Parathyroid hormone regulates calcium; most cases of hyperparathyroidism are discovered when an elevated calcium level is found incidentally during diagnostic testing. *Primary* hyperparathyroidism is caused by a primary disorder of the parathyroid glands (adenomas or hyperplasia). *Secondary* hyperparathyroidism is parathyroid gland hyperplasia caused by hyperphosphatemia and hypocalcemia related to chronic renal failure. *Tertiary* hyperparathyroidism occurs when the parathyroid hyperplasia in secondary hyperparathyroidism functions autonomously, resulting in hypercalcemia. Hypercalcemia from parathyroid disease is associated with osteoporosis and bone loss. Rarely do the parathyroid glands become enlarged enough to compromise the airway. Hypoparathyroidism is rare, but it can result from total parathyroidectomy.

Hypothalamic-Pituitary-Adrenal Disorders

Corticotropin-releasing hormone is released by the hypothalamus and regulates adrenocorticotropic hormone (ACTH) from the anterior pituitary gland, which in turn regulates cortisol from the adrenal cortex. A key component is the negative feedback suppression imposed by endogenous or exogenous glucocorticoids. Cortisol secretion varies with the circadian rhythm, and it is highest in the morning; it also increases with stress, fever, hypoglycemia, and surgery. Surgery is one of the most potent activators of the hypothalamic-pituitary-adrenal (HPA) axis. ACTH concentrations increase with incision and during the surgical procedure, but the greatest ACTH secretion occurs during termination of anesthesia, extubation of the trachea, and the immediate postoperative period.[139]

Adrenal hormone excess results from glucocorticoid treatment of disorders such as asthma or inflammatory diseases or from pituitary or adrenal tumors. Cushing disease denotes the constellation of findings associated with a pituitary tumor; Cushing syndrome refers to the same findings resulting from an adrenal tumor or hyperplasia, ectopic ACTH from neoplasms, or exogenous steroids. Its major manifestations are hypertension, weight gain, myopathy, diabetes, "moon facies," and "buffalo hump," all of which can affect airway management. Striae, easy bruising, and virilization in female patients are common. Exogenous steroids suppress the adrenals and thus blunt the normal hypersecretion expected from stress or surgery. Therefore, patients at risk need "steroid coverage." An ECG and electrolyte and glucose determinations are necessary preoperatively. In spite of bruising easily, patients have normal coagulation profiles.

Adrenal insufficiency results from destruction of the pituitary, destruction of the adrenal glands, or long-term exogenous glucocorticoid administration. Tuberculosis and HIV infection can cause primary hypoadrenalism. Prednisone or its equivalent in doses higher than 20 mg/day for more than 3 weeks suppresses the HPA axis. The axis is not suppressed with doses lower than 5 mg/day of prednisone or its equivalent. Intermediate doses of steroids taken for more than 3 weeks have equivocal effects on the HPA axis. This risk remains for up to 1 year after cessation of steroids. Patients with adrenal insufficiency have weakness, weight loss, hypotension, orthostasis, hypovolemia, hyperpigmentation, and electrolyte abnormalities. Electrolytes and orthostatic vital signs therefore must be checked.

Serum cortisol and plasma ACTH can establish the diagnosis and cause of adrenal insufficiency in most cases. If the serum cortisol concentration is inappropriately low and a simultaneous plasma ACTH concentration is very high, primary adrenal insufficiency (primary adrenal disease) is the cause. Secondary (pituitary disease) or tertiary (hypothalamic disease) is the diagnosis if both the serum cortisol and plasma ACTH concentrations are inappropriately low. In more urgent situations, one may not be able to wait for results of the ACTH determination, in which case, an ACTH stimulation test can be performed (unless the diagnosis has been ruled out by a basal serum cortisol value in the upper end of the reference range or higher).[140] Cosyntropin is synthetic ACTH, and it can be administered in either a high-dose or a low-dose stimulation test. The time of the day is not important because in patients with adrenal insufficiency, the response to cosyntropin is the same in the morning and the afternoon. A normal response to the high-dose (250 μg as an intravenous bolus) ACTH stimulation test is a rise in serum cortisol concentration, measured after 30 to 60 minutes, to a peak greater than 18 to 20 μg/dL. Low-dose (1-μg intravenous bolus) ACTH causes an increase in cortisol concentrations of more than 16 to 20 μg/dL after 20 to 30 minutes. For both tests, a subnormal response confirms the diagnosis of adrenal insufficiency, but further studies are necessary to establish the type and cause. Patients continue steroids on the day of surgery and may need supplementation with additional doses.

Aldosterone, which is produced by the adrenal cortex, regulates volume and electrolytes (absorption of sodium and chloride; secretion of potassium and hydrogen ions). It is controlled by the renin-angiotensin system, not the HPA axis.

Multiple Endocrine Neoplasia Syndromes

The multiple endocrine neoplasia (MEN) syndromes are rare, but recognition is important both for treatment and for evaluation of family members.[141] Multiple endocrine neoplasia type 2 (MEN 2) is subclassified into three distinct syndromes: MEN 2A, MEN 2B, and familial medullary thyroid cancer. The inheritance of MEN 1 and 2 is autosomal dominant. Hyperparathyroidism is the most common manifestation of MEN 1, with almost 100% penetrance by the age of 40 to 50 years. Hypersecretion of gastrin in the Zollinger-Ellison syndrome in MEN 1 often manifests with multiple peptic ulcers. The MEN 1

gene has been identified, and therefore testing for MEN 1 mutations is possible. Little evidence indicates that early presymptomatic detection reduces morbidity or mortality in MEN 1. Screening of asymptomatic family members can also be done by measurement of serum calcium because of the high penetrance of hyperparathyroidism in MEN 1.

Because undiagnosed pheochromocytoma can cause substantial morbidity or even death during surgical procedures, it is important to consider this diagnosis as a component of possible MEN 2 and, if present, to remove the tumor before removing other endocrine tumors. Extraadrenal pheochromocytoma is rare in MEN 2, but bilateral adrenal disease is common. It is unusual for pheochromocytoma to precede the development of medullary thyroid carcinoma or be the initial manifestation of MEN 2. Hyperparathyroidism in MEN 2A is often clinically occult. In contrast to MEN 1, in which the long-term benefit of early diagnosis by genetic screening is not well established, early diagnosis by screening of at-risk family members in MEN 2 kindred is essential because medullary thyroid carcinoma is a life-threatening disease that can be cured or prevented by early thyroidectomy.

Pheochromocytoma

Catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla or sympathetic ganglia are referred to as pheochromocytomas and extraadrenal catecholamine-secreting paragangliomas (extraadrenal pheochromocytomas), respectively.[142] Nonetheless, the term *pheochromocytoma* is often used for both types of tumors. Pheochromocytomas are discovered when patients present with symptoms, a suggestive family history, or an incidental adrenal mass. Approximately 3% to 10% of adrenal "incidentalomas" prove to be pheochromocytomas. The classic triad of symptoms includes episodic headache, sweating, and tachycardia. Paroxysmal hypertension occurs in half of patients, whereas most of the remaining patients have what appears to be essential hypertension. Approximately 5% to 15% of patients have *normal* BP. Headache, which is variable in severity and duration, occurs in up to 90% of symptomatic patients. *Paroxysmal* hypertension is a classic sign of pheochromocytoma, but it is nonspecific for the disorder. Sweating occurs in up to 60% to 70% of patients. Other symptoms include palpitations, dyspnea, weakness, and panic attacks (particularly in patients with tumors that produce an increase in epinephrine). Pallor, orthostatic hypotension, blurred vision, weight loss, polyuria, polydipsia, hyperglycemia, psychiatric disorders, cardiopulmonary dysfunction (particularly with the initiation of β-adrenergic blockers), dilated cardiomyopathy (from excess catecholamines), and marked hypertension have been reported. Pheochromocytoma is suspected in patients who have one or more of the following:

- Hyperadrenergic spells (nonexertional palpitations, diaphoresis, headache, tremor, pallor)
- Hypertension that is difficult to control
- Familial syndrome that includes catecholamine-secreting tumors (e.g., MEN 2, neurofibromatosis type 1, von Hippel–Lindau disease) (These individuals often have bilateral disease.)
- Family history of pheochromocytoma
- Incidentally discovered adrenal mass
- Unusual BP response during anesthesia, surgery, or angiography
- Hypertension at a young age (e.g., <20 years old)
- Idiopathic dilated cardiomyopathy
- A history of gastric stromal tumor or pulmonary chondromas (Carney triad)

Measurements of urinary and plasma fractionated metanephrines and catecholamines generally establish the diagnosis. History and physical examination should focus on the cardiovascular system (including findings of heart failure) and evaluation of vital signs (including orthostatic BP). An ECG and determinations of electrolytes, BUN, creatinine, and glucose are needed. CT, echocardiography, and cardiac consultation may be useful.

All patients with pheochromocytoma must be managed with preoperative α-adrenergic blockade at least 7 to 10 days before the surgical procedure, with the goal of normalizing BP and volume status. Phenoxybenzamine is the preferred drug for preoperative preparation to control arterial BP and arrhythmias. It is an irreversible, long-acting, nonspecific α-adrenergic blocking agent. The initial dose is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg every 2 to 3 days as needed to control BP and spells. Most patients need between 20 and 100 mg daily. BP is measured twice daily with the patient lying, sitting, and standing. The target BP is less than 120/80 mm Hg seated, with systolic BP less than 90 mm Hg while standing. Patients should be warned about common side effects of orthostasis, marked fatigue, and nasal congestion. Selective α_1-adrenergic blocking agents (e.g., prazosin, terazosin, doxazosin) are preferable to phenoxybenzamine when long-term pharmacologic treatment is indicated (e.g., metastatic pheochromocytoma) because of the favorable side effect profiles of these drugs. The disadvantage of using these agents preoperatively is their incomplete degree of α-adrenergic blockade, thus resulting in more episodes of intraoperative hypertension.[143] Conversely, preoperative preparation with phenoxybenzamine is associated with more postresection hypotension than is preparation with selective α_1-adrenergic blocking agents.[143]

After adequate α-adrenergic blockade is achieved, β-adrenergic blockade may be started cautiously with short-acting drugs. For example, 10 mg of propranolol every 6 hours can be used. After 24 to 48 hours, if the patient tolerates β-adrenergic blockade, a long-acting preparation (e.g., metoprolol, atenolol) can be substituted. The dose is then adjusted to control tachycardia with an HR goal of 60 to 80 beats/minute. β-Adrenergic blockade should *never* be initiated before α-adrenergic blockade because blockade of vasodilatory peripheral β-adrenergic receptors with unopposed α-adrenergic receptor stimulation can lead to a further elevation in BP. Additionally, depression of cardiac function with sustained hypertension can precipitate acute heart failure and death. Chronic catecholamine excess can also

produce cardiomyopathy that may become evident with the initiation of β-adrenergic blockade, with resulting acute pulmonary edema.

Although perioperative α-adrenergic blockade is most commonly used, another option involves the administration of a calcium channel blocker.[144] Nicardipine is the most commonly used calcium channel blocker for pheochromocytoma management. The starting dose of the sustained release preparation is 30 mg orally twice a day. The exclusive use of calcium channel blockers for the perioperative management of patients with catecholamine-secreting tumors does not prevent all hemodynamic changes; however, morbidity and mortality remain low with this class of drug. The main role for calcium channel blockers is likely to supplement α- and β-adrenergic blockade when BP control is inadequate or in patients with intolerable side effects. Patients with acute hypertensive crises require hospitalization and treatment with intravenous sodium nitroprusside, phentolamine, or nicardipine.

RENAL DISEASE

The type and degree of renal impairment are important. Patients with renal dysfunction have many associated comorbidities, generally related to the accompanying vasculopathy. Hypertension, cardiovascular disease, and electrolyte disturbances are most common. CKD is defined as a decreased GFR of less than 60 mL/minute/1.73 m^2 for at least 3 months, or significant proteinuria. Chronic renal failure is defined as a GFR less than 15 mL/minute/1.73 m^2. End-stage renal disease (ESRD) is loss of renal function for 3 or more months. Acute kidney injury (AKI) is a sudden decrease in renal function with the possible decrease in urine output. Two consensus-based criteria for classifying AKI are the RIFLE (risk, injury, failure, loss of function, ESRD) and Acute Kidney Injury Network (AKIN) classification schemes.[145,146] Diabetes accounts for almost half of all ESRD cases, and hypertension accounts for more than one fourth. Polycystic kidney disease (autosomal dominant 90% of time) is the causative factor in 10% of ESRD cases and can be associated with intracranial aneurysms and MVP.

AKI may be reversible if precipitating factors are identified and corrected. Classifying AKI into prerenal, renal, and postrenal causes allows for a systematic approach. Prerenal causes can often be differentiated by calculating the BUN-to-creatinine ratio. A ratio less than 20 suggests prerenal etiologies, with hypovolemia or hypotension the most common. A fractional excretion of sodium (FEN_a) less than 1% also suggests prerenal azotemia (in the absence of concomitant diuretic administration) and can be calculated using the following formula:

$$FEN_a = \frac{PCr/UCr}{PNa/UNa}$$

Obstruction results in dilated ureters and enlarged kidneys, and it is always considered in the differential diagnosis of AKI. Prompt identification with ultrasound should lead to attempts to decompress the outflow tract. Rhabdomyolysis can cause AKI and is treatable.

GFR decreases with age; the renal reserve of a normal 80-year-old person is less than half that of a 40-year-old person. The creatinine level is often not an accurate indicator of renal function, especially in older individuals.[147] The GFR can be reduced by 50% without a rise in creatinine. Creatinine does not exceed the normal limits until GFR has fallen to less than 50 mL/minute. The Cockcroft-Gault equation can be used to calculate an eGFR:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age}) \times \text{Weight (kg)} \times (0.85 \text{ If female})}{72 \times \text{Serum creatinine(mg/dL)}}$$

Another formula is the Modification of Diet in Renal Disease (MDRD)[135] equation, which is likely more accurate:

$$\text{eGFR (mL/kg/minute)} = \frac{1086 \times \text{Serum creatinine} \times \text{Age}}{(0.742 \text{ If female}) \times (1.210 \text{ If African descent})}$$

Online calculators to estimate renal function are available at www.nephron.com. Calculating an eGFR is necessary in older patients, those with an elevated serum creatinine, or with other risk factors for CKD.[147] Given the inaccuracy of these equations at lower creatinine concentrations, values of eGFR that are greater than 60 mL/kg/minute/1.73m^2 should simply be reported as ">60 mL/kg/minute/1.73m^2 ."

CKD is a significant risk factor for perioperative cardiovascular morbidity and mortality. For example, a creatinine concentration higher than 2.0 mg/dL is a risk factor in the RCRI.[47] The incidence of death from CAD in patients with both diabetes and ESRD requiring hemodialysis is 8.2% per year. Pericarditis, pericardial effusions, and diastolic and systolic dysfunction can also be present. Valvular heart disease is common in patients undergoing maintenance dialysis. Abnormalities include valvular and annular thickening, as well as calcification of the heart valves that results in regurgitation or stenosis.[148] Mitral or aortic valve calcifications (40% and 55% of patients, respectively) and stenosis (11% to 13%) occur. Valvular calcifications progress to stenosis at an accelerated rate in patients undergoing dialysis.[47] Systemic hypertension is almost ubiquitous in these patients, but it is generally easier to manage with initiation of dialysis. Pulmonary hypertension and increased cardiac output occur in many patients with an arteriovenous fistula.

Renal failure results in anemia from lack of erythropoietin production by the kidneys; however, excessive treatment of this anemia with erythropoietin may actually increase morbidity and vascular events.[149] Patients with CKD can have platelet dysfunction and increased bleeding, despite normal platelet counts, prothrombin times (PTs), and aPTT. Once dialysis is begun, patients become more prone to hypercoagulable states. Chronic metabolic acidosis is common, but it is usually mild and compensated for by chronic hyperventilation. Patients may have electrolyte (including calcium) abnormalities, pulmonary edema, peripheral edema, hypercholesterolemia, and hypoalbuminemia. Hyperkalemia is the most serious electrolyte disturbance. Hypocalcemia is common in patients undergoing dialysis, although with long-term disease, secondary and tertiary hyperparathyroidism eventually develops. Chronically elevated troponin and creatine kinase levels are common in patients undergoing dialysis. Worsening renal function should be suspected in

diabetic patients with ESRD who develop improved glycemic control or unexpected hypoglycemia because insulin is metabolized by the kidneys. Autonomic and peripheral (sensory and motor) neuropathies can occur.

Among individuals undergoing cardiac surgery, several simple preoperative risk indices have been developed for accurately predicting postoperative AKI requiring dialysis.[150,151] Important risk factors in these indices include complex surgery, nonelective surgery, preexisting renal insufficiency, diabetes, heart failure, female gender, and COPD. In the setting of noncardiac surgery, identified risk factors for AKI include increased age, male gender, symptomatic heart failure, hypertension, liver disease (including ascites), preexisting renal insufficiency, PAD, COPD, nonelective surgery, and intraperitoneal surgery.[152,153] Preoperative identification of at-risk patients can help facilitate care, such as preoperative hydration and avoidance of hypovolemia. This approach may require preoperative hospital admission. Nonsteroidal antiinflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors interfere with renal perfusion autoregulation; they should be avoided or discontinued in patients with renal insufficiency. The use of these drugs in patients with normal renal function does not increase the risks of postoperative AKI.[154] Although long-term ACEI and ARB use prevents deterioration of renal function in patients with diabetes or renal insufficiency, the use of these drugs may worsen function during hypoperfusion states and AKI.

Many drugs are metabolized or cleared by the kidneys. Drugs with particular implications for anesthesia and surgery are the LMWHs because no easy method of monitoring the anticoagulation effects exists. All the LMWHs available in the United States are cleared by the kidneys and are not removed during dialysis; thus, they have a prolonged duration of action in patients with CKD.

The emphases of the preoperative evaluation of patients with renal insufficiency are on the cardiovascular system, cerebrovascular system, fluid volume, and electrolyte status. The early stages of CKD typically cause no symptoms. Inquiring about the cardiovascular systems (i.e., chest pain, orthopnea, paroxysmal nocturnal dyspnea), urine output, associated comorbidities, medications, and dialysis schedules is vital. Monitoring of patients' weight is important for assessing volume status. Patients with or at risk of renal disease (especially if they have 2 or more of the following risk factors: diabetes, poorly controlled hypertension, advanced age) need an ECG and determinations of electrolytes, calcium, glucose, albumin, BUN, and creatinine function. Further evaluation is needed if the ECG shows LVH (hypertension), peaked T waves (hyperkalemia), flattened T waves, a prolonged PR interval, or a prolonged QT interval (hypokalemia). A chest radiograph (infection, volume overload), echocardiogram (murmurs, heart failure), and cardiology evaluation may be necessary. Venous access sites or blood draws from the brachial, cephalic (antecubital), and central veins in the nondominant upper extremity are avoided in patients who may eventually need fistulas in those locations for dialysis.

Preoperative renal replacement therapy (dialysis) schedules are coordinated, with scheduling of the surgical procedure ideally within 24 hours after dialysis. In elective surgical cases, dialysis should be performed within 24 hours of surgery but not immediately before, given the risks of acute volume depletion and electrolyte alterations. Dialysis is associated with fluid shifts and electrolyte (sodium, potassium, magnesium, phosphate) imbalance, especially related to shifting of electrolytes between intracellular and extracellular compartments. Dialysis is performed to correct volume overload, hyperkalemia, and acidosis. Coordination of the timing of dialysis in relation to elective surgery is an important aspect of preoperative care.

Contrast-Induced Nephropathy

Contrast-induced nephropathy is defined as a 25% increase in creatinine above baseline after radiocontrast administration. Patients with diabetes and CKD are at greatest risk, although radiocontrast media cause a transient decrease in GFR in most individuals. Renal failure requiring dialysis after contrast-induced nephropathy is associated with a poor prognosis, with less than a 20% 2-year survival and one third of patients dying during the initial hospitalization. A proposed preventive strategy has been developed for patients with CKD (GFR <60 mL/kg/minute) who are undergoing PCI (Box 38-13), which may be beneficial for patients undergoing any procedure involving contrast administration. However, more recent large randomized trials did not find that *N*-acetylcysteine decreased rates of contrast-induced nephropathy (see Box 38-13).[155]

HEPATIC DISORDERS

Liver disease can affect the hepatocytes, the biliary system, or both (see Chapters 22 and 73). Liver disease affects protein synthesis (e.g., coagulation factors, albumin), bile

BOX 38-13 ***Checklist for Contrast-Induced Nephropathy Risk Stratification and Prevention***

1. Calculate the eGFR: the risk is high if the eGFR is <60 mL/min/1.73 m^2.
2. If the eGFR is <15 mL/min/1.73 m^2, consider a nephrology consultation to plan for the possible need for dialysis after the procedure.
3. Determine the patient's history of diabetes (the risk is increased five times with diabetes).
4. Discuss the contrast-induced nephropathy risk in the informed consent process.
5. Discontinue nonsteroidal antiinflammatory drugs and other nephrotoxic drugs.
6. Discontinue diuretics the day before and the day of the procedure.
7. Administer hydration with intravenous saline or sodium bicarbonate at 1.5 mL/kg/hr starting 3 hours before contrast and continuing 6 hours after contrast administration.
8. Administer *N*-acetylcysteine, 1200 mg orally twice a day before contrast administration and 1600 mg orally twice a day after contrast administration.
9. The preferred urine output is >150 mL/hr after the procedure.
10. Avoid additional contrast media for 10 days.

eGFR, Estimated glomerular filtration rate.

regulation, and metabolism of drugs or toxins. Hepatocellular diseases, including hepatitis (viral, alcoholic, autoimmune hepatitis) and hepatocellular carcinoma, affect the hepatocytes and synthetic function of the liver. Obstructive disorders, including choledocholithiasis, bile duct tumors (extrahepatic), primary biliary cirrhosis (intrahepatic), and primary sclerosing cholangitis (extrahepatic and intrahepatic), cause bile stasis. Most drug-induced liver disease, as well as some forms of viral hepatitis, affect both hepatocytes and the biliary system.

The patient's history uncovers the underlying disease etiology, therapies, and associated complications. Important issues to explore include the cause and degree of hepatic dysfunction. Some patients with liver disease may be asymptomatic, whereas others may complain of fatigue, weight loss, dark urine, pale stools, pruritus, right upper quadrant pain, bloating, and jaundice. Weight and vital signs (including oxygen saturation) are needed. Physical examination may reveal jaundice, bruising, ascites, pleural effusions, peripheral edema, or hypoxia. The presence of encephalopathy, coagulopathy, ascites, volume overload, and infection need to be determined before surgery. The bilirubin level generally must exceed 2.5 mg/dL before icterus can be seen in mucous membranes and sclerae. Examination may find hepatomegaly, splenomegaly, and altered mental status. New-onset or worsening encephalopathy should prompt an evaluation for precipitating factors such as worsening liver disease, infection, drug effects, bleeding, or electrolyte disturbances.

An ECG, CBC (with platelet count), electrolytes, BUN, creatinine, LFTs, albumin, and PT are helpful. Patients suspected of having hepatitis may require screening for the hepatitis A immunoglobulin M (IgM) antibody, the hepatitis B surface and core antigens, the hepatitis B surface antibody, and the hepatitis C antibody. A chest radiograph can identify effusions, whereas ammonia levels may help in the patient with encephalopathy. Coagulopathy can be a result of vitamin K deficiency (from cholestasis), factor deficiency (from loss of synthetic function), or thrombocytopenia (from splenomegaly and portal hypertension). Therapy to correct coagulopathy should be directed at the cause. Vitamin K, fresh frozen plasma, or platelets may correct deficiencies. Vitamin K, taken at 1 to 5 mg orally or subcutaneously daily for 1 to 3 days, may correct a prolonged PT and carries minimal risk. The coagulopathy in patients with synthetic failure is not likely to correct, thus necessitating fresh frozen plasma transfusion aiming for an international normalized ratio (INR) of less than 1.5. Although anemia is a predictor of poor perioperative outcome in patients with cirrhosis,[156] correction of any anemia with transfusion remains controversial. Lactulose (30 mL orally every 6 hours for 3 days preoperatively) with the last dose within 12 hours of surgery, or oral bile salts with intravenous hydration beginning the night before the operation, may reduce perioperative progression of renal disease in patients at risk.[157] Reduction of ascites preoperatively may decrease the risk of wound dehiscence and improve pulmonary function. Sodium restriction (in diet and intravenous solutions), diuretics (especially spironolactone), and even paracentesis are useful. If ascites fluid is aspirated, it is important to analyze it for infection. Encephalopathy is frequently precipitated by an additional acute insult such as infection, gastrointestinal bleeding, hypovolemia, or sedatives. It is therefore important to determine reversible factors and treat them accordingly. Lactulose (30 mL every 6 hours orally) is first-line therapy. Addressing nutritional deficiencies with enteral or parental supplementation may have benefits, especially in alcoholic patients. Patients who abuse alcohol may be at risk for neurologic deterioration (i.e., Wernicke-Korsakoff syndrome) if thiamine, folate, and vitamin B_{12} supplements are not provided, especially when these patients are given nutrition or glucose. These patients are also at risk of alcohol withdrawal syndromes.

In some cases, it may be appropriate to delay elective surgical procedures until an acute episode of hepatitis (or exacerbation of chronic disease) has resolved or until a diagnosis is established for newly discovered hepatic dysfunction. Elective surgery is contraindicated in patients with acute or fulminant liver disease, including alcoholic, viral, or undefined hepatitis. The perioperative risk of patients with chronic hepatitis or cirrhosis is predicted by histologic severity (i.e., bridging or multilobular necrosis on biopsy), portal hypertension (i.e., ascites, varices, bleeding), and impairment of liver function (both synthetic and excretory function). Patients with severe liver disease have increased perioperative morbidity and mortality; common adverse events are bleeding, infection, liver failure, and hepatorenal syndrome. Predictors of poor perioperative outcome in patients with liver disease include the following:

- Child-Turcotte-Pugh class C cirrhosis, which is calculated using bilirubin level, albumin concentration, PT, severity of ascites, and severity of encephalopathy (Table 38-9)
- Model for end-stage liver disease (MELD)[158] score of 15 or more (The MELD score is calculated using serum bilirubin, INR, and serum creatinine concentrations.)
- Acute hepatitis (viral or alcoholic)
- Chronic active hepatitis with jaundice, encephalopathy, coagulopathy, or elevated liver enzymes
- Abdominal surgical procedures
- PT prolongation of 3 seconds or more that is refractive to vitamin K therapy

Patients with significant abnormalities or at high risk are best managed by a liver specialist.

Hepatitis

Hepatitis is defined by inflammation of hepatocytes, and it can be caused by drugs, alcohol, viruses (hepatitis A, B,

TABLE 38-9 **CHILD-TURCOTTE-PUGH CLASSIFICATION***

Parameter	1 Point	2 Points	3 Points
Ascites	Absent	Slight	Moderate

Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds over control)	<4	4-6	>6
Encephalopathy	None	Grade 1-2	Grade 3-4

*Class A, <7 points; class B, 7 to 9 points; class C, >9 points.

C, D, and E), and autoimmune diseases (see also Chapter 74). All these disorders have both an acute phase and a chronic phase, which can progress to cirrhosis (irreversible fibrosis of the liver). Risk factors for hepatitis are alcohol use, sexual activity (multiple partners, sex industry workers, sex with sex industry workers, men who have sex with men), intravenous drug use, blood transfusions administered before 1992, obesity (i.e., nonalcoholic steatohepatitis), tattoos, body piercing, and travel to developing countries. Hepatitis A, which is caused by contaminated food or water or by contact with an infected person, rarely progresses beyond the acute illness. A remote history of hepatitis A has no perioperative significance. Hepatitis B is transmitted by sexual activity or contact with blood (rarely after implementation of screening in 1986). It varies in severity, but it has become much less common since the widespread use of hepatitis B vaccination. Hepatitis C is transmitted primarily through blood exposure (all blood has been screened since 1992), most often among intravenous drug users. Many patients are unaware of infection because the acute phase is often asymptomatic. Hepatitis C infection can then advance to cirrhosis. Hepatitis D occurs only in conjunction with hepatitis B infection, whereas hepatitis E is rare in developed countries. Alcoholic hepatitis generally occurs after at least 10 years of moderate to heavy daily alcohol intake (i.e., three or more drinks per day for women, and five or more drinks per day for men) and may progress to cirrhosis. Autoimmune hepatitis primarily affects young women, and its etiology remains unknown. Many different drugs, including herbal and over-the-counter preparations, can cause hepatitis; examples of inciting medications are statins, isoniazid, and acetaminophen.

Obstructive Jaundice

Extrahepatic bile duct obstruction may be caused by gallstones, tumors (e.g., pancreatic, gallbladder, bile duct, ampulla of Vater), or scarring. Patients can present with jaundice, pruritus, and abdominal pain. Predictors of surgical mortality are a hemoglobin concentration of less than 10 g/dL, serum bilirubin exceeding 20 mg/dL, and serum albumin lower than 2.5 g/dL.[159] Perioperative AKI occurs in up to 8% of these patients,[160] and it may be prevented with administration of bile salts or lactulose.[157]

Miscellaneous Liver Diseases

Wilson disease, hemochromatosis, and α_1-antitrypsin deficiency are uncommon hereditary causes of liver disease. Gilbert disease, which is a benign hereditary disorder characterized by a mildly elevated bilirubin level, has no perioperative significance. Obesity can result in nonalcoholic steatohepatitis, also known as "fatty liver," which progresses to abnormal LFTs, fibrosis, cirrhosis, and end-stage liver disease. Primary biliary cirrhosis is an autoimmune disorder that most frequently affects women and is characterized by intrahepatic biliary obstruction and antimitochondrial antibodies. Primary sclerosing cholangitis, which most frequently affects young male patients, is characterized by bile duct destruction that can eventually progress to cirrhosis. It may be idiopathic or associated with inflammatory bowel disease. Acute nonhepatic events, such as sepsis, surgery, and anesthesia, can also cause hepatic dysfunction.

Remote History of "Hepatitis"

Patients may recount a remote history of "having hepatitis" but may be unable to recall little other related medical information. One must take a careful history to determine the circumstances surrounding the onset (e.g., transfusions, travel, high-risk exposures) and whether any sequelae of chronic liver disease are present. It is important to clarify whether the episode occurred during or soon after a surgical procedure. Although halothane is not used in adults in the United States in contemporary practice, individuals who previously had halothane hepatitis may be at risk of cross-sensitivity to other volatile anesthetics with trifluoroacetyl metabolites (e.g., enflurane, isoflurane, desflurane).

Unexpected Elevated Liver Function Tests

Elevated alanine aminotransferase and aspartate aminotransferase reflect damage to hepatocytes; bilirubin measures the liver's ability to conjugate and excrete bile salts; alkaline phosphatase rises with impaired hepatic excretion, whereas albumin or PT measures the synthetic function of the liver. Approximately 1 in 700 preoperative patients are unexpectedly found to have liver diseases, most of which are not severe.[161] Nonetheless, if abnormal LFT values are unexpectedly found, further testing or referral may be necessary. Elevations in alanine transferase or aspartate transferase should prompt hepatitis screening with hepatitis A IgM antibody, hepatitis B surface and core antigens, hepatitis B surface antibody, and hepatitis C antibody. Elevations of alkaline phosphatase or bilirubin, in association with normal or mild to moderate increased transaminase levels, may indicate obstruction in the biliary system. In these cases, abdominal ultrasound, CT scans, or endoscopic retrograde cholangiopancreatography may establish a diagnosis.

Cirrhosis

Cirrhosis is the end result of most hepatotoxic conditions. Cirrhosis often leads to portal hypertension, which is characterized by splenomegaly, esophageal varices, ascites, dependent edema, and pleural effusions. The liver has impaired synthetic (i.e., synthesis of proteins and clotting factors) and metabolic (i.e., clearance of toxins and drugs) functions. Patients may have encephalopathy, bleeding, thrombocytopenia, low albumin levels, and prolonged PT. Pulmonary shunting may cause hypoxemia and pulmonary hypertension (i.e., hepatopulmonary syndrome). Hepatorenal syndrome is renal insufficiency in patients with hepatic disease in the absence of primary renal disease; it may be related to renal hypoperfusion. Jaundiced patients are at particular risk of hepatorenal syndrome. Patients with ascites may also develop spontaneous bacterial peritonitis, which is associated with increased perioperative mortality. Patients with end-stage liver disease also develop a high–cardiac output state, characterized by increased cardiac output and decreased systemic vascular resistance.

The Child-Turcotte-Pugh classification can predict perioperative morbidity and mortality, with especially

high risks in patients assigned to class C (see Table 38-9). The MELD score can also predict perioperative risks, perhaps better than the Child-Turcotte-Pugh classification.[156] Increased perioperative risk is associated with a MELD score exceeding 14.[156] Online calculators are available to calculate MELD scores readily (see www.unos.org).

HEMATOLOGIC DISORDERS

Anemia

Anemia is a very common preoperative hematologic disorder. Preoperative anemia is a recognized risk factor (see also Chapter 61). It may be a known problem or suspected based on a patient's underlying medical conditions or indication for surgery. The goal in the preoperative clinic is to determine its etiology, duration, stability, related symptoms, and therapy (especially transfusions). Inquiring about a personal or family history of anemia is important. Patients at risk for anemia include those with histories of colon cancer, gastrointestinal bleeding, genitourinary bleeding, menorrhagia, chronic infections, inflammatory diseases, nutritional deficiencies, and prior weight reduction procedures (e.g., bariatric surgery). One should also consider the type of surgical procedure, anticipated blood loss, and comorbid conditions that may either affect oxygenation or be affected by hypoxia (e.g., pulmonary, renal, hepatic, cerebrovascular, cardiovascular disease). In addition, an accurate determination of the patient's medications is required, especially because anemia has implications for the risk-to-benefit profile of some medications in the perioperative period, such as β-adrenergic blockers.[50,51] Important components of the preoperative evaluation include assessing for palpitations, fatigue, chest pain, melena, bloody stools, weight loss, pallor, murmurs, hepatosplenomegaly, or lymphadenopathy.

The World Health Organization defines anemia as a hemoglobin level less than 13 g/dL in adult men and less than 12 g/dL in adult women. Risk is directly proportional to the degree of anemia and independent of the patient's other comorbidities.[48,49,162] In addition, any value outside of normal is associated with risk. Nonetheless, simply treating all anemic patients with red blood cell transfusions is not the solution because transfusion itself carries inherent risks.[163] The ASA Task Force on Blood Component Therapy concluded that red blood cells should not be transfused based solely on a hemoglobin level, but rather they should be used to address risks for complications from inadequate oxygenation.[164] A new report will be published by the ASA in 2015. Transfusion is rarely indicated when the hemoglobin level is higher than 10 g/dL and is almost always needed when hemoglobin is less than 6 g/dL[165](see also Chapter 61). In general, the balance of risks versus benefits of transfusing patients with hemoglobin levels between these two thresholds largely depends on comorbid conditions, especially cardiopulmonary disease states. A randomized trial found no advantage of routinely transfusing older patients who were undergoing hip fracture repair to a hemoglobin concentration of 10 g/dL as opposed to 8 g/dL.[52]

Patients with anemia or suspected anemia must have a CBC. In general, a primary care physician or hematologist performs further evaluation of newly diagnosed anemia. Usual initial studies include peripheral smear, mean corpuscular volume (MCV), and reticulocyte count; subsequent studies, such as iron studies, vitamin B_{12}, or folate levels, are guided by findings on the smear and the MCV. In iron deficiency anemia, the MCV, iron, and ferritin are low, whereas total iron binding capacity (TIBC) is high. Although the MCV and TIBC are low or normal, iron and ferritin are normal or high in anemia associated with chronic disease. The MCV is high and the vitamin B_{12} or folate levels are low in macrocytic anemia associated with these deficiencies. Blood type and screening, and in selected cases, preoperative transfusion may be necessary depending on the level of anemia and the degree of anticipated surgical blood loss.

Elective procedures must be postponed in patients found to have significant anemia, regardless of the anticipated blood loss of the planned procedure. This delay allows for evaluation for causes of the anemia, such as occult blood loss (colonoscopy), vitamin deficiencies, or undiagnosed chronic conditions (e.g., CKD). In special circumstances, such as a patient's refusal to receive perioperative blood transfusions or elective procedures with expected significant blood loss in anemic patients, postponement of surgery to facilitate preoperative treatment with recombinant human erythropoietin and iron may be warranted.

Sickle Cell Disease

Sickle cell disease is a hereditary hemoglobinopathy with associated vasoocclusive episodes that are responsible for most associated complications. Patients homozygous for hemoglobin S (HbS) have symptomatic disease; they are at risk for major morbidity and have a shortened life expectancy. Patients with SC disease, who have both HbS and HbC, have a much less severe clinical course with moderate anemia. Heterozygous patients (HbS and HbA) have sickle cell trait and rarely have any related consequences. Preoperative assessment should focus on identification of organ dysfunction and acute exacerbations.[166] Patients may have renal insufficiency, loss of renal concentration ability (and therefore are prone to dehydration), splenomegaly, pulmonary hypertension, pulmonary infarctions, acute stroke, and heart failure. They are at increased risk for infections because of splenic infarctions. Predictors of perioperative vasoocclusive complications include a recent increase in hospitalizations, advanced age, preexisting infections, and pulmonary disease.[166]

The preoperative examination focuses on the frequency, severity, and pattern of vasoocclusive crises, as well as the degree of pulmonary, cardiac, renal, and central nervous system damage. Oxygen saturation, hematocrit, measurement of BUN and creatinine, an ECG, and chest radiographs are indicated. Additional testing (e.g., echocardiogram, arterial blood gases) may be needed. Preoperative prophylactic transfusion is controversial. The objective of any red cell transfusion is to reduce the proportion of abnormal hemoglobin in the affected patient. The observational Cooperative Study of Sickle Cell Disease concluded that preoperative transfusion was associated

with fewer complications among surgical patients with sickle cell disease; nonetheless, complication rates were low following low-risk surgical procedures, even without transfusion.[167] Conversely, a randomized trial found that a conservative transfusion regimen (correcting anemia by increasing total hemoglobin to ≥10 g/dL) was as effective as a more aggressive approach (transfusing to decrease HbS to <30% and increase hemoglobin to ≥10 g/dL).[168] Thus, the decision to transfuse preoperatively should be made only in concert with a hematologist familiar with the disease. Any benefits are likely to apply only to intermediate- to high-risk surgical procedures.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a type of X-linked hereditary Coombs-positive hemolytic anemia. Hemolysis may occur with exposure to drugs (e.g., antipyretics, nitrates, sulfonamides), infections, hypoxia, hypothermia, or blood products. The severity of the hemolysis varies based on the individual patient and the underlying etiology. Steroid therapy is usually effective. The preoperative history should focus on previous episodes of hemolysis, identification of predisposing factors, and determination of the current hematocrit.

Coagulopathies

Hypocoagulable states may be inherited (e.g., hemophilia) or acquired (e.g., liver disease, malnutrition, drug exposure) disorders. To determine the diagnosis and the risk of bleeding, one should inquire about known diagnoses, tests, treatments, previous bleeding episodes, and family history. Asking about excessive bruising, prolonged bleeding after cuts, heavy menstrual cycles, and bleeding gums is sensitive but not specific. A *change* in these symptoms is more meaningful than a long-term history (because what one individual considers excessive may actually be normal). Excessive bleeding after previous procedures or childbirth (especially if transfusions were unexpectedly required) is more definitive but not diagnostic. Petechiae, multiple bruises, hematomas, jaundice, and frank bleeding are important findings. Diagnostic testing may include a platelet count, CBC, PT, and aPTT. *Routine* screening for coagulopathies is not indicated. If a specific cause of bleeding is suspected or known (e.g., liver disease, malnutrition), then appropriate targeted testing (e.g., liver enzymes, protein, albumin levels, PT) should be conducted.

Occasionally, a patient has an abnormal PT or PTT result on presentation for preoperative evaluation. The most common causes of a prolonged PT without a history of warfarin use are laboratory error, liver disease, and malnutrition. One should first repeat the test. If the test result is again abnormal, then evaluation of liver enzymes and a hepatitis panel are warranted, in addition to referral to a hematologist or primary care physician. A trial of vitamin K (1 to 5 mg orally once a day for 3 days) can be initiated. A prolonged aPTT can result from both hypocoagulable and hypercoagulable (e.g., antiphospholipid antibody syndrome) conditions. The first steps are to repeat the test and ascertain exposure to heparin. Even small amounts of heparin present in indwelling catheters, especially if the blood is drawn from that site, can inadvertently prolong the aPTT. Other than heparin exposure, the most common cause of a prolonged aPTT is von Willebrand disease (vWD), but other hemophilias can prolong the aPTT. In addition, an aPTT mixing study (in which normal blood is mixed with the subject's blood) allows for differentiation between factor deficiencies (aPTT will be corrected) and inhibitors (aPTT will not be corrected). Some hypercoagulable states can cause a prolonged aPTT, including factor V Leiden, anticardiolipin antibody, and lupus anticoagulants. Elective surgical procedures should be postponed until the etiology of abnormal tests is determined and corrections are made.

Hemophilias. Hemophilia A (factor VIII deficiency) and hemophilia B (or Christmas disease) are X-linked recessive inherited disorders that almost exclusively manifest in male patients. Hemophilia A accounts for 85% of all patients with hemophilia. Patients with hemophilia have prolonged aPTT and normal PT results. The severity of bleeding varies among individuals but tends to be similar among relatives and is directly related to the degree of factor deficiency. Even mild trauma can result in significant hemorrhage. Intramuscular injections are to be avoided. Orthopedic procedures account for 50% of operations in patients with hemophilia because recurrent intra-articular bleeding destroys joints.

A hematologist must be involved in the perioperative care of these patients. A detailed plan to monitor and replace deficient factors is paramount. Typically, factors VIII and IX are maintained at 75% to 100% of usual levels in the immediate perioperative period and then at 50% until any risk of bleeding is past. Each unit of recombinant or purified factor concentrate raises the factor level by 2% per kilogram.

von Willebrand Disease. vWD is an inherited disorder of factor VIII and von Willebrand factor (vWF) that affects both sexes. It is the most common congenital coagulopathy, occurring in approximately 1% of individuals.[169] Several types (1, 2A, 2B, 2M, and 2N) are autosomal dominant, and type 3 is autosomal recessive (Table 38-10). Factor VIII and vWF circulate as a complex, with disease resulting from both quantitative and qualitative deficiencies. Most patients have a prolonged aPTT, although patients with mild disease may have normal aPTT. The most common cause of a prolonged aPTT in patients not taking heparin is vWD. The condition is diagnosed by measuring ristocetin cofactor (functional assay for vWF, which causes platelet aggregation in the presence of ristocetin), vWF antigen, and factor VIII levels. vWF is an acute phase reactant and increases with conditions such as stress or surgery, thereby making the diagnosis sometimes difficult. Most patients with vWD have a history of bleeding, but some do not receive a diagnosis until a challenge to coagulation occurs with major surgery or antiplatelet drug exposure (e.g., aspirin, NSAIDs). A hematologist must be involved in the care of these patients. Desmopressin acetate (1-desamino-8-D-arginine vasopressin [DDAVP]) increases factor VIII, vWF, and plasminogen activator release from endothelial cells. An intravenous dose of 0.3 μg/kg (given over 15 to 30 minutes to avoid

TABLE 38-10 **CLASSIFICATION OF VON WILLEBRAND DISEASE**

Type	Characteristics	Treatment
1	80% of cases; quantitative defect	Desmopressin*
2A	Quantitative and qualitative defect	Desmopressin*
2B†	Rare; quantitative and qualitative defect, autosomal dominant	Cryoprecipitate or factor VII concentrates with vWF
2M	Qualitative defect	Desmopressin*
2N	Qualitative defect; vWF levels normal; factor VIII reduced	Desmopressin* effect may be too short-lived
3	Rare; low to undetectable levels of vWF	Desmopressin* usually not effective

vWF, Von Willebrand factor.
*Desmopressin acetate (DDAVP).
†With type 2B, desmopressin acetate may cause thrombocytopenia. If desmopressin is not effective, factor VIII concentrates containing vWF or cryoprecipitate may be used.

hypotension, flushing, and tachycardia) typically raises the vWF by three- to fourfold. Nonetheless, considerable variation in response exists among individuals, so vWF and factor VIII levels must be monitored. Desmopressin acetate is also available as a nasal spray. It should not be given more frequently than every 48 hours to prevent depletion of endothelial stores. To avoid the release of plasminogen activator by desmopressin acetate, antifibrinolytics such as ε-aminocaproic acid or tranexamic acid can be given. Desmopressin acetate is contraindicated in patients with type 2B disease because it increases abnormal vWF and may cause thrombocytopenia. For these individuals, cryoprecipitate or factor VIII concentrates containing vWF can be used to replace abnormal vWF.

Thrombocytopenia. Thrombocytopenia is defined as a platelet count of less than 150,000/mm^3, and it results from decreased production, increased destruction, or sequestration (see also Chapter 61). Causes include malignant diseases, drugs, autoimmune disorders, preeclampsia, hereditary disease, and disseminated intravascular coagulation. In patients who are unexpectedly found to have low platelet counts, the initial steps are to repeat the test, examine the peripheral smear, and collect blood for the platelet count in a tube without ethylenediaminetetraacetic acid (EDTA). This chemical, which is a chelating agent often used to prevent clotting in tubes used for determining CBC, can also cause clumping of platelets (termed pseudothrombocytopenia).

Recent exposure to heparin raises the concern of heparin-induced thrombocytopenia (HIT), which generally occurs within 5 to 10 days after heparin exposure.[170] HIT is an immune-mediated disorder characterized by antibodies directed against platelets. The disorder can result in arterial thromboses, venous thromboses, stroke, amputations, and death in up to 30% of patients. Immediate discontinuation of heparin is required, followed by testing for heparin-induced platelet antibodies. LMWH is less likely than unfractionated heparin to cause HIT; nonetheless, LMWH is contraindicated in any patient with established HIT. Alternative anticoagulants that can be used in these patients include danaparoid sodium, lepirudin, and argatroban.

Idiopathic thrombocytopenic purpura (ITP) is a chronic autoimmune disorder characterized by antiplatelet autoantibodies that cause platelet destruction. Usual treatment for ITP includes corticosteroids, splenectomy (eliminates the major site of platelet removal), and intravenous immunoglobulin. Patients with ITP often have less bleeding than expected, even at very low platelet levels, likely because of increased platelet turnover with a resulting predominance of young platelets.

Neuraxial anesthesia is considered safe in patients with platelet counts higher than 100,000/mm^3.[171] Surgery can be safely performed in patients with platelet counts higher than 50,000/mm^3. The risk of bleeding increases progressively as the count falls further, to less than 50,000/mm^3. Anemia, fever, infections, and antiplatelet drugs can increase bleeding at any platelet count. A patient with newly discovered thrombocytopenia should undergo hematology consultation before elective surgery. When platelet transfusions are used to treat thrombocytopenia, the platelet count generally rises by 10,000/mm^3 for every unit transfused.

Thrombocytosis. Thrombocytosis is defined as a platelet count of more than 500,000/mm^3. It may be physiologic (e.g., exercise, pregnancy), primary (e.g., myeloproliferative disorder), or secondary (e.g., iron deficiency, neoplasm, surgery, chronic inflammation). Platelet counts greater than 1,000,000/mm^3 can increase risks for thrombotic events such as strokes, MIs, pulmonary emboli, mesenteric emboli, and venous clots. Conversely, patients with primary thrombocytosis (also known as essential thrombocythemia) have a tendency toward increased bleeding, which is worsened with exposure to antiplatelet medications such as aspirin. Risk factors include increased age and a previous history of bleeding or thrombosis. Treatments include medications (e.g., hydroxyurea, anagrelide) that decrease platelet production and hence reduce platelet counts over 7 to 10 days. Plasmapheresis, which removes platelets from the circulation, can also be used if an immediate lowering in platelet count is required. In cases of secondary thrombocytosis, treatment of the underlying disorder usually results in normalization of the platelet level.

Polycythemia. Polycythemia is defined as a hematocrit greater than 54%. It has both primary causes (i.e., polycythemia vera) and secondary causes (e.g., COPD, high altitude, congenital heart disease), usually related to chronic hypoxia. A steep increase in blood viscosity occurs once the hematocrit increases to more than 50%, resulting in an increased thrombogenic risk. High hematocrits are associated with increased atherosclerosis (e.g., carotid stenosis, stroke) and cardiac disease (e.g., heart failure, MI). Reports on whether polycythemia increases perioperative risk are contradictory. For example, an increase in hematocrit to more than 51% was associated with increased postoperative mortality in a large study of 310,311 patients.[49] Conversely, a previous smaller study of 200 patients did

not find an increased rate of perioperative complications in individuals with secondary polycythemia.[172]

The preoperative history and physical examination of these patients should focus on the pulmonary and cardiovascular systems. Examination for cyanosis, clubbing, wheezing, and murmurs is necessary. Pulse oximetry and an ECG are required in patients with polycythemia, with analysis of arterial blood gases and a chest radiograph. An unexpected finding of polycythemia should prompt an investigation for possible causes, which if not readily apparent, should raise the possibility of polycythemia vera. In such cases, elective surgical procedures should be postponed pending an evaluation by a hematologist.

Thromboembolic Disorders. The rate of fatal pulmonary embolism is 0.1% to 0.8% after elective general surgery, 2% to 3% after elective hip replacement, and 4% to 7% after repair of a fractured hip, if prophylaxis is not administered. Primary thromboembolic prophylaxis is beyond the scope of this chapter and is covered extensively in specialty society practice guidelines.[173,174] Nonetheless, patients should be stratified preoperatively for their risks of perioperative venous thromboembolism, so appropriate measures can be implemented on the day of surgery. These risks depend on both patient-related (e.g., inflammatory bowel disease, acute illness, smoking, malignant disease, obesity, increased age, prior thromboembolism, estrogen use, hypercoagulable state, inherited thrombophilia) and procedure-related (e.g., invasiveness, trauma, immobilization) factors (Box 38-14).[175] Factor V Leiden, the most common inherited thrombophilia, accounts for 40% to 50% of cases. The remaining cases are caused by prothrombin gene mutation, as well as deficiencies in protein S, protein C, or antithrombin. Because of the high risk of thromboembolism in patients undergoing elective lower extremity joint replacement, these patients are often given a dose of warfarin the night before the surgical procedure. The American Society of Regional Anesthesiologists (ASRA) guidelines specifically state that neuraxial anesthesia can be safely performed when a single dose of warfarin has been administered within the previous 24 hours.[171]

Specific subgroups of patients are at considerably higher risk for perioperative venous thromboembolism. Recent arterial or deep vein thromboembolism (DVT) entails postponement of procedures that are not lifesaving. Without anticoagulation, the risk of recurrent DVT within 3 months following a proximal DVT is approximately 50%. A month of warfarin treatment reduces that risk to 10%, whereas a 3-month course of treatment reduces it to 5%. Elective surgery should therefore be postponed in the first month after an episode of venous or arterial thromboembolism. Ideally, a 3-month course of anticoagulation is recommended before elective surgery. If postponement is not possible, then the patient must receive preoperative bridging therapy while the INR is less than 2.0.[176] Patients who have a hereditary hypercoagulable state (e.g., antithrombin III, protein C or S deficiencies, prothrombin gene mutation, factor V Leiden), cancer, or multiple episodes of venous thromboembolism are considered at high risk indefinitely. Other high-risk subgroups include patients with nonvalvular atrial fibrillation who have had previous cerebral emboli, as well as patients with mechanical heart valves. Among patients with mechanical heart valves, multiple valves and mitral valves (as opposed to aortic valves) are associated with greater risk. Although surgery is associated with an increased risk for DVT, a similar increased risk does not occur for postoperative arterial embolism in patients with atrial fibrillation or mechanical valves.[176]

Patients having minor procedures such as dental, endoscopic, cataract, or superficial operations usually do not require interruption of anticoagulant therapy. In other individuals, withholding warfarin for 5 days typically allows the PT or INR to decrease to normal if the INR is maintained at the usual therapeutic target (2.0 and 3.0) in the long term. More doses should be withheld if the INR is more prolonged, and fewer doses should be withheld if the INR is subtherapeutic. Thus, INR should be checked during the preoperative visit to guide cessation of therapy. During the time without warfarin (Coumadin), patients may be at risk for recurrent thromboembolism; however, the risk

BOX 38-14 ***Categories of Risk for Venous Thromboembolism in Surgical Patients***

Low Risk

Minor surgery in patients <40 years of age with no additional risk factors present*

- Risk of calf DVT: 2%
- Risk of proximal DVT: 0.4%
- Risk of clinical PE: 0.2%
- Risk of fatal PE: <0.01%

Moderate Risk

Minor surgery in patients with additional risk factor present* **or** surgery in patients 40 to 60 years old with no additional risk factors

- Risk of calf DVT: 10-20%
- Risk of proximal DVT: 2-4%
- Risk of clinical PE: 1-2%
- Risk of fatal PE: 0.1-0.4%

High Risk

Surgery in patients ≥60 years old **or** surgery in patients 40 to 60 years old with additional risk factors*

- Risk of calf DVT: 20-40%
- Risk of proximal DVT: 4-8%
- Risk of clinical PE: 2-4%
- Risk of fatal PE: 0.4-1.0%

Highest Risk

Surgery in patients ≥40 years old with multiple risk factors,* hip or knee arthroplasty, hip fracture surgery, **m**ajor trauma, or spinal cord injury

- Risk of calf DVT: 40-80%
- Risk of proximal DVT: 10-20%
- Risk of clinical PE: 4-10%
- Risk of fatal PE: 0.2-5%

Data from Geerts WH, Pineo GF, Heit JA, et al: Prevention of venous thromboembolism: the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy, Chest *126:338S-340S, 2004.*

DVT, Deep vein thrombosis; *PE,* pulmonary embolism.

*Additional risk factors include one or more of the following: advanced age, cancer, prior venous thromboembolism, obesity, heart failure, paralysis, or molecular hypercoagulable state (e.g., protein C deficiency, factor V Leiden).

is relatively small in all but the highest-risk patients. The decision to bridge with intravenous unfractionated heparin or with LMWH subcutaneously, or not to bridge at all, in high-risk patients must be made in concert with the treating physician or a cardiologist. Previously, the only option for bridging was costly hospital admission for intravenous heparin therapy. With the availability of LMWH in contemporary clinical practice, patients can now receive bridging therapy with subcutaneous (usually self-administered) LMWH at home, without the need for monitoring.

Anticoagulant Therapy. Warfarin may increase perioperative bleeding, except for minor procedures such as cataract surgery without bulbar blocks. No consensus exists on the optimal perioperative management of patients receiving warfarin. The usual recommendation is to withhold warfarin starting 4 to 5 days preoperatively (if the INR is between 2.0 and 3.0) to allow the INR to decrease to less than 1.5, which is a level considered safe for surgical procedures and neuraxial blockade.[171] If the INR is greater than 3.0, it is usually necessary to withhold warfarin longer than 4 to 5 days. If the INR is measured the day before the surgical procedure and remains higher than 1.8, a small dose of vitamin K (1 to 5 mg administrated orally or subcutaneously) can reverse anticoagulation.[176] Vitamin K has an effect within 6 to 10 hours after oral or subcutaneous administration (more predictable with oral administration), and it peaks within 24 hours to 48 hours. Administration of higher doses may lead to warfarin resistance when therapy is initiated again.

Decisions to use bridging therapy with unfractionated heparin or LMWH must be individualized and made in concert with the treating physician or a cardiologist. If bridging is planned, the INR must be checked 2 days after the last warfarin dose. When the INR drops to less than 1.5, the patient is either admitted for intravenous heparin, or LMWH therapy (thromboprophylaxis dose: enoxaparin 40 mg once daily, dalteparin 2500 to 5000 International Units once daily, or tinzaparin 175 International Units/kg once daily) can be initiated. Adjustments in LMWH doses are necessary for patients with impaired renal function (eGFR <30 mL/minute). Intravenous unfractionated heparin is usually discontinued approximately 6 hours before the surgical procedure to allow for normal intraoperative coagulation. The last dose of *therapeutic* LMWH is given 24 hours (prophylactic doses must be held for just 12 hours) preoperatively to allow normalization of coagulation. Factor Xa levels are not usually monitored, with the possible exception of patients with an eGFR of less than 30 mL/minute. Both unfractionated heparin and LMWH are contraindicated in patients with a history of HIT. Fondaparinux is a synthetic pentasaccharide that inhibits factor X, and it can be given subcutaneously once daily (thromboprophylaxis dose: 2.5 mg) in patients with a history of HIT. It is not recommended for patients with an eGFR of less than 30 mL/minute. Aspirin does reduce the risk of perioperative venous thromboembolism,[177] but not to the same degree as anticoagulants.

Caution is used when performing neuraxial techniques in patients who have recently discontinued long-term warfarin therapy (see also Chapter 56). The anticoagulant therapy must be stopped (ideally 4 to 5 days before the planned procedure) and PT or INR measured before initiation of neuraxial block. Adequate levels of factors II, VII, IX, and X may not be present until the PT or INR is within normal limits. For patients receiving an initial preoperative dose of warfarin, practice guidelines recommend checking the PT or INR before neuraxial block if either the first dose was given more than 24 hours before the surgical procedure or more than one dose of oral anticoagulant had been administered.[171]

Prophylactic LMWH is stopped 12 hours before any planned neuraxial block, whereas therapeutic LMWH doses should be stopped 24 hours before neuraxial blocks. The subsequent dose of LMWH must occur 2 or more hours after the neuraxial block.[171] Monitoring of the anti-Xa level is not recommended because the anti-Xa level is generally not predictive of the risk of bleeding. Subcutaneous (minidose) unfractionated heparin prophylaxis is not a contraindication to the use of neuraxial techniques.[171] Combining neuraxial techniques with intraoperative anticoagulation by intravenous unfractionated heparin is acceptable, provided the patient has no other coagulopathies and heparin administration is delayed for at least 1 hour after needle placement.[171] Preoperative unfractionated intravenous heparin is generally stopped 6 to 8 hours before planned spinal or epidural anesthesia; in addition, return to normal coagulation can be monitored with aPTT, and further reversal can be achieved with protamine. Epidural catheters can be safely left in place while patients receive a single daily dose of prophylactic LMWH, but not with larger doses. When removing epidural catheters, the optimal time is 12 hours after the last prophylactic dose *and* 2 hours before the next dose. Any patients receiving fibrinolytic and thrombolytic drugs should be cautioned against receiving neuraxial anesthesia, except in highly unusual circumstances.[171]

Antiplatelet Therapy. Traditionally, aspirin has been discontinued leading up to surgery (often 7 to 10 days before the operation) because of concern about increased bleeding. The 7- to 10-day withdrawal period is itself likely excessive, especially given that new platelets formed after the discontinuation of aspirin (its half-life is ≈15 minutes) are not inhibited. Given that approximately 10% of platelets are turned over every 24 hours, and the minimum (normal functioning) platelet count needed to control surgical bleeding is 50,000 per mm^3, it is likely that aspirin must be stopped only 3 to 4 days preoperatively.

Although a systematic review of patients undergoing noncardiac surgery found that perioperative aspirin increased bleeding complications by approximately 50%,[71] aspirin was not associated with increased severity of bleeding complications, except in intracranial surgery and possibly transurethral resection of the prostate. Nonetheless, low-dose aspirin (100 mg/day) was shown to increase major bleeding in the POISE-2 trial of 10,010 surgical patients.[71] Notably, when surgeons are blinded to aspirin administration, they cannot differentiate between patients who were taking aspirin and those who were not, based on clinical inspection of perioperative bleeding.[178]

Withdrawing aspirin itself has important potential risks. A rebound hypercoagulable state results when

long-term aspirin therapy is withdrawn,[179] and withdrawal or noncompliance with aspirin is associated with a threefold increase in the risk of major cardiac events.[180] When considered in combination with a hypercoagulable state induced by many surgical procedures, preoperative aspirin withdrawal has important theoretical risks. Observational studies,[181,182] as well as a randomized trial of 220 participants,[73] support an increased risk of vascular events when long-term aspirin is stopped perioperatively.

Despite these promising reasons for continuing aspirin during noncardiac surgery, the actual benefits are uncertain. For example, a randomized trial of 291 participants found no benefit from continuing, as opposed to withdrawing, aspirin therapy before elective noncardiac surgery.[72] Most recently, the POISE-2 trial found no differences in rates of cardiac complications in patients receiving aspirin.[71] Thus, aspirin should neither be continued or withdrawn *routinely*. Any benefits from continuing aspirin are most likely to be seen in patients for whom the risk of cardiac events is felt to outweigh the risk of bleeding (e.g., high-risk CAD).

The risk of dual antiplatelet therapy with respect to increasing perioperative bleeding and mortality, especially in noncardiac surgery, is not well established.[5] The usual recommended time point for discontinuing clopidogrel is 5 days to 7 days preoperatively. This interval is consistent with pharmacokinetic data showing complete restoration of platelet function in healthy volunteers by 7 days following discontinuation of clopidogrel.[183] In some selected cases, the best overall option for a patient may be to proceed to surgery while continuing thienopyridine therapy (e.g., drug-eluting stent within 1 year before urgent surgical procedures). Decisions regarding the perioperative management of such a case must be individualized and based on extensive discussion with the patient's cardiologist and surgeon. A newer antiplatelet drug, prasugrel, may be more potent than aspirin or thienopyridines. Studies support the safety of neuraxial and peripheral anesthesia in patients taking long-term aspirin,[184] and the ASRA endorses this opinion.[171] The risk of spinal hematoma with ticlopidine or clopidogrel is unknown. Based on labeling, ASRA guidelines, and surgical reviews, the suggested time interval between discontinuation of thienopyridine therapy and neuraxial blockade is 14 days for ticlopidine and 7 days for clopidogrel.[171]

Information on the perioperative safety of continuing other antiplatelet therapies, such as glycoprotein IIb/IIIa inhibitors, is limited. Platelet glycoprotein IIb/IIIa inhibitors (e.g., abciximab, eptifibatide, tirofiban) exert profound effects on platelet aggregation. Following administration, the time to restoration of normal platelet aggregation is 24 to 48 hours for abciximab and 4 to 8 hours for eptifibatide and tirofiban. Neuraxial techniques should be avoided until platelet function has recovered.[171]

NEUROLOGIC DISEASE

For a patient with neurologic disease, the detailed history should focus on recent events, exacerbations, and evidence of poor control of the underlying medical condition. Information about prior investigations or therapy is important. A basic neurologic examination evaluating deficits in mental status, speech, cranial nerves, gait, motor function, and sensory function is important. This baseline determination also allows for comparison of possible new deficits postoperatively.

Cerebrovascular Disease

If a stroke or transient neurologic deficit has occurred recently or has not been fully evaluated, elective surgical procedures should be delayed pending complete evaluation, especially because a history of cerebrovascular disease is a very strong predictor of subsequent perioperative stroke.[185,186] No good data are available on the safe interval required between an acute stroke and subsequent surgery. Investigators have suggested that the appropriate interval is at least 1 to 3 months, although research is needed to define this optimal duration more clearly.[187] The etiology and treatment of previous strokes or transient ischemic attacks should guide further perioperative management. For example, an embolic stroke from a patent foramen ovale may require correction of the defect or strict attention to avoid air emboli. A left atrial or ventricular thrombus, as well as an embolic stroke believed secondary to atrial fibrillation, requires a minimum of 1 month and preferably 3 months of anticoagulation therapy (in addition to possible bridging with unfractionated heparin or LMWH).

Cerebrovascular disease is a predictor of perioperative cardiac complications, and attention is required to determine the risk of ischemic heart disease.[47] In addition, the presence of concomitant cerebrovascular disease should be carefully considered in any decision to initiate new β-adrenergic blocker therapy in a patient awaiting a noncardiac surgical procedure. Although β blockade does decrease perioperative cardiac risk, it may also significantly increase the risk for acute stroke following noncardiac surgery.[40,68]

Asymptomatic Bruit

A newly discovered carotid bruit requires a careful search for symptoms of cerebral ischemia or transient ischemic attack, especially if the procedure involves manipulation of the neck or if the patient has a potentially difficult airway. Patients often fail to volunteer pertinent symptoms until they are specifically probed, especially if the symptoms were transient. Patients with risk factors for carotid atherosclerosis, including patients who received head and neck irradiation at younger ages, should be questioned specifically about *amaurosis fugax*, dysphagia, dysarthria, and other symptoms of cerebrovascular insufficiency.

Carotid Doppler ultrasound studies are simple, effective tools to evaluate at-risk patients with suspicious carotid bruits. Significant abnormalities on Doppler studies should prompt a referral to a neurologist or vascular surgeon. In patients who have truly asymptomatic bruits, significant carotid lesions are present 40% to 60% of cases. The risk of stroke in this group is 1% to 2% per year, with most strokes preceded by transient symptoms.[188] Carotid endarterectomy for asymptomatic carotid stenosis should be considered only if the patient has 80% or greater stenosis and the operating surgeon has a low (i.e., ≤3%) perioperative complication rate.[188,189] No evidence

indicates that truly asymptomatic bruits increase the risk of *perioperative* stroke.[187]

Seizure Disorder

The type of seizure (e.g., *grand mal*, absence) and specific symptoms (e.g., staring, focal findings) are important to document. Absence (previously *petit mal*) seizures may be particularly difficult to recognize because they lack generalized motor signs. More typical symptoms such as staring and obtundation may be misinterpreted as residual anesthetic effects in the postoperative period. Determining the etiology of the seizure disorder is also important because of possible associated morbidities. Important associated comorbidities include brain tumors, aneurysms, arteriovenous malformations (AVMs), classic epilepsy, drug toxicity, electrolyte disorders, infections, cerebrovascular disease, sickle cell disease, and SLE.

Careful documentation of anticonvulsants and adequacy of seizure control is necessary. Routine measurement of serum drug levels of anticonvulsants is not indicated unless toxicities or ongoing breakthrough seizures pose a concern. Indeed, patients with good control of seizures may have levels outside the therapeutic range. Drug levels are highly influenced by when the blood draw occurs relative to the timing of drug administration. In general, trough levels should be measured. Medications to control seizures have multiple side effects (e.g., bone marrow suppression, macrocytic anemia, leucopenia, hyponatremia), and testing should be directed based on suspected abnormalities. The most commonly ordered tests are CBC and electrolyte levels. Poorly controlled or new-onset seizures entail a consultation with a neurologist before the patient undergoes anything other than emergency surgery. Continuation of anticonvulsant therapy in the perioperative period is necessary.

Multiple Sclerosis

Multiple sclerosis is believed to be an inflammatory immune disorder with two general clinical patterns: exacerbating-remitting and chronic progressive. Symptoms can include ataxia, motor weakness, sensory deficits, autonomic dysfunction, emotional lability, bladder or bowel dysfunction, and visual disturbances. Exacerbations of multiple sclerosis can be triggered by stress, infections, pregnancy, and elevated temperatures. Various treatments have been tried, including steroids, immunosuppressants, monoclonal antibodies, plasmapheresis, benzodiazepines, and baclofen. During the preoperative assessment, the history and pattern of disease, especially symptoms and physical deficits affecting the respiratory system (including oxygen saturation), should be documented. Medications, previous triggers, and preexisting neurologic deficits should be documented. Testing is generally directed toward associated disturbances (e.g., chest radiography and white blood cell count if pulmonary infection is suspected) and possible medication side effects. For example, azathioprine can suppress bone marrow or affect liver function, cyclophosphamide may cause electrolyte abnormalities, and steroids can cause hyperglycemia. Patients with minor, stable disease require no special testing. Medications should be continued on the day of surgery. No clear association has been shown between the type of anesthetic or a specific anesthetic drug and disease exacerbations.[190] Regional anesthesia may offer advantages for patients with respiratory compromise or cognitive dysfunction.

Aneurysms and Arteriovenous Malformations

Cerebral and spinal vascular lesions consist of aneurysms and AVMs, which may be intact, ruptured, symptomatic, or incidental findings. Risk factors include polycystic kidney disease, fibromuscular dysplasia, type IV Ehlers-Danlos syndrome, and a family history of aneurysms. An AVM may also be large enough to cause a mass effect. Pregnancy increases the risk of aneurysmal and possibly AVM bleeding. Before rupture, most patients have minimal symptoms other than headache or seizures, but it is important to document complaints in all patients. Any rupture can result in altered mental status, syncope, increased intracranial pressure, inappropriate antidiuretic hormone secretion, and hemodynamic perturbations. The hemodynamic changes include bradycardia, tachycardia, and ectopic beats. Usual tests ordered include an ECG and determination of electrolytes, glucose, BUN, and creatinine. Chest radiography and echocardiography are also often needed. The ECG changes, often ST-segment and T-wave changes, commonly mimic those seen with myocardial ischemia. Significant cardiac dysfunction with depressed contractility and wall motion abnormalities can also be present on echocardiography. Although the bleeding may be responsible for these cardiovascular changes, concomitant CAD or preexisting cardiomyopathy should also be considered. Measures aimed at controlling increased intracranial pressure, arterial BP, and blood glucose are most important.

Parkinson Disease

Parkinson disease is a degenerative disorder of the basal ganglia characterized by failure of dopamine secretion that results in diminished inhibition of the extrapyramidal motor system.[191] Patients typically have diminution of spontaneous movements, rigidity (cogwheel rigidity is classic), resting tremor, masked facies, difficulty speaking, difficulty walking, depression, and dementia. Autonomic dysfunction with orthostatic hypotension, excessive salivation, and impaired thermoregulation may also occur. Patients are at risk of pulmonary complications resulting from difficulty swallowing, altered mental status, increased aspiration risk, and ventilatory muscle dysfunction. Standard treatments include levodopa (often combined with carbidopa), anticholinergic agents, bromocriptine, amantadine, and selefiline. Levodopa can cause dyskinesias (i.e., dystonic and myoclonic involuntary movements). Selefiline is a monoamine oxidase inhibitor (MAOI) that inhibits dopamine degradation. Some individuals also undergo implantation of deep brain stimulators to manage their symptoms.

Preoperative evaluation focuses on the pulmonary system, signs of dysphagia, and degree of disability. Both room air saturation and orthostatic vital signs are important to document. Evidence of significant pulmonary symptoms or possible infection requires chest radiography, pulmonary consultation, and possible delay of the

procedure for improvement. Individuals with deep brain stimulators require deactivation of the devices before any procedures in which electrocautery will be used. All associated medications should be continued, including MAOIs. Abrupt withdrawal of levodopa may exacerbate symptoms (especially dysphagia and chest wall rigidity) or precipitate neuroleptic malignant syndrome. The latter disorder is characterized by autonomic instability, altered mental status, rigidity, and fever. Some medications encountered in the perioperative setting, such as metoclopramide and phenothiazines, may exacerbate symptoms of Parkinson disease by interfering with dopamine.

Neuromuscular Junction Disorders

Myasthenia gravis is an autoimmune disorder of skeletal muscle neuromuscular junctions that is caused by antibodies against nicotinic acetylcholine receptors (see also Chapter 42).[192] The disease is characterized by muscle weakness that worsens with activity and improves with rest. Box 38-15 presents a classification system for myasthenia gravis with increasing numeric classes indicating increasing levels of involvement and debilitation. Weakness is exacerbated by stress, infections, hypokalemia, medications (e.g., aminoglycosides, propranolol, ciprofloxacin, clindamycin), and surgery. Cardiac and smooth muscles are unaffected. Patients with myasthenia gravis commonly have other autoimmune diseases, such as rheumatoid arthritis, polymyositis, and thyroid disorders.

Affected individuals may have thymic hyperplasia and tumors. Because the thymus is located in the anterior mediastinum, thymic enlargement has implications for anesthesia care. Cranial nerve and bulbar involvement are common, with an associated increase in aspiration risk resulting from pharyngeal and laryngeal muscle weakness. Ocular symptoms (i.e., diplopia, ptosis) are almost always present; often, they are the presenting or only complaints. Patients are usually treated with thymectomy, anticholinesterase, and immunosuppressant medications. Worsening symptoms may reflect worsening disease (i.e., myasthenic crisis) or excessive anticholinesterase treatment (i.e., cholinergic crisis). A short-acting anticholinesterase (edrophonium) can help distinguish the two states. Specifically, only a myasthenic crisis improves with more anticholinesterase. Plasmapheresis and intravenous immunoglobulins have been used to treat myasthenic crises and prepare patients for surgery, but they require several days to weeks to produce signs of improvement.

Documentation of medication dosages and continuation of medications until the surgical procedure are paramount. Patients taking azathioprine require a CBC and LFTs because of drug-induced bone marrow suppression and liver dysfunction. Patients treated with steroids need glucose measurement, as well as steroid supplementation in the perioperative period. Because ventilatory function can be compromised, preoperative PFTs may also be indicated for selected patients, particularly those with severely affected ventilatory function. These tests may also be helpful if patients are being considered for ambulatory surgery, especially in freestanding surgical centers. Even though anticholinesterases may cause bradycardia, salivation, and altered effects of neuromuscular blocking drugs, these agents must be continued in the perioperative period.[193] Avoidance of drugs that can exacerbate myasthenic symptoms is also necessary.

Lambert-Eaton syndrome is similar to myasthenia gravis, with muscle weakness including oculobulbar involvement and dysautonomia. It is caused by antibodies against voltage-gated calcium channels that result in a decrease in acetylcholine release. Lambert-Eaton syndrome is not associated with thymic abnormalities, but it commonly occurs in patients with malignant diseases, especially small cell lung cancer and gastrointestinal tumors. The other distinguishing feature of this disorder is that the muscle weakness classically improves with activity and is worse after inactivity. Therapies for Lambert-Eaton syndrome are similar to those used for myasthenia gravis. In addition, a selective potassium channel blocker, namely 3,4-diaminopyridine, is used and should be continued perioperatively. Preoperative evaluation and management are similar to those for myasthenia gravis.

BOX 38-15 ***Osserman Classification System for Myasthenia Gravis***

Class I: Ocular myasthenia
Class IIA: Mild generalized myasthenia with slow progression: no crises, responsive to drugs
Class IIB: Moderately severe generalized myasthenia: severe skeletal and bulbar involvement but no crises; drug response less than satisfactory
Class III: Acute fulminating myasthenia: rapid progression of severe symptoms, with respiratory crises and poor drug response
Class IV: Late severe myasthenia, same as class III but progression over 2 years from class I to II

Data from Osserman KE, Genkins G: Studies in myasthenia gravis: review of a twenty-year experience in over 1200 patients. Mt Sinai J Med 1971; 38: 497–537.

Muscular Dystrophies and Myopathies

Muscular dystrophies and myopathies are inherited disorders that affect the neuromuscular junction. They share many similarities but do have a few differences. The hallmark of these disorders is progressive skeletal muscle weakness that commonly leads to respiratory failure. No effective therapy is available. Many individuals have associated cardiomyopathies and possible association with MH.

Duchenne and Becker muscular dystrophies are X-linked recessive disorders that occur primarily in male patients. Affected individuals have elevated creatine phosphokinase (CK) levels, often preceding the onset of symptoms. Male patients with a family history of either Duchenne or Becker muscular dystrophy should be considered at risk (even when they have not been formally tested), and they require precautions similar to those in patients with diagnosed disease. Cardiomyopathy and respiratory failure are the usual causes of death. Female carriers of the abnormal gene may have dilated cardiomyopathy despite having no other manifestations of the disease. The focus of the preoperative history is on eliciting details pertaining to palpitations, dyspnea, chest pain, syncope, orthopnea, dependent edema, aspiration, and pneumonia. The physical examination generally concentrates on the cardiopulmonary system, whereas

important additional preoperative tests include an ECG, PFTs, and echocardiography.

Facioscapulohumeral muscular dystrophy (also known as faciohumeroscapular or Landouzy-Dejerine muscular dystrophy) is an autosomal dominant disorder that affects both sexes and causes a slow, progressive weakness of muscles in the shoulders and face. Cardiomyopathy occurs much less frequently than in other dystrophies, but arrhythmias have been reported. Limb-girdle dystrophies have a variable genetic inheritance pattern and primarily affect the muscles of the shoulders and pelvis. Conduction abnormalities are present in some patients, although frank cardiomyopathies are less frequent. The preoperative evaluation is largely similar to that described previously for Duchenne muscular dystrophy.

Myotonic Dystrophies. Myotonia consists of prolonged contraction and delayed relaxation of muscles. It is a common symptom of several dystrophies, including classic myotonic dystrophy, congenital myotonic dystrophy, myotonia congenital, and central core disease. Myotonic dystrophy, which is the most common of these conditions, is an autosomal dominant inherited disorder affecting both sexes. Congenital myotonic dystrophy is a severe form of this disease that manifests in infancy, often in the children of affected mothers. The classic findings are severe muscle wasting, typically involving the diaphragm, as well as muscles in the face, hands, pharynx, and larynx. Cold temperatures can often trigger myotonia. The disease severity is variable, with symptoms often not apparent until the second or third decade of life; therefore, obtaining a family history is important. Cardiomyopathies, arrhythmias, and conduction abnormalities are common, while some patients also have cardiac valvular abnormalities. Cardiac involvement may not correlate with the degree of atrophy or weakness in skeletal muscle. Once an affected individual shows any evidence of second- or third-degree AV block, a pacemaker should be implanted (even if the patient is asymptomatic) because an unpredictably rapid progression of the cardiac conduction disease may occur. Given this potential for rapid disease progression, pacemaker placement may even be considered in patients with first-degree AV block, regardless of symptoms. Affected individuals are also at risk for aspiration, pneumonia, respiratory failure, and postoperative pulmonary complications.[194]

Central core disease is a rare disorder caused by deficiency of mitochondrial enzymes. The name derives from findings of muscle biopsies, which reveal "cores" of abnormalities. Affected individuals have proximal muscle weakness, scoliosis, and sometimes cardiomyopathies. As with myotonic dystrophy, patients are at risk for respiratory failure and aspiration. Myotonia congenita is a hereditary disorder that involves only skeletal muscles, causes less severe symptoms, and does not cause cardiac abnormalities.

Patients with myotonia may be at increased risk for MH, although this association is controversial. They may have a clinical presentation similar to that in patients with MH as a result of uncontrolled myotonic contraction with elevated metabolism and rhabdomyolysis.[195]

Symptomatic treatments for myotonic contractions include steroids, quinine, and procainamide; otherwise, these diseases have no cure. These treatments should be continued during the perioperative period. The preoperative evaluation focuses on the cardiopulmonary system, with special emphasis on evaluating for pulmonary infection, heart failure, palpitations, syncope, conduction abnormalities, and valvular abnormalities. Preoperative testing includes an ECG, an echocardiogram (except for myotonia congenita), and a chest radiograph (if symptoms of pulmonary disease are present). Any evidence of a conduction abnormality on ECG should trigger a cardiology consultation. Myotonia is not inhibited by regional anesthesia, but local anesthetic infiltration into muscle may provide symptomatic relief.

Central Nervous System Tumors

Pituitary tumors may be classified as functioning (associated with endocrine abnormalities) versus nonfunctioning, as well as benign (adenomas are the most common pituitary lesion) versus malignant (see also Chapter 70). The mass effect of the tumor can also lead to some associated symptoms, such as headaches, visual field defects, and increased intracranial pressure (with associated gait disturbances, vomiting, cranial nerve deficits, and bladder or bowel incontinence). Other symptoms may be related to pituitary insufficiency (e.g., hypoadrenalism, hypothyroidism, infertility) or overactivity. Manifestations of pituitary overactivity include the following: Cushing syndrome from ACTH-secreting tumors; acromegaly from growth hormone secretion; hyperthyroidism from TSH production; and gynecomastia, lactation, and sex hormone–related changes from prolactin and gonadotropin (follicle stimulating and luteinizing hormones) secretion. These hormones are all produced by the anterior lobe of the pituitary and are controlled by a feedback loop from the hypothalamus. The posterior pituitary stores and secretes vasopressin and oxytocin, which are synthesized in the hypothalamus.

Acromegaly results in enlargement of connective tissue, bone, and visceral organs. Patients have an enlarged jaw (i.e., macrognathia), nose, feet, hands, pharyngeal, and laryngeal tissues (including macroglossia and enlarged epiglottis). Affected individuals have increased risks of sleep apnea (both central and obstructive), neuropathies (from nerve entrapment), hypertension, LVH, diastolic dysfunction, and valvular abnormalities. CAD, heart failure, diabetes, hypothyroidism, and difficulty with airway management (mask ventilation, laryngoscopy, intubation) may also occur. The preoperative evaluation should document any chest pain, dyspnea, snoring, numbness, polydipsia, headaches, and visual disturbances. The physical examination focuses on BP, airway examination, murmurs, neurologic findings, and peripheral edema. It is important to plan for possible difficult airway management and to make the patient aware of the possible use of awake fiberoptic intubation. Preoperative testing may include ECG, electrolytes, glucose, and thyroid function tests. TSH increases production of thyroid hormones (T_3 and T_4) by the thyroid gland (see the earlier section on thyroid disease). Prolactin- and gonadotropin-secreting tumors have little impact on anesthetic management, but associated symptoms may alert clinicians to an undiagnosed pituitary tumor.

Posterior pituitary tumors result in failure to secrete vasopressin or antidiuretic hormone (ADH), which regulates renal water excretion. A deficiency results in diabetes insipidus, which is characterized by excessive urine output from a failure to reabsorb water. Unless treated with DDAVP, these patients may develop hypernatremia and volume depletion. Therefore, the need exists for a careful evaluation of their intravascular volume status, including orthostatic vital signs and blood testing for electrolytes, BUN, and creatinine levels. Patients with pituitary tumors, pituitary apoplexy (hemorrhage into pituitary, associated with hypertension, trauma, or pregnancy), or previous resection of a pituitary tumor may require hormone replacement therapy, such as with steroids, thyroid replacement, or DDAVP. These medications must not be interrupted during the perioperative period. The adequacy of replacement therapy can be determined based on the history and physical examination, as well as by determining electrolyte, BUN, and creatinine levels and performing thyroid function tests and an ECG.

Other intracranial tumors include gliomas (45% of tumors), astrocytomas, ependymomas, medulloblastomas, oligodendrocytomas (malignant and highly lethal), benign meningiomas (15% of tumors), schwannomas, craniopharyngiomas, and dermoid tumors. Metastatic lesions (6% of intracranial tumors) can also occur with virtually all types of primary malignant diseases. Common primary sources of metastatic intracranial lesions include breast, colorectal, and lung cancers. Most intracranial tumors are detected either incidentally or when patients develop seizures of symptoms related to mass effect. Symptoms of mass effect include headaches, strokelike symptoms, vomiting, visual disturbances, altered cognitive function, and ataxia. If the intracranial pressure becomes elevated, hypertension, bradycardia, arrhythmias, ECG abnormalities, and brainstem herniation may occur. Careful questioning and documentation of neurologic deficits are important. For patients with metastatic lesions, issues pertaining to the primary malignant disease and previous treatment (e.g., chemotherapy, radiation, steroids, anticonvulsants) must be clarified. Continuation of preexisting steroids (for decreasing brain edema) and anticonvulsant medications is important.

MUSCULOSKELETAL AND CONNECTIVE TISSUE DISEASES

These disorders are characterized by deformities and chronic inflammation. Assessment of any deformities is important, given their potential implications on airway management and regional anesthetic technique. Chronic inflammation, which is associated with rheumatoid arthritis, SLE, and systemic sclerosis, can result in vasculopathy and associated multiorgan dysfunction. Organ systems that may be affected include the cardiovascular, pulmonary, renal, hematologic, integumentary, gastrointestinal, central nervous, and peripheral nervous systems.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic autoimmune disorder that primarily affects joints, but it often also affects multiple organ systems.[196] The disease affects approximately 1% of the population, and women are more than twice as likely to be affected as are men.[196] Distal joints are involved more often than proximal, often in a symmetric pattern. Joint involvement is characterized by inflammation that can progress to severe deformity, although the disease course can vary dramatically. The temporomandibular joints and cricoarytenoid cartilage can be involved, resulting in limited mouth opening, hoarseness, and possible difficulties with airway management. Atlantodens subluxation and instability of the cervical spine can also occur. Subluxation, which is caused by ligamentous laxity, as opposed to joint disease, may occur in as many as 46% of patients.[197] Cervical spine disease can be asymptomatic. CAD, pericardial effusions, aortic regurgitation, and conduction abnormalities may be present in affected individuals. Symptoms of cardiac ischemia may be masked in patients with rheumatoid arthritis because of impairment of functional status by concomitant joint disease. In addition, dyspnea, which can be an anginal equivalent, may be confused with pulmonary involvement. Pulmonary manifestations include restrictive lung disease secondary to decreased thoracic mobility, pulmonary fibrosis, and pleural effusions. Patients have an increased risk of renal dysfunction secondary to both vasculitis and long-term NSAID use. Peripheral neuropathy can result from vasculitis or entrapment. Anemia, leukocytosis, thrombocytosis (from chronic inflammation), and thrombocytopenia (from splenomegaly) may be present. Patients may also have rheumatoid nodules that occur subcutaneously (usually over extensor joints) or in the lungs.

The preoperative examination must document symptoms related to the many organ systems affected by rheumatoid arthritis. Special detail is directed to the neurologic, airway, pulmonary, and cardiovascular systems. Documentation of deformities and neurologic deficits is important to establish a baseline level of function. Significant hoarseness should prompt an evaluation by an otolaryngologist to assess the mobility of the vocal cords and the presence of cricoarytenoid arthritis. A careful history may elicit neurologic deficits, neck pain, upper extremity pain, or crunching sound with neck movement. Indications for preoperative cervical spine radiographs include neurologic findings, long-standing severely deforming disease, or procedures requiring prone positioning or manipulation of the cervical spine. The specific radiographs required are anteroposterior and lateral cervical spine films with flexion, extension, and open-mouth odontoid views.[197] Significant abnormalities (i.e., anterior atlas-dens interval >9 mm or posterior interval <14 mm) require consultation with a neurologist or neurosurgeon. However, the disease duration, severity, and symptoms do not correlate with cervical spine subluxation. New or worsening pulmonary symptoms should trigger further evaluation with pulse oximetry, chest radiographs, PFTs, or possibly a pulmonary consultation. Muffled heart sounds, pericardial rubs, enlarged heart (examination or radiograph), and low voltage on an ECG suggest the presence of a pericardial effusion, which necessitates an echocardiogram. Any suspicious murmur merits further investigation in these patients. Because rheumatoid arthritis is associated with a very high prevalence of CAD, patients require ECGs, as well as possible cardiac stress

testing, with cardiology referral as indicated. Other preoperative tests should include blood sampling for a CBC and determination of BUN and creatinine levels.

Advanced planning for management of potential difficult airways is important, including discussion of regional anesthetic options and possible awake fiberoptic intubation. When possible, steroids, analgesic and antiplatelet medications should be continued. Patients with complex treatment regimens (especially immunosuppressant therapy) or severe disease are best managed in concert with their rheumatologist or primary physician.

Ankylosing Spondylitis

Ankylosing spondylitis is a progressive, inflammatory arthropathy that primarily affects the spine and sacroiliac joints, although peripheral joints may be involved as well. It usually occurs in male patients and can have extraarticular manifestations, including uveitis, vasculitis, aortitis, and aortic insufficiency. Affected individuals may develop restrictive lung disease secondary to pulmonary fibrosis or chest wall movement restriction (secondary to joint fixation and kyphosis). Kyphosis can be so extreme that patients are unable to face forward, thereby making mask ventilation, direct laryngoscopy, and intubation very difficult. The patient's history and physical examination should focus on the skeletal and cardiopulmonary systems, with the physical examination including measurement of oxygen saturation on room air. The presence of a murmur on physical examination warrants an ECG and an echocardiogram. If ventilatory compromise is suspected or present, a chest radiograph and PFTs are necessary. Any acute change must be managed preoperatively. Any NSAID therapy is usually discontinued for 2 days before the surgical procedure, but other drugs can be continued unless laboratory tests suggest complications. Patients receiving treatment with leflunomide should undergo LFTs, whereas patients receiving NSAIDs should undergo CBC, BUN, and creatinine testing. Planning for perioperative airway management and discussion with the patient about the possibility of awake fiberoptic intubation are important. Peripheral nerve blocks are an option, but neuraxial anesthesia is often unsuccessful in the presence of severe spinal involvement.

Systemic Lupus Erythematosus

SLE is a systemic autoimmune disease that is predominantly caused by vasculitis and has a variable course with flares and periods of remissions. It affects mainly female patients and is typically more severe in African Americans than in other ethnic groups. Common manifestations include fever, chronic fatigue, and migratory arthritis affecting the small joints of the hands and feet. The fevers may be explained by disease activity itself, as well as frequent infections attributable to disease-induced immune dysfunction and immunosuppressant treatment. Many patients have dermatologic conditions including alopecia, photosensitivity, and the typical "butterfly rash" across the cheeks and nose. Vasospasm of the digits (i.e., Raynaud phenomenon), often associated with atrophy of nails and fingernails, can make it difficult to obtain pulse oximetry readings. Interstitial lung disease, pleural effusions, frequent infections, and pulmonary hypertension may be present. Pulmonary hypertension, which can result from recurrent pulmonary emboli, pulmonary vasculopathy, and interstitial lung disease, carries a high risk of perioperative complications.[198] Cardiac involvement includes premature CAD, pericarditis, myocarditis, coronary artery vasculitis, cardiomyopathy, aseptic endocarditis, and pleural effusions. Hypertension is almost ubiquitous and is often difficult to control. Neurologic disease includes cerebral vasculitis, stroke, cerebrovascular disease, cognitive dysfunction, seizures, peripheral neuropathy, headache, neuropsychiatric manifestations, and affective disorders. Lupus nephritis is a common end-organ complication that carries a poor prognosis and often results in renal failure. Patients with SLE are frequently anemic and may also have leukopenia and thrombocytopenia. Affected individuals frequently have antiphospholipid antibodies, which can result in pulmonary emboli, stroke, and recurrent venous or arterial thromboses. Despite their prothrombotic tendency, these patients typically have a prolonged aPTT. Antinuclear antibodies are present in most cases, and these antibodies can help establish a diagnosis.

The history and physical examination should evaluate all major organ systems and describe all relevant medications. Patients with severe disease, infections, or exacerbations are best managed in concert with their rheumatologist or primarily responsible physician. Detailed questioning regarding cough, dyspnea, chest pain, orthopnea, neurologic symptoms, fever, disease course, and medications is paramount. A description of any prior thromboembolic events, precipitating factors, and treatment (type and duration) is important, especially to plan preoperative anticoagulant discontinuation and the need for bridging therapy. Given the prevalence of CAD and cerebrovascular disease in patients with SLE, the evaluation should include careful questioning about exercise capacity, atypical symptoms of ischemia, and the results of any previous relevant diagnostic studies (e.g., cardiac stress testing, echocardiography, CT, MRI).

The preoperative physical examination concentrates on the pulmonary (rales, decreased breath sounds), cardiac (pericardial rubs, murmurs, arrhythmias, jugular venous distention, peripheral edema), and nervous (motor deficits, sensory deficits, visual disturbances) systems. Preoperative ECG, CBC, electrolyte, glucose, BUN, creatinine levels, and aPTT (unless the patient has a known antiphospholipid syndrome) are often necessary. Significant ECG abnormalities (e.g., conduction delays, arrhythmias, Q waves, low voltage) should prompt consideration for further testing, cardiology consultation, or pulmonology consultation. Other tests that may be considered include a PT (patients receiving warfarin), echocardiogram (murmurs, suspected heart failure, suspected effusion), chest radiograph (pulmonary symptoms or suspected heart failure), and PFTs (worsening or undiagnosed dyspnea). Patients with advanced cardiomyopathy, decompensated heart failure, pulmonary hypertension, systemic vasculitis, and recent or recurrent thromboembolism are considered to be at high risk, and they are best managed in concert with the appropriate specialists. Most medications, with the exception of anticoagulants, are continued into the perioperative period (see Box 38-3).

Systemic Sclerosis

Systemic sclerosis (previously known as scleroderma) is an autoimmune disease that is characterized by excessive fibrosis and occurs more commonly in female patients.[199] Aside from skin thickening, the most common skin manifestation is Raynaud phenomenon. Scleroderma has several variants. *Localized scleroderma* involves just the skin and not any other organs. *Limited systemic sclerosis* has cutaneous manifestations "limited" to the skin of the face and upper extremities, as well as systemic involvement in the gastrointestinal tract (e.g., dysphagia, reflux) and lungs (e.g., interstitial lung disease, pulmonary hypertension). *Diffuse systemic sclerosis* has generalized skin involvement and causes multiple end-organ damage. Manifestations include myocardial fibrosis, pericarditis, heart failure, coronary artery fibrosis, severe hypertension, renal failure, dysphagia, fatigue, weight loss, gastroesophageal reflux, and right-sided heart failure. Pulmonary hypertension, which may result from interstitial lung disease or vasculopathy, is a leading cause of death in systemic sclerosis and is associated with increased perioperative risk.[198]

The preoperative evaluation focuses on the organ systems in the manner outlined before in the section on systemic lupus erythematosus, with special attention to evidence of pulmonary hypertension (see the earlier section on pulmonary hypertension). A careful history to elicit symptoms of pulmonary disease (e.g., cough, dyspnea) or cardiac disease (e.g., dyspnea, orthopnea, chest pain) is vital. Patients may develop limited mouth opening (i.e., microstomia), limited neck mobility, poor dentition, and oropharyngeal lesions secondary to skin involvement. Careful airway evaluation and planning for airway management are essential in such individuals, especially because they may also be at high risk for aspiration secondary to gastroesophageal reflux. Dermal involvement, edema, and contractures may also make venous access and regional anesthesia technically challenging. Thus, it is helpful to discuss central venous access and possible awake fiberoptic intubation during the preoperative assessment; in some cases, consideration should be given to arranging for interventional radiology to place intravenous lines.

Patients with systemic sclerosis usually need an ECG, CBC (especially if receiving immunosuppressant therapy), and determinations of BUN and creatinine levels. A chest radiograph and PFTs can be useful for evaluating patients with evidence of possible interstitial lung disease or pulmonary fibrosis. Echocardiography is useful as a screening tool in patients suspected of having pulmonary hypertension. Antihypertensive agents (including calcium channel blockers used to treat Raynaud phenomenon) and immunosuppressant therapy must be continued into the perioperative period.

Raynaud Phenomenon

Raynaud phenomenon is an exaggerated vascular response to cold or emotional stress that results in color changes of the digits (typical sequence is pallor to cyanosis to rubor).[200] It is classified as primary (termed *Raynaud disease*) or secondary (termed *Raynaud phenomenon*, and associated with connective tissue diseases, autoimmune disorders, drugs, and use of vibrating tools). The prevalence of Raynaud phenomenon is 95% or more in patients with systemic sclerosis, 20% to 30% in patients with Sjögren disease or SLE, but less than 5% in patients with rheumatoid arthritis.[201] Raynaud phenomenon most often affects the hands, typically resulting in a sudden onset of cold digits with sharply demarcated pallor or cyanosis. Cutaneous vasospasm is also common in other sites such as the face and ears, where it causes pain and numbness. Criteria for the diagnosis of Raynaud disease (primary disease) include symmetric episodic attacks, absence of PAD, absence of tissue injury or gangrene, normal nail fold capillary examination, normal erythrocyte sedimentation rate, and negative antinuclear antibody test. Raynaud disease requires no special preoperative evaluation. Secondary Raynaud phenomenon should prompt an assessment for associated disease states. It is also important to distinguish Raynaud phenomenon from PAD, especially given the difference in associated comorbidities. Calcium channel blockers are useful treatments in many patients and should be continued in the perioperative period.

Inherited Connective Tissue Disorders

Ehlers-Danlos syndrome is a disorder of collagen synthesis. It consists of several subtypes that have various manifestations but are almost all characterized by joint hypermobility. Type IV disease is more serious because affected individuals may have vascular fragility and skin fragility, as well as predisposition to vascular rupture, visceral rupture, and pneumothoraces. Patients with type VI Ehlers-Danlos syndrome have muscle weakness, scoliosis, ocular fragility, skin fragility, and osteopenia.

Marfan syndrome is characterized by tall stature, arachnodactyly (i.e., long digits), scoliosis, pectus excavatum, valvular disease (e.g., aortic insufficiency, MVP, mitral regurgitation), arrhythmias, and ascending aortic dilatation. These patients are at risk for aortic dissection. Ocular (e.g., ectopia lentis, strabismus, glaucoma) and pulmonary (e.g., spontaneous pneumothoraces) complications can also occur.[202] Other manifestations include retrognathia and high arched palates. Careful auscultation for the diastolic murmur of aortic insufficiency is important (see Table 38-6). If such a murmur is detected, subsequent tests should include an ECG, an echocardiogram, and a chest radiograph.

The most distinguishing feature of osteogenesis imperfecta is the propensity for fractures from extremely fragile bones. These patients may have blue sclerae, short stature, scoliosis, joint hypermobility, hearing loss, pulmonary complications, muscle weakness, MVP, aortic insufficiency, and platelet dysfunction. An ECG and an echocardiogram are necessary if physical examination reveals a murmur.

Epidermolysis bullosa is distinguished by blistering, skin fragility, and scarring caused by abnormal epidermal-dermal anchoring. Even measurement of BP may cause skin blistering and breakdown in an affected individual.

Kyphoscoliosis

Kyphoscoliosis is a curvature of the spine in both lateral and posterior directions. It can involve the thoracic region, the lumbar region, or both. Kyphoscoliosis may

occur alone or as a manifestation of other diseases such as collagen vascular disorders, Marfan syndrome, neurofibromatosis, muscular dystrophies, and cerebral palsy. Therefore, the preoperative evaluation should focus on identifying any coexisting abnormalities. Severe thoracic deformity may cause cardiopulmonary compromise as a consequence of restrictive lung disease, pulmonary hypertension, heart failure, tracheobronchial compression, or cardiac compression. The history should focus on assessing functional capacity and cardiopulmonary symptoms. The ability of the patient to lie supine, to permit airway access and management, must also be determined. The physical examination should include evaluation of vital signs (including oxygen saturation), pulmonary system (rales, decreased air entry), and cardiovascular system (murmurs, additional heart sounds, edema, jugular venous distention). A CBC, as well as a blood type and screen, is required in any patient scheduled to undergo spine correction surgery for kyphoscoliosis, and an ECG and a chest radiograph may be useful. If symptoms or signs of heart failure are present, a preoperative echocardiogram should be considered. Any reversible lung disease or heart failure must be optimized preoperatively.

CANCERS AND TUMORS IN PREOPERATIVE PATIENTS

Patients With Cancer

Patients with a history of cancer may have complications related to the disease or the treatment. Typically, patients are aware of the side effects of their cancer treatments. It is often helpful to ask patients whether any unexpected complications occurred during treatment or whether chemotherapy or radiation therapy had to be interrupted because of adverse effects. A hypercoagulable state is common in patients with cancer, particularly those with advanced disease, primary brain tumors, ovarian adenocarcinoma, pancreatic cancer, colon cancer, gastric cancer, lung cancer, prostate cancer, and kidney tumors. The risk of thromboembolic events is increased sixfold in patients with cancer, and active cancer accounts for 20% of new cases of thromboembolism.

The preoperative evaluation focuses on cardiac, pulmonary, neurologic, and hematologic systems. Previous head and neck irradiation may cause carotid artery disease, hypothyroidism, or difficulty with airway management. Auscultation for bruits, thyroid function tests, and carotid Doppler studies are therefore recommended. Mediastinal, chest wall, or left breast irradiation can cause pericarditis, conduction abnormalities, cardiomyopathy, valvular abnormalities, and premature CAD, even in the absence of traditional cardiovascular risk factors.[203] Thus, younger patients with a history of radiation therapy, even if they may not otherwise be at risk for heart disease, should be assessed for symptoms of cardiac disease and should undergo a preoperative ECG. Based on these initial results, stress testing and echocardiography may be indicated. Previous irradiation to the lungs, breast, or mediastinum may also cause radiation pneumonitis. In such individuals, an oxygen saturation measurement and chest radiograph may be required, with consideration for PFTs if appropriate.

Other important chemotherapy-associated side effects include cardiomyopathy with doxorubicin (Adriamycin), pulmonary toxicity with bleomycin, hemorrhagic cystitis with cyclophosphamide, and peripheral neuropathy with vincristine or cisplatin. Many chemotherapeutic agents are toxic to the kidneys, liver, and bone marrow, and patients commonly exhibit preoperative anemia. Patients who received steroids as part of their cancer treatment may be at risk for adrenal insufficiency. These individuals can be assessed with an ACTH stimulation test (see the earlier section on hypothalamic-pituitary-adrenal disorders) or given supplemental perioperative steroids (Table 38-11). Based on the type of chemotherapy, a CBC; determinations of electrolytes, BUN, and creatinine levels; LFTs; an ECG; and a chest radiograph may be needed. In some cases, consideration may be given to delaying the surgical procedure to allow resolution of neutropenia and thrombocytopenia. In general, advance planning of blood component replacement (including type and screening in the preoperative clinic) can avoid delays on the day of surgery.

TABLE 38-11 RECOMMENDATIONS FOR PERIOPERATIVE GLUCOCORTICOID COVERAGE

Surgical Stress	Target Hydrocortisone Equivalent	Preoperative Steroid Dose	Intraoperative Steroid Dose	Postoperative Steroid Dose	Postoperative Steroid Dose Day 1	Postoperative Steroid Dose Day 2
Minor (e.g., inguinal hernia repair)	25 mg/day for 1 day	Usual daily dose of steroid	None*	None*	Usual daily dose*	Usual daily dose*
Moderate (e.g., colon resection, total joint replacement, lower extremity revascularization)	50-75 mg/day for 1-2 days	Usual daily dose of steroid	50 mg hydrocortisone	20 mg hydrocortisone every 8 hr	20 mg hydrocortisone every 8 hr†	Usual daily dose
Major (e.g., esophagectomy, pancreatoduodenectomy)	100-150 mg/day for 2-3 days	Usual daily dose of steroid	50 mg hydrocortisone	50 mg hydrocortisone every 8 hr	50 mg hydrocortisone every 8 hr	50 mg hydrocortisone every 8 hr †

From Salem M, Tainsh RE, Bromberg J, et al: Perioperative glucocorticoid coverage: a reassessment 42 years after emergence of a problem, Ann Surg *219: 416-425, 1994.*

*If the postoperative course is uncomplicated, the patient can resume his or her usual steroid dose on postoperative day 1.

†If postoperative complications occur, continued glucocorticoid administration will be necessary commensurate with the level of stress.

The direct effects of cancers depend on the specific organ systems involved. Issues pertaining to intracranial tumors are discussed in the section on central nervous system tumors. Bone and liver involvement with metastases can commonly occur in patients with breast, colorectal, lung, and head and neck tumors. The resulting bony lesions can in turn cause hypercalcemia or pancytopenia. Head and neck tumors, as well as associated therapy (e.g., surgery, radiation), may cause difficulty with airway management and thyroid dysfunction. Lung cancer can cause airway problems, compromised pulmonary function, or mediastinal masses (see the next section, on mediastinal masses). In these cases, CT scans of the head, neck, or chest may be indicated. Paraneoplastic syndromes can also complicate almost any type of malignant disease, but these syndromes are most commonly seen with lung cancer. Typical manifestations of these syndromes include hypercalcemia, inappropriate antidiuretic hormone secretion, Lambert-Eaton syndrome, Cushing syndromes, and neuropathies.

Patients who are receiving opioids on a long-term basis for cancer pain are likely to require larger than usual doses of medication for postoperative pain control (see the later section on planning for postoperative pain management). On the day of surgery, these patients typically take their usual analgesic medications, with the exception of NSAIDs.

Mediastinal Masses

Tumors that may occur in the anterior mediastinal space include lymphomas, thymomas, teratomas, thyroid goiters, and metastatic disease. Anterior mediastinal masses can obstruct the great vessels (i.e., aorta, pulmonary arteries, pulmonary vein, superior vena cava), heart, trachea, and bronchi. Patients may complain of dyspnea, dysphagia, stridor, wheezing, coughing (especially when recumbent), and orthopnea. Superior vena cava syndrome is the consequence of the compression of the superior vena cava, and it results in jugular venous distention and edema in the face, neck, chest, and upper extremity. Evidence of increased intracranial pressure and airway compromise may also be present. Imaging of the chest (CT or MRI) and echocardiography are needed if airway, cardiac, or vascular compression is suspected. Flow-volume loops may also be useful to assess the location (extrathoracic versus intrathoracic) and degree of airway obstruction. Patients with tracheobronchial, cardiac, or major vessel compression require special anesthetic precautions, including possible awake fiberoptic intubation.

Von Hippel–Lindau disease

von Hippel–Lindau disease is an inherited, autosomal dominant syndrome characterized by a variety of benign and malignant tumors. Associated tumors include hemangioblastomas, retinal angiomas, clear cell renal cell carcinomas, pheochromocytomas, and neuroendocrine tumors of the pancreas. Preoperative evaluation of these patients includes an evaluation of renal function and assessment of symptoms compatible with pheochromocytomas or neuroendocrine tumors. Findings from a thorough patient history and physical examination (with vital signs) should guide any further testing (e.g., electrolytes, ECG, BUN, creatinine, glucose).

Carcinoid Tumors

Carcinoid tumors are rare neuroendocrine tumors that release mediators. They are associated with MEN 1. These tumors typically occur in the gastrointestinal tract and are the most common neoplasms of the appendix; in addition, carcinoid tumors can also occur in the pancreas and bronchi. Carcinoid syndrome is caused by vasoactive amines (e.g., serotonin, norepinephrine, histamine, dopamine), polypeptides (e.g., bradykinin, somatostatin, vasoactive intestinal peptide, glucagon), and prostaglandins released by the tumors. Typical manifestations include flushing, tachycardia, arrhythmias, diarrhea, malnutrition, bronchospasm, and carcinoid heart disease. Nonetheless, most patients are asymptomatic because the liver inactivates the bioactive products of carcinoid tumors. Thus, patients with gastrointestinal carcinoid tumors have manifestations of carcinoid syndrome only if they have hepatic metastases. Carcinoid heart disease is characterized by endocardial fibrosis of pulmonic and tricuspid valves. Affected individuals may then develop tricuspid regurgitation, pulmonic stenosis, pulmonic regurgitation, right-sided heart failure, peripheral edema, and hepatomegaly. Some individuals may also develop *carcinoid crisis*, which is associated with profound flushing, bronchospasm, tachycardia, and hemodynamic instability. These life-threatening episodes can occur with induction of anesthesia, intraoperative handling of a tumor, or other invasive procedure on a tumor (e.g., tumor embolization).[204]

The initial evaluation should focus on possible dyspnea, orthopnea, wheezing, edema, arrhythmias, and murmurs; subsequent diagnostic tests are guided by the initial assessment. Patients with chronic diarrhea need measurement of orthostatic vital signs, electrolytes, BUN, and creatinine. Patients with cardiac involvement must have an ECG, electrolyte determinations, and an echocardiogram. Malnourished patients need measurement of orthostatic vital signs, an ECG, and electrolyte and albumin levels. Predictors of perioperative adverse events in these patients are elevated urinary 5-hydroxyindoleacetic acid levels and the presence of carcinoid heart disease. [205] Histamine receptor blockers (both H_1 and H_2), ketanserin (serotonin receptor antagonist), and octreotide are useful in blocking mediator release or their associated effects. Preoperative treatment with an intravenous infusion of octreotide, starting 12 hours preoperatively, may help mitigate the risks of intraoperative carcinoid crises.[204,206]

SPECIAL ISSUES IN PREOPERATIVE EVALUATION

PSEUDOCHOLINESTERASE DEFICIENCY

A personal or family history of pseudocholinesterase, or butyrylcholinesterase, deficiency should be identified preoperatively (see Chapter 34). Pseudocholinesterase, which is found in the plasma, liver, pancreas, heart, and brain, is distinct from acetylcholinesterase, which is

found in erythrocytes. Patients reporting an "allergy to succinylcholine" should be suspected of having either this disorder or MH. Inquiring whether the patient was intubated postoperatively, gravely ill, or in need of intensive care may help differentiate these disorders. Previous anesthetic records may also help clarify an uncertain history.

Pseudocholinesterase activity may be reduced permanently because of abnormal genotypes or transiently altered because of disease, drugs, pregnancy, or infancy. In patients with a history suggestive of pseudocholinesterase deficiency, plasma cholinesterase activity, as well as the dibucaine number and fluoride number, should be measured. Plasma cholinesterase activity is a *quantitative* measure of enzyme activity, whereas the dibucaine number and fluoride number are *qualitative* measures. Plasma cholinesterase activity should not be confused with acetylcholinesterase activity, which is an assessment of erythrocyte cholinesterase. The *dibucaine number* represents the percentage inhibition of the enzyme by the local anesthetic dibucaine, and the fluoride number represents the percentage inhibition by fluoride. Normal individuals, who are homozygous for the wild-type gene have a dibucaine number of 80 because their plasma cholinesterase is 80% inhibited by dibucaine. Individuals who are homozygous for the atypical genes have a dibucaine number of 20 (corresponding to 20% inhibition) and can be paralyzed for up to 4 to 8 hours after receiving succinylcholine. In heterozygous individuals who have a dibucaine number of 60 (corresponding to 60% inhibition), the duration of action of succinylcholine is prolonged by 50% to 100%. The combination of dibucaine number and plasma cholinesterase activity can therefore help differentiate genetic from acquired causes of prolonged apnea after succinylcholine administration. Patients with known or suspected pseudocholinesterase deficiency should be urged to obtain proper medical alert identification and be educated that this enzyme also metabolizes ester-linked local anesthetics.

MALIGNANT HYPERTHERMIA

A history of MH or a suggestion of it (e.g., hyperthermia or rigidity during anesthesia) in a patient or family member must be clearly documented in the preoperative assessment, as well as communicated to the surgeon and eventual anesthesia provider. This is critical to ensure that special arrangements are made preoperatively (see Chapter 43). Individuals who are genetically predisposed to MH are asymptomatic until they are exposed to triggering agents. Certain neuromuscular diseases are also associated with a risk for MH, including specific muscular dystrophies (i.e., Duchenne, Becker, myotonic), King-Denborough syndrome, central core disease, periodic paralysis, osteogenesis imperfecta, myelomeningocele, and strabismus.

MORBIDLY OBESE PATIENTS

The morbidly obese patient presents a special set of preoperative risks (see Chapter 71). Obesity is associated with several important comorbidities, including diabetes, hypertension, cardiovascular disease, cerebrovascular disease, cancer, OSA (see the earlier section on obstructive sleep apnea), and poor functional capacity. Obese individuals are also at risk for nonalcoholic steatohepatitis (or "fatty liver"), which can result in abnormal LFTs; liver fibrosis; and, in some cases, end-stage liver disease. In addition, patients with extreme obesity are at risk for right-sided heart failure and pulmonary hypertension. Such individuals can have obesity-hypoventilation syndrome (OHS), also known as pickwickian syndrome. Obesity-hypoventilation syndrome is characterized by impaired central ventilatory drive and is distinct from OSA. It is associated with awake, chronic hypoxemia (PaO_2 <65 mm Hg) without a diagnosis of COPD or primary lung disease. In the perioperative setting, obese patients experience higher rates of difficult bag-mask ventilation and difficult tracheal intubation.

The preoperative evaluation focuses on relevant coexisting diseases, airway, cardiopulmonary system, and vital signs (including pulse oximetry). When measuring BP, the BP cuff should have a width that is approximately two thirds of the arm and a length that can adequately encircle the extremity. Assessment of neck circumference can also identify individuals at risk for difficulty with endotracheal intubation. Treatments for obesity can have important perioperative implications. For example, drugs or methods of weight reduction (e.g., purging, diuretics, laxatives, gastric bypass procedures) may result in electrolyte abnormalities, vitamin deficiencies, malnutrition, anemia, and cardiopulmonary disorders. Two previously available antiobesity medications, fenfluramine and dexfenfluramine (both were withdrawn from the market in 1997), had significant cardiac side effects, including regurgitant valvular lesions and pulmonary hypertension. Any individual who was ever exposed to these drugs should undergo a cardiovascular evaluation, including an ECG and an echocardiogram.

PATIENTS WITH TRANSPLANTED ORGANS

The number of patients with transplanted organs who require nontransplant surgical procedures increases yearly. During preoperative evaluation, these patients present special issues relating to transplant function, allograft denervation, immunosuppression, and other posttransplant physiologic and pharmacologic issues (see Chapter 74). Close interaction with the transplant team is one of the most important steps in the perioperative care of these patients. Clinicians performing the preoperative assessment should ensure that the transplant care providers are made aware of the upcoming procedure and are given an opportunity to make recommendations.

Some general preoperative considerations apply to all transplant recipients, as well as additional concerns based on the specific organ transplanted.[207] In all transplant recipients, the level of function of the transplanted organ and the presence of any rejection should be evaluated. The dosage regimen of all immunosuppressant medications should be noted, and patients should be instructed to continue taking all these medications through the perioperative period. However, these drugs can modify the pharmacology of many other agents administered during the

perioperative period, as has been extensively summarized in the literature.[208,209] Patients should also be assessed for complications related to immunosuppressant therapy. These complications include the following: hyperglycemia and adrenal suppression (steroids); increased risks of infection, hypertension, and renal insufficiency (steroids, cyclosporine, tacrolimus); and myelosuppression causing anemia, thrombocytopenia, and leukopenia (azathioprine, sirolimus). Although transplant recipients are at increased risk for postoperative infectious complications, no evidence indicates that higher doses of antibiotic prophylaxis provide added benefit. Instead, usual preoperative recommendations for antibiotic prophylaxis should be followed. Despite the controversy regarding the need for "stress-dose" supplementation in patients taking low-dose corticosteroids, it is still used frequently because of the low risks involved.

Careful cardiac evaluation is important in all transplant recipients because of their increased risk for cardiovascular disease. The bases for this increased risk include the impact of underlying diseases that led to the initial organ failure (e.g., diabetes, hypertension) and the potential for drug regimens, transplantation, and rejection episodes to create or worsen traditional cardiovascular risk factors. Preoperative renal function should also be assessed because long-term immunosuppressive regimens often lead to chronic renal insufficiency. Although the effects of transplantation and immunosuppressive regimens on intravascular coagulation are controversial, appropriate thromboprophylaxis should be considered in all transplant recipients.

Kidney transplant recipients present some specific issues for preoperative evaluation. Despite the presence of a normal creatinine concentration, the average GFR in these individuals is generally decreased. This impairment in renal function predisposes these patients to electrolyte abnormalities and altered drug metabolism.[208,209] Nephrotoxic drugs, including NSAIDs and COX-2 inhibitors, should be avoided in all renal transplant recipients. In addition, their risk for cardiovascular disease is increased to approximately twice that of the general population. Careful preoperative cardiac evaluation is essential.

Successful liver transplantation usually results in resolution of the hepatic and cardiovascular effects of end-stage liver disease. Nonetheless, some pretransplant disturbances present in these patients may not resolve after transplantation, thus necessitating careful evaluation of pulmonary function. These disturbances can include hepatopulmonary syndrome, which involves hypoxemia from intrapulmonary vascular shunting. Other patients may demonstrate ventilation-perfusion mismatch secondary to pulmonary effusions, ascites, or diaphragmatic dysfunction, as well as diffusion abnormalities resulting from interstitial pneumonitis or impaired hypoxic pulmonary vasoconstriction.

Following successful lung transplantation, recipients may require months to achieve peak pulmonary function. Compared with all other allografts, the transplanted lung is especially susceptible to infection and rejection as a result of its unique exposure to the external environment. Careful preoperative evaluation with PFTs should be considered in all lung transplant recipients, with postponement of elective surgical procedures when allograft rejection or infection is suspected. Other perioperative considerations include airway hyperresponsiveness, the loss of the cough reflex, and the potential for injury to the airway anastomosis with intubation. These patients are also at increased risk for pulmonary edema, which has been attributed to disruption of the lymphatic drainage in the transplanted lung.

Most issues relating to heart transplant recipients relate to the absence of autonomic innervation in the transplanted heart. This denervation has multiple physiologic effects, such as a higher than normal resting HR (from absence of vagal tone); the absence of cardiac baroreflexes; and the lack of response to carotid sinus massage, Valsalva maneuver, laryngoscopy, or tracheal intubation. Denervation also affects responses to medications; the allograft demonstrates a normal or augmented response to direct-acting drugs (e.g., epinephrine), a blunted response to indirect-acting agents (e.g., ephedrine), and no response to vagolytic agents. Chronic allograft rejection can manifest as accelerated coronary heart disease and as both systolic and diastolic dysfunction. Because allograft denervation causes any myocardial ischemia to be silent, typical manifestations of chronic rejection include fatigue, ventricular dysrhythmias, congestive heart failure, and silent MI on the ECG. Should preoperative evaluation raise clinical suspicions of worsening rejection, the patient's recent cardiac testing must be reviewed. Heart transplant recipients undergo routine periodic evaluation for CAD (stress testing or coronary angiography) and cardiac function (echocardiogram or radionuclide angiography). With respect to other preoperative cardiac investigations in these patients, the preoperative ECGs often reveal conduction abnormalities and may show two P waves (a nonconducted P wave from the native atria and a conducted P wave from the donor atria). Many heart transplant recipients also require permanent pacemakers, and pacemaker function should be confirmed during the preoperative assessment.

PATIENTS WITH ALLERGIES

The patient's preoperative record should include careful documentation of any history of allergies and adverse drug reactions. True anaphylactic reactions should be distinguished from adverse side effects (e.g., nausea with opioid use), especially because a patient's definition of an allergy may differ significantly from the true clinical definition. In some cases, patients may incorrectly attribute previous perioperative difficulties to "allergies" to anesthetic or analgesic medications. The true incidence of anaphylactic and anaphylactoid reactions during anesthesia is probably underestimated because reactions are generally underreported. The reported incidence ranges from 1 in 10,000 to 1 in 20,000 procedures, with an increased incidence of 1 in 5200 to 1 in 6500 in cases involving administration of neuromuscular blocking agents[210] (see also Chapter 34). The most common precipitating drugs are neuromuscular blocking agents (50% to 70% of cases), followed by latex and antibiotics.[210] Anaphylaxis also accounts for up to 3% of perioperative deaths that are totally or partially related to anesthesia.[211] Nonetheless,

a careful history generally allows for avoidance of precipitating agents; thus, premedication with histamine blockers and steroids is not generally recommended. In selected cases in which the clear diagnosis of a specific allergy is required to guide perioperative management, skin testing may also be considered.

Latex is the second most common precipitant of anaphylaxis during anesthesia. Although the rate of latex sensitization continues to increase, the development of better ways to identify at-risk patients has led to a decreased incidence of latex-induced anaphylaxis.[212] The diagnosis of a latex allergy during preoperative evaluation is based on a careful history. Individuals at particular risk for latex allergy include those with a history of multiple surgical procedures, health care workers, and those with atopic histories. In Europe, this history may be supplemented using commercially available skin tests (not currently approved in the United States).[210] When latex allergy is identified during the preoperative evaluation, the operative team should be notified in advance to ensure that all appropriate equipment is available. The ASA Task Force outlines detailed intraoperative considerations for these patients.[213]

Among antibiotics, penicillins and cephalosporins are the most common causes of anaphylaxis. A small risk of cross-reactivity exists between penicillins and cephalosporins, but most of these reported reactions involve rashes, not anaphylaxis. Reported allergies to vancomycin should be distinguished from "red man syndrome." This histamine-induced side effect, which is associated with rapid injection of vancomycin, consists of flushing, pruritus, erythematous rash, and hypotension.

With respect to other medications commonly encountered in the perioperative setting, anaphylactic reactions to amide local anesthetics are extremely rare. Most true anaphylactic reactions following exposure to ester local anesthetics do not involve an allergy to the local anesthetic, but rather to associated preservatives (e.g., *para*-aminobenzoic acid). Patients may incorrectly interpret adverse side effects from epinephrine in local anesthetic solutions as allergies, especially with dental procedures. Such reports should be carefully distinguished from true allergies. Similarly, true allergies to opioids are rare, with most reports of such "allergies" being simply opioid-related side effects, such as nausea and vomiting. No reports of anaphylactic reactions to volatile anesthetics have been published. Most reactions to commonly used antiseptic solutions such as bacitracin or povidone-iodine involve contact dermatitis; in contrast, true anaphylactic reactions have only rarely been reported.[214]

The scientific status of multiple chemical sensitivity disorder, or idiopathic environmental intolerance syndrome, is controversial. These individuals report chronic, diffuse, nonspecific symptoms with low levels of multiple chemical substances. Symptoms involve multiple organ systems and include fatigue, headache, memory loss, palpitations, and gastrointestinal symptoms. The symptoms are not generally accompanied by biologic test abnormalities or changes on physical examination, but they are frequently associated with psychiatric symptoms, notably depression and anxiety.[215] This disorder is also often associated with fibromyalgia. Preoperative evaluation of these patients can be extremely challenging because they have significant concerns about the multiple exposures involved during the perioperative period and the potential impact on their symptoms. No current recommendations are available on the perioperative care of these patients.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Acute infection with HIV causes a mononucleosis-like illness, which then progresses to chronic lymphadenopathy (lasting 3 to 5 years). Infection can culminate in cell-mediated immune deficiency characterized by opportunistic infections, malignant diseases (e.g., Kaposi sarcoma, non-Hodgkin lymphoma), and death (usually secondary from infections, wasting, or cancer). Although the prognosis of untreated HIV infection is very poor,[216] outcomes have improved substantially in individuals compliant with highly active antiretroviral therapy (HAART).[217] Risk factors for HIV infection include sexual contact with an infected individual, bloodborne contamination, men who have sex with men, sexual workers, and those having contact with sexual workers. Most infection transmitted by blood exposure occurs in intravenous drug users, whereas infection through blood product transfusion in the United States is very rare (1 per 1.5 to 2 million blood transfusions). Mothers can transmit the disease to infants, which occurs usually during breastfeeding or delivery.[218] Many patients infected with HIV are unaware of their status.

HIV infection can affect all organs and cause multiple complications.[219] Cardiac complications include myocarditis, dilated cardiomyopathy, valvular disease, pulmonary hypertension, pericardial effusions, and tamponade. Pulmonary effects include lymphoid interstitial pneumonitis, as well as drug-resistant infections with *Pneumocystis jiroveci*, *Mycobacterium avium* or *Mycobacterium tuberculosis*, cytomegalovirus, and *Cryptococcus*. Nervous system manifestations include central nervous system tumors, infections, aseptic meningitis, and acquired immunodeficiency syndrome (AIDS)–related dementia. Malignant diseases can occur, such as lymphomas, Kaposi sarcoma, and cervical cancer. These tumors can also have direct consequences for anesthetic management. For example, supraglottic or intraoral Kaposi sarcoma may interfere with ventilation and intubation, whereas non-Hodgkin lymphoma can cause mediastinal masses. Gastrointestinal manifestations include dysphagia, diarrhea, and esophagitis, which can in turn cause malnutrition, dehydration, and electrolyte imbalance. Renal complications include acute tubular necrosis, glomerulonephritis, renovascular disease, and HIV-associated nephropathy with nephritic syndrome. Antiretroviral medications used to treat HIV infection also have important side effects. The major classes of antiretroviral medications include nucleoside reverse transcriptase inhibitors (e.g., lamivudine, zidovudine, tenofovir, abacavir), nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine, efavirenz, rilpivirine), protease inhibitors (e.g., atazanavir, darunavir, lopinavir, fosamprenavir, saquinavir), attachment inhibitors (e.g., maraviroc), and integrase strand transfer inhibitors

(e.g., raltegravir).[220] Side effects of relevance to anesthesiologists include lactic acidosis (nucleoside reverse transcriptase inhibitors), hepatotoxicity (nucleoside reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, protease inhibitors), hyperlipidemia (protease inhibitors), insulin resistance (protease inhibitors), and bone marrow suppression (all classes). [221] Protease inhibitors are also associated with premature CAD[222] and cardiac conduction abnormalities (especially PR interval prolongation). Patients' antiretroviral therapy must be continued through the perioperative period.

If the preoperative evaluation of a relatively young, otherwise healthy individual elicits a history of thrush, fever of unknown origin, chronic diarrhea, lymphadenopathy, or herpes zoster in more than one dermatome, these findings should raise concern of undiagnosed HIV infection. In these cases, the enzyme-linked immunosorbent assay (ELISA) is the primary initial screening test. It demonstrates very high sensitivity exceeding 99% but yields a high number of false-positive results. The Western blot technique is used as the confirmatory test following an initial positive ELISA result. Patients with known HIV infection frequently require further evaluation, including an ECG, a chest radiograph, and blood sampling for CBC, determination of electrolytes, creatinine, and LFTs. If the patient shows evidence of malnourishment or nephrotic syndrome, further blood tests for albumin, total protein, and magnesium levels may be beneficial. The patient's perioperative prognosis may be estimated based on the CD4 lymphocyte count and viral load, which reflect the patients' immunologic status during the previous 3 months. In general, rates of postoperative complications and mortality are higher among patients with CD4 counts lower than 200 cells/mm^3 and viral loads greater than 10,000 copies/mL.[223,224]

PATIENTS WITH A HISTORY OF SUBSTANCE ABUSE

A patient with a history of current or previous alcohol or drug addiction presents special challenges for the perioperative team (see Chapter 110). The lifetime prevalence of these addictions is significant, at 14% for alcohol addiction and 7% for drug addiction in the United States population.[225] Nonetheless, very limited data from clinical trials are available to help guide the perioperative management of these individuals.

The preoperative evaluation is an opportunity to obtain a detailed history of addiction and recovery. In a suggested classification system, abused drugs can be categorized as central nervous system depressants (e.g., heroin, alcohol, sedatives, hypnotics), stimulants (e.g., cocaine, amphetamines), and other psychotropic substances (e.g., cannabis).[226] Many addicts are polysubstance abusers. Addictive disease should be considered *permanent* even in patients who have had long periods of abstinence. Some patients in the process of recovery from addiction may be receiving specific medications to maintain recovery. For example, previous opioid abusers may be receiving methadone, clonidine, or buprenorphine (a partial μ-agonist). The dosage of any such medications should be documented and verified. Patients in recovery may also have heighted anxiety regarding upcoming surgical procedures because of concerns about relapse into addiction and inadequate pain treatment, given their history of addiction. Such concerns may be appropriate. Patients receiving opioid substitution therapy do experience normal pain responses to nociceptive stimuli but require additional analgesia for control of postprocedural pain.[227] These patients should therefore be reassured that anxiety and pain will be adequately treated. The clinicians performing preoperative evaluation may have prejudicial attitudes and lack the educational background to formulate appropriate perioperative pain management plans. For example, pain medication may be underdosed and inappropriately restricted because of concerns about provoking relapses. Early involvement of the acute pain service and addiction specialists to assist in the management of these at-risk patients may be helpful.

The preoperative period should be used to develop appropriate management plans based on the types of abused drugs. All pertinent preoperative information and management plans should be transmitted to members of the perioperative team. Individuals addicted to alcohol, sedatives, or hypnotics may require stabilization with benzodiazepines, whereas heroin addicts may require substitution with methadone. It is important to document the dosage of opioids consumed by individuals abusing these drugs, especially to help guide postoperative pain management. To avoid inadequate analgesia (which could potentially activate addiction) in these patients, the preoperative evaluation should be used to discuss and plan the optimal use of nonopioid analgesics and regional techniques. Patients actively abusing cocaine and amphetamines are at especially high risk during anesthesia because of the potential for intraoperative hemodynamic instability. Urine testing, especially on the day of surgery, may be appropriate to ensure the absence of abused substances in such patients.

Addicts are at risk for myriad perioperative complications, including withdrawal, acute intoxication, infections, end-organ damage, and altered tolerance of anesthetic or opioid medications.[228] A history of intravenous drug use should prompt an evaluation for cardiovascular, pulmonary, neurologic, and infectious complications such as endocarditis, abscesses, osteomyelitis, hepatitis, and HIV infection. Opioid (including heroin) users have a tolerance to narcotics. Patients with alcoholism are at risk for delirium tremens, a potentially life-threatening form of withdrawal characterized by autonomic instability and hyperpyrexia. These patients may also have liver disease (alcoholic hepatitis, cirrhosis, portal hypertension, end-stage liver disease), alcohol-induced cardiomyopathy, arrhythmias, seizures, neuropathies, dementia, Wernicke-Korsakoff syndrome (ataxia and cognitive dysfunction secondary to thiamine deficiency), macrocytic anemia, and coagulopathies (from hepatic dysfunction or vitamin K deficiency). Cocaine and amphetamine addicts can develop cerebrovascular accidents, cardiomyopathy, and arrhythmias. Additionally, cocaine and amphetamine inhibit the uptake of sympathomimetic neurotransmitters, thereby increasing risks for hypertension, tachycardia, paranoia, anxiety, seizures, and myocardial ischemia. Long-term use can result in ventricular hypertrophy, MI,

and nasal septal perforation. Solvents can cause cardiac dysrhythmias, pulmonary edema, cerebral edema, diffuse cortical atrophy, and hepatic failure. Hallucinogens, such as lysergic acid diethylamide (LSD), can cause autonomic dysregulation and paranoia. Ecstasy, or more specifically 3,4-methylenedioxymethamphetamine (MDMA), can cause excessive thirst that results in hyponatremia, pulmonary edema, or cerebral edema. Marijuana can cause tachycardia, vasodilatation, and increased cardiac output. The risk of pulmonary complications in patients who smoke marijuana is similar to that of individuals who smoke tobacco.[229]

During the preoperative evaluation interview, patients who abuse alcohol or drugs may not give a reliable history. The subsequent physical examination must include careful measurement of vital signs, including temperature. For example, cocaine and amphetamines may cause hypertension and tachycardia, whereas acute opioid use may result in a slow respiratory rate. Acute opioid use may also manifest as lethargy and pinpoint pupils, and recent alcohol consumption can often be detected by smell. Especially in individuals suspected of being intravenous drug abusers, examination of venous access sites for signs of abscesses and skin and soft tissue infections is important. In addition, careful auscultation for murmurs is essential because of the risk of bacterial endocarditis in these patients. Cocaine or alcohol abusers can also exhibit important findings in their cardiovascular examination, such as symptoms and signs of heart failure or arrhythmias. Long-term alcohol abuse may manifest with physical findings of chronic liver disease. In addition to identifying the presence of substance abuse and its related complications, clinicians should ascertain whether, and for how long, patients can stop consuming alcohol or addictive drugs. If patients do stop consumption occasionally, it is especially important to determine what complications, if any, occur. When an alcoholic patient reports previously interrupting drinking for several days, the interviewer should inquire whether agitation, seizures, delirium tremens, or other signs of withdrawal developed. Preoperative testing largely depends on symptoms and findings from the history and physical examination, as well as the specific drug that is being abused. For example, an ECG may be warranted to assess for previous MI in an individual with a history of cocaine abuse or in an individual receiving methadone (which prolongs the QT interval) to treat opioid addiction.

Ideally, patients with drug or alcohol dependence should be drug free well before elective surgical procedures. A randomized trial of a preoperative alcohol cessation program demonstrated significant reductions in postoperative complications,[230] although these benefits were not replicated in a subsequent similar trial.[231] Preanesthesia clinic staff should be prepared to refer patients to addiction specialists or to prescribe medications to prevent withdrawal in the preoperative period if patients agree to abstinence. For example, benzodiazepines can be useful in preventing or treating alcohol withdrawal symptoms.

Some medications used to manage withdrawal or facilitate recovery have specific perioperative considerations.[225] Patients taking selective serotonin reuptake inhibitors (SSRIs) or methadone should continue maintenance doses in the perioperative period. Patients who are taking disulfiram because of a history of alcohol abuse may have an altered response to sympathomimetic drugs; some authors therefore suggest that disulfiram be discontinued 10 days before the surgical procedure.[225] If disulfiram is continued, users can experience flushing, nausea, and tachycardia in response to small amounts of alcohol, such as amounts encountered in skin preparations or medications. For patients taking naltrexone for a history of alcohol abuse, consideration should be given to discontinuing it 3 days preoperatively.[225] Naltrexone alters responses to opioid analgesics and may make postoperative pain management very challenging. Buprenorphine-containing medications (i.e., Suboxone, Subutex), which are used to treat opioid addiction, should also be discontinued 3 days before surgical procedures because they too alter responses to opioid analgesics. If medications needed to manage recovery from addiction are discontinued preoperatively, patients may require substitution with alternative medications that can be continued perioperatively (e.g., SSRIs).

BREASTFEEDING PATIENTS

Research data to help guide recommendations for the safety of anesthetics and medications in the babies of breastfeeding mothers who receive these agents are limited. For elective surgical cases, women should be advised to pump and store milk preoperatively; this milk can be used in the first 24 hours after administration of an anesthetic or for the duration of breast milk exposure to potentially harmful agents. The mother should discard milk produced within the first 24 hours after anesthesia and should generally resume breastfeeding after this period. Very young or premature babies, especially those at risk for apnea, may have complications if the mother continues to take opioid or sedating drugs. Mothers should be advised to first discuss the safety of breastfeeding while taking medications with their child's pediatrician.

PATIENTS WITH DO NOT RESUSCITATE ORDERS

Some patients scheduled for procedures have advance directives or a do not resuscitate (DNR) status (see Chapter 108). The ASA adopted guidelines for the care of these patients and updated them in 2013 (Box 38-16).[232] Frequently, in circumstances with DNR orders, care providers are focused on a procedure-directed approach (i.e., do not intubate, do not administer resuscitative drugs). This approach is problematic in the perioperative period because much of anesthesia care involves such procedures. Within the context of anesthesia care, some authors have proposed that a better approach is to discuss DNR status in a goal-directed approach (i.e., from the perspective of the patient's values and objectives, such as quality-of-life concerns).[233] The ideal time to have this emotional and complex discussion is during the preoperative evaluation. Short discussions in the preoperative clinic have been shown to foster dialogue among patients, their proxies, and physicians regarding advance directives concerning

BOX 38-16 ***Do Not Resuscitate Orders in the Perioperative Period***

Policies automatically suspending DNR orders or other directives that limit treatment before procedures involving anesthetic care may not sufficiently address a patient's rights to self-determination in a responsible and ethical manner. Such policies, if they exist, should be reviewed and revised, as necessary, to reflect the content of these guidelines.

- **Full attempt at resuscitation:** The patient or designated surrogate may request the full suspension of existing directives during the anesthetic and immediate postoperative period, thereby consenting to the use of any resuscitation procedures that may be appropriate to treat clinical events that occur during this time.
- **Limited attempt at resuscitation defined with regard to specific procedures:** The patient or designated surrogate may elect to continue to refuse certain specific resuscitation procedures (e.g. chest compressions, defibrillation, or tracheal intubation). The anesthesiologist should inform the patient or designated surrogate about (1) which procedures are essential to the success of the anesthesia and the proposed procedure and (2) which procedures are not essential and may be refused.
- **Limited attempt at resuscitation defined with regard to the patient's goals and values:** The patient or designated surrogate may allow the anesthesiologist and surgical team to use clinical judgment in determining which resuscitation procedures are appropriate in the context of the situation and the patient's stated goals and values. For example, some patients may want full resuscitation procedures to be used to manage adverse clinical events that are believed to be quickly and easily reversible but to refrain from treatment for conditions that are likely to result in permanent sequelae, such as neurologic impairment or unwanted dependence on life-sustaining technology.

Modified from Committee on Ethics, American Society of Anesthesiologists: Ethical guidelines for the anesthesia care of patients with do-not-resuscitate orders or other directives that limit treatment, 2013. Available at http:// http://www.asahq.org/For-Members/Standards-Guidelines-and-Statements.aspx

DNR, Do not resuscitate.

end-of-life care, as demonstrated by a randomized trial of 397 patients at a preoperative evaluation clinic.[234] Individuals who received the information session were significantly more likely to complete a durable power-of-attorney (27% versus 10%) and discuss end-of-life care with their proxy decision makers (87% versus 66%).

PREOPERATIVE LABORATORY AND DIAGNOSTIC STUDIES

The value of preoperative diagnostic testing has become a central issue in delivering cost-effective health care to surgical patients. The role of preoperative testing to screen for disease and to evaluate the patient's fitness for surgery has been extensively studied. Research in this field has largely concluded that a practice of routine preoperative testing in all surgical patients, without consideration for their age or medical condition, cannot be justified. Unnecessary testing is inefficient and expensive, and it entails additional technical resources. In addition, it may lead to costly evaluation of borderline or false-positive test abnormalities. Aside from potentially causing operating room delays or cancellations, these unnecessary follow-up tests may pose risks to patients that are attributable to both the tests and any associated interventions. Therefore, the targeting of testing in appropriate patients has both clinical and economic benefits.

At many hospitals where surgeons and primary care physicians order all preoperative tests, the common practice has been to order tests without any diagnostic focus, other than speculation that the anesthesiologist may "require them" for surgery to proceed without delay or cancellation. Other justifications offered for this nonselective ordering of tests include routine screening for disease states, establishment of a diagnostic baseline, personal habit (e.g., "standard" testing checklist for all patients), physician reassurance, and a perceived medicolegal necessity "not to miss anything." Routine preoperative testing in asymptomatic healthy patients has very poor diagnostic yield, provides little to no additional prognostic information, and has not shown any beneficial effect on outcomes.[235-238] This practice can therefore no longer be justified. Indeed, Medicare and most private insurance carriers no longer reimburse routine preoperative screening tests without specific indications.

The ordering of preoperative diagnostic tests should be based on a patient's medical history, the proposed surgical procedure, and the potential for intraoperative blood loss. Testing should be targeted to detecting specific clinical indications that may increase perioperative risk. Randomized trials have demonstrated that such a shift in strategy from nonselective to selective preoperative testing in low-risk surgical procedures can reduce costs while preserving patients' safety.[239,240] As experts in perioperative medicine, anesthesiologists are in a unique position to appropriately select the preoperative laboratory tests needed to guide perioperative care. Indeed, anesthesiologist-led preoperative evaluation has been shown to result in more selective ordering of laboratory tests than evaluation led by surgeons or primary care physicians.[9-12] Thus, by educating and providing specific guidance to surgeons and other physician specialists on the appropriate ordering of preoperative tests, anesthesiologists can expedite patient care, reduce health care costs, and enhance the standing of the specialty in perioperative medicine.

A proposed framework for ordering preoperative diagnostic tests based on a patient's medical history is presented in Table 38-12. These disease-specific recommendations are not intended as absolute or standard. Indeed, many individual hospitals, as well as certain regional jurisdictions (e.g., Ontario Pre-Operative Testing Grid),[241] have developed their own specific recommendations for preoperative laboratory testing. In addition, the National Institute for Health and Care Excellence (NICE) has developed explicit guidelines for preoperative testing in the United Kingdom, following an extensive systematic review of the literature.[237,238] Although the most recent ASA "Practice Advisory for Preanesthesia Evaluation" did recommend against routine preoperative testing,[242] it did not make explicit recommendations about which tests should be ordered for specific clinical conditions. The practice advisory stated that the indications for

testing should be "based on information obtained from medical records, patient interview, physical examination, and type and invasiveness of the planned procedure." In addition, it described patient-related and surgery-related factors that anesthesiologists should consider when deciding to order a specific laboratory test.[242] Specific preoperative laboratory tests are discussed in the following subsections, with an emphasis on clinical indications for testing.

COMPLETE BLOOD COUNT, HEMOGLOBIN, AND HEMATOCRIT

The proposed surgical procedure, associated potential blood loss, and individualized patient-level clinical indications should determine the requirement for a preoperative blood count. Primary clinical indications include a history of increased bleeding, hematologic disorders, renal disease, recent chemotherapy or radiation treatment, corticosteroid or anticoagulant therapy, poor nutritional status, surgical procedures with anticipated high blood loss, and trauma.

RENAL FUNCTION TESTING

Tests of renal function measure the degree of renal tubular dysfunction and glomerular filtration. Primary clinical indications include diabetes, hypertension, cardiac disease, potential dehydration (e.g., vomiting, diarrhea), anorexia, bulimia, fluid overload (e.g., congestive heart failure, peripheral edema, ascites), renal disease, liver disease, relevant recent chemotherapy (e.g., cisplatin, carboplatin), hematuria, nocturia, polyuria, oliguria, anuria, and renal transplantation.

LIVER FUNCTION TESTING

The ordering of LFTs should be based on a history of liver injury and physical examination findings. Primary clinical indications include a history of hepatitis (viral, alcohol, drug-induced, autoimmune), jaundice, cirrhosis, portal hypertension, biliary or gallbladder disease, hepatotoxic drug exposure, tumor involvement of the liver, and bleeding disorders.

COAGULATION TESTING

Clotting studies are not indicated in routine preoperative evaluation, even in patients undergoing regional procedures, unless an indication exists of a known or suspected coagulopathy. A careful history and physical examination provide guidance on whether coagulation testing is indicated. Primary clinical indications include a known bleeding disorder, previous excessive intraoperative surgical bleeding, hepatic disease, poor nutritional status, and use of anticoagulants or other drugs that affect coagulation.

URINALYSIS

No indication exists for routine urinalysis during preoperative evaluation. Primary clinical indications could include a suspected urinary tract infection or unexplained fever or chills.

PREGNANCY TEST

Pregnancy testing is often determined by hospital-specific protocols and can be based on findings in the history. Clinical indications relate to the date of the last menstrual period, sexual activity, use (and type) of birth control, and patient or physician intuition.

SICKLE CELL TEST

Individuals at risk for sickle cell disease include those of African, Caribbean, Eastern Mediterranean, and Middle Eastern origin. Consideration should be given to offering the sickle cell test to *previously untested* patients from at-risk ethnic groups. Given the very low yield of routine testing in these at-risk populations,[243] testing should also be guided by other factors. These factors include patient-related (e.g., family history of sickle cell disease, unknown family history, anemia, sickle cell symptoms) and surgery-related (e.g., deliberate hypothermia, cardiopulmonary bypass, intrathoracic procedures, intraabdominal procedures, orthopedic procedures involving tourniquet use) indications. The test should be accompanied by pretest and posttest counseling, so that patients are aware of the implications of both positive and negative test results for themselves and family members.

ELECTROCARDIOGRAM

The ECG can help determine a previous history of MI, conduction or rhythm disturbances, ischemia, chamber hypertrophy, and electrolyte disorders. Nonetheless, when combined with usual clinical examination, the preoperative ECG may not provide additional prognostic information to identify individuals at risk for postoperative cardiac complications.[54] Primary clinical indications preoperatively include a history of CAD, hypertension, diabetes, congestive heart failure, chest pain, palpitations, abnormal valvular murmurs, peripheral edema, syncope, dizziness, dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, and cerebrovascular disease. The ACCF/AHA 2009 guidelines on perioperative cardiovascular evaluation provide additional recommendations about when to order preoperative resting ECGs (see Box 38-2).[5]

CHEST RADIOGRAPH

No compelling evidence indicates that routine preoperative chest radiographs provide prognostically important information for assessing patients' perioperative risk.[244] A preoperative chest radiograph should therefore be ordered only to assess concerning abnormalities that are present in the history or physical examination. Clinical indications for a preoperative chest radiograph include auscultation of rales or rhonchi, advanced COPD, bullous lung disease, suspected pulmonary edema, suspected pneumonia, suspected pulmonary or mediastinal masses, suspicious findings on physical examination (e.g., rales,

rhonchi, tracheal deviation), aortic aneurysm, cardiomegaly, pulmonary hypertension, or dextrocardia.

PREOPERATIVE RISK ASSESSMENT

A critical objective for the preanesthesia evaluation is assessment of a patient's risk for undergoing anesthesia and surgery. This assessment improves patients' understanding of the risks inherent to the perioperative period and better informs health care providers' clinical decision making. For example, these risk assessments can help identify individuals who warrant potentially beneficial interventions, enhanced levels of postoperative monitoring, or consideration for alternative nonoperative treatment for their underlying condition. An anesthesiologist's designation of a surgical patient as being high risk is clinically important. Specifically, when an initial preanesthesia evaluation deems that a patient is an unacceptably high risk for anesthesia and surgery, this assessment is accurate, and adherence to the anesthesiologist's recommendations for further perioperative management is associated with lower postoperative complication rates.[245] In addition, accurate risk assessments facilitate fairer comparisons of perioperative outcomes across different health care providers and institutions; specifically, estimates of patients' risks are required by statistical methods that can adjust for case-mix differences across providers and institutions.[246]

The most commonly used method by anesthesiologists to assess overall perioperative risk is the ASA physical status (ASA-PS) classification system (Table 38-13). This classification system, which was developed in 1941 by Meyer Sakland at the request of the ASA,[247] was originally intended to facilitate collection and comparison of statistical data in anesthesia. The ASA-PS classification system seeks to describe a patient's preoperative medical status, but it does not consider risks inherent to the planned surgical procedure. Although *not* intended to guide estimation of patients' risks for anesthesia and surgery, the ASA-PS is often used for this very purpose, especially given its simplicity of use.

Indeed, several studies have shown a correlation of ASA-PS scores with postoperative mortality and major complications.[47,111,248,249] An important limitation to the classification system is its inherent subjectivity; consequently, previous research has shown only fair to modest interrater agreement when different individuals attempt to assign to an ASA-PS category to the same patient.[250-252]

In addition to patients' preoperative medical status, which is described by the ASA-PS system, operative procedure is an important determinant of perioperative risk.[249,253,254] Overall perioperative risk is necessarily a function of both the risk associated with the specific operative procedure and the risk associated with a patient's underlying medical status. For example, ambulatory surgical procedures are very safe with respect to risks of postoperative mortality and major adverse events,[255-257] as evidenced by a 7-day postoperative mortality rate of only 41 per 100,000 procedures in a large cohort of Medicare beneficiaries 65 years old or older.[255] Thus, although older patients with an increased burden of comorbidity do have increased relative risks of mortality and morbidity following ambulatory surgery, their *absolute* risks remain very low. The inherent importance of operative risk also explains why specialty society practice guidelines recommend that, in the absence of an unstable cardiac condition, patients can proceed directly to elective low-risk ambulatory surgical procedures without any additional preoperative cardiac workup.[5] Classification schemes have been proposed for assessing operative risk, such as the Johns Hopkins risk classification system (Table 38-14) and the strata proposed by the ACCF/AHA (see Table 38-4).[5] Although these consensus-based classification schemes are clinically sensible, their accuracy in predicting outcomes is less clear.

Several commonly used and methodologically sound clinical indices can predict mortality and major morbidity after cardiac surgery with reasonable accuracy, such as the EuroSCORE,[258] or Society of Thoracic Surgeons (STS) risk score.[259-261] For noncardiac surgery, the American

TABLE 38-13 AMERICAN SOCIETY OF ANESTHESIOLOGISTS PHYSICAL STATUS CLASSIFICATION

Category*	Definition
ASA-PS 1	A normal, healthy patient
ASA-PS 2	A patient with mild systemic disease
ASA-PS 3	A patient with severe systemic disease
ASA-PS 4	A patient with severe systemic disease that is a constant threat to life
ASA-PS 5	A moribund patient who is not expected to survive without the operation
ASA-PS 6	A declared brain-dead patient whose organs are being removed for donor purposes

ASA-PS, American Society of Anesthesiologists physical status.
*The addition of "E" to the classification category indicates emergency surgery.

TABLE 38-14 JOHNS HOPKINS SURGERY RISK CLASSIFICATION SYSTEM

Category	Description
1	Minimal risk to the patient independent of anesthesia; minimally invasive procedure with little or no blood loss; procedures often done in an office setting, with the operating room used principally for anesthesia and monitoring
2	Minimal to moderately invasive procedure, with expected blood loss not exceeding 500 mL; mild risk to patient independent of anesthesia
3	Moderately to significantly invasive procedure, with expected blood loss of 500 to 1500 mL; moderate risk to patient independent of anesthesia
4	Highly invasive procedure, with expected blood loss exceeding 1500 mL; major risk to patient independent of anesthesia
5	Highly invasive procedure, with expected blood loss exceeding 1500 mL; critical risk to patient independent of anesthesia; usually requiring postoperative critical care unit stay with invasive monitoring

College of Surgeons National Surgical Quality Improvement Project (NSQIP) risk calculator is available on the Internet and provides an estimate of risk based on patients' comorbidities and proposed surgical procedures (http://riskcalculator.facs.org). Large multinational prospective epidemiologic studies of surgical patients, which included accurate capture of perioperative characteristics and outcomes,[39,249] will likely help lead to the development of similar indices for noncardiac surgery. Initial results from the VISION study, a multinational prospective cohort study of 15,133 individuals who were 45 years old or older and who underwent noncardiac surgical procedures, identified several independent predictors of postoperative 30-day mortality, including age, operative procedure, nonelective surgery, and specific comorbid conditions (Table 38-15).

Despite the paucity of clinical risk indices for predicting postoperative mortality following noncardiac surgery, high-quality indices have been developed for predicting other major postoperative complications such as cardiovascular events,[47] pneumonia,[132] respiratory failure,[262] and AKI.[153] Among these indices, the RCRI is likely the most commonly used (see Table 38-3), especially because it is simple (an important determinant of uptake into clinical practice), is strongly recommended by ACCF/AHA practice guidelines, and has consistently predicted cardiac complications across many different surgical samples.[46]

TABLE 38-15 PREOPERATIVE PREDICTORS OF 30-DAY MORTALITY AFTER NONCARDIAC SURGERY

Characteristic	Adjusted Hazard Ratio for 30-day Mortality	95% Confidence Interval
Age		
45-64 yr	Reference group	
76-74 yr	1.67	1.18-2.36
≥75 yr or older	3.03	2.20-4.18
Urgent or Emergency Surgery	4.62	3.57-5.98
Operative Procedure		
Major intraabdominal or head and neck surgery	3.25	1.64-6.45
Craniotomy or multilevel spine surgery	3.72	1.68-8.20
Major vascular surgery	2.38	1.04-5.47
Comorbid Disease		
High-risk coronary artery disease in previous 6 months*	3.12	1.71-5.68
History of congestive heart failure	1.60	1.09-2.36
History of stroke	2.01	1.42-2.84
History of peripheral arterial disease	2.13	1.47-3.10
Chronic obstructive pulmonary disease	2.15	1.61-2.89
Active cancer†	2.38	1.79-3.18

Data from VISION Study Investigators: Association between postoperative troponin levels and 30-day mortality among patients undergoing noncardiac surgery, JAMA *307:2295-2304, 2012.*

*Defined as acute myocardial infarction, acute coronary syndrome, or severe (Canadian Cardiovascular Society class 3 or 4) angina within 6 months before surgery.

†Defined as active treatment (chemotherapy, radiation or surgery) for cancer within 6 months before surgery, known metastatic disease, or planned surgery for cancer.

ROLE OF SPECIALIZED TESTING IN PREOPERATIVE RISK ASSESSMENT

Based on an initial preoperative clinical evaluation, anesthesiologists may order subsequent specialized tests to help define a patient's perioperative risk more accurately. Such tests may include noninvasive cardiac stress tests (see the earlier section on ischemic heart disease), coronary angiography (see the earlier section on ischemic heart disease), echocardiography, CPET, and PFTs.

Resting echocardiography can provide information related to valvular lesions, pulmonary hypertension, fixed wall motion abnormalities, and ventricular function. Especially in cases of a suspicious murmur or other clinical indication, a preoperative echocardiogram can help diagnose prognostically important valvular or other cardiac lesions, such as aortic stenosis or pulmonary hypertension.[263,264] Similarly, an echocardiogram can identify fixed wall motion abnormalities suggestive of a previous MI. Nonetheless, in the absence of concurrent reversible wall abnormalities (which are identified instead by noninvasive stress testing), fixed wall motion abnormalities are not associated with increased perioperative cardiac risk.[59] Systolic ventricular dysfunction is associated with increased cardiac risk.[264-266] However, this finding may not provide additional prognostic information when it is combined with routine preoperative clinical evaluation.[266] Aside from the assessment of suspicious murmurs, current ACCF/AHA practice guidelines recommend preoperative echocardiography (or other noninvasive measure of ventricular function) to help assess dyspnea of unknown origin or recent altered clinical status in an individual with known heart failure.[5] Conversely, these guidelines also specifically discourage routine preoperative assessment of ventricular function. Unlike noninvasive stress testing,[267] preoperative resting echocardiography is not associated with improved short- or long-term postoperative outcomes.[268]

CPET is a noninvasive global assessment of exercise capacity; it involves a patient exercising on a bicycle or treadmill for 8 to 12 minutes while undergoing continuous measurement of respiratory gas exchange (i.e., oxygen uptake and carbon dioxide production).[269] In some geographic settings,[270] CPET is also used to aid preoperative risk assessment. Limited available data suggest that poor exercise capacity during CPET, based on low peak oxygen consumption or low anaerobic threshold, may be associated with increased postoperative mortality and morbidity.[271,272] CPET has been used by some practitioners to guide the decision regarding the appropriateness of undergoing a surgical procedure.

The role of PFTs for guiding preoperative assessment in the setting of specific comorbidities is discussed previously in this chapter. These tests do have an established and important role for assessing perioperative risk in

lung resection surgery, as discussed in detail in Chapter 66.[273] These tests also play an important diagnostic role. For example, PFTs may help differentiate between pulmonary and cardiac causes of dyspnea of unknown origin. Aside from these specific circumstances, the *prognostic* value of preoperative PFTs is limited. Indeed, practice guidelines from the American College of Physicians recommend against routine preoperative spirometry for predicting risks for pulmonary complications of noncardiothoracic surgical procedures. Research has *not* found a consistent link between poor PFT results and increased risks for perioperative pulmonary complications,[111] with older studies being generally limited by important methodologic flaws.[274] A critical PFT threshold below which patients should not be offered surgical treatment does not appear to exist.[111] For example, a previous study of patients with severe obstructive findings on preoperative PFTs (i.e., FEV_1 <50% of predicted and an FEV_1/FVC ratio <70%) demonstrated rates of mortality (5.6%) and respiratory failure (5.6%) that were not unacceptably high.[275]

PREOPERATIVE MEDICATION MANAGEMENT

The patient's comorbidities and planned procedure must be considered when managing medications in the perioperative period. Some medications have beneficial effects during surgical procedures, whereas others may be detrimental. In some cases, withdrawal of medications suddenly can have a negative effect. Box 38-3 outlines the medications to continue or discontinue preoperatively. Although issues pertaining to many of these drugs are covered in other sections of this chapter (e.g., the section on ischemic heart disease), several issues deserve special mention.

Antihypertensive medications should generally be continued preoperatively. Stopping β-blockers or α_2-agonists (e.g., clonidine) may be associated with rebound hypertension. For patients who cannot tolerate hypotension, consideration may be given to discontinuing ACEI or ARB agents 12 to 24 hours preoperatively. Continuation of these agents up to the morning of surgery can lead to increased risks for intraoperative hypotension,[45] especially in individuals receiving concomitant diuretic therapy.[276] This hypotension can be refractory to fluid administration and typical vasopressors, although vasopressin has been used successfully to treat hypotension in these instances. The benefit of withholding ACEI and ARB agents may be especially pertinent for cardiac surgery, complex spine surgery, procedures involving significant blood loss or fluid shifts, patients taking multiple antihypertensive medications, or procedures involving intraoperative positioning that may impair hemodynamics. Both ARBs and ACEIs may have long-term protective effects in patients with CAD or associated risk factors, and the negative consequences of abrupt preoperative discontinuation are not clear. Thus, the potential for intraoperative hypotension must be balanced against possible benefits of continuing these agents up to the time of the surgical procedure. Thus, decisions about withholding ACEIs or ARBs are better made on a case-by-case basis, as opposed to a uniform approach for all patients.

Diuretics are generally discontinued preoperatively, with the exception of thiazide diuretics (e.g., hydrochlorothiazide, chlorthalidone) if taken for hypertension. Loop diuretics, which may cause volume depletion and hypokalemia, have generally been discontinued on the day of surgery. Nonetheless, a randomized trial found no increased risk of intraoperative hypotension when loop diuretics were continued, as opposed to withdrawn, on the day of surgery.[88] Thus, it is reasonable to continue loop diuretics in patients with significant volume overload, severe heart failure, or ascites, especially if the scheduled procedure is minor and unlikely to involve major fluid shifts or blood loss.

Patients with heart disease or associated cardiovascular risk factors may be taking a variety of medications, such as β-blockers, statins, digoxin, and antiarrhythmic medications. These agents are generally continued up until the time of the surgical procedure because of their beneficial effects and the potential for negative consequences if discontinued. The perioperative use of these medications is discussed in detail in the section of this chapter on cardiovascular disease.

NSAIDs have *reversible* antiplatelet effects; hence, once the drugs have been eliminated, platelet function returns to normal. Concomitant NSAID use does not appear to increase the risk of spinal hematoma with neuraxial anesthesia.[171] Preoperative discontinuation of NSAIDs may be of value in patients at risk for perioperative AKI. Typically, NSAIDs are discontinued 24 to 72 hours preoperatively. Earlier discontinuation does not increase safety, and it may be burdensome to many patients with significant arthritis or chronic pain. COX-2 inhibitors (e.g., celecoxib) have minimal effect on platelet function and can usually be continued in the perioperative period. However, the long-term use of COX-2 inhibitors in the nonoperative setting does increase the risk of cardiac events, in comparison with placebo or naproxen.[277] Conversely, COX-2 inhibitors have a cardiac risk profile similar to that of ibuprofen or diclofenac.[277] In general, no clear evidence indicates increased cardiac risk from *short-term* perioperative administration of COX-2 inhibitors. The only exception is a randomized trial of valdecoxib (now withdrawn from the market) in cardiac surgery in which the drug caused an excess of cardiac events.[278]

Patients with either type 1 or type 2 diabetes should discontinue short-acting insulin while fasting. The exception to this rule pertains to diabetic patients with continuous subcutaneous insulin infusion pumps. Such individuals should instead continue their infusion at the lowest basal rate, which is usually the nighttime fasting rate. On the day of surgery, patients with type 1 diabetes typically need to take a small amount (one third to one half) of their usual morning dose of intermediate-acting or long-acting insulin (e.g., lente, NPH) to avoid diabetic ketoacidosis. Patients with type 2 diabetes can either take no insulin or up to one half of their usual dose of intermediate-acting, long-acting, or combination (e.g., 70/30 preparations) insulin on the morning of surgery.

Metformin does not have to be routinely discontinued before the day of surgery. No data support such a recommendation, and routine discontinuation before the day of surgery may increase the risk of poor perioperative

glycemic control. Conversely, a very low risk of lactic acidosis exists in patients who then go on to develop renal and hepatic failure while taking metformin. Thus, withholding metformin before the day of surgery may be considered if the anticipated procedure poses a high risk of acute kidney or liver injury (e.g., intravenous contrast exposure, significant hemodynamic instability). In addition, metformin should likely not be restarted in patients postoperatively until any important risk of hepatic or renal failure has passed. Sulfonylurea agents with very long half-lives (e.g., chlorpropamide) can cause hypoglycemia in the fasting patient and should therefore be withheld on the day of surgery. Several newer oral agents (e.g., acarbose, pioglitazone) do not carry a risk of hypoglycemia in the fasting patient when they are used as single-agent therapy. Nonetheless, to avoid confusion, oral hypoglycemic agents are generally held the day of surgery except for minor, short procedures performed during the morning in ambulatory patients who are able to resume oral intake soon after the procedure. Hyperglycemia in the immediate perioperative period is best managed with insulin.

Patients taking steroids on a long-term basis should take their usual dose on the day of surgery. Stress-associated adrenal insufficiency may occur in patients taking steroids unless additional steroid therapy is instituted perioperatively. Approximately 5 to 7.5 mg of prednisone is equivalent to the normal daily adrenal output of cortisol, which is approximately 30 mg. The HPA axis is not suppressed in patients who take less than 5 mg/day of prednisone or its equivalent. In patients who take 5 to 20 mg/day of prednisone or its equivalent for 3 or more weeks, the HPA axis may or may not be suppressed. Patients who take more than 20 mg/day of prednisone or its equivalent for 3 or more weeks have suppression of their HPA axis. The risk of adrenal insufficiency remains for up to 1 year after the cessation of high-dose steroid therapy. The stress associated with surgery, trauma, or infection leads an intact HPA to increase adrenal output of glucocorticoids. In most patients, the circulating cortisol concentration then returns to normal within 24 to 48 hours.[279] Surgical procedures also induce a range of stress from minimal to severe; thus, the amount of supplementation should vary based on the estimated amount of surgical stress and the long-term daily dose of steroid (see Table 38-11). The risks of infection, psychosis, decreased wound healing, and hyperglycemia outweigh the benefits of unnecessarily high doses of perioperative steroids.[279]

Postmenopausal hormone replacement therapies that contain estrogen increase the risk of thromboembolic events.[280] It may therefore be reasonable to discontinue these medications before operations. Estrogens must be stopped approximately 1 month preoperatively for coagulation function to return to baseline. Most modern oral contraceptives contain low doses of estrogen that minimally increase thromboembolic risk. Because the risk of unanticipated pregnancy may outweigh the benefits of discontinuing oral contraceptives preoperatively, it is reasonable to continue oral contraceptives in the perioperative period.

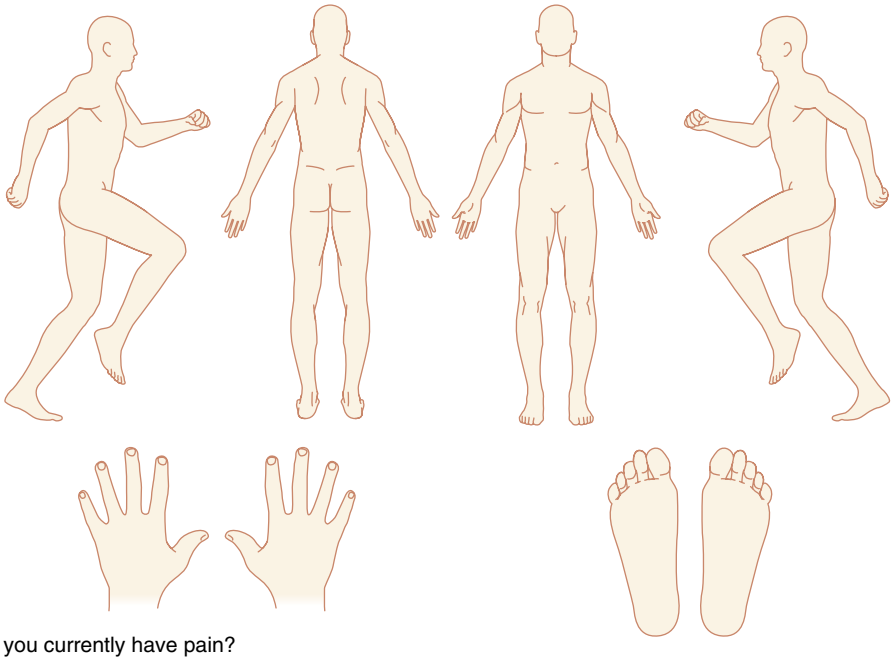
Most medications for psychiatric and psychological problems should be continued into the preoperative period. Thus, antidepressants, antipsychotics, and benzodiazepines are best maintained to avoid exacerbations of symptoms. Anxiolytics are continued up until the time of the procedure. Historically, MAOI antidepressants were discontinued preoperatively; however, elimination of the risks associated with many of these drugs required drug discontinuation at least 3 weeks before surgical procedures. This long withdrawal period specifically applied to MAOIs that caused *irreversible* inhibition of MAO. Some newer agents, such as moclobemide, cause *reversible* enzyme inhibition and have effects lasting less than 24 hours. Preoperative withdrawal of these drugs has potential risks. Specifically, case reports of suicides or severe depression following discontinuation of MAOIs have been reported in the literature. Thus, the safest approach may be to continue these drugs and adjust the anesthetic plan to make changes such as avoiding meperidine and indirect-acting vasopressors (e.g., ephedrine). Details regarding a patient's MAOI use must be clearly communicated to health care providers on the day of the surgical procedure. Patients receiving tricyclic antidepressants require a preoperative ECG, given the potential for associated prolongation of the QT interval. Because tricyclic antidepressants block the reuptake of norepinephrine and serotonin, high doses may also result in augmented responses to vasopressor drugs, with the potential for exaggerated hemodynamic changes. Patients taking lithium require evaluation of electrolytes, BUN, and creatinine. Discontinuation of lithium has also been associated with suicide. Similarly, abrupt discontinuation of SSRIs can also cause adverse effects, including dizziness, headache, nausea, irritability, visual disturbances, and sensations of electric shocks.

Complementary and alternative medications may interact with anesthetic agents, alter effects of prescription medications, and increase bleeding. In addition, many patients do not consider these agents "medications" and hence do not include them in a list of their medications unless specifically asked. The perioperative management of complementary and alternative medications is discussed in further detail in Chapter 40.

PLANNING FOR ANESTHESIA

PREOPERATIVE FASTING STATUS

The primary goal of preoperative fasting recommendations has been to reduce the occurrence of pulmonary aspiration. The ASA published practice guidelines pertaining to preoperative fasting in nonlaboring individuals undergoing elective procedures.[281] The recommended fasting period following clear fluids for all patients is 2 hours. In general, the volume of liquid ingested is less important than the type of liquid ingested. For neonates and infants, the recommended fasting period is 4 hours following breast milk, and 6 hours following formula and solids. For patients other than infants, a fasting period of 6 hours after a light meal is recommended; this period may have to be increased to 8 hours or more if the meal includes fried or fatty foods. In addition to implementing these fasting intervals, these guidelines recommend that the preoperative evaluation include assessment of



the potential for difficult airway management, as well as factors that may increase the risk for aspiration (e.g., gastrointestinal motility disorders, diabetes).

PLANNING FOR POSTOPERATIVE PAIN MANAGEMENT

The Joint Commission recognizes that all patients have the right to appropriate assessment and treatment of pain and mandates assessment of pain in all patients. A preoperative evaluation should therefore always include baseline pain assessment, which often occurs as part of the preoperative nursing assessment.

Standardization of pain measurement is difficult because of the subjective nature of the variable. The scales used fall into the categories of single-dimension scales, such as visual analog and numeric rating scales, and multidimensional scales, such as the McGill pain questionnaire.[282] Figure 38-9 shows one example used for pain assessment in a preoperative evaluation. The location of the pain is noted on the figure; the character, duration, and frequency are documented, and intensity is recorded with a numeric rating scale from 1 to 10, with 1 being no pain and 10 being the worst pain imaginable. If a numeric scale cannot be used, a scale using faces can be substituted. Use of these scales readily allows comparison when reassessments are performed postoperatively.

The preoperative evaluation provides an important opportunity to discuss and plan for the management of acute postoperative pain (see Chapter 98), for several reasons. First, adequacy of perioperative pain control is a frequent concern for patients during preoperative evaluation.[283,284] Second, intensive preoperative pain instructions may help improve postoperative pain control in surgical patients.[285] Third, preoperative anesthesia consultation is associated with improved patient acceptance of perioperative regional techniques,[14] which themselves can help improve the quality of postoperative analgesia.[286] Fourth, preoperative evaluation facilitates planning the perioperative care of patients with chronic pain conditions, who often present significant challenges with respect to managing postoperative analgesia. Specific issues include their tolerance to usual doses of opioid analgesics and the potential for acute withdrawal reactions if they receive

Do you currently have pain?

☐ Numeric

☐ Faces

What makes the pain better? _____

What makes the pain worse? _____

What is an acceptable pain level to you? _____

Figure 38-9. Pain status and history form.

insufficient doses of opioids postoperatively. The preoperative consultation should therefore be used to carefully document their usual baseline opioid requirements (to ensure adequate postoperative dosing), facilitate early involvement of an acute pain service or chronic pain specialist, encourage regional analgesic techniques, and plan adjunct analgesic medications (e.g., NSAIDs, gabapentin, pregabalin, clonidine). Patients with preexisting chronic pain should be encouraged to develop reasonable goals for adequacy of postoperative pain control. They should be informed that although care providers will do everything possible to maintain comfort postoperatively, patients should not expect to have no pain at all.

In general, patients do not have to be weaned from pain medications preoperatively. If patients are instructed by the surgeon to discontinue NSAIDs or COX-2 analgesics, they may have to be transitioned to alternative analgesics leading up to the surgical procedure. Patients should be instructed to take their usual morning doses of pain medication, including the continued use of any transdermal fentanyl patch.

REGULATORY ISSUES

Providers must be aware of various governmental regulatory requirements. These requirements may be driven by quality regulations such as those developed by The Joint Commission or by payment requirements as set by the Centers for Medicare and Medicaid Services (CMS) in the United States. Local regulations may also be in effect. These regulations often differ by individual municipalities and countries, meaning that one needs to stay abreast of updates. For example, the CMS has determined that a comprehensive anesthesia evaluation can be done within 30 days, and a focused update is required within 48 hours of a procedure requiring anesthesia services. At a minimum, the preanesthesia evaluation must include the following:

- Notation of anesthesia risk (e.g., ASA-PS classification)
- Review of the medical, anesthesia, drug, and allergy history
- Interview and examination of the patient
- Potential anesthesia problems (e.g., difficult airway, limited intravascular access)
- Additional evaluation, if deemed necessary (e.g., stress tests, specialist consultation)
- Development of a plan for anesthesia, including the type of medications for induction, maintenance, and postoperative care
- Discussion of the risks and benefits of anesthesia with the patient or the patient's representative

A practitioner qualified to provide anesthesia must perform this evaluation.

PREOPERATIVE EVALUATION CLINIC

Many anesthesia groups and medical centers have developed preoperative evaluation programs and clinics, with the objectives of improving patient care and operating room efficiency.[9,17,287] Although these programs may differ with respect to staffing, structure, financial support, and daily operations, they all share a common goal of preventing delays, last-minute cancellations, and adverse patient outcomes that could have been addressed before the day of surgery.

The decision to develop a preoperative evaluation clinic depends on several key factors. They include the anticipated daily volume of surgical patients, the predominant level of medical acuity among these patients, the availability of clinic facilities, relevant patient demographics (e.g., average travel distances from patients' homes to the clinic), and requisite support from the anesthesia department, perioperative staff, and hospital administration. If the decision to implement a preoperative evaluation program is made, anesthesiologists must play a key role in its leadership and management. When this role is instead undertaken by other specialties, such as internal medicine, anesthesiologists' expertise in perioperative patient management often becomes secondary. This shift to a secondary role can result in interdepartmental conflicts concerning patients' preoperative evaluation, risk stratification, and fitness to proceed with anesthesia and surgery. These conflicts can, in turn, result in unplanned delays or cancellations of planned surgical procedures, despite the completion of an assessment in an outpatient preoperative evaluation clinic.

Such conflicts often relate to surgeons' interpretation of a nonanesthesia specialist's judgment that a patient is "cleared for surgery" as evidence that the patient is fit for anesthesia. Unfortunately, this "clearance" is frequently made with limited knowledge of factors critical to the responsible anesthesiologist in the operating room, such as current anesthesia practice and intraoperative patient management. Indeed, previous research has shown that preoperative histories, physical examinations, and assessments performed by medical specialists often fail to address specific anesthesia-related concerns.[30] As the specialist who makes the final determination of whether a patient is fit to proceed with anesthesia and surgery, the responsible anesthesiologist is a critical "end-user" of any assessment performed in a preoperative evaluation clinic. Consequently, a reliance on nonanesthesia specialists can result in preoperative assessments that are deemed inadequate by the responsible anesthesia providers and that lead to potential last-minute surgical delays and cancellations, with associated significant frustration among both patients and surgeons. Conversely, preoperative-to-intraoperative communication is likely significantly improved when anesthesiologists are responsible for most outpatient preanesthesia evaluations, as confirmed by previous studies showing fewer last-minute case cancellations,[9,15-17] shorter durations of hospitalization,[16,17] and lower hospital costs,[16] with institution of anesthesia-led preoperative evaluation programs.

Awareness of the local hospital context is critical if a preoperative evaluation program is to have good outcomes. In a hospital with limited resources that has mostly healthy outpatient and same-day-admission surgical patients, the anesthesia group may be unable to evaluate all patients preoperatively in a clinic before the day of surgery. In this situation, the preoperative program must develop a means for accurate screening and

triage of patients based on their current health status. An accurate triage process helps target the use of preoperative clinic visits only among selected higher-risk patients without compromising patients' quality of care and outcomes. An example of such a triage process may involve having patients initially complete an anesthesia questionnaire (see Fig. 38-2) in their surgeons' office. This questionnaire can be a Web-based online document or even a paper version that would then be faxed to the anesthesia group before the date of surgery. In the case of a patient with a questionable medical history, a telephone call by the anesthesiologist could clarify any issues of concern. This opportunity to review a patient's medical history before the day of surgery helps reduce unresolved or unexpected medical concerns on the day of surgery. It also helps determine whether a patient requires formal preoperative consultation in advance of the surgical procedure, as opposed to evaluation on the day of surgery itself.

Conversely, anesthesia groups at hospitals with many medically complex surgical patients may benefit from the establishment of a formal preoperative evaluation facility with multiple examination rooms, dedicated staffing, and a full-time operational system. The establishment of a successful preoperative evaluation clinic requires commitment, collaboration, and support from several hospital disciplines.[9] At a minimum, the departments of anesthesia, surgery, nursing, and hospital administration must agree that such a clinic has value for the hospital, and they must commit to support its operational goals (Box 38-17).

BOX 38-17 ***Operational Goals for a Preoperative Evaluation Clinic***

- Improve patients' perception of the preoperative evaluation experience by increasing personalized care, comfort, and convenience.
- Provide a centralized site for preoperative evaluation.
- Institute a clinic scheduling system for timely patient access and flow.
- Ensure the presence of an anesthesiologist on site when patients are present.
- Appoint a medical director to coordinate all activities.
- Ensure the availability of medical records and surgical notes at the time of the preoperative evaluation.
- Decrease logistic shuffling of patients to multiple other hospital service areas.
- Integrate and coordinate services through on-site facilities for admission, registration, insurance authorization, laboratory tests, radiographs, and electrocardiographic studies.
- Educate patients and families about the elements of their surgical procedure and the proposed anesthesia care, including postoperative pain control options.
- Educate patients about what to expect regarding postoperative feeding and discharge needs.
- Ensure medically appropriate and cost-effective ordering of preoperative laboratory and diagnostic studies.
- Provide a medical consultation service for evaluation of medically complex surgical patients.
- Decrease the number of cancellations and delays on the day of surgery.
- Enlist nurses or mid-level providers to assist in preoperative evaluation and in patient and family education.
- Develop protocols, policies, and clinical pathways for preoperative care.
- Perform quality assurance reviews.
- Maximize efficiency in operating room function by coordinating all preoperative information at one location in the preoperative evaluation clinic.
- Enhance patient and surgeon satisfaction.

COLLABORATION, COMMITMENT, AND TEAMWORK

The preoperative evaluation clinic is a visible partnership among the departments of anesthesia, surgery, nursing, and hospital administration to achieve common goals, as illustrated in Figure 38-10. This collaboration conveys the important theme that the new clinical program is an integrated enterprise that requires shared obligation, endeavor, and financial responsibility. Although these clinics are best led by anesthesiologists,[9,15-17] engagement with medical specialists and hospitalists remains important to the success of any preoperative program. These nonanesthesia specialties provide unique expertise in the preoperative management of selected medically complex patients; furthermore, they can facilitate enhanced postoperative monitoring of high-risk patients through, for example, the comanagement model of postoperative care (see the earlier section on the role of the medical consultant in preoperative evaluation).

Surgeons may be initially reluctant to send their patients to a newly established anesthesia-led preoperative evaluation clinic. This reluctance often stems from

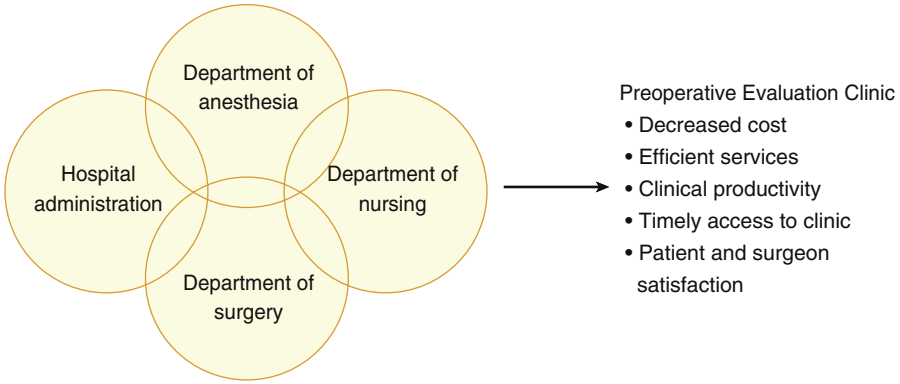

Figure 38-10. The anesthesia preoperative evaluation clinic is a constructive partnership working toward common goals.

an unclear understanding of the benefits of outpatient preoperative anesthesia evaluation. Consequently, the surgeons' hesitation can be reduced by clearly identifying the specific advantages of an integrated anesthesia-led preoperative evaluation program. First, the proven benefits of anesthesia-led preoperative evaluation should be highlighted.[9,14-17] Second, anesthesiologists should emphasize the important practical advantages of an integrated assessment of medically complex surgical patients. Specifically, when relevant medical concerns are identified before the surgical procedure, the preoperative program can acquire all relevant prior medical data, coordinate any additional workup or consultation, prearrange any required specialized postoperative monitoring, and discuss the case beforehand with the surgeon and responsible anesthesiologist. This approach ensures that when such a patient presents for the operation, the responsible anesthesia provider is satisfied to proceed with the surgical procedure, and the perioperative team has all required medical information to manage the patient optimally during the hospitalization.

Third, informal assurances should be made to the surgical services that, if a patient is managed by the preoperative evaluation program, surgery will proceed without cancellation or delay by the assigned anesthesiologist unless an intervening illness or adverse medical event occurs between the outpatient evaluation and the scheduled operation. Because cancellations and delays on the day of surgery can be a prominent source of aggravation for surgeons and patients, these informal assurances would be viewed as a key strength of the newly developed preoperative program. Such assurances depend heavily on the anesthesia department's addressing relevant clinical practice variations. Specifically, issues that are subject to important interpractitioner differences, such as what fasting blood glucose level or degree of preoperative hypertension would merit cancelling a surgical case, must be discussed to achieve a departmental consensus standard. The absence of consensus standards can lead to situations in which half the anesthesia providers may proceed with a higher-risk surgical case, whereas the other half would cancel it instead. Wide inconsistency in practice will foster a lack of support among surgeons and will lead to reluctance to have their patients evaluated. Such a preoperative program is unlikely to be successful.

STRUCTURES AND ACTIVITIES OF THE PREOPERATIVE EVALUATION CLINIC

The daily operations of a preoperative evaluation clinic vary based on the patient volume, the general level of medical complexity among surgical patients, the type of available clinic facilities, and staffing resources. Nonetheless, a general operational structure can be proposed based on examination of several preoperative clinic models currently in practice.

Centers with large surgical case volumes should have their patients formally scheduled in the clinic before the day of evaluation, to allow for medical records and relevant outside information to be acquired and collated. The surgeon's office should schedule this clinic appointment at the same time that it books the operating room case. To ensure timely patient access and flow through the facility, these appointments should be booked using an efficient clinic scheduling system. Ideally, appointments should be scheduled to allow sufficient time between the clinic visit and the scheduled surgical procedure, to facilitate any additional preoperative testing, consultations, or interventions. Some degree of flexibility in the clinic schedule is also needed, especially to accommodate patients who have urgent indications for surgery. One approach for incorporating some flexibility is to include a few open appointment slots in the daily clinic schedule that can be used as needed for last-minute patient referrals. Such flexibility is required for individuals residing in rural and remote areas, who have been reported to have reduced rates of access to preoperative evaluation clinic facilities.[288] Anesthesiologists at some centers have also adopted telemedicine technology (defined as health care delivery and sharing of medical knowledge over a distance using telecommunications systems)[289] so that patients residing at remote locations can undergo preanesthesia consultations without traveling long distances to the clinic.[290]

At the clinic, a clinician interviews and examines the patient, obtains historical medical information and outside records, and determines whether (and which) additional laboratory tests, ECGs, radiographs or other diagnostic tests are required. Phlebotomy, ECG, and hospital admitting and insurance registration services are typically available in the preoperative clinic facility. The ECGs are assessed during the clinic visit itself, whereas laboratory test results are evaluated at the end of each clinic day, with follow-up of abnormal findings as needed. In this manner, significant abnormalities can be addressed immediately; thus, any required delays or cancellations of surgical cases can occur well in advance of the scheduled day of surgery. This centralization of multiple services is also a significant convenience for patients, who no longer have to visit multiple hospital locations to complete their preoperative requirements. This arrangement should also centralize all medical data relevant to the scheduled hospital admission into a single chart, which remains in the preoperative evaluation clinic area until the date of surgery. In addition to addressing medical aspects relevant to the scheduled surgery, the preoperative evaluation program plays an important role in educating surgical patients. Typically, both the clinician performing the preoperative assessment and a specifically trained nurse educator discuss the forthcoming perioperative process with each patient and family members. By increasing patients' awareness of important components pertaining to their scheduled hospital admission (e.g., analgesic options, risks of anesthesia), this education process can decrease patients' anxiety,[13] as well as increase their willingness to receive regional analgesia.[14] The types of clinicians who perform the preanesthesia assessment include anesthesiologists and specially trained nurse practitioners. Some authors have questioned whether the responsible anesthesiologist in the operating room would be satisfied with preanesthesia assessments performed by another individual.[291] Patients themselves often report a preference for having the same anesthesiologist in both the preoperative clinic and the operating room.[292] Nonetheless, it

is simply not feasible for all patients in the preoperative clinic to be evaluated by their eventual anesthesia providers. Furthermore, a large Dutch study of 21,454 surgical patients demonstrated that responsible anesthesia providers were satisfied with 95% of outpatient preanesthesia assessments performed by other anesthesiologists or trained nurses.[293]

Preoperative programs must adopt several strategies to ensure that anesthesia providers in the operating room will be satisfied with the quality of outpatient preoperative assessments. First, the anesthesia department must develop consensus standards for determining when patients should have scheduled surgery cancelled for medical reasons. Second, the documentation required for all preanesthesia assessments in the clinic should be standardized. This standardization helps prevent situations in which an assessment does not contain information needed by the anesthesia provider in the operating room to determine a patient's fitness for surgery or to develop an anesthetic management plan. Some national anesthetic groups have initiated work on consensus-based documentation standards for all preanesthesia assessments.[294] Strategies for improving the consistency of documentation across preanesthesia assessments include the use of checklists, as well as structured electronic or paper-based forms for documenting preanesthesia assessments. Third, all nurse practitioners or other nonanesthesia clinicians assessing patients in the clinic should undergo an intensive and ongoing education in preoperative assessment. Anesthesiologists with strong interest and expertise in preoperative evaluation should lead this education program. Previous research has shown that well-trained nurses do perform effectively in both screening and evaluating patients in preoperative clinics.[295-297]

IMPACT ON OPERATING ROOM EFFICIENCY AND OUTCOMES

Anesthesia-led preoperative assessment clinics have been shown to have a positive impact on operating room efficiency and outcomes (see the earlier section on the goals and benefits of preanesthesia evaluation). The demonstrated benefits of these clinics include fewer case cancellations on the day of surgery[9,15-17] and a shorter duration of hospitalization.[14,16,17] Other mechanisms whereby preoperative evaluation clinics reduce health care costs include more selective ordering of preoperative laboratory tests and specialist referrals.[9,11,12] Thus, although preoperative evaluation programs do incur costs (e.g., facility development costs, staff salaries), they can still lead to an overall reduction in hospital costs as a result of these associated cost savings.[16]

PATIENT SATISFACTION WITH PREOPERATIVE EVALUATION CLINICS

In addition to addressing perioperative efficiencies and clinical outcomes, preoperative programs should also consider the experience and satisfaction of patients attending their clinics. During development of strategies to improve patient satisfaction, the key underlying determinants of improved satisfaction should be considered. They include being assessed by the same anesthesiologist who will administer anesthesia in the operating room, shorter wait times in the clinic, and good quality of communication from the clinic staff.[292,298,299] Because it is simply not feasible to have all patients in the clinic seen by their eventual anesthesia providers, the major focus should be on improving wait times and the quality of communication. Changes in appointment booking systems,[300] process flows, and clinic operations can decrease wait times,[295] which in turn can substantially improve patients' satisfaction.[295] In addition, preoperative programs can ensure that patients receive an accurate estimate of average waiting times before their scheduled clinic visit and use any encountered wait times to conduct other clinic-related activities (e.g., physical therapy instructions, video-based preoperative education).

The development of an ongoing patient survey and feedback system is an important initial step to help improve patients' experience and satisfaction with preoperative evaluation programs. Specifically, such surveys can be used to measure the baseline level of patients' satisfaction, identify opportunities for improvement, and determine responses to any subsequent interventions. When attempting to choose a survey instrument, preoperative programs will find that most currently available surveys, such as the Press Ganey Patient Satisfaction Survey and Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) patient satisfaction survey, reflect the overall perioperative experience. These surveys are not effective for discerning patients' satisfaction with particular elements of the preoperative process. Therefore, several studies developed specialized questionnaires to measure and help drive improvement in patient-reported quality of care in preoperative evaluation clinics.[295,301]

CONCLUSION

The practice of anesthesiology has changed.[2] The expanding role of the anesthesiologist outside the operating room will redefine our specialty's contribution to high-quality patient care in the health care system. Within the context of preoperative evaluation, anesthesiologists must be knowledgeable and adept at assessing patients of highly varying medical complexity, whether in an outpatient preoperative evaluation clinic before the day of the surgical procedure or at the bedside immediately before induction of anesthesia. Anesthesiologists must be familiar with the impact of a broad range of chronic and acute medical conditions on patients' risks for anesthesia and surgery. In addition, this role entails awareness of multiple practice guidelines, regulatory requirements, and approaches for efficient management of outpatient clinics. Despite this evolving and expanding role of anesthesiologists in preoperative care, the primary purpose of preoperative evaluation will never change. It is the clinical foundation for guiding perioperative patient management, and it has the potential to reduce perioperative morbidity and enhance patient outcome.

Chapter 39

Anesthetic Implications of Concurrent Diseases

LEE A. FLEISHER • MICHAEL MYTHEN

Acknowledgment: The editors and the publisher would like to thank Dr. Michael F. Roizen, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The history and physical examination most accurately predict the risks of anesthesia and the likelihood of required changes in monitoring or therapy.
- For diabetic patients, end-organ dysfunction and the degree of glucose control in the perioperative and periprocedural periods are the critical issues with regard to risk.
- The keys to managing blood glucose levels in diabetic patients perioperatively are to set clear goals and then monitor blood glucose levels frequently enough to adjust therapy to achieve these goals.
- Obesity is associated with multiple comorbid conditions, including diabetes, hyperlipidemia, and cholelithiasis, but the primary concern is derangements of the cardiopulmonary system.
- Obstructive sleep apnea is important to recognize because of the increased sensitivity to and the consequence of the depressing effects of hypnotics and opioids on airway muscle tone and respiration, as well as the difficulty with laryngoscopy and mask ventilation.
- Although no controlled, randomized prospective clinical studies have been performed to evaluate the use of adrenergic receptor blocking drugs in patients undergoing resection of pheochromocytoma, the preoperative use of such drugs is generally recommended.
- For patients with hypertension, the routine administration of all drugs preoperatively is recommended, except angiotensin-converting enzyme inhibitors and angiotensin II antagonists.
- Evaluation of a patient with cardiovascular disease depends on clinical risk factors, the extent of surgery, and exercise tolerance.
- In patients with pulmonary disease, the following should be assessed: dyspnea, coughing and the production of sputum, recent respiratory infection, hemoptysis, wheezing, previous pulmonary complications, smoking history, and physical findings.
- In patients with pulmonary disease, several strategies have been suggested, including cessation of smoking 8 weeks or more preoperatively.
- Risk factors for perioperative renal dysfunction include advanced age, congestive heart failure, previous myocardial revascularization, diabetes, and increased baseline blood creatinine concentration.
- One of the primary objectives for a patient with renal disease is ensuring that the renal dysfunction is not augmented and thereby increasing the chance for renal failure, coma, and death.
- Mild perioperative anemia may be clinically significant only in patients with ischemic heart disease.
- Careful management of long-term drug administration should include questions about the effects and side effects of alternative as well as prescription drugs.

This chapter reviews many conditions requiring special preoperative and preprocedure evaluation, intraoperative or intraprocedure management, or postprocedure care. Patients undergoing surgical procedures move through a continuum of medical care to which a primary care physician, an internist or pediatrician, an anesthesiologist, and a surgeon, radiologist, or obstetrician-gynecologist contribute to ensure the best outcome possible. No aspect of medical care requires greater cooperation among physicians than does performance of a surgical operation or a complex procedure involving multiple specialists and the perioperative care of a patient. Moreover, nowhere else can counseling make so huge a difference in so many lives. The preoperative evaluation also represents a time when education on tobacco cessation, physical inactivity, and poor food choices can be discussed (see also Chapter 38). The importance of integrating physicians' expertise is even greater within the context of the increasing life span of our population. As the number of older adults and very old adults (those >85 years old) grows, so does the need of surgical patients for preoperative consultation to help plan for comorbidity and multiple drug regimens, knowledge of which is crucial to successful patient management (see also Chapter 80). At a time when medical information is encyclopedic, it is difficult, if not impossible, for even the most conscientious anesthesiologist to keep abreast of the medical issues relevant to every aspect of perioperative or periprocedure patient management. This chapter reviews such issues with primary emphasis on the anesthesiologist providing preoperative evaluation and care, rather than transferring these responsibilities to other providers.

As with "healthy" patients (see also Chapter 38), the history and physical examination most accurately predict not only the associated risks but also the likelihood that a monitoring technique or change in therapy will be beneficial or necessary for survival. This chapter emphasizes instances in which specific information should be sought in history taking, physical examination, or laboratory evaluation. Although controlled studies designed to confirm that optimizing a patient's preoperative or preprocedure physical condition would result in a less frequent rate of morbidity have not been performed for most diseases, it is logical to assume that such is the case. That such preventive measures would cost less than treating the morbidity that would otherwise occur is an important consideration in a cost-conscious environment.

Minimally invasive procedures such as cataract extraction, magnetic resonance imaging (MRI), or diagnostic arthroscopy, performed in conjunction with the best current anesthetic practices, may pose no greater risk than daily living and thus may not be considered an opportunity for special evaluation. Nevertheless, the preoperative evaluation may identify conditions that could change perioperative management and that may improve both throughput of surgery and the speed of recovery. Examples include the following: ensuring the administration of long-term medications such as a β-adrenergic blocking drug, aspirin for patients with coronary stents, or a statin (or any combination); administering a histamine type 2 (H_2) antagonist 1 to 2 hours before entry into the operating room; ensuring the availability of equipment to measure blood glucose levels; obtaining a history of the patient's diabetic course and treatment from the primary care physician, as well as from the patient; and performing a fiberoptic laryngoscopic examination or procuring additional skilled attention.

The following conditions are discussed in this chapter:

1. Diseases involving the endocrine system and disorders of nutrition (discussed first because of its increasing importance to care)
2. Diseases involving the cardiovascular system
3. Disorders of the respiratory and immune system
4. Diseases of the central nervous system (CNS), neuromuscular diseases, and mental disorders
5. Diseases involving the kidney, infectious diseases, and disorders of electrolytes
6. Diseases involving the gastrointestinal (GI) tract or the liver
7. Diseases involving hematopoiesis and various forms of cancer
8. Diseases of aging or those that occur more commonly in older adults, as well as chronic and acute medical conditions requiring drug therapy (see also Chapter 80)

ROLE OF THE PRIMARY CARE PHYSICIAN OR CONSULTANT

The roles of the primary care physician or consultant are not to select and suggest anesthetic or surgical methods but rather to optimize the patient's preoperative and preprocedure status regarding conditions that increase the morbidity and mortality associated with surgery and to alert the anesthesia care team about these conditions.

Quotations and a box in a Medical Knowledge Self-Assessment Program published by the leading organization representing internists, the American College of Physicians, highlight this role for the consultant[1]:

Effective interaction with colleagues in other specialties requires a thorough grounding in the language and science of these other disciplines as well as an awareness of basic guidelines for consultation [Box 39-1]. The consulting internists' role in perioperative care is focused on the elucidation of medical factors that may increase the risks of anesthesia and surgery. Selecting the anesthetic technique for a given patient, procedure, surgeon, and anesthetist is highly individualized and remains the responsibility of the anesthesiologist rather than the internist.

Optimizing a patient's preoperative and preprocedure condition and, in settings with a preoperative clinic, counseling a patient about needed future lifestyle changes such as walking, food choices, and tobacco cessation are cooperative ventures between the anesthesiologist and the internist, pediatrician, surgeon, or family physician (see also Chapter 38). If available, the primary

BOX 39-1 *Guidelines for Consultation Practice*

- Complete a prompt, thorough, generalist-oriented evaluation.
- Respond specifically to the question or questions posed.
- Indicate clearly the perioperative importance of any observations and recommendations outside the area of initial concern.
- Provide focused, detailed, and precise diagnostic and therapeutic guidance.
- Emphasize verbal communication with the anesthesiologist and surgeon, particularly to resolve complex issues.
- Avoid chart notations that unnecessarily create or exacerbate regulatory or medicolegal risk.
- Use frequent follow-up visits in difficult cases to monitor clinical status and compliance with recommendations.

From American College of Physicians: Medical consultation. In Medical knowledge self-assessment program IX, *part C, book 4. Philadelphia, 1992, American College of Physicians, p 939.*

care physician should affirm that the patient is in the very best physical state attainable (for that patient), or the anesthesiologist and primary care physician should do what is necessary to optimize that condition. Statements that describe the preoperative and preprocedure physical condition of the patient (e.g., "This patient is in optimum shape" and "I believe the mitral stenosis is more severe than the slight degree of mitral insufficiency") are much more useful to the anesthesiologist than statements that suggest overall clearance ("cleared for surgery") or perioperative procedures ("prevent hypoxia and hypotension").

Primary care physicians can prepare and treat a patient to provide optimal conditions for daily life. However, they often do not have the depth of understanding of the anesthesiologist regarding the physiologic changes brought on by surgery and the manipulations in function that must be made to facilitate surgery and procedures and to optimize perioperative and periprocedure outcomes. One example is the induction of some degree of prerenal azotemia in a patient with congestive heart failure (CHF) by the primary care physician. The intravascular volume depletion associated with prerenal azotemia may make a patient with a cardiac condition more comfortable in daily life but would predispose that patient to hypovolemic problems during and after surgery and complex procedures. The preoperative clinic should collaborate with the primary care physician to start the process of preparing the patient for the needs of surgery or complex procedures (see Chapter 38). Although such education is more readily available and of better quality than in previous decades and although cardiologic organizations have provided considerable data on the importance of this aspect of care,[2-4] the primary care physician's training, knowledge, and ability must be verified when he or she is part of the preoperative evaluation process. Without understanding the physiologic changes that occur perioperatively, appropriate therapy is difficult to prescribe. It is therefore part of the anesthesiologist's job to instruct the patient's consultants about the type of information needed from the preoperative and preprocedure consultation.

DISEASES INVOLVING THE ENDOCRINE SYSTEM AND DISORDERS OF NUTRITION

PANCREATIC DISORDERS

Preoperative and Preprocedure Diabetes Mellitus

Diabetes mellitus is a heterogeneous group of disorders that have the common feature of a relative or absolute lack of insulin. The disease is characterized by a multitude of hormone-induced metabolic abnormalities, by diffuse microvascular lesions, and by long-term end-organ complications. The diagnosis of diabetes is made with a fasting blood glucose level greater than 110 mg/dL (6.1 mmol/L), and impaired glucose tolerance is diagnosed if the fasting glucose level is less than 110 mg/dL (6.1 mmol/L) but greater than 100 mg/dL (5.5 mmol/L). Diabetes can be divided into two very different diseases that share these end-organ abnormalities. Type 1 diabetes is associated with autoimmune diseases and has a concordance rate of 40% to 50% (i.e., if one of a pair of monozygotic twins had diabetes, the likelihood that the other twin would have diabetes is 40% to 50%). In type 1 diabetes, the patient is insulin deficient and susceptible to ketoacidosis if insulin is withheld. In type 2 diabetes, the concordance rate is 100% (i.e., genetic material is both necessary and sufficient for the development of type 2 diabetes). How markedly the aging and end-organ effects of these genes are expressed is based on lifestyle choices of food and physical activity. These patients are not susceptible to the development of ketoacidosis in the absence of insulin, and they have peripheral insulin resistance. Patients with non–insulin-dependent (type 2) diabetes now account for most (>90%) of the diabetic patients in Europe and North America. These individuals tend to be overweight, relatively resistant to ketoacidosis, and susceptible to the development of a hyperglycemic-hyperosmolar nonketotic state. Plasma insulin levels are normal or increased in type 2 diabetes but are relatively low for the level of blood glucose. This hyperinsulinemia by itself is postulated to cause accelerated cardiovascular disease. Gestational diabetes develops in more than 3% of all pregnancies and increases the risk of type 2 diabetes by 17% to 63% within 15 years.

Type 1 and type 2 diabetes differ in other ways as well. Contrary to long-standing belief, a patient's age does not allow a firm distinction between type 1 and type 2 diabetes; type 1 diabetes can develop in an older person, and clearly, type 2 diabetes can develop in overnourished children. Type 1 diabetes is associated with a 15% prevalence of other autoimmune diseases, including Graves disease, Hashimoto thyroiditis, Addison disease, and myasthenia gravis.

Over the next decade, the prevalence of diabetes is expected to increase by 50%. This growth is primarily the result of the increase in type 2 diabetes caused by excessive weight gain in adults (see also Chapter 71) and now also in the pediatric population (see also Chapter 93). Large clinical studies show that long-term, strict control of blood glucose levels and arterial blood pressure, along with regular physical activity, results in a major delay in microvascular complications and perhaps indefinite postponement of type 2 diabetes in patients.[5,6]

The common orally administered drugs can be classified into six major groups: acarbose, meglitinide (e.g., repaglinide or nateglinide), metformin, sulfonylureas (e.g., glibenclamide, glipizide, glimepiride, gliuidone), thiazolidinediones (e.g., pioglitazone), and dipeptidyl peptidase-4 (DPP-IV) inhibitors (e.g., sitagliptin, saxagliptin, vildagliptin). Physicians advocating tight control of blood glucose levels usually give insulin to "maturity-onset" insulin-dependent diabetic patients twice a day or even more frequently.

Patients with insulin-dependent diabetes tend to be young, nonobese, and susceptible to the development of ketoacidosis. Plasma insulin levels are low or not measurable, and therapy requires insulin replacement. Patients with insulin-dependent diabetes experience an increase in their insulin requirements in the postmidnight hours, which may result in early morning hyperglycemia (dawn phenomenon). This accelerated glucose production and impaired glucose use reflect nocturnal surges in secretion of growth hormone (GH). Physiologically normal patients and diabetic patients taking insulin have steady-state levels of insulin in their blood. (Unfortunately, traditional values for insulin pharmacokinetics are derived from studies designed as though the diabetic patient received only one shot of insulin in a lifetime.) Absorption of insulin is highly variable and depends on the type and species of insulin, the site of administration, and subcutaneous blood flow. Nevertheless, attainment of a steady state depends on periodic administration of the preparations received by the patient. Thus, it seems logical to continue the combinations of preparations perioperatively that the patient had been receiving on a long-term basis after examining the patient's blood glucose monitoring logbook for the degree of control.

The major risk factors for diabetic patients undergoing surgery are the end-organ diseases associated with diabetes: cardiovascular dysfunction, renal insufficiency, joint collagen tissue abnormalities (limitation in neck extension,[7] poor wound healing), inadequate granulocyte production, and neuropathies.[8-15] Thus, a major focus of the anesthesiologist should be the preoperative and preprocedure evaluation and treatment of these diseases to ensure optimal preoperative and preprocedure conditions. Poor preoperative glucose control, as measured by the hemoglobin A_{1C} (glycosylated hemoglobin) level, is an independent predictor of worse perioperative outcome.[16-18]

Glucotoxicity

Long-term tight control of blood glucose has been motivated by a theoretic concern about three potential glucotoxicities, in addition to the results from major randomized outcome studies involving diabetic patients.[5-13]

1. Glucose itself may be toxic because high levels can promote nonenzymatic glycosylation reactions that lead to the formation of abnormal proteins. These proteins may weaken endothelial junctions and decrease elastance, which is responsible for the stiff joint syndrome (and difficult intubation secondary to fixation of the atlanto-occipital joint), as well as decrease wound healing tensile strength.
2. Furthermore, elevations in glucose may increase macroglobulin production by the liver (which would increase blood viscosity) and promote intracellular swelling by favoring the production of nondiffusible, large molecules (e.g., sorbitol). Some drug therapies (e.g., aldose reductase inhibitors) endeavor to decrease intracellular swelling by inhibiting the formation of such large molecules.
3. Glycemia also disrupts autoregulation. Glucose-induced vasodilation prevents target organs from protecting against increases in systemic blood pressure. A glycosylated hemoglobin level of 8.1% is the threshold at which the risk for microalbuminuria increases logarithmically. A person with type 1 diabetes who has microalbuminuria of greater than 29 mg/day has an 80% chance of experiencing renal insufficiency. The threshold for glycemic toxicity differs for various vascular beds. For example, the threshold for retinopathy is a glycosylated hemoglobin value of 8.5% to 9.0% (12.5 mmol/L or 225 mg/dL), and that for cardiovascular disease is an average blood glucose value of 5.4 mmol/L (96 mg/dL). Thus, different degrees of hyperglycemia may be required before different vascular beds are damaged, or certain degrees of glycemia are associated with other risk factors for vascular disease. Another view is that perhaps severe hyperglycemia and microalbuminuria are simply concomitant effects of a common underlying cause. For instance, diabetic patients in whom microalbuminuria develops are more resistant to insulin, insulin resistance is associated with microalbuminuria in first-degree relatives of patients with type 2 diabetes, and persons who are normoglycemic but subsequently have clinical diabetes are at risk for atherogenesis before the onset of disease.

Diabetes itself may not be as important to perioperative outcome as are its end-organ effects. Epidemiologic studies segregated the effects of diabetes itself on the organ system from the effects of the complications of diabetes (e.g., cardiac, nervous system, renal, and vascular disease) and the effects of old age and the accelerated aging that diabetes causes. Even in patients requiring intensive care unit (ICU) management, long-standing diabetes does not appear to be as important an issue as the end-organ dysfunction that exists and the degree of glucose control in the perioperative or periprocedure and ICU periods.[8-13]

The World Health Organization's surgical safety checklist bundle suggests control with a target perioperative blood glucose concentration of 6 to 10 mmol/L (acceptable range, 4 to 12 mmol/L).[19] Poor perioperative glycemic control has a significant impact on the risk of postoperative infection across a variety of surgical specialities.[20] Different regimens permit almost any degree of perioperative control of blood glucose levels, but the tighter the control desired, the greater the risk of hypoglycemia. Therefore, debate regarding optimal control during the perioperative period has been extensive. Tight control retards all these glucotoxicities and may have other benefits in retarding the severity of diabetes itself.[5-13,21] Management of intraoperative glucose may be influenced by specific situations, such as the following: the type of operation, pregnancy,[22] expected global CNS insult, the bias of the patient's primary care physician, or the type of diabetes.

Much of the research on perioperative control is derived from studies in the ICU, as opposed to the operating

TABLE 39-1 RECOMMENDED GLUCOSE TARGET RANGES FOR INTENSIVE CARE PATIENTS AND RELATED SUBGROUPS

Society, Guideline	Patient Group	Trigger Blood Glucose Value to Start Insulin Infusion (mM [mg/dL])	Target range, (mM [mg/dL])	Rationale
Society of Critical Care Medicine's clinical practice guideline[26]	General recommendation	8.3 (150)	5.6-8.3 (100-150)	
	Cardiac surgical patients		<8.3 (150)	Decreased risk for deep sternal wound infection and death[73,118-121]
	Critically ill trauma patients	8.3 (150)	<10 (180)	
	Patients with traumatic brain injury	8.3 (150)	<10 (180)	
	Neurologic ICU patients Ischemic stroke Intraparenchymal hemorrhage Aneurysmal subarachnoid hemorrhage	8.3 (150)	<10 (180)	
American Diabetes Association guidelines[471]	General recommendation	10 (180)	7.8-10 (140-180)	
	Adaptation		6.1-7.8 (110-140)	Adjust to lower target range in documented low rate of severe hypoglycemia
American Association of Clinical Endocrinologists[472]	General recommendation		7.8-10 (140-180)	
	Surgical patients		Lower range	Only in units showing low rates of hypoglycemia
Surviving Sepsis Campaign[473]	General recommendation	10 (180)	<10 (180)	Based on the NICE-SUGAR study
Clinical Practical Guideline from the American College of Physicians[474]	General recommendation		7.8-11.1 (140-200)	If insulin infusion is applied; however, guideline does not recommend intensive insulin therapy
Spanish Society of Intensive Care Medicine and Coronary Units[476]	General recommendation		<8.3 (150)	
French Society of Anaesthesia and Intensive Care[475]	General recommendation		10 (180)	
	Surgical patients		<6.1 (110)	
	Cardiac patients		<6.1 (110)	
Society of Thoracic Surgeons[477]	Cardiac surgical patients		<10 (180) except <8.3 (150) for those with devices in place	

Data from Sebranek JJ, Lugli AK, Coursin DB: Glycaemic control in the perioperative period, Br J Anaesth *111(Suppl 1):i18-34, 2013; and Jacobi J, Bircher N, Krinsley J, et al: Guidelines for the use of an insulin infusion for the management of hyperglycemia in critically ill patients,* Crit Care Med *40:3251-3276, 2012.*
ICU, Intensive care unit; *NICE-SUGAR,* Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation.

room. The first major trial demonstrating the benefit of tight glucose control was in medical ICU patients in Leuven, Belgium.[23] The most recent trial was from the NICE-SUGAR (Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation) group.[24] In this randomized controlled trial, the investigators examined the associations between moderate and severe hypoglycemia (blood glucose, 41 to 70 mg/dL [2.3 to 3.9 mmol/L] and ≤40 mg/dL [2.2 mmol/L, respectively) and death among 6026 critically ill patients in ICUs. Intensive glucose control leads to moderate and severe hypoglycemia, both of which are associated with an increased risk of death. The association exhibits a dose-response relationship and is strongest for death from distributive shock. The optimal perioperative management has been reviewed elsewhere.[25] Guidelines have been developed on the use of insulin infusions in the critical care unit to achieve these goals[26] (Table 39-1).

Diabetes and Accelerated Physiologic Aging

Adverse perioperative outcomes have repeatedly and substantially correlated with the age of the patient,[2,3,27-30] and diabetes does cause physiologic aging. When one translates the results of the Diabetes Control and Complications Trials into age-induced physiologic changes, a patient with type 1 diabetes who has poor control of blood glucose ages approximately 1.75 years physiologically for every chronologic year of the disease and 1.25 years if blood glucose has been controlled tightly.[27-29] A patient with type 2 diabetes ages approximately 1.5 years for every chronologic year of the disease and approximately 1.06 years with tight control of blood glucose and blood pressure.[6,27-29,31] Thus, when providing care for a diabetic patient, one must consider the associated risks to be those of a person who is much older physiologically; the physiologic age of a diabetic patient is considerably older than that person's calendar age just by virtue of having the disease.[1]

The pervasiveness of obesity and the lack of physical exercise seem to be major contributors to the increased prevalence of type 2 diabetes. As with type 1 diabetes, tight control of blood glucose, increased physical activity, and reduction in weight appear to reduce the accelerated aging associated with type 2 diabetes and even to delay the appearance of the disease and aging from it substantially.[27-29,31] Although such a reduction in aging should reduce the perioperative risk for diabetic patients, no controlled trials have confirmed this theory.

The key to managing blood glucose levels perioperatively in diabetic patients is to set clear goals and then monitor blood glucose levels frequently enough to adjust therapy to achieve these goals.

Other Conditions Associated With Diabetes

Diabetes is associated with microangiopathy (in retinal and renal vessels), peripheral neuropathy, autonomic dysfunction, and infection. Diabetic patients are often treated with angiotensin-converting enzyme (ACE) inhibitors, even in the absence of gross hypertension, in an effort to prevent the effects of disordered autoregulation, including renal failure.[5,6,32]

Preoperatively, assessment and optimization of treatment of the potential and potent end-organ effects of diabetes are at least as important as assessment of the diabetic patient's current overall metabolic status. The preoperative evaluation of diabetic patients is also discussed in Chapter 38.

The presence of autonomic neuropathy likely makes the operative period more hazardous and the postoperative period crucial to survival. Evidence of autonomic neuropathy may be routinely sought before the surgical procedure. Patients with diabetic autonomic neuropathy are at increased risk for gastroparesis (and consequent aspiration of gastric contents) and for perioperative cardiorespiratory arrest. Diabetic patients who exhibit signs of autonomic neuropathy, such as early satiety, lack of sweating, lack of pulse rate change with inspiration or orthostatic maneuvers, and impotence, have a very frequent incidence of painless myocardial ischemia,[15,33] as well as gastroparesis. Administration of metoclopramide, 10 mg preoperatively to facilitate gastric emptying of solids, may be helpful (Fig. 39-1). Interference with respiration or sinus automaticity by pneumonia or by anesthetic agents, pain medications, or sedative drugs is likely the precipitating cause in most cases of sudden cardiorespiratory arrest. Measuring the degree of sinus arrhythmia or beat-to-beat variability provides a simple, accurate test for significant autonomic neuropathy. The difference between the maximum and minimum heart rate on deep inspiration is normally 15 beats/minute, but it is 5 beats/minute or less in all patients who subsequently sustain cardiorespiratory arrest.[15,33]

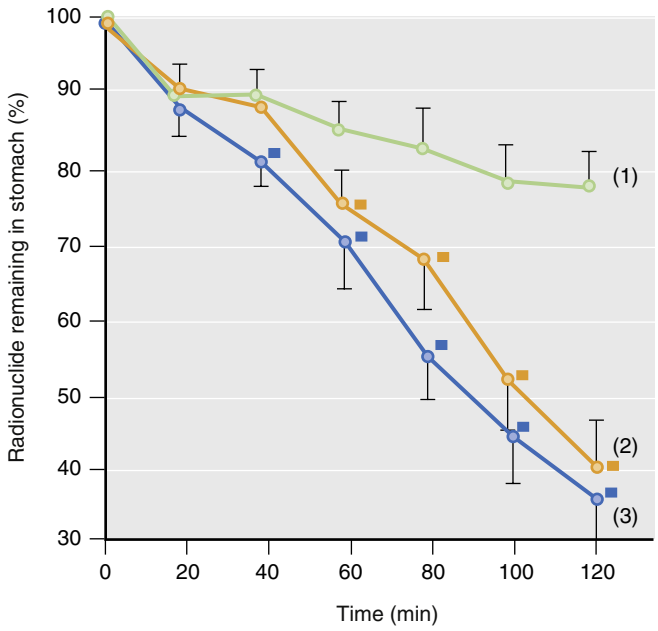

Figure 39-1. Gastric emptying time (mean ± standard deviation) of a solid test meal in three groups of patients: diabetic patients *(line 1)*, diabetic patients given metoclopramide (10 mg intravenously) 1.5 hours before the test meal *(line 2)*, and nondiabetic patients *(line 3)*. *(From Wright RA, Clemente R, Wathen R: Diabetic gastroparesis: an abnormality of gastric emptying of solids,* Am J Med Sci *289:240, 1985.)*

Other characteristics of patients with autonomic neuropathy include postural hypotension with a decrease in arterial blood pressure of more than 30 mm Hg, resting tachycardia, nocturnal diarrhea, and dense peripheral neuropathy. Diabetic patients with significant autonomic neuropathy may have impaired respiratory responses to hypoxia and are particularly susceptible to the action of drugs that have depressant effects. These patients may warrant very close, continuous cardiac and respiratory monitoring for 24 to 72 hours postoperatively, although such logical treatment has not been tested in a rigorous, controlled trial.[15] In the absence of autonomic neuropathy, outpatient surgery is preferred for a diabetic patient if possible (see Table 39-1).

Emergency Surgery

Many diabetic patients requiring emergency surgery for trauma or infection have significant metabolic decompensation, including ketoacidosis (see also Chapter 81). Frequently, little time is available to stabilize the patient, but even a few hours may be sufficient for correction of any fluid and electrolyte disturbances that are potentially life-threatening. It is futile to delay surgery in an attempt

to eliminate ketoacidosis completely if the underlying surgical condition will lead to further metabolic deterioration. The likelihood of intraoperative cardiac arrhythmias and hypotension resulting from ketoacidosis will be reduced if intravascular volume depletion and hypokalemia are at least partially treated.

Insulin therapy is initiated with a 10-unit intravenous bolus of regular insulin, followed by continuous insulin infusion. The rate of infusion is determined most easily if one divides the last serum glucose value by 150 (or 100 if the patient is receiving steroids, has an infection, or is considerably overweight [body mass index ≥35]). The actual amount of insulin administered is less important than is regular monitoring of glucose, potassium, and arterial pH. Because the number of insulin binding sites is limited, the maximum rate of decline in glucose is fairly constant and averages 75 to 100 mg/dL/hour, regardless of the dose of insulin.[34] During the first 1 to 2 hours of fluid resuscitation, the glucose level may decrease more precipitously. When serum glucose reaches 250 mg/dL, the intravenous fluid should include 5% dextrose.

The volume of intravenously administered fluid required varies with the overall deficit; it ranges from 3 to 5 L and may be as large as 10 L. Despite losses of water in excess of losses of solute, sodium levels are generally normal or reduced. Factitious hyponatremia caused by hyperglycemia or hypertriglyceridemia may result in this seeming contradiction. The plasma sodium concentration decreases by approximately 1.6 mEq/L for every 100 mg/dL increase in plasma glucose greater than normal. Initially, normal saline solution is infused at a rate of 250 to 1000 mL/hour, depending on the degree of intravascular volume depletion and cardiac status. Some measure of left ventricular volume should be monitored in diabetic patients who have a history of myocardial dysfunction. Approximately one third of the estimated fluid deficit is corrected during the first 6 to 8 hours and the remaining two thirds over the next 24 hours.

The degree of acidosis is determined by analysis of arterial blood gases and detection of an increased anion gap (see also Chapter 60).

Acidosis with an increased anion gap (≥16 mEq/L) in an acutely ill diabetic patient may be caused by ketones in ketoacidosis, lactic acid in lactic acidosis, increased organic acids from renal insufficiency, or all three disorders. In ketoacidosis, plasma levels of acetoacetate, β-hydroxybutyrate, and acetone are increased. Plasma and urinary ketones are measured semiquantitatively with Ketostix and Acetest tablets. The role of bicarbonate therapy in diabetic ketoacidosis is controversial. Myocardial function and respiration are known to be depressed at a blood pH lower than 7.0 to 7.10, yet rapid correction of acidosis with bicarbonate therapy may result in alterations in CNS function and structure. These alterations may be caused by (1) paradoxical development of cerebrospinal fluid and CNS acidosis from rapid conversion of bicarbonate to carbon dioxide and diffusion of the acid across the blood-brain barrier, (2) altered CNS oxygenation with decreased cerebral blood flow, and (3) the development of unfavorable osmotic gradients. After treatment with fluids and insulin, β-hydroxybutyrate levels decrease rapidly, whereas acetoacetate levels may remain stable or even increase before declining. Plasma acetone levels remain elevated for 24 to 42 hours, long after blood glucose, β-hydroxybutyrate, and acetoacetate levels have returned to normal; the result is continuing ketonuria.[34] Persistent ketosis with a serum bicarbonate level less than 20 mEq/L in the presence of a normal glucose concentration is an indication of the continued need for intracellular glucose and insulin for reversal of lipolysis.

The most important electrolyte disturbance in diabetic ketoacidosis is depletion of total-body potassium. Deficits range from 3 to 10 mEq/kg body weight. Serum potassium levels decline rapidly and reach a nadir within 2 to 4 hours after the start of intravenous insulin administration. Aggressive replacement therapy is required. The potassium administered moves into the intracellular space with insulin as the acidosis is corrected. Potassium is also excreted in urine because of the increased delivery of sodium to the distal renal tubules that accompanies volume expansion. Phosphorus deficiency in ketoacidosis as a result of tissue catabolism, impaired cellular uptake, and increased urinary losses may give rise to significant muscular weakness and organ dysfunction. The average phosphorus deficit is approximately 1 mmol/kg body weight. Replacement is needed if the plasma concentration decreases to less than 1.0 mg/dL.[34]

Anticipated Newer Treatments of Diabetes

At least three major changes in the care of diabetic patients have made it to the clinical trial stage:

- Implanted (like a pacemaker) glucose analyzer with electronic transmission to a surface (watch) monitor
- New islet transplantation medication that makes islet cell transplants much more successful and rejection medication less hazardous
- Medications such as INGAP (islet neogenesis–associated protein) peptide, which may cause regrowth of normally functioning islet cells (without the need for transplantation)

Some of these treatments may radically change the therapies used in the perioperative period. If regrowth of islet cells becomes common, type 1 diabetes could all but disappear; if implanted minute-to-minute glucose reading is possible, tight control may be much easier and more expected.

Insulinoma and Other Causes of Hypoglycemia

Hypoglycemia in persons not treated for diabetes is rare. Hypoglycemia in nondiabetic patients can be caused by such diverse entities as pancreatic islet cell adenoma or carcinoma, large hepatoma, large sarcoma, alcohol ingestion, use of β-adrenergic receptor blocking drugs, haloperidol therapy, hypopituitarism, adrenal insufficiency, altered physiology after gastric or gastric bypass surgery, hereditary fructose intolerance, ingestion of antidiabetic drugs, galactosemia, or autoimmune hypoglycemia.[35] The last four entities cause postprandial reactive hypoglycemia. Because restriction of oral intake prevents severe hypoglycemia, the practice of keeping the patient NPO (nothing by mouth) and infusing small amounts of a solution containing 5% dextrose greatly lessens the

possibility of perioperative postprandial reactive hypoglycemia. The other causes of hypoglycemia can cause serious problems during the perioperative period.[35]

Symptoms of hypoglycemia fall into one of two groups: adrenergic excess (tachycardia, palpitations, tremulousness, or diaphoresis) or neuroglycopenia (headache, confusion, mental sluggishness, seizures, or coma). All these symptoms may be masked by anesthesia, so blood glucose levels should be determined frequently in such patients to ensure that hypoglycemia is not present. Because manipulation of an insulinoma can result in massive insulin release, this tumor should probably be operated on only at centers equipped with a mechanical pancreas. Perioperative use of the somatostatin analogue octreotide, which suppresses insulin release from such tumors, makes the perioperative period a logarithm safer in anecdotal experience.

DISORDERS OF NUTRITION, INCLUDING OBESITY

Hyperlipoproteinemia, Hyperlipidemia, and Hypolipidemia

Hyperlipidemia may result from obesity, estrogen or corticoid therapy, uremia, diabetes, hypothyroidism, acromegaly, alcohol ingestion, liver disease, inborn errors of metabolism, or pregnancy. Hyperlipidemia may cause premature coronary or peripheral vascular disease or pancreatitis.

Coronary events can be decreased by treating individuals with even normal levels of low-density lipoprotein (LDL) cholesterol with the "statins" (3-hydroxy-3-methylglutaryl–coenzyme A [HMG-CoA] reductase inhibitors)—drugs that increase high-density lipoprotein (HDL) and decrease LDL cholesterol levels. This approach has markedly decreased the rate of myocardial reinfarction in high-risk patients.[36-38] Secondary prevention efforts were successful when these high-risk patients stopped smoking, reduced their arterial blood pressure, controlled stress, increased physical activity, and used aspirin, folate, β-blocking drugs, angiotensin inhibitors, diet, and other drugs to reduce their levels of LDL and increase their levels of HDL.

Although controlling the diet remains a major treatment modality for all types of hyperlipidemia, the drugs fenofibrate and gemfibrozil, which are used to treat hypertriglyceridemia, can cause myopathy, especially in patients with hepatic or renal disease; clofibrate is also associated with an increased incidence of gallstones. Cholestyramine binds bile acids, as well as oral anticoagulants, digitalis drugs, and thyroid hormones. Nicotinic acid causes peripheral vasodilation and should probably not be continued through the morning of the surgical procedure. Probucol (Lorelco) decreases the synthesis of apoprotein A-1; its use is associated on rare occasion with fetid perspiration or prolongation of the QT interval, or both, and sudden death in animals.

The West of Scotland Coronary Prevention Study and its congeners produced convincing evidence that drugs in the statin class prevent the morbidity and mortality related to arterial aging and vascular disease, as well as their consequences, such as coronary artery disease (CAD), stroke, and peripheral vascular insufficiency.[37] Thus, the statins—lovastatin (Mevacor), pravastatin (Pravachol), simvastatin, fluvastatin, atorvastatin (Lipitor), and rosuvastatin (Crestor)—are mainstays of therapy.

However, the report of Downs and co-workers from the Air Force/Texas Coronary Atherosclerosis Prevention Study went further.[37] This report showed a 37% reduction in the risk for first acute major coronary events in patients who had no risk factors and normal (average) LDL cholesterol levels. In this study lovastatin did not alter mortality rates, but that had been true for many early short-term trials with the statins. Although much of the effect of the statins has been attributed to their lipid-lowering effects, statins also influence endothelial function, inflammatory responses, plaque stability, and thrombogenicity. In 2013, the American College of Cardiology (ACC) and the American Heart Association (AHA) released a new clinical practice guideline for the treatment of blood cholesterol in people at high risk for cardiovascular diseases.[39] They now advocate statin therapy for the following:

- Patients who have cardiovascular disease
- Patients with an LDL, or "bad" cholesterol, level of 190 mg/dL or higher
- Patients with type 2 diabetes who are between 40 and 75 years old
- Patients with an estimated 10-year risk of cardiovascular disease of 7.5% or higher who are between 40 and 75 years old (the report provides formulas for calculating 10-year risk)

Statins are drugs that block HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis. Their use is occasionally accompanied by liver dysfunction, CNS dysfunction, and severe depression not related to the high cost of each drug and its congeners. Based on the available evidence, statin therapy should be continued in patients already taking these drugs.[40] Other drugs that reduce LDL and increase HDL cholesterol and decrease triglycerides are docosahexaenoic acid (an ω-3 fatty acid) and niacin. Statins also provide the substantial benefit of reversing inflammation in arteries, as evidenced by their ability to decrease highly specific C-reactive protein and pull cholesterol from plaque.[41]

Hypolipidemic conditions are rare diseases often associated with neuropathy, anemia, and renal failure. Although anesthetic experience with hypolipidemic conditions has been limited, some specific recommendations can be made: continuation of caloric intake and intravenous administration of protein hydrolysates and glucose should be continued throughout the perioperative period.

Obesity

Although many conditions associated with obesity (diabetes, hyperlipidemia, cholelithiasis, gastroesophageal reflux disease, cirrhosis, degenerative joint and disk disease, venous stasis and thrombotic or embolic disease, sleep disorders, and emotional and altered body image disorders) contribute to chronic morbidity in obese patients, the main concerns for the anesthesiologist have been the same since the 1970s—derangements of the cardiopulmonary system (see also Chapter 71).

Morbid obesity with minimal or no coexisting pulmonary conditions (e.g., no obesity-hypoventilation

syndrome or chronic obstructive pulmonary disease [COPD]) is referred to here as "simple" obesity. In simple obesity, the pathophysiology of mild alterations in daytime gas exchange and pulmonary function may also result from compression and restriction of the chest wall and diaphragm by excess adipose tissue.[42] Typically, in obese patients, the expiratory reserve volume and functional residual capacity are most affected and are reduced to 60% and 80% of normal, respectively.

Other Eating Disorders: Anorexia Nervosa, Bulimia, and Starvation

Many endocrine and metabolic abnormalities occur in patients with anorexia nervosa, a condition characterized by starvation to the point of 40% loss of normal weight, hyperactivity, and a psychiatrically distorted body image. Many anorectic patients exhibit impulsive behavior, including suicide attempts, and intravenous drug use is much more common than in the general population. Acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypothermia, diabetes insipidus, and severe endocrine abnormalities mimicking panhypopituitarism need attention before patients undergo anesthesia and surgery. Similar problems occur in bulimia (bulimorexia), a condition that may affect as many as 50% of female college students and is even unintentionally present in many older adults. As in severe protein deficiency (kwashiorkor), anorexia nervosa and bulimia may be accompanied by the following: alterations on the electrocardiogram (ECG), including a prolonged QT interval, atrioventricular (AV) block, and other arrhythmias; sensitivity to epinephrine; and cardiomyopathy.[43] Total depletion of body potassium makes the addition of potassium to glucose solutions useful; however, fluid administration can precipitate pulmonary edema in these patients. Esophagitis, pancreatitis, and aspiration pneumonia are more frequent in these patients, as is delayed gastric emptying. One review reported that in patients with severe anorexia with a body mass index less than 13 kg/m^2, marked hypoglycemia or leukocytopenia lower than 3.0 × 10^9/L, or both, potentially fatal complications frequently occur.[44] Accordingly, patients need strict nutritional support to avoid refeeding syndrome until the surgical procedure. Intraoperatively, glucose or catecholamine administration may lead to disturbance of electrolytes or fatal arrhythmia. Intensive care and early feeding as soon as possible postoperatively are important to prevent surgical site infection.

HYPERALIMENTATION (TOTAL PARENTERAL OR ENTERAL NUTRITION)

Hyperalimentation (i.e., total parenteral nutrition [TPN]) consists of concentrating hypertonic glucose calories in the normal daily fluid requirements (see also Chapter 106). The solutions contain protein hydrolysates, soybean emulsions (i.e., Intralipid), or synthetic amino acids (or any combination of these ingredients). The major benefits of TPN or enteral nutrition have been fewer complications postoperatively and shorter hospital stays for patients scheduled to have no oral feeding for 7 days or who were malnourished preoperatively.[45,46] Starker and colleagues found that the response to TPN, as monitored by serum albumin levels, predicted the postoperative outcome.[47] The group of patients demonstrating an increase in serum albumin concentrations from TPN had diuresis, weight loss, and fewer complications (1 of 15 patients) than did the group that gained weight and had a decrease in serum albumin (8 of 16 patients had 15 complications) (Fig. 39-2). The Veterans Administration (former name for Veterans Affairs [VA used for both]) studies also found that the serum albumin level was one of the most powerful predictors of perioperative outcome.[45]

The major complications of hyperalimentation are sepsis and metabolic abnormalities. The central lines used for TPN require application with an absolutely aseptic technique and should not be used routinely as an intravenous route for drug administration. Major metabolic complications of TPN relate to deficiencies and the development of hyperosmolar states. Complications of hypertonic dextrose can develop if the patient has insufficient insulin (diabetes mellitus) to metabolize the sugar or if insulin resistance occurs (e.g., because of uremia, burns, or sepsis).

A gradual decrease in the infusion rate of TPN prevents the hypoglycemia that can occur on abrupt discontinuance. Thus, the infusion rate of TPN should be decreased the night before anesthesia and surgery or should be continued throughout the operation at its current rate. The main reason for slowing or discontinuing TPN before anesthesia is to avoid intraoperative hyperosmolarity secondary to accidental rapid infusion of the solution or hypoglycemia if the infusion is discontinued because of high levels of endogenous insulin and lower levels of glucose present in the usual crystalloid solutions.[45] Hypophosphatemia is a particularly serious complication that results from the administration of phosphate-free or phosphate-depleted solutions for hyperalimentation.

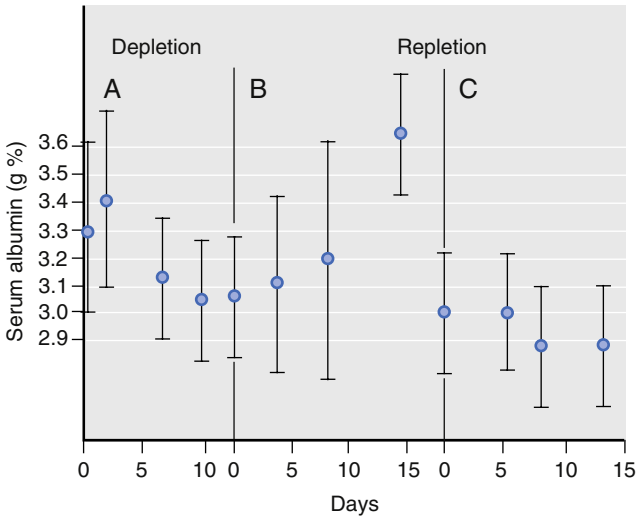

Figure 39-2. The response to hyperalimentation (*A,* repletion), as measured by variation in serum albumin levels, predicted the outcome of surgery. Patients who responded (*B*) to nutritional support with increased albumin levels had a significantly better outcome than did those whose albumin level did not increase (*C*). See the text for a more complete explanation. *(Modified from Starker PM, Group FE, Askanazi J, et al: Serum albumin levels as an index of nutritional support,* Surgery *91:194, 1982.)*

The low serum phosphate level causes a shift of the oxygen dissociation curve to the left. The resulting low 2,3-diphosphoglycerate and adenosine triphosphatase levels mean that cardiac output must increase for oxygen delivery to remain the same. Hypophosphatemia of less than 1.0 mg/dL of blood may cause hemolytic anemia, cardiac failure, tachypnea, neurologic symptoms, seizures, and death. In addition, long-term TPN is associated with deficiencies in trace metals such as copper (refractory anemia), zinc (impaired wound healing), and magnesium.

ADRENOCORTICAL MALFUNCTION

Three major classes of hormones—androgens, glucocorticoids, and mineralocorticoids—are secreted by the adrenal cortex. For each class, an excess or a deficiency of hormone produces a characteristic clinical syndrome. The widespread use of steroids can also make the adrenal cortex unable to respond normally to the demands placed on it by surgical trauma and subsequent healing. The increase in unindicated (scanning) computed tomography (CT) abdominal imaging procedures has meant that many adrenal masses have unfortunately been discovered only incidentally. These adrenal "incidentalomas," as they are termed because they were initially thought a nuisance discovered by unindicated body scans, have proved more serious. As many as 30% are hormonally active; in a review of 2000 such masses, 82% were not hormonally active, 5.3% proved to be cortisone-secreting adenomas, 5.1% were pheochromocytomas, 4.7% were adrenal carcinomas, 2.5% were unsuspected metastatic disease, and 1% were aldosterone-secreting adenomas. Incidentalomas may therefore require serious pursuit. Several points relative to adrenal cortical management deserve attention.

Controlled comparisons of the perioperative management of patients who have disorders of adrenal function are lacking, although steroids are used more and more commonly, with the results of some controlled trials available for specific uses. However, a review of the possible pathophysiologic changes in the adrenal cortex and techniques for their management should enable physicians to improve the perioperative care of patients with adrenal abnormalities.

Physiologic Properties of Adrenocortical Hormones

Androgens. Androstenedione and dehydroepiandrosterone, weak androgens arising from the adrenal cortex, constitute major sources of androgen in women (and have gained prominence for their use or abuse by baseball players seeking to hit more home runs). Excess secretion of androgen causes masculinization, pseudopuberty, or female pseudohermaphroditism. With some tumors, androgen is converted to an estrogenic substance, in which case feminization results. No special anesthetic evaluation is needed for such patients. Some congenital enzyme defects that cause androgen abnormalities also result in glucocorticoid and mineralocorticoid abnormalities that should be evaluated preoperatively. Most of these patients are treated with exogenous glucocorticoids and mineralocorticoids and consequently require supplementation of these hormones perioperatively (see later).

Glucocorticoids. The principal glucocorticoid, cortisol, is an essential regulator of carbohydrate, protein, lipid, and nucleic acid metabolism. Cortisol exerts its biologic effects through a sequence of steps initiated by binding of hormone to stereospecific intracellular cytoplasmic receptors. This bound complex stimulates nuclear transcription of specific mRNA molecules. These molecules are then translated to give rise to proteins that mediate the ultimate effects of hormones.

Most cortisol is bound to corticosterone-binding globulin (CBG, transcortin). The relatively small amounts of unbound cortisol enter cells to induce actions or to be metabolized. Conditions that induce changes in the amount of CBG include liver disease and nephrotic syndrome, both of which result in decreased circulating levels of CBG, and estrogen administration and pregnancy, which result in increased CBG production. Total serum cortisol levels may become elevated or depressed under conditions that alter the amount of bound cortisol, and yet the unbound, active form of cortisol is present in normal amounts. The most accurate measure of cortisol activity is the level of urinary cortisol (i.e., the amount of unbound, active cortisol filtered by the kidney).

The serum half-life of cortisol is 80 to 110 minutes. However, because cortisol acts through intracellular receptors, pharmacokinetic data based on serum levels are not good indicators of cortisol activity. After a single dose of glucocorticoid, serum glucose is elevated for 12 to 24 hours; improvement in pulmonary function in patients with bronchial asthma can still be measured 24 hours after glucocorticoid administration. Treatment schedules for glucocorticoid replacement are therefore based not on the measured serum half-life but on the well-documented prolonged end-organ effect of these steroids. Hospitalized patients requiring long-term glucocorticoid replacement therapy are usually treated twice daily, with a slightly higher dose given in the morning than in the evening to simulate the normal diurnal variation in cortisol levels. For patients who require parenteral "steroid coverage" during and after surgery (see later paragraphs), administration of glucocorticoid every 12 hours is appropriate.[48] The relative potencies of glucocorticoids are listed in Table 39-2. Cortisol is inactivated

TABLE 39-2 RELATIVE POTENCIES AND EQUIVALENT DOSES FOR COMMONLY USED GLUCOCORTICOIDS

Steroids	Relative Glucocorticoid Potency	Equivalent Glucocorticoid Dose (mg)
Short Acting		
Cortisol (hydrocortisone)	1.0	20.0
Cortisone	0.8	25.0
Prednisone	4.0	5.0
Prednisolone	4.0	5.0
Methylprednisolone	5.0	4.0
Intermediate Acting		
Triamcinolone	5.0	4.0
Long Acting		
Betamethasone	25.0	0.60
Dexamethasone	30.0	0.75

Data from Axelrod L: Glucocorticoid therapy, Medicine (Baltimore) *55:39, 1976.*

primarily in the liver and is excreted as 17-hydroxycorticosteroid. Cortisol is also filtered and excreted unchanged into urine.

The synthetic glucocorticoids vary in their binding specificity in a dose-related manner. When given in supraphysiologic doses (>30 mg/day), cortisol and cortisone bind to mineralocorticoid receptor sites and cause salt and water retention and loss of potassium and hydrogen ions. When these steroids are administered in maintenance doses of 30 mg/day or less, patients require a specific mineralocorticoid for electrolyte and volume homeostasis. Many other steroids do not bind to mineralocorticoid receptors, even at high doses, and have no mineralocorticoid effect (see Table 39-2).

Secretion of glucocorticoids is regulated by pituitary adrenocorticotropic hormone (ACTH). ACTH is synthesized from a precursor molecule (pro-opiomelanocortin) that is metabolized to form an endorphin (β-lipotropin) and ACTH. Episodic secretion of ACTH has a diurnal rhythm that is normally greatest during the early morning hours in men and later in women and is regulated at least in part by light-dark cycles. Its secretion is stimulated by release of corticotropin-releasing factor (CRF) from the hypothalamus. (An abnormality in the diurnal rhythm of corticoid secretion has been implicated as a cause of so-called jet lag.) Cortisol and other glucocorticoids exert negative feedback at both the pituitary and hypothalamic levels to inhibit the secretion of ACTH and CRF. If the CRF- or ACTH-producing cells are destroyed, the adrenal gland takes more than 30 days to atrophy to the point at which short-term administration of exogenous ACTH will cause almost no adrenal responsiveness.

Mineralocorticoids. Aldosterone, the major mineralocorticoid secreted in humans, comes from the zona glomerulosa of the adrenal cortex and causes reabsorption of sodium and secretion of potassium and hydrogen ions, thereby contributing to electrolyte and volume homeostasis. This action is most prominent in the distal renal tubule but also occurs in the salivary and sweat glands. The major regulator of aldosterone secretion is the renin-angiotensin system. Juxtaglomerular cells in the cuff of renal arterioles are sensitive to decreased renal perfusion pressure or volume and, consequently, secrete renin. Renin transforms the precursor angiotensinogen (from the liver) into angiotensin I, which is further converted by a converting enzyme, primarily in the lung, to angiotensin II. Angiotensin II binds to specific receptors to increase mineralocorticoid secretion, which is also stimulated by an increased potassium concentration and, to a lesser degree, by ACTH.

Adrenocortical Hormone Excess

Glucocorticoid Excess. Glucocorticoid excess (Cushing syndrome) resulting from either endogenous oversecretion or long-term treatment with glucocorticoids at higher than physiologic doses produces a moon-faced plethoric individual with a centripetal distribution of fat (truncal obesity and skinny extremities), thin skin, easy bruising, and striae. Muscle wasting is common, but the heart and diaphragm are usually spared. A test for this syndrome is to ask the patient to get up from a chair without using the hands. An inability to do so indicates proximal muscle weakness consistent with Cushing syndrome. These patients often have osteopenia as a result of decreased formation of bone matrix and impaired absorption of calcium. Fluid retention and hypertension (because of increases in renin substrate and vascular reactivity caused by glucocorticoid) are common. Such patients may also have hyperglycemia and even diabetes mellitus from inhibition of peripheral use of glucose, as well as antiinsulin action and concomitant stimulation of gluconeogenesis (Table 39-3).

The most common cause of Cushing syndrome is the administration of glucocorticoids for such conditions as arthritis, asthma, and allergies. In these conditions, the adrenal glands atrophy and cannot respond to stressful situations (e.g., the preoperative and preprocedure period) by secreting more steroid. Thus, additional glucocorticoids may be required perioperatively (see the later section "Patients Taking Steroids for Other Reasons"). Spontaneous Cushing syndrome may be caused by pituitary production of ACTH (65% to 75% of all spontaneous cases), which is usually associated with pituitary microadenoma, or by nonendocrine ectopic ACTH production (principally by tumors of the lung, pancreas, or thymus).[49] Ten percent to 20% of cases of spontaneous Cushing syndrome are caused by an ACTH-independent process, either an adrenal adenoma or carcinoma.

Special preoperative and preprocedure considerations for patients with Cushing syndrome include regulating diabetes and hypertension and ensuring that intravascular fluid volume and electrolyte concentrations are normal. Ectopic ACTH production may cause marked hypokalemic alkalosis. Treatment with the aldosterone antagonist spironolactone stops the potassium loss and helps mobilize excess fluid. Because of the high incidence of severe osteopenia and the risk of fractures, meticulous attention must be paid to positioning of the patient. In addition,

TABLE 39-3 CLINICAL FEATURES OF HYPERADRENALISM (CUSHING SYNDROME) AND HYPOADRENALISM

Cushing Syndrome	Hypoadrenalism
Central obesity	Weight loss
Proximal muscle weakness	Weakness, fatigue, lethargy
Osteopenia at a young age	Muscle and joint pain and back pain
Hypertension	Postural hypotension and dizziness
Headache	Headache
Psychiatric disorders	Anorexia, nausea, abdominal pain, constipation, diarrhea
Purple striae	
Spontaneous ecchymoses	
Plethoric facies	
Hyperpigmentation	Hyperpigmentation
Hirsutism	
Acne	
Hypokalemic alkalosis	Hyperkalemia, hyponatremia
Glucose intolerance	Occasional hypoglycemia
Kidney stones	Hypercalcemia
Polyuria	Prerenal azotemia
Menstrual disorders	
Increased leukocyte count	

glucocorticoids are lympholytic and immunosuppressive and thus increase the patient's susceptibility to infection. The tensile strength of healing wounds decreases in the presence of glucocorticoids, an effect that is at least partially reversed by the topical administration of vitamin A.

Specific considerations pertain to the surgical approach for each cause of Cushing syndrome. For example, nearly three fourths of cases of spontaneous Cushing disease result from a pituitary adenoma that secretes ACTH. In the experience of Dr. Michael Roizen, a previous author of this chapter in earlier editions, perioperative treatment of patients who have Cushing disease and a pituitary microadenoma differs from that of patients who have a pituitary adenoma associated with amenorrhea and galactorrhea. A patient with Cushing disease is inclined to bleed more easily and (on the basis of anecdotal evidence) tends to have higher central venous pressure (CVP). Thus, during transsphenoidal tumor resection in such patients, routine practice is to monitor CVP and maintain it at the low end of the normal range. In other cases of transsphenoidal resection of microadenoma, such monitoring is needed only infrequently.

Ten percent to 15% of patients with Cushing syndrome exhibit adrenal overproduction of glucocorticoids from an adrenal adenoma or carcinoma. If either unilateral or bilateral adrenal resection is planned, the physician should begin administering glucocorticoids at the start of resectioning of the tumor. Despite the absence of definitive studies, 100 mg of hydrocortisone hemisuccinate or hydrocortisone phosphate every 24 hours intravenously is reasonable. This amount can be reduced over a period of 3 to 6 days until a maintenance dose is reached. Beginning on day 3, the surgeons may also give a mineralocorticoid, 9α-fluorocortisol (0.05 to 0.1 mg/day). In certain patients, both steroids may require several adjustments. This therapy continues if the patient has undergone bilateral resection. For a patient who has undergone unilateral adrenal resection, therapy is individualized according to the status of the remaining adrenal gland. The incidence of pneumothorax in open adrenal resection approach can be as high as 20%; the diagnosis of pneumothorax is sought and treatment is initiated before the wound is closed. The use of the laparoscopic technique has markedly decreased this complication.

Bilateral adrenalectomy in patients with Cushing syndrome is associated with a high incidence of postoperative complications and a perioperative mortality rate (higher than that of even cardiac surgery) of 5% to 10%; this procedure often results in permanent mineralocorticoid and glucocorticoid deficiency. Ten percent of patients with Cushing syndrome who undergo adrenalectomy have an undiagnosed pituitary tumor. After cortisol concentrations are decreased by adrenalectomy, the pituitary tumor will likely enlarge. These pituitary tumors are potentially invasive and may produce large amounts of ACTH and melanocyte-stimulating hormone, thereby increasing pigmentation.

Approximately 85% of adrenal tumors are discovered incidentally during screening CT scans. Nonfunctioning adrenal adenomas are found in patients on autopsy, ranging from 1% to 32% in different series. Functioning adenomas are generally treated surgically; often, the contralateral gland resumes functioning after several months. Frequently, however, the effects of carcinomas are not cured surgically. In such cases, administration of inhibitors of steroid synthesis, such as metyrapone or mitotane (*o*,*p*′-DDD[2,2-bis(2-chlorophenyl4-chlorophenyl)-1, 1-dichloroethane]), may ameliorate some symptoms but may not improve survival. These drugs and specific aldosterone antagonists may aid in reducing symptoms in the case of ectopic ACTH secretion if the primary tumor proves unresectable. Patients given these adrenal suppressants are also prescribed long-term glucocorticoid replacement therapy (i.e., the goal of therapy is complete adrenal suppression). These patients should be considered to have suppressed adrenal function, and glucocorticoid replacement should be increased perioperatively.

Mineralocorticoid Excess. Excess mineralocorticoid activity (common with glucocorticoid excess because most glucocorticoids have some mineralocorticoid properties) leads to potassium depletion, sodium retention, muscle weakness, hypertension, tetany, polyuria, inability to concentrate urine, and hypokalemic alkalosis. These symptoms constitute primary hyperaldosteronism, or Conn syndrome (a cause of low-renin hypertension because renin secretion is inhibited by the effects of the high levels of aldosterone).

Primary hyperaldosteronism is present in 0.5% to 1% of hypertensive patients who have no other known cause of hypertension. Primary hyperaldosteronism most often results from unilateral adenoma, although 25% to 40% of patients have been found to have bilateral adrenal hyperplasia. Intravascular fluid volume, electrolyte concentrations, and renal function should be restored to within normal limits preoperatively by administering the aldosterone antagonist spironolactone. The effects of spironolactone are slow in onset and increase for 1 to 2 weeks. A patient who has a serum potassium level of 2.9 mEq/L may have a total-body potassium deficit of as little as 40 mEq or as much as 400 mEq. Frequently, a period of at least 24 hours is required to restore potassium equilibrium. A normal serum potassium level does not necessarily imply correction of a total-body deficit of potassium. In addition, patients with Conn syndrome have a high incidence of hypertension and ischemic heart disease; hemodynamic monitoring should be appropriate for the degree of cardiovascular impairment.

A retrospective anecdotal study indicated that intraoperative hemodynamic status was more stable when arterial blood pressure and electrolytes were controlled preoperatively with spironolactone than when other antihypertensive drugs were used. However, the efficacy of optimizing the perioperative status of patients who have disorders of glucocorticoid or mineralocorticoid secretion has not been clearly established. We have assumed that gradual restoration of a normal condition is good medicine and that it would decrease perioperative morbidity and mortality.

Adrenocortical Hormone Deficiency

Glucocorticoid Deficiency. Withdrawal of steroids or suppression of synthesis by steroid therapy is the leading cause of underproduction of corticosteroids. Management of this type of glucocorticoid deficiency is discussed in the later section "Patients Taking Steroids for Other

Reasons". Other causes of adrenocortical insufficiency include the following: defects in ACTH secretion and destruction of the adrenal gland by autoimmune disease, tuberculosis, hemorrhage, or cancer; some forms of congenital adrenal hyperplasia (see previous discussion); and administration of cytotoxic drugs.

Primary adrenal insufficiency (Addison disease) is associated with local destruction of all zones of the adrenal cortex and results in both glucocorticoid and mineralocorticoid deficiency if the insufficiency is bilateral; common symptoms and signs are listed in Table 39-3. Autoimmune disease is the most common cause of primary (nonexogenous) bilateral ACTH deficiency in the United States, whereas tuberculosis is the most common cause worldwide. Tuberculosis is associated with decreased adrenal function but large adrenal glands, as is also common in sarcoidosis, histoplasmosis, amyloidosis, metastatic malignant disease, and adrenal hemorrhage. Destruction or partial destruction by trauma and by human immunodeficiency virus (HIV) and other infections, such as cytomegalovirus, mycobacteria, and fungi, is being recognized more frequently.

An increasingly common cause of adrenal insufficiency associated with large adrenal glands is heparin-induced thrombocytopenia, which may be considered in every patient who has received heparin and has hypotension.

Autoimmune destruction of the adrenal glands may be associated with other autoimmune disorders, such as some forms of type 1 diabetes and Hashimoto thyroiditis. Enzymatic defects in cortisol synthesis also cause glucocorticoid insufficiency, compensatory elevations in ACTH, and congenital adrenal hyperplasia. Because adrenal insufficiency usually develops slowly, such patients are subject to marked pigmentation (from excess ACTH trying to stimulate an unproductive adrenal gland) and cardiopenia (apparently secondary to chronic hypotension).

Secondary adrenal insufficiency occurs when ACTH secretion is deficient, often because of a pituitary or hypothalamic tumor. Treatment of pituitary tumors by surgery or radiation therapy may result in hypopituitarism and subsequent adrenal failure.

If unstressed, glucocorticoid-deficient patients usually have no perioperative problems. However, acute adrenal crisis (addisonian crisis) can occur when even a minor stress is present (e.g., upper respiratory infection). Preparation of such a patient for anesthesia and surgery should include treatment of hypovolemia, hyperkalemia, and hyponatremia. Because these patients cannot respond to stressful situations, it was traditionally recommended that they be given a stress dose of glucocorticoids (≈200 mg hydrocortisone/70 kg body weight/day) perioperatively. However, Symreng and colleagues gave 25 mg of hydrocortisone phosphate intravenously to adults at the start of the operative procedure, followed by 100 mg intravenously over the next 24 hours.[50] Because using the minimum drug dose that would produce an appropriate effect is desirable, this latter regimen seems attractive. Such a regimen has proved to be as successful as a regimen using maximum doses (≈300 mg hydrocortisone/70 kg body weight/day—see the later section "Patients Taking Steroids for Other Reasons"). Thus, we now recommend giving 100 mg of hydrocortisone phosphate intravenously every 24 hours.

Mineralocorticoid Deficiency. Hypoaldosteronism, a less common condition, can be congenital or can occur after unilateral adrenalectomy or prolonged administration of heparin. In addition, it can also be a consequence of long-standing diabetes and renal failure. Nonsteroidal inhibitors of prostaglandin synthesis may also inhibit renin release and exacerbate this condition in patients with renal insufficiency. Plasma renin activity is lower than normal and fails to increase appropriately in response to sodium restriction or diuretic drugs. Most symptoms are caused by hyperkalemic acidosis rather than hypovolemia; in fact, some patients are hypertensive. These patients can have severe hyperkalemia, hyponatremia, and myocardial conduction defects. These defects can be treated successfully by administering mineralocorticoids (9α-fluorocortisol, 0.05 to 0.1 mg/day) preoperatively. Doses must be carefully titrated and monitored to avoid an increase in hypertension.

Patients Taking Steroids for Other Reasons

Perioperative Stress and the Need for Corticoid Supplementation. The adrenal responses of normal patients to the perioperative period, as well as those responses of patients taking steroids for other diseases, indicate the following:

1. Perioperative stress is related to the degree of trauma and the depth of anesthesia. Deep general or regional anesthesia delays the usual intraoperative glucocorticoid surge to the postoperative period.
2. A few patients with suppressed adrenal function will have perioperative cardiovascular problems if they do not receive supplemental steroids perioperatively.
3. Although a patient who takes steroids on a long-term basis may become hypotensive perioperatively, glucocorticoid or mineralocorticoid deficiency is rarely the cause.
4. Acute adrenal insufficiency rarely occurs, but it can be life-threatening.
5. Giving these patients steroid coverage equivalent to 100 mg of hydrocortisone hemisuccinate perioperatively has little risk.

In a well-controlled study of glucocorticoid replacement in nonhuman primates, the investigators clearly defined the life-threatening events that can be associated with inadequate perioperative corticosteroid replacement.[48] An alternative dose regimen has altered management methods that will likely improve patients' safety. In this study, adrenalectomized primates and sham-operated controls were given physiologic doses of steroids for 4 months. The animals were then randomly allocated to groups that received subphysiologic (one tenth of the normal cortisol production), physiologic, or supraphysiologic (10 times the normal cortisol production) doses of cortisol for 4 days preceding abdominal surgery (cholecystectomy). Hemodynamic variables were measured by means of arterial and pulmonary artery catheters. The animals were maintained on their randomized dosage schedules during and after the surgical procedures. The group given subphysiologic doses of steroid perioperatively had a significant increase in postoperative mortality. Death rates

TABLE 39-4 RECOVERY OF HYPOTHALAMIC-PITUITARY-ADRENAL FUNCTION AFTER WITHDRAWAL OF STEROIDS

Recovery Time (mo)	Plasma 17-Hydroxycorticoid Values	Plasma ACTH Values	Adrenal Response to Exogenous ACTH	Response to Metyrapone

for the physiologic and supraphysiologic replacement groups were the same and did not differ from the rate for sham-operated controls. Death in the subphysiologic replacement group was related to severe hypotension associated with a significant decrease in systemic vascular resistance and a reduced left ventricular stroke work index. Filling pressures of the heart were unchanged when compared with those in control animals. No evidence of hypovolemia or severe CHF was observed. Despite the low systemic vascular resistance, the animals did not become tachycardic. All these responses are compatible with the previously documented interaction of glucocorticoids and catecholamines and thus suggest that glucocorticoids mediate catecholamine-induced increases in cardiac contractility and maintenance of vascular tone.

The investigators used a sensitive measure of wound healing involving accumulation of hydroxyproline. All treatment groups, including the group given supraphysiologic doses of glucocorticoids, had the same capacity for wound healing. Furthermore, perioperative administration of supraphysiologic doses of corticosteroids produced no adverse metabolic consequences.

This well-conducted study confirms several longstanding intuitive impressions concerning patients who have inadequate adrenal function as a result of either underlying disease or administration of exogenous steroids. Inadequate replacement of corticosteroids perioperatively can lead to addisonian crisis and death. Administration of supraphysiologic doses of steroids for a short time perioperatively caused no discernible complications. However, at least theoretic negative consequences can occur when large doses of steroids are given (see later). It is clear that inadequate corticosteroid coverage can cause death. What is not so clear is what dose of steroid should be recommended for replacement therapy. Yong and colleagues reviewed the randomized controlled trials for a Cochrane Systemic Review and reported only 2 trials involving 37 patients that met the inclusion criteria.[51] These studies reported that supplemental perioperative steroids were not required during surgery for patients with adrenal insufficiency, but neither study reported any adverse effects or complications in the intervention and control groups. The authors concluded that they were unable to support or refute the use of supplemental perioperative steroids for patients with adrenal insufficiency during surgery.

Because the risk is low, physicians should consider providing supplementation for any patient who has received steroids within a year.[48,50] Data indicate that topical application of steroids (even without the use of occlusive dressings) can suppress normal adrenal responses for as long as 9 months to 1 year (Table 39-4).

How can one determine when adrenal responsiveness has returned to normal? The morning plasma cortisol level does not reveal whether the adrenal cortex has recovered sufficiently to ensure that cortisol secretion will increase adequately to meet the demands of stress. Inducing hypoglycemia with insulin has been advocated as a sensitive test of pituitary-adrenal competence, but it is impractical and is probably a more dangerous practice than simply administering glucocorticoids. If the plasma cortisol concentration is measured during acute stress, a value of greater than 25 μg/dL assuredly (and a value >15 μg/dL probably) indicates normal pituitary-adrenal responsiveness. In another test of pituitary-adrenal sufficiency, the baseline plasma cortisol level is determined. Then, 250 μg of synthetic ACTH (cosyntropin) is given, and plasma cortisol is measured 30 to 60 minutes later. An increase in plasma cortisol of 6 to 20 μg/dL or more is normal.[52,53] A normal response indicates recovery of pituitary-adrenal axis function. A lesser response usually indicates pituitary-adrenal insufficiency, possibly requiring perioperative supplementation with steroids.

It is unusual for laboratory data defining pituitary-adrenal adequacy to be available preoperatively. Rather than delay surgery or test most patients, we assume that any patient who has taken steroids at any time during the preceding year has suppressed pituitary-adrenal function and will require perioperative supplementation.

Under perioperative conditions, the adrenal glands secrete 116 to 185 mg of cortisol daily. Under maximum stress, they may secrete 200 to 500 mg/day. Good correlation exists between the severity and duration of the operation and the response of the adrenal gland. "Major surgery" would be represented by procedures such as laparoscopic colectomy and "minor surgery" by procedures such as herniorrhaphy. In a study of 20 patients during major surgery, the mean maximal concentration of cortisol in plasma was 47 μg/dL (range, 22 to 75 μg/dL). Values remained higher than 26 μg/dL for a maximum of 72 hours postoperatively. During minor surgery, the mean maximal concentration of cortisol in plasma was 28 μg/dL (range, 10 to 44 μg/dL).

Although the precise amount required has not been established, we usually intravenously administer the maximum amount of glucocorticoid that the body manufactures in response to maximal stress (i.e., approximately 200 mg/day of hydrocortisone phosphate/70 kg body weight). For minor surgical procedures, we usually give hydrocortisone phosphate intravenously, 100 mg/day/70 kg body weight. Unless infection or some other perioperative complication develops, we decrease this dose by approximately 25% per day until oral intake can be resumed. At this point, the usual maintenance dose of glucocorticoids can be administered.

Risks of Supplementation. Rare complications of perioperative steroid supplementation include aggravation of hypertension, fluid retention, inducement of stress ulcers, and psychiatric disturbances. Two common complications of short-term perioperative supplementation with glucocorticoids are abnormal wound healing and an increased rate of infections. This evidence is inconclusive, however, because it relates to short-term glucocorticoid administration and not to long-term administration of glucocorticoids with increased doses at times of stress. In contrast to a deleterious effect of perioperative glucocorticoid administration on wound healing in rats, a study involving primates suggested that large doses of glucocorticoids, administered perioperatively, do not impair sensitive measures of wound healing.[48] An overall assessment of these results suggests that short-term perioperative supplementation with steroids has a small but definite deleterious effect on wound healing that is perhaps partially reversed by topical administration of vitamin A.

Information on the risk of infection from perioperative glucocorticoid supplementation is also unclear. In many studies of long-term use by patients and supplementation, no increased risk of serious infections was reported with long-term use of steroids alone. Data indicate that the risk of infection in a patient taking steroids on a long-term basis is real, but whether perioperative supplementation with steroids increases that risk is not clear.

Adrenal Cortex Function in Older Adults

Production of androgens by the adrenal gland progressively decreases with age; this change has no known implications for anesthesia (see also Chapter 80). Plasma levels of cortisol are unaffected by increasing age. Levels of CBG are also unaffected by age, a finding suggesting that a normal fraction of free cortisol (1% to 5%) is present in older patients. Older patients have a progressively impaired ability to metabolize and excrete glucocorticoids. In normal individuals, the quantity of 17-hydroxycorticosteroids excreted is reduced by half by the seventh decade. This decreased excretion undoubtedly reflects the reduced renal function that occurs with aging. When excretion of cortisol metabolites is expressed as a function of creatinine clearance, the age difference disappears. Further reductions in cortisol clearance may reflect impaired hepatic metabolism of circulating cortisol.

The rate of secretion of cortisol is 30% slower in older adults. This reduced secretion may be an appropriate compensatory mechanism for maintaining a normal cortisol level in the presence of decreased hepatic and renal clearance of cortisol. The reduced cortisol production can be overcome during periods of stress, and even extremely old patients (>100 years old) display an entirely normal adrenal response to the administration of ACTH and to stresses such as hypoglycemia.

Both underproduction and overproduction of glucocorticoids are generally considered diseases of younger individuals. The highest incidence of Cushing disease of either pituitary or adrenal origin occurs during the third decade of life. The most common cause of spontaneous Cushing disease is benign pituitary adenoma. However, in patients older than 60 years in whom Cushing disease develops, the most likely cause is adrenal carcinoma or ectopic ACTH production from tumors usually located in the lung, pancreas, or thymus.

ADRENAL MEDULLARY SYMPATHETIC HORMONE EXCESS: PHEOCHROMOCYTOMA

Less than 0.1% of all cases of hypertension are caused by pheochromocytomas, or catecholamine-producing tumors derived from chromaffin tissue.[54] Nevertheless, these tumors are clearly important to the anesthesiologist inasmuch as 25% to 50% of hospital deaths in patients with pheochromocytoma occur during induction of anesthesia or during operative procedures for other causes.[55] Although usually found in the adrenal medulla, these vascular tumors can occur anywhere, such as in the right atrium, the spleen, the broad ligament of the ovary, or the organs of Zuckerkandl at the bifurcation of the aorta. Malignant spread, which occurs in less than 15% of pheochromocytomas, usually proceeds to venous and lymphatic channels with a predisposition for the liver. This tumor is occasionally familial or part of the pluriglandular-neoplastic syndrome known as multiple endocrine adenoma type IIa or type IIb and is manifested as an autosomal dominant trait. Type IIa consists of medullary carcinoma of the thyroid, parathyroid adenoma or hyperplasia, and pheochromocytoma. What used to be called type IIb is now often called pheochromocytoma in association with phakomatoses such as von Recklinghausen neurofibromatosis and von Hippel–Lindau disease with cerebellar hemangioblastoma. Frequently, bilateral tumors are found in the familial form. Localization of tumors can be achieved by MRI or CT, metaiodobenzylguanidine (MIBG) nuclear scanning, ultrasonography, or intravenous pyelography (in decreasing order of combined sensitivity and specificity).

Symptoms and signs that may be solicited before surgery or procedures and are suggestive of pheochromocytoma are as follows: excessive sweating; headache; hypertension; orthostatic hypotension; previous hypertensive or arrhythmic response to induction of anesthesia or to abdominal examination; paroxysmal attacks of sweating, headache, tachycardia, and hypertension; glucose intolerance; polycythemia; weight loss; and psychological abnormalities. In fact, the occurrence of combined symptoms of paroxysmal headache, sweating, and hypertension is probably a more sensitive and specific indicator than any one biochemical test for pheochromocytoma

TABLE 39-5 **CHARACTERISTICS OF TESTS FOR PHEOCHROMOCYTOMA**

Test/Symptoms	Sensitivity (%)	Specificity (%)	Likelihood Ratio	
			Positive Result*	Negative Result†
Vanillylmandelic acid excretion	81	97	27.0	0.20
Catecholamine excretion	82	95	16.4	0.19
Metanephrine excretion	83	95	16.6	0.18
Abdominal computed tomography	92	80	4.6	0.10
Concurrent paroxysmal hypertension, headache, sweating, and tachycardia‡	90	95	18.0	0.10

Modified from Pauker SG, Kopelman RI: Interpreting hoofbeats: can Bayes help clear the haze? N Engl J Med *327:1009, 1992.*
*The ratio representing the likelihood of a positive result is obtained by dividing the sensitivity by 1 and then subtracting the specificity.
†The ratio representing the likelihood of a negative result is obtained by subtracting the sensitivity from 1 and the dividing by the specificity.
‡Data for concurrent paroxysmal symptoms are best estimates from available data.

(Table 39-5). Despite more than 2000 articles in the literature on pheochromocytoma, little is known about what factors in care affect perioperative morbidity.

The value of preoperative and preprocedure use of adrenergic receptor blocking drugs probably justifies the use of such drugs preoperatively. These drugs probably reduce the complications of hypertensive crisis, the wide arterial blood pressure fluctuations during manipulation of the tumor (especially until venous drainage is obliterated), and the myocardial dysfunction that occurs perioperatively. Mortality is decreased with resection of pheochromocytoma (from 40% to 60% to the current 0% to 6%) when adrenergic receptor blockade is introduced as preoperative and preprocedure preparatory therapy for such patients.[56-60]

α-Adrenergic receptor blockade with prazosin or phenoxybenzamine restores intravascular plasma volume by counteracting the vasoconstrictive effects of high levels of catecholamines. This reexpansion of intravascular fluid volume is often followed by a decrease in hematocrit. Because some patients may be very sensitive to the effects of phenoxybenzamine, this drug should initially be given in doses of 20 to 30 mg/70 kg orally once or twice a day. Most patients usually require 60 to 250 mg/day. The efficacy of therapy should be judged by the reduction in symptoms (especially sweating) and stabilization of arterial blood pressure. For patients who have carbohydrate intolerance because of inhibition of insulin release mediated by α-adrenergic receptor stimulation, α-adrenergic receptor blockade may reduce fasting blood glucose levels. For patients who exhibit ST-T changes on the ECG, long-term preoperative and preprocedure α-adrenergic receptor blockade (1 to 6 months) has produced ECG and clinical resolution of catecholamine-induced myocarditis.[56,57,59-63]

β-Adrenergic receptor blockade with propranolol is suggested for patients who have persistent arrhythmias or tachycardia,[56,57,59-63] the reason being that these conditions can be precipitated or aggravated by α-adrenergic receptor blockade. β-Adrenergic receptor blockade should not be used without concomitant α-adrenergic receptor blockade lest the vasoconstrictive effects of the latter go unopposed and thereby increase the risk of dangerous hypertension.

The optimal duration of preoperative therapy with phenoxybenzamine has not been studied. Most patients require 10 to 14 days, as judged by the time needed to stabilize arterial blood pressure and ameliorate symptoms. Because the tumor spreads slowly, little is lost by waiting until medical therapy has optimized the patient's preoperative condition. The following criteria are reasonable for assessing the adequacy of treatment:

1. No in-hospital arterial blood pressure reading higher than 165/90 mm Hg should be evident for 48 hours preoperatively. We often measure arterial blood pressure every minute for 1 hour in a stressful environment (our postanesthesia care unit). If no blood pressure reading is higher than 165/90 mm Hg, this criterion is considered satisfied.
2. Orthostatic hypotension is acceptable as long as arterial blood pressure when the patient is standing is not less than 80/45 mm Hg.
3. The ECG should be free of ST-T changes that are not permanent.
4. No more than one premature ventricular contraction (PVC) should occur every 5 minutes.

Other drugs, including prazosin, calcium channel blocking drugs, clonidine, dexmedetomidine, and magnesium, have also been used to achieve suitable degrees of α-adrenergic blockade preoperatively. Multiple case series have confirmed the clinical utility of this approach in adults before tumor excision, including in a hemodynamic catecholamine crisis.[64] Magnesium therapy has shown efficacy for the resection of pheochromocytoma or paraganglioma during pregnancy. The dosing of magnesium for the management of pheochromocytoma has been reviewed elsewhere.[65]

The key clinical components of ideal patient care include optimal preoperative preparation, gentle (slow) induction of anesthesia, and good communication between the surgeon and the anesthesiologist. Virtually all anesthetic drugs and techniques (including isoflurane, sevoflurane, sufentanil, remifentanil, fentanyl, and regional anesthesia) have been used with success. In fact, all drugs studied are associated with a high rate of transient intraoperative arrhythmias.[59]

Because of ease of use, the preference is to give phenylephrine hydrochloride (Neo-Synephrine) or dopamine for hypotension and nitroprusside or theoretically, clevidipine, for hypertension. Phentolamine (Regitine) has too long an onset and duration of action. Painful or stressful events such as intubation often cause an exaggerated stress response in less than perfectly anesthetized patients who have pheochromocytoma. This response is caused by release of catecholamines from nerve endings that

are "loaded" by the reuptake process. Such stresses may result in catecholamine levels of 200 to 2000 pg/mL in normal patients. For a patient with pheochromocytoma, even simple stress can lead to blood catecholamine levels of 2000 to 20,000 pg/mL. However, infarction of a tumor, with release of products onto peritoneal surfaces, or surgical pressure causing release of products, can result in blood levels of 200,000 to 1,000,000 pg/mL—a situation that should be anticipated and avoided (ask for a temporary stay of surgery, if at all possible, while the rate of nitroprusside infusion is increased). Once the venous supply is secured and if intravascular volume is normal (as measured by pulmonary wedge pressure or echocardiography), normal arterial blood pressure usually results. However, some patients become hypotensive and occasionally require massive infusions of catecholamines. Vasopressin has also been used for hemodynamic rescue in catecholamine-resistant vasoplegic shock after resection of a massive pheochromocytoma.[66] On rare occasion, patients remain hypertensive intraoperatively. Postoperatively, approximately 50% of patients remain hypertensive for 1 to 3 days—and initially have markedly increased but declining plasma catecholamine levels—at which time all but 25% will become normotensive. Other family members should be advised to inform their future anesthesiologist about the potential for such familial disease.

HYPOFUNCTION OR ABERRATION IN FUNCTION OF THE SYMPATHETIC NERVOUS SYSTEM (DYSAUTONOMIA)

Disorders of the sympathetic nervous system include Shy-Drager syndrome, Riley-Day syndrome, Lesch-Nyhan syndrome, Gill familial dysautonomia, diabetic dysautonomia, and the dysautonomia of spinal cord transection.

Although individuals can function well without an adrenal medulla, a deficient peripheral sympathetic nervous system occurring late in life poses major problems for many facets of life; nevertheless, perioperative sympathectomy or its equivalent is often recommended.[67-73] A primary function of the sympathetic nervous system appears to be regulation of arterial blood pressure and intravascular fluid volume during changing of body position. Common features of all the syndromes of hypofunctioning of the sympathetic nervous system are orthostatic hypotension and decreased beat-to-beat variability in heart rate. These conditions can be caused by deficient intravascular volume, deficient baroreceptor function (as also occurs in carotid artery disease[74]), abnormalities in CNS function (as in Wernicke or Shy-Drager syndrome), deficient neuronal stores of norepinephrine (as in idiopathic orthostatic hypotension[75] and diabetes), or deficient release of norepinephrine (as in traumatic spinal cord injury[76]). These patients may have an increased number of available adrenergic receptors (a compensatory response) and an exaggerated response to sympathomimetic drugs. In addition to other abnormalities, such as retention of urine or feces and deficient heat exchange, hypofunctioning of the sympathetic nervous system is often accompanied by renal amyloidosis. Thus, electrolyte and intravascular fluid volume status should be evaluated preoperatively. Because many of these patients have cardiac abnormalities, intravascular fluid volume may be assessed preoperatively with a Swan-Ganz catheter or intraoperatively via transesophageal echocardiography rather than measurement of CVP.

Because the functioning of the sympathetic nervous system is not predictable in these patients, gentle induction of anesthesia and treatment of sympathetic excess or deficiency by infusing drugs that directly constrict (phenylephrine) or dilate (nitroprusside) blood vessels or that stimulate (isoproterenol) or depress (esmolol) the heart rate are suggested. A 20% perioperative mortality rate for 2600 patients after spinal cord transection has been reported, thus indicating that such patients are difficult to manage and deserve particularly close attention.

After reviewing 300 patients with spinal cord injuries, Kendrick and co-workers concluded that autonomic hyperreflexia syndrome does not develop if the lesion is below spinal dermatome T7.[77] If the lesion is above that level (splanchnic outflow), 60% to 70% of patients experience extreme vascular instability. The trigger to this instability, or a mass reflex involving noradrenergic and motor hypertonus, can be a cutaneous, proprioceptive, or visceral stimulus (a full bladder is a common initiator). The sensation enters the spinal cord and causes a spinal reflex, which in normal persons is inhibited from above. Sudden increases in arterial blood pressure are sensed in the pressure receptors of the aorta and carotid sinus. The resulting vagal hyperactivity produces bradycardia, ventricular ectopia, or various degrees of heart block. Reflex vasodilation may occur above the level of the lesion and result in flushing of the head and neck. Two newer techniques to help reduce acute injury or aid in repair (high-dose docosahexaenoic acid and acute cooling) may also have anesthetic implications, but reports of these effects, if any, have not been published.

Depending on the length of time since spinal cord transection, other abnormalities may occur. In the short term (i.e., <3 weeks from the time of spinal injury), retention of urine and feces is common and, by elevating the diaphragm, may impair respiration. Disimpaction of the intestine alleviates this respiratory problem. Hyperesthesia is present above the lesion; reflexes and flaccid paralysis are present below the lesion. The intermediate period (3 days to 6 months) is marked by a hyperkalemic response to depolarizing drugs.[78] The chronic phase is characterized by return of muscle tone, Babinski sign, and, frequently, the occurrence of hyperreflexia syndromes (e.g., mass reflex [see earlier]).

Thus, in addition to meticulous attention to perioperative intravascular volume and electrolyte status, the anesthesiologist should know—by history taking, physical examination, and laboratory data—the status of the patient's myocardial conduction (as revealed by the ECG), the status of renal functioning (by noting the ratio of creatinine to blood urea nitrogen [BUN]), and the condition of the respiratory muscles (by determining the ratio of forced expiratory volume in 1 second [FEV_1] to forced vital capacity [FVC]) (see also Chapter 44). The anesthesiologist may also obtain a chest radiograph if atelectasis or pneumonia is suspected on the basis of history taking or the physical examination. Temperature control, the presence of bone fractures or decubitus ulcers, and normal

TABLE 39-6 BIOCHEMICAL MEASUREMENTS OF THYROID FUNCTION THAT ACCOUNT FOR VARIATION IN PRODUCTION OF THYROXINE-BINDING GLOBULIN

	Examples of Normal Thyroid Status*					
	FT_4E	=	T_4	×	THBR	TSH
Normal	0.19 (0.12-0.25)	=	0.6 (0.4-0.9)	×	31% (25%-35%)	0.2 (0.2-0.8)
During use of oral contraceptives	0.19	=	1.3	×	15%	0.3
During use of corticosteroids	0.18	=	0.3	×	60%	0.3

*FT_4E is the free T_4 (thyroxine) estimate. It is usually obtained by multiplying the total T_4 concentration (the free amount and the amount bound to protein) by the thyroid hormone–binding ratio (THBR, formerly called the resin T_3 uptake). THBR is a measure of the bound thyroid hormone–binding protein. TSH is the thyroid-stimulating hormone secreted by the pituitary in the negative feedback loop. (TSH increases when FT_4E is low in hypothyroidism.)

functioning of the urination and defecation systems must be assessed. Confirmation of the latter prevents postoperative pneumonia or atelectasis caused by high positioning of the diaphragm.

THYROID DYSFUNCTION

The major thyroid hormones are thyroxine (T_4), a prohormone product of the thyroid gland, and the more potent 3,5,3-triiodothyronine (T_3), a product of both the thyroid and extrathyroidal enzymatic deiodination of T_4. Under normal circumstances, approximately 85% of T_3 is produced outside the thyroid gland. Production of thyroid secretions is maintained by secretion of thyroid-stimulating hormone (TSH) in the pituitary, which in turn is regulated by secretion of thyrotropin-releasing hormone (TRH) in the hypothalamus. Secretion of TSH and TRH appears to be negatively regulated by T_4 and T_3. Many investigators believe that all effects of thyroid hormones are mediated by T_3 and that T_4 functions only as a prohormone.

Because T_3 has greater biologic effect than does T_4, one would expect the diagnosis of thyroid disorders to be based on levels of T_3. However, this is not usually the case. The diagnosis of thyroid disease is confirmed by one of several biochemical measurements: levels of free T_4 or total serum concentrations of T_4 and the "free T_4 estimate." This estimate is obtained by multiplying total T_4 (free and bound) by the thyroid-binding ratio (formerly called resin T_3 uptake) (Table 39-6). Free T_4 can be accurately measured by many laboratories. Direct measurement of free T_4 obviates the need to account for changes in binding protein synthesis and affinity caused by other conditions. The T_3-binding ratio measures the extra quantity of serum protein-binding sites. This measurement is necessary because thyroxine-binding globulin (TBG) levels are abnormally high during pregnancy, hepatic disease, and estrogen therapy (all of which would elevate the total T_4 level) (Box 39-2). Reliable interpretation of measurements of the total hormone concentration in serum necessitates data on the percentage of bound hormone. The thyroid hormone–binding ratio test provides this information. In this test, iodine-labeled T_3 is added to a patient's serum and is allowed to reach an equilibrium binding state. A resin is then added that binds the remaining radioactive T_3. Resin uptake is greater if the patient has fewer TBG-binding sites. In normal patients, resin T_3 uptake (the thyroid hormone–binding ratio) is 25% to 35%. When serum TBG is elevated, the thyroid hormone–binding ratio is diminished (see Table 39-6). When serum TBG is diminished, as in nephrotic syndrome, in conditions in which glucocorticoids are increased, or in chronic liver disease, the thyroid hormone–binding ratio is increased.

BOX 39-2 ***Factors Influencing Serum Levels of Thyroxine-Binding Globulin***

Conditions Increasing Serum Levels

- Use of oral contraceptives
- Pregnancy
- Use of estrogen
- Infectious hepatitis
- Chronic active hepatitis
- Neonatal state
- Acute intermittent porphyria
- Inherited conditions

Conditions Decreasing Serum Levels

- Testosterone
- Use of corticosteroids
- Severe illness
- Cirrhosis
- Nephrotic syndrome
- Inherited conditions

The free T_4 estimate and the free T_3 estimate are frequently used as measures of a patient's serum T_4 and T_3 hormone concentrations, respectively. To obtain these estimates, the concentration of total serum T_4 or total serum T_3 is multiplied by the measured thyroid hormone–binding ratio. Values of these two indices are normal in the event of a primary alteration in binding but not with an alteration in secretion of thyroid hormone.

Hyperthyroidism can be diagnosed by measuring levels of TSH after the administration of TRH. Although administering TRH normally increases TSH levels in blood, even a small increase in the T_4 or T_3 level in blood abolishes this response. Thus, a subnormal or absent serum TSH response to TRH is a very sensitive indicator of hyperthyroidism. In one group of disorders involving hyperthyroidism, serum TSH levels are elevated in the presence of elevated levels of free thyroid hormone.

Measurement of the α-subunit of TSH has been helpful in identifying the rare patients who have a pituitary

neoplasm and who usually have increased α-subunit concentrations. Some patients are clinically euthyroid in the presence of elevated levels of total T_4 in serum. Certain drugs, notably gallbladder dyes, propranolol, glucocorticoids, and amiodarone, block the conversion of T_4 to T_3 and thereby elevate T_4 levels. Severe illness also slows this conversion. Levels of TSH are often high in situations in which the rate of conversion is decreased. In hyperthyroidism, cardiac function and responses to stress are abnormal; return of normal cardiac function parallels the return of TSH levels to normal.

Hyperthyroidism

Although hyperthyroidism is usually caused by the multinodular diffuse enlargement in Graves disease (also associated with disorders of the skin or eyes, or both), it can also occur with pregnancy, thyroiditis (with or without neck pain), thyroid adenoma, choriocarcinoma, or TSH-secreting pituitary adenoma. Five percent of women have thyrotoxic effects 3 to 6 months postpartum and tend to have recurrences with subsequent pregnancies. Major manifestations of hyperthyroidism are weight loss, diarrhea, warm and moist skin, weakness of large muscle groups, menstrual abnormalities, osteopenia, nervousness, jitteriness, intolerance to heat, tachycardia, cardiac arrhythmias, mitral valve prolapse, and heart failure. When the thyroid is functioning abnormally, the entity most threatened is the cardiovascular system. When diarrhea is severe, dehydration should be corrected preoperatively. Mild anemia, thrombocytopenia, increased serum alkaline phosphatase, hypercalcemia, muscle wasting, and bone loss frequently occur in hyperthyroidism. Muscle disease usually involves the proximal muscle groups; it has not been reported to cause respiratory muscle paralysis. In the apathetic form of hyperthyroidism (seen most commonly in persons >60 years old), cardiac effects dominate the clinical picture. Signs and symptoms include weight loss, anorexia, and cardiac effects such as tachycardia, irregular heart rhythm, atrial fibrillation (in 10%), heart failure, and occasionally, papillary muscle dysfunction.

Although β-adrenergic receptor blockade can control the heart rate, its use is fraught with hazard in a patient already experiencing CHF. However, a decreasing heart rate may improve heart-pumping function. Thus, hyperthyroid patients who have fast ventricular rates, who are in CHF, and who require emergency surgery are given short-acting β-blockers guided by changes in pulmonary artery wedge pressure and their condition. If slowing the heart rate with a small dose of esmolol (50 μg/kg) does not aggravate the heart failure, the physician should administer more esmolol. Antithyroid medications include propylthiouracil and methimazole, both of which decrease the synthesis of T_4 and may enhance remission by reducing TSH receptor antibody levels (the primary pathologic mechanism in Graves disease). Propylthiouracil also decreases the conversion of T_4 to the more potent T_3. However, the literature indicates a trend toward preoperative preparation with propranolol and iodides alone.[79] This approach is quicker (i.e., 7 to 14 days versus 2 to 6 weeks); it shrinks the thyroid gland, as does the more traditional approach; it decreases conversion of the prohormone T_4 into the more potent T_3; and it treats symptoms but may not correct abnormalities in left ventricular function. Regardless of the approach, antithyroid drugs should be administered on a long-term basis and on the morning of the surgical procedure. If emergency surgery is necessary before the euthyroid state is achieved, if subclinical hyperthyroidism progresses without adequate treatment, or if hyperthyroidism is out of control intraoperatively, intravenous administration of esmolol, 50 to 500 μg/kg, could be titrated to restore a normal heart rate (assuming the absence of CHF) (see earlier). In addition, intravascular fluid volume and electrolyte balance should be restored. However, administering propranolol or esmolol does not invariably prevent "thyroid storm."

No specific anesthetic drug is preferred for surgical patients who are hyperthyroid. Anticholinergic drugs (especially atropine) are sometimes not used because they interfere with the sweating mechanism and cause tachycardia; yet atropine has been given as a test for the adequacy of antithyroid treatment. Because patients are now subjected to operative procedures only (or almost only) when euthyroid, the traditional "steal" of a heavily premedicated hyperthyroid patient in the operating room has vanished.

A patient with a large goiter and an obstructed airway can be managed in the same way as any other patient with a problematic airway (see also Chapter 55). In this type of case, reviewing CT scans of the neck preoperatively may provide valuable information regarding the extent of compression. Maintenance of anesthesia usually presents little difficulty. Postoperatively, extubation of the trachea should be performed under optimal circumstances for reintubation in the event that the tracheal rings have been weakened and the trachea collapses.

Of the many possible postoperative complications (nerve injury, bleeding, and metabolic abnormalities), thyroid storm (discussed in the next section), bilateral recurrent nerve trauma, and hypocalcemic tetany are the most feared. Bilateral recurrent laryngeal nerve injury (secondary to trauma or edema) causes stridor and laryngeal obstruction as a result of unopposed adduction of the vocal cords and closure of the glottic aperture. Immediate endotracheal intubation is required, usually followed by tracheostomy to ensure an adequate airway. This rare complication occurred only once in more than 30,000 thyroid operations at the Lahey Clinic. Unilateral recurrent nerve injury often goes unnoticed because of compensatory overadduction of the uninvolved cord. However, we often test vocal cord function before and after this operation by asking the patient to say "e" or "moon." Unilateral nerve injury is characterized by hoarseness and bilateral nerve injury by aphonia. Selective injury to the adductor fibers of both recurrent laryngeal nerves leaves the abductor muscles relatively unopposed, and pulmonary aspiration is a risk. Selective injury to the abductor fibers leaves the adductor muscles relatively unopposed, and airway obstruction can occur. Bullous glottic edema, an additional cause of postoperative respiratory compromise, has no specific cause or known preventive measure.

The intimate involvement of the parathyroid gland with the thyroid gland can result in inadvertent

hypocalcemia during surgery for thyroid disease. Complications related to hypocalcemia are discussed in the later section on this disorder.

Because postoperative hematoma can compromise the airway, neck and wound dressings are placed in a crossing fashion (rather than vertically or horizontally) and should be examined for evidence of bleeding before a patient is discharged from the recovery room.

Thyroid Storm

Thyroid storm is the name for the clinical diagnosis of a life-threatening illness in a patient whose hyperthyroidism has been severely exacerbated by illness or surgery. Thyroid storm is characterized by hyperpyrexia, tachycardia, and striking alterations in consciousness. It clinically manifests in a manner similar to that of malignant hyperthermia, pheochromocytoma, and neuroleptic malignant syndrome. No laboratory tests are diagnostic of thyroid storm, and the precipitating (nonthyroidal) cause is the major determinant of survival. Therapy can include blocking the synthesis of thyroid hormones by administering antithyroid drugs and the release of preformed hormone with iodine. Blocking the sympathetic nervous system with reserpine, α- and β-receptor antagonists, or α_2 drugs may be exceedingly hazardous and requires skillful management and constant monitoring of the critically ill patient.

Thyroid dysfunction, either hyperthyroidism or hypothyroidism, develops in more than 10% of patients treated with the antiarrhythmic agent amiodarone.[80] Approximately 35% of the drug's weight is iodine, and a 200-mg tablet releases approximately 20 times the optimal daily dose of iodine. This iodine can lead to reduced synthesis of T_4 or increased synthesis. In addition, amiodarone inhibits the conversion of T_4 to the more potent T_3.

Patients receiving amiodarone may be considered to be in need of special attention preoperatively and intraoperatively, not just because of the arrhythmia that led to such therapy but also to ensure that no perioperative dysfunction or surprises result from unsuspected thyroid hyperfunction or hypofunction.[81] Many patients with amiodarone-induced thyrotoxicosis receive steroids for a period, another area of questioning that may be triggered by the use of amiodarone in a preoperative patient.

Hypothyroidism

Hypothyroidism is a common disease that has been detected in 5% of a large population in Great Britain, in 3% to 6% of a healthy older population in Massachusetts, and in 4.5% of a medical clinic population in Switzerland. The apathy and lethargy that often accompany hypothyroidism frequently delay its diagnosis, so the perioperative period may be the first opportunity to spot many such hypothyroid patients. However, hypothyroidism is usually subclinical, serum concentrations of thyroid hormones are in the normal range, and only serum TSH levels are elevated. The normal range of TSH is 0.3 to 4.5 milliunits/L, and TSH values of 5 to 15 milliunits/L are characteristic of this entity. In such cases, hypothyroidism may have little or no perioperative significance. However, a retrospective study of 59 mildly hypothyroid patients found that more hypothyroid patients than control subjects required prolonged postoperative intubation (9 of 59 versus 4 of 59) and had significant electrolyte imbalances (3 of 59 versus 1 of 59) and bleeding complications (4 of 59 versus 0 of 59).[82] Because only a few charts were examined, these differences did not reach statistical significance. In another study, overt hypothyroidism later developed in a high percentage of patients with a history of subclinical hypothyroidism.[83,84] Thus, a previous history of subclinical hypothyroidism may be a clue to the possibility of overt hypothyroidism.

Overt hypothyroidism may cause slow mental functioning, slow movement, dry skin, arthralgias, carpal tunnel syndrome, periorbital edema, intolerance to cold, depression of the ventilatory responses to hypoxia and hypercapnia, impaired clearance of free water with or without hyponatremia, "hung-up reflexes," slow gastric emptying, sleep apnea,[85] and bradycardia. In extreme cases, cardiomegaly, heart failure, and pericardial and pleural effusions manifest as fatigue, dyspnea, and orthopnea. Hypothyroidism is often associated with amyloidosis, which may produce an enlarged tongue, abnormalities of the cardiac conduction system, and renal disease. Hypothyroidism decreases the anesthetic requirement slightly. The tongue may be enlarged in a hypothyroid patient even in the absence of amyloidosis, and such enlargement may hamper endotracheal intubation.

An increasing TSH level is the most sensitive indicator of failing thyroid function. Ideal preoperative and preprocedure management of hypothyroidism consists of restoring normal thyroid status: the physicians should consider administering the normal dose of levothyroxine the morning of the surgical procedure, even though these drugs have long half-lives (1.4 to 10 days). Reduced GI absorption of levothyroxine may occur with the coadministration of cholestyramine or aluminum hydroxide, iron, a high-bran meal, or sucralfate or colestipol. For patients in myxedema coma who require emergency surgery, liothyronine can be given intravenously (with fear of precipitating myocardial ischemia, however) while supportive therapy is undertaken to restore normal intravascular fluid volume, body temperature, cardiac function, respiratory function, and electrolyte balance.

In hypothyroidism, respiratory control mechanisms do not function normally. However, the response to hypoxia and hypercapnia and clearance of free water become normal with thyroid replacement therapy. Drug metabolism is anecdotally reported to be slowed, and awakening times from sedatives are reported to be prolonged by hypothyroidism. However, few formal studies and none in humans of the pharmacokinetics and pharmacodynamics of sedatives or anesthetic drugs have been published. These concerns disappear when thyroid function is normalized preoperatively. Addison disease (with its relative steroid deficiency) is more common in hypothyroidism, and some endocrinologists routinely treat patients with noniatrogenic hypothyroidism with stress doses of steroids perioperatively because both conditions are commonly caused by autoimmune responses. The possibility that this steroid deficiency exists should be considered if the patient becomes hypotensive perioperatively. Body heat mechanisms are inadequate in hypothyroid patients, so temperature should be monitored and

maintained, especially in patients requiring emergency surgery. Because of an increased incidence of myasthenia gravis in hypothyroid patients, it may be advisable to use a peripheral nerve stimulator to guide administration of muscle relaxants.

Thyroid Nodules and Carcinoma

More than 90% of thyroid nodules are benign, yet identifying malignancy in a solitary thyroid nodule is a difficult and important procedure. Male patients and patients with previous radiation therapy to the head and neck have an increased likelihood of malignant disease in their nodules. Often, needle biopsy and scanning are sufficient for the diagnosis, but occasionally excisional biopsy is needed. Papillary carcinoma accounts for more than 70% of all thyroid carcinomas. Simple excision of lymph node metastases appears to be as efficacious as radical neck procedures for the patient's survival. Follicular carcinoma accounts for approximately 15% of thyroid carcinomas, is more aggressive, and has a less favorable prognosis.

Medullary carcinoma, the most aggressive form of thyroid carcinoma, is associated with a familial occurrence of pheochromocytoma, as are parathyroid adenomas. For this reason, a history may be obtained from patients who have a surgical scar in the thyroid region so that the possibility of occult pheochromocytoma can be excluded.

DISORDERS OF CALCIUM METABOLISM

The three substances that regulate serum concentrations of calcium, phosphorus, and magnesium—parathyroid hormone (parathyrin, PTH), calcitonin, and vitamin D—act on bone, kidney, gut, and their own receptors (the last has led to an important advance in treatment). Calcium excess in blood is caused by either malignant disease or hyperparathyroidism in more than 90% of patients.[86] PTH stimulates bone resorption, inhibits renal excretion of calcium, and increases conversion to active vitamin D, three conditions that lead to hypercalcemia. Calcitonin can be considered an antagonist to PTH. Through its metabolites, vitamin D aids in the absorption of calcium, phosphate, and magnesium from the gut and facilitates the bone resorptive effects of PTH. Secretion of PTH is modulated through the calcium-sensing receptor on the cell surface of parathyroid cells. An increase in ionized calcium stimulates this receptor and thus causes a decrease in PTH secretion. Recognition of this effect has led to reevaluation of the therapy for hyperparathyroidism inasmuch as a drug up-regulating this receptor's sensitivity reduces PTH levels.[87]

Hyperparathyroidism and Hypercalcemia

Primary hyperparathyroidism occurs in approximately 0.1% of the population, most commonly begins in the third to fifth decades of life, and occurs two to three times more frequently in women than in men. Primary hyperparathyroidism usually results from enlargement of a single gland, commonly an adenoma and very rarely a carcinoma. Hypercalcemia almost always develops.

Calcium is the chief mineral component of the body; it provides structure to the skeleton and performs key roles in neural transmission, intracellular signaling, blood coagulation, and neuromuscular functioning. Ninety-nine percent of the 1000 g of calcium present in the average human body is stored in the bone mineral reservoir. The normal total serum calcium level is 8.6 to 10.4 mg/dL, as measured in most laboratories. Fifty percent to 60% is bound to plasma proteins or is complexed with phosphate or citrate. The value depends on the albumin level, with a decline of 0.8 mg/dL for each 1 g/dL drop in albumin. Binding of calcium to albumin depends on pH: binding decreases with acidic pH and increases with alkaline pH. Serum calcium, not ionized calcium, decreases with reductions in albumin levels. Although ionized calcium is the clinically significant fraction, the cost and technical difficulties of stabilizing the electrodes used for measurement have limited the available assays. Nevertheless, PTH and vitamin D_3 work to keep the level stable within 0.1 mg/dL in any individual.

Many of the prominent symptoms of hyperparathyroidism are a result of the hypercalcemia that accompanies it. Regardless of the cause, hypercalcemia can produce any of a number of symptoms, the most prominent of which involve the renal, skeletal, neuromuscular, and GI systems—anorexia, vomiting, constipation, polyuria, polydipsia, lethargy, confusion, formation of renal calculi, pancreatitis, bone pain, and psychiatric abnormalities. Free intracellular calcium initiates or regulates muscle contraction, release of neurotransmitters, secretion of hormones, enzyme action, and energy metabolism.

Nephrolithiasis occurs in 60% to 70% of patients with hyperparathyroidism. Sustained hypercalcemia can result in tubular and glomerular disorders, including proximal (type II) renal tubular acidosis. Polyuria and polydipsia are common complaints.

Skeletal disorders related to hyperparathyroidism are osteitis fibrosa cystica, simple diffuse osteopenia, and osteoporosis. The rate of bone turnover is five times higher in patients with hyperparathyroidism than in normal controls. Patients may have a history of frequent fractures or may complain of bone pain, especially pain in the anterior margin of the tibia.

Because free intracellular calcium initiates or regulates muscle contraction, neurotransmitter signaling, hormone secretion, enzyme action, and energy metabolism, abnormalities in these end organs are often symptoms of hyperparathyroidism. Patients may experience profound muscle weakness, especially in proximal muscle groups, as well as muscle atrophy. Depression, psychomotor retardation, and memory impairment may occur. Lethargy and confusion are frequent complaints.

Peptic ulcer disease is more common in these patients than in the rest of the population. Production of gastrin and gastric acid is increased. Anorexia, vomiting, and constipation may also be present.

Approximately one third of all hypercalcemic patients are hypertensive, but the hypertension usually resolves with successful treatment of the primary disease. Neither hypertension nor minimally invasive surgery seems to alter the perioperative risk associated with surgery in such patients in comparison with the usual hypertensive patients.[88,89] Even octogenarians with asymptomatic hyperparathyroidism can be operated on without

mortality and with morbidity no different from that in younger individuals, thus encouraging the use of parathyroidectomy as preventive therapy.[90] Long-standing hypercalcemia can lead to calcifications in the myocardium, blood vessels, brain, and kidneys. Cerebral calcifications may cause seizures, whereas renal calcifications lead to polyuria that is unresponsive to vasopressin.

The most useful confirmatory test for hyperparathyroidism is radioimmunoassay for PTH. In fact, two changes have radically reduced anesthesia involvement in the care of patients with primary hyperparathyroidism. One, use of the calcimimetic drug class, which modulates the calcium-sensitive PTH cell receptor and thereby decreases calcium levels, discussed earlier, has been emphasized in older individuals (see later). The other change is use of minimally invasive approaches after imaging procedures with just local anesthesia or a cervical plexus block—as with thyroidectomy.[91,92] Most surgeons now performing minimally invasive parathyroid removal monitor PTH levels intraoperatively to determine whether the causative adenoma has been resected. The baseline PTH level should be determined before induction of anesthesia because even monitored anesthesia care increases PTH levels.[93] In hyperparathyroid patients, hormone levels are abnormal for a given level of calcium. The level of inorganic phosphorus in serum is usually low, but it may be within normal limits. Alkaline phosphatase levels are elevated if considerable skeletal involvement is present.

Glucocorticoid administration reduces the level of calcium in blood in many other conditions that cause hypercalcemia, but not usually in primary hyperparathyroidism. In sarcoidosis, multiple myeloma, vitamin D intoxication, and some malignant diseases, all of which can cause hypercalcemia, administration of glucocorticoids may lower serum calcium levels through an effect on GI absorption. This effect occurs to a lesser degree in primary hyperparathyroidism.

Hypercalcemia may also occur as a consequence of secondary hyperparathyroidism in patients who have chronic renal disease. When phosphate excretion decreases as a result of decreased nephron mass, serum calcium levels fall because of deposition of calcium and phosphate in bone. Secretion of PTH subsequently increases, and this causes the fraction of phosphate excreted by each nephron to increase. Eventually, the chronic intermittent hypocalcemia of chronic renal failure leads to chronically high levels of serum PTH and hyperplasia of the parathyroid glands—one of the entities termed secondary hyperparathyroidism.

Symptomatic primary hyperparathyroidism in patients younger than 50 years or with serum calcium levels more than 1 mg/dL higher than the upper limit of normal, a 30% or greater reduction in the glomerular filtration rate (GFR), or severe bone demineralization is usually treated surgically. If the patient refuses surgery or if other illnesses render surgery inadvisable, medical management with the calcimimetic cinacalcet makes management much more feasible. The difficulty with such management is that the hyperfunctioning parathyroid glands secrete more hormone as the serum calcium concentration is lowered—as though the calcium set point for feedback regulation of PTH secretion had been raised. Blanchard and colleagues

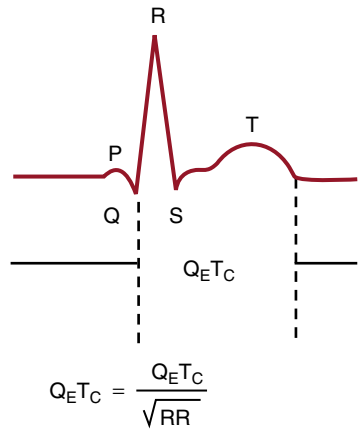

Figure 39-3. Measurement of the QTc interval (properly termed Q_ET_C to indicate that it begins with the start of the Q wave, lasts throughout the QT interval, ends with the end of the T wave, and is corrected for heart rate). RR is the RR interval in seconds. *(From Hensel P, Roizen MF: Patients with disorders of parathyroid function,* Anesthesiol Clin North Am *5:287, 1987.)*

demonstrated that patients with "asymptomatic" primary hyperparathyroidism have clinical improvement of their symptoms postoperatively even after 1 year.[94] Younger patients and those with higher preoperative calcium levels show the best improvement.

Patients with moderate hypercalcemia who have normal renal and cardiovascular function present no special preoperative and preprocedure problems. The ECG can be examined preoperatively and intraoperatively for shortened PR or QT intervals (Fig. 39-3). Because severe hypercalcemia can result in hypovolemia, normal intravascular volume and electrolyte status should be restored before commencement of anesthesia and surgery.

Management of hypercalcemia preoperatively should include (even in urgent or emergency situations) treatment of the underlying cause—a frequent strategy in surgical patients with malignancy-associated hypercalcemia. Antitumor therapy preoperatively for both malignant and nonmalignant causes of hypercalcemia can include hydration and diuresis to increase urinary calcium excretion. Restoration of intravascular volume, augmentation and excretion of urinary sodium (with saline infusion), and administration of diuretics (furosemide is commonly used) generally increase urinary calcium excretion substantially. Infusion rates of 200 to 400 mL/hour preoperatively are commonly used, but monitoring is needed to avoid administration of an excessive amount of intravenous fluids, especially because many patients have compromised cardiac pumping ability. Other complications of these interventions include hypomagnesemia and hypokalemia.

In emergency situations, vigorous expansion of intravascular volume usually reduces serum calcium to a safe level (<14 mg/dL); administration of furosemide is also often helpful in these situations. Phosphate should be given to correct hypophosphatemia because it decreases calcium uptake into bone, increases calcium excretion, and stimulates breakdown of bone. Hydration and diuresis, accompanied by phosphate repletion, suffice in the management of most hypercalcemic patients. Other

measures to decrease reabsorption of bone include the bisphosphonates pamidronate sodium (90 mg intravenously) and zoledronate (4 mg intravenously), salmon calcitonin (100 to 400 units every 12 hours).

Calcitonin lowers serum calcium levels through direct inhibition of bone resorption. It can decrease serum calcium levels within minutes after intravenous administration. Side effects include urticaria and nausea. It is so rapid acting that it can be used to reduce calcium levels while waiting for hydration and a bisphosphonate to take effect. Dialysis can also be used when appropriate.

It is especially important to know whether the hypercalcemia has been chronic because serious cardiac, renal, or CNS abnormalities may have resulted.

Hypocalcemia

Hypocalcemia (caused by hypoalbuminemia, hypoparathyroidism, hypomagnesemia, hypovitaminosis D, hungry bones after correction of hyperparathyroidism, anticonvulsant therapy, citrate infusion, or chronic renal disease) is not usually accompanied by a clinically evident cardiovascular disorder. The most common cause of hypocalcemia is hypoalbuminemia. In true hypocalcemia (i.e., when the free calcium concentration is low), myocardial contractility is affected. In other words, myocardial contractility varies directly with levels of blood ionized calcium, although contractility decreased only 20% when ionized calcium levels changed from 1.68 to 1.34 mmol/L. The clinical signs of hypocalcemia are as follows: clumsiness; convulsions; laryngeal stridor; depression; muscle stiffness; paresthesia (oral and perioral); parkinsonism; tetany; Chvostek sign; dry and scaly skin, brittle nails, and coarse hair; low serum concentrations of calcium; prolonged QT intervals; soft tissue calcifications; and Trousseau sign.

Hypocalcemia delays ventricular repolarization, hence increasing the QTc interval (normal, 0.35 to 0.44 second). With electrical systole prolonged, the ventricles may fail to respond to the next electrical impulse from the sinoatrial node, and a second-degree heart block results. Prolongation of the QT interval is a moderately reliable ECG sign of hypocalcemia, not for the population as a whole, but for the individual patient.[95] Thus, monitoring the QT interval as corrected for the heart rate is a useful, but not always accurate means of monitoring hypocalcemia in any individual patient (see Fig. 39-3). CHF may also occur with hypocalcemia, but this is rare. Because CHF in patients with coexisting heart disease is reduced in severity when calcium and magnesium ion levels are restored to normal, these levels may be normalized preoperatively in a patient with impaired exercise tolerance or signs of cardiovascular dysfunction; normalization can be achieved intravenously over a 15-minute period if absolutely necessary. Sudden decreases in blood levels of ionized calcium (as with chelation therapy) can result in severe hypotension.

Patients with hypocalcemia may have seizures. They may be focal, jacksonian, petit mal, or grand mal in appearance, indistinguishable from such seizures in the absence of hypocalcemia. Patients may also have a type of seizure called cerebral tetany, which consists of generalized tetany followed by tonic spasms. Therapy with standard anticonvulsants is ineffective and may even exacerbate these seizures (by an anti–vitamin D effect). In long-standing hypoparathyroidism, calcifications may appear above the sella; these calcifications represent deposits of calcium in and around small blood vessels of the basal ganglia. They may be associated with a variety of extrapyramidal syndromes.

The most common cause of acquired hypoparathyroidism is surgery of the thyroid or parathyroid glands. Other causes include autoimmune disorders, therapy with iodine-131, hemosiderosis or hemochromatosis, neoplasia, and granulomatous disease. Idiopathic hypoparathyroidism has been divided into three categories: an isolated persistent neonatal form, branchial dysembryogenesis, and autoimmune candidiasis related to multiple endocrine deficiency.

Pseudohypoparathyroidism and pseudopseudohypoparathyroidism are rare hereditary disorders characterized by short stature, obesity, rounded face, and shortened metacarpals. Patients with pseudohypoparathyroidism have hypocalcemia and hyperphosphatemia despite high serum levels of PTH. These patients have a deficient end-organ response to PTH as a result of abnormalities in G-protein function.

Because treatment of hypoparathyroidism is not surgical, hypoparathyroid patients who come to the operating room are those who require surgery for unrelated conditions. Their calcium, phosphate, and magnesium levels should be measured both preoperatively and postoperatively. Patients with symptomatic hypocalcemia may be treated with intravenous calcium gluconate preoperatively. Initially, 10 to 20 mL of 10% calcium gluconate may be given at a rate of 5 mL/minute. The effect on serum calcium levels is of short duration, but a continuous infusion with 10 mL/minute of 10% calcium gluconate in 500 mL of solution over a period of 6 hours helps keep serum calcium at adequate levels. Magnesium and phosphate levels may also require normalization to normalize cardiovascular and nervous system function.

The objective of therapy is to bring the symptoms under control before the surgical procedure and anesthesia. For patients with chronic hypoparathyroidism, the objective is to keep the serum calcium level in the lower half of the normal range. A preoperative and preprocedure ECG is useful for maintaining the QTc interval. The preoperative and preprocedure QTc value may be used as a guide to the serum calcium level if rapid laboratory assessment is not possible. Changes in the calcium level may alter the duration of muscle relaxation, so such alterations may be monitored by using a twitch monitor in these (as well as all other) patients.

The intimate involvement of the parathyroid gland with the thyroid gland can result in unintentional hypocalcemia during surgery for diseases of either organ. Because of the affinity of their bones for calcium, this relationship is crucial in patients with advanced osteitis. Internal redistribution of magnesium, calcium, or both ions may occur (into "hungry bones") after parathyroidectomy and may cause hypomagnesemia, hypocalcemia, or both conditions. Because the tendency to tetany increases with alkalosis, hyperventilation is usually

assiduously avoided. The most prominent manifestations of acute hypocalcemia are distal paresthesias and muscle spasm (tetany). Potentially fatal complications of severe hypocalcemia include laryngeal spasm and hypocalcemic seizures. The clinical sequelae of magnesium deficiency include cardiac arrhythmias (principally ventricular tachyarrhythmias), hypocalcemic tetany, and neuromuscular irritability independent of hypocalcemia (tremors, twitching, asterixis, and seizures).

In addition to monitoring total serum calcium or ionized calcium postoperatively, one can test for the Chvostek and Trousseau signs. (Serum calcium, not ionized calcium, depends on the albumin level, with a decline of approximately 0.8 mg/dL for each 1 g/dL drop in serum albumin level.) Because the Chvostek sign can be elicited in 10% to 15% of patients who are not hypocalcemic, an attempt should be made to elicit this sign preoperatively to ensure that its appearance is meaningful. The Chvostek sign is a contracture of the facial muscles produced by tapping the ipsilateral facial nerve at the angle of the jaw. The Trousseau sign is elicited by applying a blood pressure cuff at a level slightly above the systolic level for a few minutes. The resulting carpopedal spasm, with contraction of the fingers and inability to open the hand, stems from the increased muscle irritability in hypocalcemic states, aggravated by ischemia produced by the blood pressure cuff.

Osteoporosis

Fifty percent of women who are older than 65 years sustain an osteoporotic fracture. (Because men are living longer, osteoporosis has become an increasing problem for them, too, and reports indicate a 15% per decade hip fracture rate for men >65 years old).[95] Men with COPD (even without steroid treatment) are at high risk for vertebral fractures and thus may be allowed to position and move themselves onto and off surgical tables. Furthermore, in either gender, each vertebral fracture is associated with a 10% decrease in lung capacity. Diagnosis and treatment of these conditions have increased with routine use of dual-energy x-ray absorptiometry or quantitative ultrasonography. Because T-scores and Z-scores were developed to relate changes in white postmenopausal women to those at age 21 years, care must be used in interpreting the results. Known risk factors include age, relative lifetime estrogen deficiency (late menarche, amenorrhea, early menopause, nulliparity), deficiency of dietary calcium, tobacco use, increased aerobic exercise in combination with decreased weight-bearing exercise, decreased weight-bearing exercise by itself, use of soft drinks, and Asian or white ancestry. Although therapy for osteoporosis (use of biphosphates, bone mineral depositors, weight-bearing exercises, calcium, vitamin D, estrogen, and now designer estrogens that may be useful for men, such as raloxifene [Evista]) does not have major known implications for anesthesia care,[96-98] bone fractures in such patients have occurred on movement to and from an operating table. Recombinant PTH and calcitonin are also used, but again, no reports of perioperative interactions have been prominent. Thus, the precautions mentioned earlier for hyperparathyroid patients relative to self-positioning and careful positioning may be useful.

PITUITARY ABNORMALITIES

Anterior Pituitary Hypersecretion

The anterior pituitary gland (or master endocrine gland) consists of five identifiable types of secretory cells (and the hormones that they secrete): somatotrophs (GH), corticotrophs (ACTH), lactotrophs (prolactin), gonadotrophs (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), and thyrotrophs (TSH). Secretion of these pituitary hormones is largely regulated by a negative-feedback loop by hypothalamic regulatory hormones and by signals that originate from the target site of pituitary action. Six hypothalamic hormones have been characterized: dopamine, the prolactin-inhibiting hormone; somatostatin, the GH release–inhibiting hormone; GH-releasing hormone (GHRH); corticotropin-releasing hormone (CRH); gonadotropin-releasing hormone (GnRH or LHRH); and TRH. Most pituitary tumors (>60%) are hypersecretory and are classified according to the excess production of a specific anterior pituitary hormone.

The most common disorders of pituitary hypersecretion are those related to excesses of prolactin (amenorrhea, galactorrhea, and infertility), ACTH (Cushing syndrome), and GH (acromegaly). In addition to knowing the pathophysiologic processes of the disease involved, the anesthesiologist must determine whether the patient recently underwent air pneumoencephalography (almost obsolete, but still used rarely). If so, nitrous oxide should not be used to lessen the risk of intracranial hypertension from gas collection. CT or MRI of the sella has largely replaced neuroencephalography.

More than 99% of cases of acromegaly are attributable to pituitary adenoma (or use of recombinant GH for unapproved aging prevention, for which this substance is not effective, as of current data). Thus, the primary treatment of acromegaly is transsphenoidal surgery (or withdrawal of drug) and symptomatic treatment of the carpal tunnel or other syndromes provoked. If the pituitary tumor is not totally removed, patients are often offered external pituitary irradiation. In the case of suprasellar extension, conventional transfrontal hypophysectomy is often performed. The dopaminergic agonist bromocriptine can lower GH levels, but the long-term follow-up with this drug is not favorable. Octreotide, a long-acting analogue of somatostatin, now given in depot form approximately once a month, produces effective palliation in 50% of patients. Other medical therapies such as pegvisomant or somatostatin analogues are also medications that have been tried before surgical intervention. In 2011, new guidelines were published with few changes to the available recommendations.[99] However, the new guidelines reported some evidence that medication taken preoperatively may result in a better postoperative outcome.

Difficulty with endotracheal intubation should be anticipated in a patient with acromegaly; lateral neck radiographs or CT scans of the neck and direct or indirect visualization can identify patients with subglottic stenosis or an enlarged tongue, mandible, epiglottis, or vocal cords. If placement of an arterial line is necessary, a brachial or femoral site may be preferable to a radial site.[100]

Anterior Pituitary Hypofunction

Anterior pituitary hypofunction results in deficiency of one or more of the following hormones: GH, TSH, ACTH, prolactin, or gonadotropin. No special preoperative and preprocedure preparation is required for a patient deficient in prolactin or gonadotropin; deficiency in GH, however, can result in atrophy of cardiac muscle, a condition that may necessitate preoperative and preprocedure cardiac evaluation. Nonetheless, anesthetic problems have not been documented in patients with isolated GH deficiency. Acute deficiencies are another matter.

Acute pituitary deficiency is often caused by bleeding into a pituitary tumor. In surgical specimens of resected adenomas, as many as 25% show evidence of hemorrhage. These patients often have acute headache, visual loss, nausea or vomiting, ocular palsy, disturbances of consciousness, fever, vertigo, or hemiparesis. In such patients, rapid transsphenoidal decompression should be accompanied by consideration of replacement therapy, including glucocorticoids, and treatment of increased intracranial pressure.

Obstetric anesthesiologists are often aware of these pituitary failure problems (see also Chapter 77); Sheehan syndrome is the clinical manifestation of pituitary infarction associated with hypotension after or during obstetric hemorrhage. Conditions that strongly suggest this diagnosis are failure to start postpartum lactation, increasing fatigue, cold intolerance, and especially hypotension unresponsive to volume replacement and pressors.

Posterior Pituitary Hormone Excess and Deficiency

Secretion of vasopressin or antidiuretic hormone (ADH) is enhanced by increased serum osmolality or the presence of hypotension. Inappropriate secretion of vasopressin, without relation to serum osmolality, results in hyponatremia and fluid retention. This inappropriate secretion can result from the following: a variety of CNS lesions; drugs such as nicotine, narcotics, chlorpropamide, clofibrate, vincristine, vinblastine, and cyclophosphamide; and pulmonary infections, hypothyroidism, adrenal insufficiency, and ectopic production from tumors. Preoperative and preprocedure management of a surgical patient with inappropriate secretion of vasopressin includes appropriate treatment of the causative disorders and restriction of water. Occasionally, drugs that inhibit the renal response to ADH (e.g., lithium or demeclocycline) should be administered preoperatively to restore normal intravascular volume and electrolyte status.

Most of the clinical features associated with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) are related to hyponatremia and the resulting brain edema; such features include weight gain, weakness, lethargy, mental confusion, obtundation, and disordered reflexes and may culminate in convulsions and coma. This form of edema rarely leads to hypertension.

Investigators have recognized that 10% to 20% of long-distance and marathon runners have SIADH with increased vasopressin secretion. Because such people not infrequently undergo surgical treatment of injuries, SIADH symptoms and laboratory evaluation may be routine for that group as well.

SIADH should be suspected in any patient with hyponatremia who excretes urine that is hypertonic relative to plasma. The following laboratory findings further support the diagnosis:

1. Urinary sodium greater than 20 mEq/L
2. Low serum levels of BUN, creatinine, uric acid, and albumin
3. Serum sodium lower than 130 mEq/L
4. Plasma osmolality lower than 270 mOsm/L
5. Urine hypertonic relative to plasma

Noting the response to water loading is a useful way of evaluating patients with hyponatremia. Patients with SIADH are unable to excrete dilute urine even after water loading. Assay of ADH in blood can confirm the diagnosis. Too vigorous treatment of chronic hyponatremia can result in disabling demyelination.[101,102] The increase in serum sodium should not be greater than 1 mEq/L/hour[101,102] (see the discussion of hyponatremia in the later section on electrolyte disorders).

Patients with mild to moderate symptoms of water intoxication can be treated with restriction of fluid intake to approximately 500 to 1000 mL/day. Patients with severe water intoxication and CNS symptoms may need vigorous treatment consisting of intravenous administration of 200 to 300 mL of a 5% saline solution over a period of several hours, followed by fluid restriction.

Treatment should be directed at the underlying problem. If SIADH is drug induced, use of the drug should be withdrawn. Inflammation should be treated with appropriate measures, and neoplasms should be managed by surgical resection, irradiation, or chemotherapy, whichever is indicated.

No drugs are available that can suppress release of ADH from the neurohypophysis or from a tumor. Phenytoin (Dilantin) and narcotic antagonists such as naloxone and butorphanol have some inhibiting effect on physiologic ADH release but are clinically ineffective in patients with SIADH. Drugs that block the effect of ADH on renal tubules include lithium, which is rarely used because its toxicity often outweighs its benefits, and demethylchlortetracycline in doses of 900 to 1200 mg/day. Demethylchlortetracycline interferes with the ability of the renal tubules to concentrate urine, thereby causing excretion of isotonic or hypotonic urine and lessening the hyponatremia. This drug can be used in ambulatory patients with SIADH when it is difficult to restrict fluids.

When a patient with SIADH comes to the operating room for any surgical procedure, fluids are managed by measuring central volume status by CVP, pulmonary artery lines, or the cross-sectional left ventricular area at end-diastole on transesophageal echocardiography and by frequent assays of urine osmolarity, plasma osmolarity, and serum sodium, including the period immediately after the surgical procedure. Despite the common impression that SIADH is frequently seen in older patients in the postoperative period, studies have shown that the patient's age and the type of anesthetic used have no bearing on the postoperative development of SIADH. It

is not unusual to see several patients in the neurosurgical ICU suffering from this syndrome. The diagnosis is usually one of exclusion. Patients with SIADH generally require only restriction of intravenous fluids; very rarely is hypertonic saline needed.

Lack of ADH, which results in diabetes insipidus, is caused by pituitary disease, brain tumors, infiltrative diseases such as sarcoidosis, head trauma (including trauma after neurosurgery), or lack of a renal response to ADH. The last can result from such diverse conditions as hypokalemia, hypercalcemia, sickle cell anemia, obstructive uropathy, and renal insufficiency. Preoperative or preprocedure treatment of diabetes insipidus consists of restoring normal intravascular volume by replacing urinary losses, administering desmopressin acetate (DDAVP) nasally, and giving daily fluid requirements intravenously.

Perioperative management of patients with diabetes insipidus is based on the extent of the ADH deficiency. Management of a patient with complete diabetes insipidus and a total lack of ADH does not usually present any major problem as long as the side effects of the drug are avoided and the presence of the condition is known preoperatively. Just before the surgical procedure, the patient is given the usual dose of DDAVP intranasally or an intravenous bolus of 100 milliunits of aqueous vasopressin, followed by a constant infusion of 100 to 200 milliunits/hour.[1] The dose is usually adjusted to permit the daily breakthrough polyuria that prevents the iatrogenic syndrome of SIADH. All the intravenous fluids given intraoperatively should be isotonic to reduce the risk of water depletion and hypernatremia. Plasma osmolality should be measured every hour, both intraoperatively and immediately postoperatively. If plasma osmolality rises much higher than 290 mOsm/L, hypotonic fluids can be administered; the rate of the intraoperative vasopressin infusion can be increased to greater than 200 milliunits/hour.

For patients who have a partial deficiency of ADH, it is not necessary to use aqueous vasopressin perioperatively unless plasma osmolality rises to more than 290 mOsm/L. Nonosmotic stimuli (e.g., volume depletion) and the stress of surgery usually cause the release of large quantities of ADH perioperatively. Consequently, these patients require only frequent monitoring of plasma osmolality during this period.

Because of side effects, the dose of vasopressin should be limited to that necessary for control of diuresis. The oxytocic and coronary artery–constricting properties of vasopressin make this limit especially applicable to patients who are pregnant or have CAD.

DISEASES INVOLVING THE CARDIOVASCULAR SYSTEM

HYPERTENSION

Analysis of the perioperative treatment of hypertension is important because of the prevalence of the condition (30% of the general population in the United States), the great risk in perioperative care of a hypertensive patient, and the high cost of unnecessary delays in surgical treatment. Numerous studies over the years have evaluated the impact of hypertension as one of the risk factors for cardiac morbidity. More recently, the need to delay surgery because of poorly controlled hypertension has been questioned. Weksler and colleagues studied 989 hypertensive patients who were treated on a long-term basis and who underwent noncardiac surgery with diastolic blood pressure between 110 and 130 mm Hg and no previous myocardial infarction (MI), unstable or severe angina pectoris, renal failure, pregnancy-induced hypertension, left ventricular hypertrophy, previous coronary revascularization, aortic stenosis, preoperative dysrhythmias, conduction defects, or stroke.[103] The control group had their surgical procedures postponed and remained in the hospital for control of blood pressure, and the study patients received 10 mg of nifedipine intranasally. No statistically significant differences in postoperative complications were observed, thus suggesting that this subset of patients without significant cardiovascular comorbid conditions can proceed with surgery despite elevated blood pressure on the day of the operation.

Several studies have assessed the relationship between cardiovascular disease and preoperative hypertension. In a multicenter study of patients undergoing coronary artery bypass graft (CABG), the presence of isolated systolic hypertension was associated with a 30% increased incidence of perioperative cardiovascular complications when compared with normotensive individuals.[104] Kheterpal and colleagues integrated data from their anesthesia information system (AIMS) and the American College of Surgeons National Surgical Quality Improvement Project (NSQIP) and found hypertension to be one of the independent predictors of events.[105] Wax and colleagues used their AIMS to identify independent predictors of troponin elevation or death, and independent predictors of adverse outcome included increased baseline systolic blood pressure, intraoperative diastolic blood pressure lower than 85 mm Hg, increased intraoperative heart rate, blood transfusion, and anesthetic technique, controlling for standard risk factors.[106] A delay of surgery did not result in interval normalization of blood pressure.

Although preoperative blood pressure (both systolic and diastolic) is a significant predictor of postoperative morbidity, no data definitively establish whether preoperative treatment of hypertension reduces perioperative risk. Until a definitive study is performed, we recommend letting the weight of evidence guide preoperative treatment of a patient with hypertension. Such treatment would be based on three general beliefs: (1) the patient should be educated regarding the importance of lifelong treatment of hypertension, even isolated systolic hypertension; (2) perioperative hemodynamic fluctuations occur less frequently in treated than in untreated hypertensive patients (as demonstrated by Prys-Roberts and colleagues[107] and confirmed by Goldman and Caldera[108] and Mangano and associates[109]); and (3) hemodynamic fluctuations have some relation to morbidity. Kheterpal and colleagues demonstrated that patients who sustained a cardiac adverse event were more likely to experience an episode of mean arterial pressure lower than 50 mm Hg,

an episode of 40% decrease in mean arterial pressure, and an episode of heart rate higher than 100 beats/minute.[105] The data of Pasternack and colleagues and Weksler and associates imply that rapid correction of blood pressure or prevention of increases in heart rate may be all that is needed.[103,110] Taken together, these data suggest that maintenance of normal blood pressure is critical in patients with hypertension.

Preoperative data should be used to determine the individualized range of suitable arterial blood pressure values that are tolerable by a particular patient during and after a surgical procedure. That is, if blood pressure is 180/100 mm Hg and the heart rate is 96 beats/minute on admission with no signs or symptoms of myocardial ischemia, these levels can likely be tolerated during a surgical procedure. Conversely, if during the night blood pressure decreases to 80/50 mm Hg and the heart rate to 48 beats/minute and a new cerebral deficit does not occur, the patient can probably safely tolerate such levels during anesthesia. Therefore, on the basis of preoperative data, we derive an individualized set of values for each patient. However, hypotension in patients at risk for a cerebrovascular event should be avoided. For example, the POISE (Perioperative Ischemic Evaluation) study demonstrated that short-term β-blocker administration resulted in an increased incidence of stroke and death that was associated with an increased rate of hypotension.[111]

Preoperative Administration of All Antihypertensive Drugs

Continuation of all antihypertensive drugs preoperatively should be considered, except ACE inhibitors or angiotensin II antagonists, for which no clear consensus exists. Coriat and colleagues found that ACE inhibitors were associated with hypotension in 100% of patients during induction versus approximately 20% in whom ACE inhibitors were withheld on the morning of the surgical procedure.[112] Bertrand and co-workers performed a prospective randomized study that demonstrated that more severe hypotensive episodes requiring vasoconstrictor treatment occurred after induction of general anesthesia in patients treated on a long-term basis with an angiotensin II antagonist and receiving the drug on the morning before the operation than in those in whom angiotensin II antagonists were discontinued on the day before the surgical procedure.[113] Kheterpal and colleagues performed a propensity-matched analysis of 12,381 noncardiac surgical cases.[114] Patients with long-term ACE inhibitor or angiotensin receptor blocker and diuretic therapy showed more periods with a mean arterial blood pressure lower than 70 mm Hg, periods with a 40% decrease in systolic blood pressure, periods with a 50% decrease in systolic blood pressure, and vasopressor boluses than did patients receiving diuretic therapy alone. If these drugs are continued, vasopressin is the drug of choice for refractory hypotension. Investigators at the Cleveland Clinic evaluated 79,228 patients (9905 ACE inhibitor users [13%] and 66,620 [87%] non–ACE inhibitor users) who had noncardiac surgery between 2005 and 2009.[115] These investigators did not find any association between use of ACE inhibitors and intraoperative or postoperative upper airway complications. ACE inhibitor use was not associated with in-hospital complications or increased 30-day mortality.

ISCHEMIC HEART DISEASE

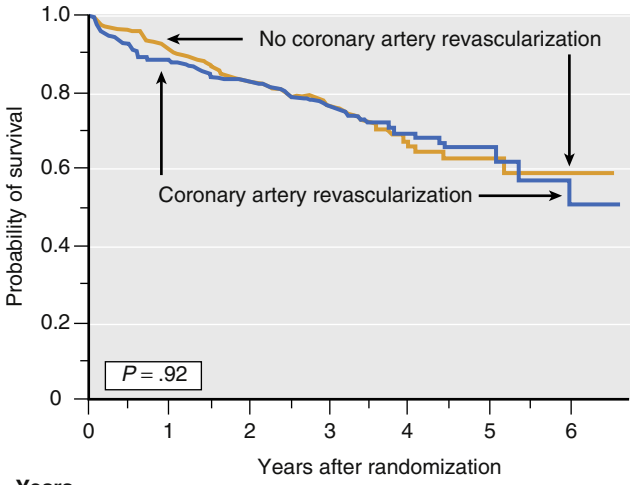
Preoperative evaluation of a patient with ischemic heart disease (see also Chapter 67) and a discussion of the AHA/ACC guidelines can be found in Chapter 38.[116] New guidelines were published in 2014 by both the AHA/ACC and the European Society of Cardiology.[116a,166b]

Role of Coronary Artery Bypass Graft or Percutaneous Coronary Interventions Before Noncardiac Surgical Procedures

Coronary revascularization may reduce the perioperative risk before noncardiac surgery (see also Chapter 67). Earlier successful preoperative revascularization may decrease postoperative cardiac risk twofold to fourfold in patients undergoing elective vascular surgery.[117,118] The strongest retrospective evidence comes from the Coronary Artery Surgery Study (CASS) registry, which enrolled patients from 1978 to 1981. Operative mortality in patients with CABG performed before noncardiac surgery was 0.9% but was significantly higher at 2.4% in patients without previous CABG. However, a 1.4% mortality rate was associated with the CABG procedure itself.

Eagle and colleagues reported on a long-term analysis of patients entered into the CASS.[119] These investigators studied patients assigned to medical or surgical therapy for CAD for more than 10 years who subsequently underwent 3368 noncardiac operations in the years after assignment of coronary treatment. Intermediate-risk surgery such as abdominal, thoracic, or carotid endarterectomy were associated with a combined morbidity and mortality rate of 1% to 5% and a small but significant improvement in outcome in patients who had previously undergone revascularization. The most significant improvement in outcome occurred in patients who underwent major vascular surgery such as abdominal or lower extremity revascularization. However, this observational study did not randomize patients and was undertaken in the 1970s and 1980s, before significant advances in medical, surgical, and percutaneous coronary strategies.[119]

Landesberg and coauthors retrospectively reviewed long-term outcomes in 578 major vascular procedures.[120] By multivariate analysis, age, type of vascular surgery, presence of diabetes, previous MI, and moderate to severe ischemia on preoperative thallium scanning independently predicted mortality, and preoperative coronary revascularization predicted improved survival. Long-term survival after major vascular surgery was significantly improved if patients with moderate to severe ischemia on preoperative thallium scanning underwent selective coronary revascularization.



The benefit of percutaneous coronary intervention (PCI) before noncardiac surgery has also been examined in several cohort studies. Posner and colleagues used an administrative data set of patients who underwent PCI and noncardiac surgery in Washington State.[121] These

investigators matched patients with coronary disease who were undergoing noncardiac surgery with and without previous PCI and looked at cardiac complications. In this nonrandomized design, Posner and colleagues noted a significantly lower rate of 30-day cardiac complications in patients who underwent PCI at least 90 days before the noncardiac surgery. However, PCI within 90 days of noncardiac surgery did not improve outcome. Although the explanation for these results is unknown, they may support the notion that PCI performed "to get the patient through surgery" may not improve perioperative outcome because cardiac complications may not occur in patients with stable or asymptomatic coronary stenosis. PCI may actually destabilize coronary plaque, which becomes manifest in the days or weeks after noncardiac surgery.

Godet and associates studied a cohort of 1152 patients after abdominal aortic surgery in which 78 patients underwent PCI.[122] In the PCI group, the observed percentages of patients with a severe postoperative coronary event (9.0%; 95% confidence interval [CI], 4.4 to 17.4) or death (5.1% [95% CI, 2.0 to 12.5]) were not significantly different from the expected percentages (8.2% and 6.9%, respectively), which was confirmed by propensity analysis. PCI did not seem to significantly limit cardiac risk or death after aortic surgery.

Several randomized trials have addressed the value of testing and CABG or PCI, or both, in a subset of patients. McFalls and colleagues reported the results of a multicenter randomized trial in the VA Health System in which patients with documented CAD on coronary angiography, excluding those with left main CAD or a severely depressed ejection fraction (<20%), were randomized to CABG (59%) or percutaneous transluminal coronary angioplasty (PTCA) (41%) versus routine medical therapy.[123] At 2.7 years after randomization, mortality in the revascularization group was not significantly different (22%) from that in the no-revascularization group (23%) (Fig. 39-4). Within 30 days after the vascular operation, postoperative MI, defined by elevated troponin levels, occurred in 12% of the revascularization group and in 14% of the no-revascularization group (P = .37). The authors suggested that coronary revascularization is not indicated in patients with stable CAD, and their results further support the lack of efficacy of PCI or CABG for single- or double-vessel disease before noncardiac surgery. However, in a follow-up analysis, Ward and coauthors reported improved outcome in the subset of patients who underwent CABG versus PCI.[124]

Poldermans and colleagues randomized 770 patients about to undergo major vascular surgery and considered to have intermediate cardiac risk, defined as the presence of 1 or 2 cardiac risk factors, to either undergo further risk stratification with stress imaging or proceed directly to surgery.[125] All patients received bisoprolol with a targeted heart rate of 60 to 65 beats/minute initiated before and continued after the surgical procedure. The 30-day incidence of cardiac death and nonfatal MI was similar in both groups (1.8% in the no-testing group versus 2.3% in the tested group). The conclusions of the authors were that further risk stratification in this group of patients considered to be at intermediate risk based on clinical history alone was unnecessary as long as perioperative β-blockers

Figure 39-4. Long-term survival in patients randomized to coronary revascularization or routine care in patients with coronary artery disease on angiography and undergoing major vascular surgical procedures in the Coronary Artery Revascularization Prophylaxis trial. *(From McFalls EO, Ward HB, Moritz TE, et al: Coronary-artery revascularization before elective major vascular surgery,* N Engl J Med *351:2795-2804, 2004.)*

were used and that testing only delayed necessary vascular surgery. In a pilot study, Poldermans and associates tested patients with more than 3 risk factors; 101 (23%) showed extensive ischemia and were randomly assigned to revascularization (n = 49) or no revascularization.[126] Revascularization did not improve 30-day outcome; the incidence of the composite end-point was 43% versus 33% (odds ratio [OR], 1.4; 95% CI, 0.7 to 2.8; P = .30). In addition, no benefit during 1-year follow-up was observed after coronary revascularization (49% versus 44%; OR, 1.2; 95% CI, 0.7 to 2.3; P = .48). Concern was expressed by Erasmus University (Rotterdam, the Netherlands) regarding the scientific integrity of studies led by Poldermans, as detailed in Erasmus MC Follow-up Investigation Committee: *Report on the 2012 follow-up investigation of possible breaches of academic integrity, September 30, 2012* (http://www.erasmusmc.nl/5663/135857/3675250/3706798/Integrity_report_2012-10.pdf?lang=en). At the time of writing this chapter, the articles have not been retracted, but these data should be viewed with some skepticism. The authors of the 2014 AHA/ACCF Guidelines decided that the nonretracted decrease publications and/or other derivative studies by Poldermans that are relevant to the topic can only be cited in the text with a comment about the finding compared with the current recommendation but did not form the basis of that recommendation.

One issue in interpreting the results is that the length of time between coronary revascularization and noncardiac surgery most likely has an impact on its protective effect and potential risks. Back and co-workers studied 425 consecutive patients undergoing 481 elective major vascular operations at an academic VA Medical Center.[127] Coronary revascularization was classified as recent (CABG <1 year; PTCA <6 months) in 35 cases (7%),

prior (CABG >1 year and ≤5 years; PTCA >6 months and ≤2 years) in 45 cases (9%), and remote (CABG ≥5 years; PTCA ≥2 years) in 48 cases (10%). Outcomes in patients with previous PTCA were similar to those after CABG (P = .7). Significant differences in adverse cardiac events and mortality were found among patients with CABG performed within 5 years or PTCA within 2 years (6.3%, 1.3%, respectively), individuals with remote revascularization (10.4%, 6.3%), and nonrevascularized patients stratified at high risk (13.3%, 3.3%) or intermediate/low risk (2.8%, 0.9%). The authors concluded that previous coronary revascularization (CABG <5 years; PTCA <2 years) may provide only modest protection against adverse cardiac events and mortality after major arterial reconstruction.

PCI using coronary stenting poses several special issues. Kaluza and associates reported on the outcome of 40 patients who underwent prophylactic coronary stent placement less than 6 weeks before major noncardiac surgery requiring general anesthesia.[128] Among these patients, 7 MIs, 11 major bleeding episodes, and 8 deaths were noted. All deaths and MIs, as well as 8 of the 11 bleeding episodes, occurred in patients subjected to surgical procedures less than 14 days after stenting. Four patients died after undergoing surgical procedures 1 day after stenting. Wilson and colleagues reported on 207 patients who underwent noncardiac surgery within 2 months of stent placement.[129] Eight patients died or suffered an MI, all of whom were among the 168 patients who had surgical procedures 6 weeks after stent placement. Vicenzi and co-workers studied 103 patients and reported that the risk of suffering a perioperative cardiac event was 2.11-fold greater in patients with recent stents (<35 days before surgery) than in those who underwent PCI more than 90 days before surgical procedures.[130] Leibowitz and associates studied a total of 216 consecutive patients who underwent PCI within 3 months of noncardiac surgery (PTCA, 122; stent, 94).[131] A total of 26 patients (12%) died, 13 in the stent group (14%) and 13 in the PTCA group (11%), a nonsignificant difference. The incidence of acute MI and death within 6 months was not significantly different (7% and 14% in the stent group and 6% and 11% in the PTCA group, respectively). Significantly more events occurred in the 2 groups when noncardiac surgery was performed within 2 weeks of PCI. Based on the accumulating data, elective noncardiac surgery after PCI, with or without stent placement, should be delayed for 4 to 6 weeks.

Drug-eluting stents may represent an even greater problem during the perioperative period based on case reports. Nasser and coauthors described two patients with in-stent thrombosis occurring 4 and 21 months after the implantation of sirolimus-eluting stents.[132] Drug-eluting stents may represent an additional risk over a prolonged period (≤12 months), particularly if antiplatelet drugs are discontinued.[133] One study demonstrated that although the frequency of major noncardiac surgery in the year after drug-eluting stent placement was more than 4%, the overall risk of adverse outcomes was less than previously reported when surgical procedures were performed months after drug-eluting stent placement.[134] However, the risk was significantly increased in the week after major noncardiac surgery. A population-based study in Canada using administrative health care databases demonstrated that the earliest optimal time for elective surgery is 46 to 180 days after bare metal stent implantation or more than 180 days after drug-eluting stent implantation.[135] Hawn and colleagues used a national, retrospective cohort study of 41,989 VA and non-VA operations occurring in the 24 months after coronary stent implantation between 2000 and 2010.[136] Among patients undergoing noncardiac surgery within 2 years of coronary stent placement, major adverse cardiac events were associated with emergency surgery and advanced cardiac disease but not stent type or timing of surgery beyond 6 months after stent implantation (Fig. 39-5).

Perioperative Risk Factors for Cardiac Morbidity and Mortality

A thorough history should focus on cardiovascular risk factors and symptoms or signs of unstable cardiac disease states, such as myocardial ischemia with minimal exertion, active CHF, symptomatic valvular heart disease, and significant cardiac arrhythmias. The presence of unstable angina is associated with a 28% incidence of perioperative MI.[137] Such patients would benefit from delaying elective surgery to address their CAD. For those patients with chronic stable angina, exercise tolerance appears to be a good method of assessing perioperative risk.

In virtually all studies, the presence of active CHF has been associated with increased perioperative cardiac morbidity.[138] In addition, multiple studies have demonstrated that reduced ejection fraction is associated with an increased incidence of perioperative cardiac events.[139,140] Flu and colleagues performed echocardiography in patients undergoing vascular surgery and found that for open surgical procedures, asymptomatic systolic left ventricular dysfunction and asymptomatic diastolic left ventricular dysfunction were both associated with increased 30-day cardiovascular event rates (OR, 2.3; 95% CI, 1.4 to 3.6; and OR, 1.8; 95% CI 1.1 to 2.9, respectively) and long-term cardiovascular mortality (hazard ratio, 4.6; 95% CI 2.4 to 8.5; and hazard ratio, 3.0; 95% CI 1.5 to 6.0, respectively).[141] In patients undergoing endovascular surgery (n = 356), only symptomatic heart failure was associated with an increase in 30-day cardiovascular events and long-term cardiovascular mortality. These results suggest that stabilization of ventricular function and treatment of pulmonary congestion is prudent before elective surgery.

A recent MI has traditionally been an important predictor of perioperative risk. The more recent the MI, particularly within 3 to 6 months, the greater is the perioperative risk. However, like the Goldman Cardiac Risk Index, medicine has changed and outcomes are improved. The classic article by Rao and associates that was published in 1983 cited a reinfarction rate of nearly 30% if noncardiac surgery occurred within 3 months of a prior infarction.[142] These reinfarctions had a very high mortality rate. With the advent of dedicated postoperative ICUs, more vigilant monitoring, and early intervention, the postoperative reinfarction rate has decreased by almost an order of magnitude. The 2014 AHA/ACC Foundation (AHA/ACCF) guidelines advocate the use of 60 days as being high risk.[116a] After that time, further risk stratification depends on clinical symptoms.

[Epub ahead of print.])*

For those patients without overt symptoms or a history of CAD, the probability of CAD varies with the type and number of atherosclerotic risk factors present. Diabetes accelerates the progression of atherosclerosis, which can frequently be silent, leading many clinicians to assume that diabetes is a CAD equivalent and treating patients as such. Diabetes is an independent risk factor for perioperative cardiac morbidity, and the preoperative treatment with insulin has been included in the Revised Cardiac Risk Index (RCRI). In attempting to determine the degree of the increased risk associated with diabetes, the treatment modality, duration of the disease, and other associated end-organ dysfunction should be taken into account.

Significant intraoperative factors that correlate with perioperative risk and that may be avoided or altered are (1) unnecessary use of vasopressors,[143,144] (2) unintentional hypotension[145-147] (this point is controversial, however, because some investigators have found that unintentional hypotension does not correlate with perioperative morbidity[144]), (3) hypothermia,[148] (4) too low or too high a hematocrit,[149,150] and (5) lengthy operations.[146]

Significant intraoperative factors that correlate with perioperative morbidity and probably cannot be avoided are (1) emergency surgery and (2) thoracic or intraperitoneal surgery or above-the-knee amputations.[146,151-164]

Several risk indices were developed in a prospective cohort study by Lee and asociates.[165] They studied 4315 patients 50 years old or older who were undergoing elective major noncardiac procedures in a tertiary care teaching hospital. The 6 independent predictors of complications included in a RCRI were high-risk type of surgery, history of ischemic heart disease, history of CHF, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine greater than 2.0 mg/dL; increasing cardiac complication rates were noted with an increasing number of risk factors.[165] The RCRI has become the standard tool in the literature for assessing perioperative cardiac risk in a given individual and has been used to direct the decision to perform cardiovascular testing and implement perioperative management protocols. It has been validated for both short-term and long-term cardiovascular outcomes.[166] It has also been shown to predict long-term quality of life.[166] Therefore, the RCRI can be used to help define both the short-term and long-term risks of cardiovascular disease in the surgical patient.

The American College of Surgeons NSQIP created a Surgical Risk Calculator from 525 participating hospitals

and more than 1 million operations.[167] This risk calculator uses the specific current procedural terminology code of the procedure being performed to enable procedure-specific risk assessment and includes 21 patient-specific variables (e.g., age, sex, body mass index, dyspnea, previous MI). From this input, it calculates the percentage of risk of a major adverse cardiac event, death, and 8 other outcomes. Use of this risk calculator may offer the best estimation for surgery-specific risk of a major adverse cardiac event and death.

The American College of Surgeons NSQIP Myocardial Infarction and Cardiac Arrest (MICA) risk prediction rule is more specific for cardiac complications.[168] Using these definitions of outcome and chart-based data collection methods, the authors derived a risk index that was robust in the derivation and validation stages and appeared to outperform the RCRI (which was tested in the same data set) in terms of discriminative power, particularly among patients undergoing vascular surgery.

A primary issue with all these indices is that a simple estimate of risk does not help in refining perioperative management for an individual patient. Therefore, the consultant must communicate the extent and stability of the patient's CAD, rather than make a simple statement of risk classification.

The goal in providing anesthesia to patients with ischemic heart disease is to achieve the best preoperative condition obtainable by treating conditions that correlate with perioperative risk. The next step is to intraoperatively monitor for conditions that correlate with perioperative risk and avoid circumstances that lead to perioperative risk.

Preoperative and Preprocedure Therapy

The only way known to increase oxygen supply to the myocardium of patients with coronary artery stenosis is to maintain adequate diastolic blood pressure, hemoglobin concentration, and oxygen saturation (see also Chapter 38). The main goals of anesthesia practice for these patients have been to decrease the determinants of myocardial oxygen demand, heart rate, ventricular wall tension, and contractile performance and to improve plaque stabilization. Thus, medical management designed to preserve all viable myocardial tissue may include the following:

1. Continuation of β-adrenergic receptor blocking drugs (propranolol, atenolol, esmolol, or metoprolol) to avoid β-blocker withdrawal leading to increased contractility and heart rate. Multiple studies have demonstrated improved outcome in patients given perioperative β-adrenergic blockers, especially if the heart rate is controlled.[169,170] However, newer studies have demonstrated that β-adrenergic blockers may not be effective if the heart rate is not well controlled or in lower-risk patients.[171-173] The POISE trial enrolled 8351 high-risk β-blocker–naive patients who were randomized to high-dose continuous-release metoprolol versus placebo.[111] A significant reduction in the primary outcome of cardiovascular events was reported, along with a 30% reduction in the MI rate, but with a significantly increased rate of 30-day all-cause mortality and stroke. The current ACC/AHA guidelines on perioperative β blockade advocate that perioperative β blockade is a class I indication and should be used in patients previously taking β-blockers and those with a positive stress test who are undergoing major vascular surgery, although short-term administration without titration may be associated with harm (Box 39-3).
2. Vasodilation (with nitroglycerin or its "long-acting" analogues nitroprusside, hydralazine, or prazosin) to decrease ventricular wall tension may be beneficial, although currently no randomized trials support the prophylactic use of these agents.[109,110,174] The use of Swan-Ganz catheters and transesophageal echocardiography for this type of patient is described in Chapter 45,[159,175] and the intraoperative management of patients with ischemic heart disease is discussed in further detail in Chapter 67 and in published guidelines.[116]
3. Aspirin, statins, exercise, and diet. These choices seem to be indicated in many patients. Briefly, we believe that drugs given on a long-term basis (e.g., antihypertensive medications and some ACE inhibitors) should be continued through the morning of the surgical procedure (see earlier). The topic of long-term drug

BOX 39-3 *2014 ACCF/AHA Recommendations for Perioperative β-Blockade*

Class I

- β-Blockers should be continued in patients undergoing surgery who have been on β-blockers chronically.[111-117] **(Level of Evidence: B)**

Class IIa

- It is reasonable for the management of β-blockers after surgery to be guided by clinical circumstances, independent of when the agent was started.[110,117,118] **(Level of Evidence: B)**

Class IIb

- In patients with intermediate- or high-risk myocardial ischemia noted in preoperative risk stratification tests, it may be reasonable to begin perioperative β-blockers.[119] **(Level of Evidence: C)**
- In patients with three or more RCRI risk factors (e.g., diabetes mellitus, heart failure, coronary artery disease, renal insufficiency, cerebrovascular accident), it may be reasonable to begin β-blockers before surgery.[117] **(Level of Evidence: B)**
- In patients with a compelling long-term indication for β-blocker therapy but no other RCRI risk factors, initiating beta blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit.[111,117,120] **(Level of Evidence: B)**
- In patients in whom β-blocker therapy is initiated, it may be reasonable to begin perioperative β-blockers long enough in advance to assess safety and tolerability, preferably more than 1 day before surgery.[110,121-123] **(Level of Evidence: B)**

Class III: Harm

- β-Blocker therapy should not be started on the day of surgery.[110] **(Level of Evidence: B)**

RCRI, Revised Cardiac Risk Index.

therapy is discussed in more detail in the last section of this chapter, on drug therapy.

4. Perioperative transfusion therapy is discussed in more detail in Chapter 61. The FOCUS (Functional Outcomes in Cardiovascular Patients Undergoing Surgical Repair of Hip Fracture) trial was unable to demonstrate benefit in high-risk patients with hip fracture between a high and low transfusion trigger.[176]

VALVULAR HEART DISEASE

Major alterations in the preoperative management of patients with valvular heart disease have been made regarding the use of anticoagulant therapy and are now based on the causes of the disease. Preoperative and intraoperative management of patients with valvular heart disease is discussed in Chapters 38 and 67.

The prognosis and, presumably, the perioperative risk for patients with valvular heart disease depend on the stage of the disease. Although stenotic lesions progress faster than do regurgitant lesions, regurgitant lesions secondary to infective endocarditis, rupture of the chordae tendineae, or ischemic heart disease can be rapidly fatal. Left ventricular dysfunction is common in the late stage of valvular heart disease.

Preoperative maintenance of drug therapy can be crucial; for example, the condition of a patient with aortic stenosis can deteriorate rapidly with the onset of atrial fibrillation or flutter because the atrial contribution to left ventricular filling can be critical in maintaining cardiac output. One of the most serious complications of valvular heart surgery and of preoperative valvular heart disease is cardiac arrhythmia. Conduction disorders and long-term therapy with antiarrhythmic and inotropic drugs are discussed elsewhere in this chapter. The reader is referred to Chapter 94 and to other sources for discussion of the management of a child with congenital heart disease who is undergoing noncardiac surgery.[177]

Preoperative Antibiotic Prophylaxis for Endocarditis

Patients who have any form of valvular heart disease, as well as those with intracardiac (ventricular septal or atrial septal defects) or intravascular shunts, should be protected against endocarditis at the time of a known bacteremic event. Endocarditis has occurred in a sufficiently significant number of patients with hypertrophic cardiomyopathy (subvalvular aortic stenosis, asymmetric septal hypertrophy) and mitral valve prolapse to warrant the inclusion of these two conditions in the prophylaxis regimen.

Bacteremia occurs after the following events: dental extraction, 30% to 80%; brushing of teeth, 20% to 24%; use of oral irrigation devices, 20% to 24%; barium enema, 11%; transurethral resection of the prostate (TURP), 10% to 57%; upper GI endoscopy, 8%; nasotracheal intubation, 16% (4 of 25 patients); and orotracheal intubation, 0% (0 of 25 patients). The most recent guidelines from the AHA consisted of an update in 2008 from the AHA/ACC on endocarditis in patients with valvular heart disease, with changes from the 2006 document shown in Table 39-7.[178]

Cardiac Valve Prostheses and Anticoagulant Therapy and Prophylaxis for Deep Vein Thrombosis

In patients with prosthetic valves, the risk of increased bleeding during a procedure in a patient receiving antithrombotic therapy must be weighed against the increased risk of thromboembolism caused by stopping the therapy. Common practice in patients undergoing noncardiac surgery with a mechanical prosthetic valve in place is cessation of anticoagulant therapy 3 days preoperatively. This time frame allows the international normalized ratio to fall to less than 1.5 times normal. The oral anticoagulants can then be resumed on postoperative day 1. Using a similar protocol, Katholi and colleagues found no perioperative episodes of thromboembolism or hemorrhage in 25 patients.[179] An alternative approach in patients at high risk for thromboembolism is conversion to heparin during the perioperative period. The heparin can then be discontinued 4 to 6 hours preoperatively and resumed shortly thereafter. Current prosthetic valves may have a lower incidence of this complication, and the risk associated with heparin may outweigh its benefit in the perioperative setting. According to the AHA/ACC guidelines, heparin can usually be reserved for patients who have had a recent thrombus or embolus (arbitrarily within 1 year), those with demonstrated thrombotic problems when previously off therapy, those with a Björk-Shiley valve, and those with more than three risk factors (atrial fibrillation, previous thromboembolism, hypercoagulable condition, and mechanical prosthesis).[180] A lower threshold for recommending heparin should be considered in patients with mechanical valves in the mitral position, in whom a single risk factor would be sufficient evidence of high risk. Subcutaneous low-molecular-weight heparin offers an alternative outpatient approach.[181] It is appropriate for the surgeon and cardiologist to discuss the optimal perioperative management for such a patient, including a review of the most recent guidelines.[182] A new guideline publication was published in 2014.[182a]

Regional anesthetic techniques may be avoided, although this issue is controversial.[183] Many practitioners do not hesitate to use regional anesthesia in patients who are receiving prophylaxis for deep vein thrombosis.[184-186] However, epidural hematoma has been associated with anticoagulant therapy in many reports. Large retrospective reviews of outcome after epidural or spinal anesthesia, or both, during or shortly before initiation of anticoagulant therapy with heparin have not reported neurologic dysfunction related to hematoma formation in any patient.[187,188] This paucity of damaging epidemiologic evidence, although reassuring, does not reduce the need for frequent evaluation of neurologic function and a search for back pain in the perioperative period after regional anesthesia in any patient receiving any clotting function inhibitor, including aspirin.[183,189-191] The risk of regional anesthesia concurrent with prophylaxis for deep vein thrombosis with heparin is greater with the use of low-molecular-weight heparin. (Heparin-induced thrombocytopenia has been treated successfully with intravenous immunoglobulin.[185]) The American Society of Regional Anesthesia and Pain Management has issued a consensus statement on the use of regional anesthesia in anticoagulated patients.[192] They

A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines: Endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons, Circulation *118:887-896, 2008.*

suggest that the decision to perform spinal or epidural anesthesia or analgesia and the timing of catheter removal in a patient receiving antithrombotic therapy should be made on an individual basis, with the small but definite risk of spinal hematoma weighed against the benefits of regional anesthesia for a specific patient.

Deep vein thrombosis is so common in postoperative patients that almost 1% of postsurgical patients die of fatal pulmonary embolism (Table 39-8).[193] Because of this high mortality risk, prophylaxis against deep vein thrombosis has attained widespread acceptance; thus, prophylaxis often begins with 5000 units of heparin given subcutaneously 2 hours preoperatively.[193-195] Other trials have shown equal effect with external pneumatic compression.[194,196] Persuading surgeons to use this technique may provide greater assurance in using regional anesthesia. Such an option, however, is not available for patients with a prosthetic valve. Newer recommendations are available from the American College of Chest Physicians for prophylaxis against venous thromboembolism.[197]

Another problem that can arise is managing a pregnant patient with a prosthetic valve during delivery. It is recommended that warfarin be replaced by subcutaneous heparin during the peripartum period. During labor and delivery, elective induction of labor is advocated with discontinuance of all anticoagulant therapy, as indicated for the particular valve prosthesis (discussed earlier).[198]

Auscultation of the prosthetic valve should be performed preoperatively to verify normal functioning. Abnormalities in such sounds warrant preoperative consultation and verification of functioning.

CARDIAC CONDUCTION DISTURBANCES: CARDIAC ARRHYTHMIAS

Bradyarrhythmias, especially if profound or associated with dizziness or syncope, are generally managed with pacemakers (see also Chapters 45 to 47). However, chronic bifascicular block (right bundle branch block with a left anterior or posterior hemiblock or left bundle

branch block with combined left anterior and posterior hemiblocks), even when only a first-degree heart block is present, can progress to complete heart block and sudden perioperative death on rare occasion. In 6 studies, less than 2% of the approximately 266 patients with bifascicular block progressed to complete heart block perioperatively.[199] Conversely, these patients have a high 5-year mortality rate (160 of 554 patients, or 29%). Most of the deaths were related to tachyarrhythmias or MI—events not usually preventable by traditional pacemakers.[200] Thus, the presence of a bifascicular block on the ECG should make the anesthesiologist more worried about associated CAD or left ventricular dysfunction. Nevertheless, these patients rarely have complete heart block perioperatively. Therefore, prophylactic preoperative insertion of temporary pacing wires for bifascicular block does not seem warranted. However, a central route can be established in advance in the event that a temporary pacemaker needs to be inserted (most operating rooms do not rely on transthoracic pacing, although it may be attempted if available).[201] The actual pacemaker equipment and appropriate personnel should be immediately available, and the equipment should be tested regularly, because symptomatic heart block does occur perioperatively in more than 1% of patients. One study appears to have confirmed this rate of at least 1% for patients undergoing cardiac surgery.[202] One percent of patients in whom a pacing pulmonary artery catheter was not inserted preoperatively subsequently required pacing before cardiopulmonary bypass. By contrast, 19% of patients who had such a catheter in place underwent cardiac pacing before cardiopulmonary bypass. Predictors of the need for pacing included previous symptomatic bradyarrhythmia, a history of transient complete AV block, and aortic valve disease.

Older studies demonstrated that a rate of more than five PVCs per minute on preoperative examination correlates with perioperative cardiac morbidity.[146,153-155] To the classic criteria for treating PVCs (the presence of R-on-T couplets, the occurrence of more than three PVCs per minute, and multifocality of PVCs) must be added frequent (>10/hour over a 24-hour period) and repetitive ventricular beats. Electrophysiologic and programmed ventricular stimulation studies are being used to indicate and guide treatment of patients with ischemic heart disease or recurrent arrhythmias and survivors of out-of-hospital cardiac arrest. Although such patients are often treated with antiarrhythmic therapy, attention to their underlying condition should be a focus of our preoperative management. Long-term antiarrhythmic therapy is discussed in the last section of this chapter, on drug therapy. Torsades de pointes is an arrhythmia characterized by episodes of alternating electrical polarity such that the major vector of the QRS complex seems to alternate around an isoelectric line. The hallmark enabling differential diagnosis from ventricular tachycardia is the unusual response of this arrhythmia to commonly used antiarrhythmic drugs. In other words, the use of drugs that prolong the QT interval (e.g., quinidine, procainamide, disopyramide, some of the antihistamines, and the antipsychotic phenothiazines) may well make the arrhythmia more frequent or of longer duration. Reports of the sudden occurrence of torsades de pointes during surgical procedures have been rare in the anesthesia literature. Immediate therapy consists of the administration of magnesium or electrical cardioversion, followed by overdrive cardiac pacing or the administration of β-adrenergic agonists and discontinuation of drugs that prolong the QT interval.

Premature atrial contractions and cardiac rhythm other than sinus also correlate with perioperative cardiac morbidity.[146,154] These arrhythmias may be more a marker of poor cardiovascular reserve than a specific cause of perioperative cardiac complications.

Preexcitation syndrome is the name for supraventricular tachycardias associated with AV bypass tracts.[203]

Successful treatment, which is predicated on an understanding of the clinical and electrophysiologic manifestations of the syndrome, consists of either catheter ablation techniques[200] or surgery using preoperative and intraoperative techniques that avoid release of sympathetic and other vasoactive substances and therefore tachyarrhythmias.[204,205] Anesthesia for electrophysiologic procedures is discussed in Chapter 68.

DISORDERS OF THE RESPIRATORY AND IMMUNE SYSTEMS

GENERAL PREOPERATIVE AND PREPROCEDURE CONSIDERATIONS

Pulmonary complications after procedures requiring anesthesia are as common as cardiovascular complications—even more common if deep vein thrombosis is included. Moreover, pulmonary complications are equally important or more important to the patient and the health system in terms of morbidity, mortality, length-of-stay extension, and cost.

Although little may seem to have changed in the preoperative preparation of patients with respiratory disease, this impression is not true. Major changes in drug therapy have occurred, and appreciation of the effects of smoking and sleep apnea on perioperative and long-term care has increased.[206-223] (Preoperative and preprocedure identification and perioperative care of patients with sleep apnea are discussed in the earlier section on obesity and in Chapter 71.)

The main purpose of preoperative testing is to identify patients at risk for perioperative complications so that appropriate perioperative therapy can be instituted to foster return to functional status. Preoperative assessment can also establish baseline function and the feasibility of surgical intervention. Whereas numerous investigators have used pulmonary function tests to define inoperability or high-risk versus low-risk groups for pulmonary complications, few have been able to demonstrate that the performance of any specific preoperative or intraoperative measure, except perhaps smoking cessation and physical activity such as a walking program, reliably decreases perioperative pulmonary morbidity or mortality. Because routine preoperative pulmonary testing and care are discussed extensively in Chapter 51, the current discussion is limited to an assessment of the effectiveness of this type of care.

In fact, few randomized prospective studies indicate an outcome benefit of preoperative preparation. Stein and Cassara randomly allocated 48 patients to undergo preoperative therapy (cessation of smoking, administration of antibiotics for purulent sputum, and use of bronchodilating drugs, postural drainage, chest physiotherapy, and ultrasonic nebulizer) or no preoperative therapy.[219] The no-treatment group had a mortality of 16% and morbidity of 60%, as opposed to 0% and 20%, respectively, for the treatment group. In addition, the treatment group spent an average of 12 postoperative days in the hospital as compared with 24 days for the 21 survivors in the no-treatment group.

Collins and colleagues prospectively examined the benefits of preoperative antibiotics, perioperative chest physiotherapy and therapy with bronchodilating drugs, and routine postoperative analgesia (morphine) on postoperative respiratory complications in patients with COPD.[224] Of these therapies, only preoperative treatment with antibiotics had a beneficial effect.

Hulzebos and colleagues performed a single-center randomized trial of intensive inspiratory muscle training.[225] Preoperative inspiratory muscle training reduced the incidence of postoperative pulmonary complications and the duration of postoperative hospitalization in patients at high risk of developing a pulmonary complication who were undergoing CABG surgery.

Warner and co-workers collected data retrospectively about smoking history and prospectively (concurrently) about pulmonary complications for 200 patients undergoing CABG.[226] These investigators documented that 8 weeks or more of smoking cessation was associated with a 66% reduction in postoperative pulmonary complications. Smokers who stopped for less than 8 weeks actually had an increase (from 33% for current smokers to 57.1% for recent quitters) in the rate of 1 or more of the 6 complications surveyed: purulent sputum with pyrexia; need for respiratory therapy care; bronchospasm requiring therapy; pleural effusion or pneumothorax (or both) necessitating drainage; segmental pulmonary collapse, as confirmed by radiography; or pneumonia necessitating antibiotic therapy. Other investigators have found that both shorter and longer periods of cessation of smoking were needed before achieving cardiovascular[227] and hematologic benefit.[228] Bluman and associates performed a retrospective chart review of 410 patients undergoing noncardiac surgery at a VA hospital.[229] Current smoking was associated with a nearly 6-fold increase in the risk of a postoperative pulmonary complication. Reduction in smoking within 1 month of surgery was not associated with a decreased risk for postoperative pulmonary complications. Nakagawa and coauthors also reported higher pulmonary complication rates in patients undergoing pulmonary surgery who quit within 4 weeks of surgery than in current smokers or those who had stopped smoking for more than 4 weeks.[230] Wong and colleagues performed a systematic review of 25 studies of smoking cessation.[231] At least 4 weeks of abstinence from smoking reduced respiratory complications, and abstinence of at least 3 to 4 weeks reduced wound healing complications. Short-term (<4 weeks) smoking cessation did not appear to increase or reduce the risk of postoperative respiratory complications.

Two randomized trials focused on smoking cessation. Wong and colleagues performed a prospective, multicenter, double-blind, placebo-controlled trial, in which 286 patients were randomized to receive varenicline or placebo.[232] A perioperative smoking cessation intervention with varenicline increased abstinence from smoking 3, 6, and 12 months after elective noncardiac surgery with no increase in serious adverse events. Lee and colleagues randomized patients to a group receiving no specific smoking cessation intervention or to an intervention group that received (1) brief counseling by the preadmission nurse, (2) brochures on smoking cessation, (3) referral to the Canadian Cancer Society's Smokers' Helpline, and (4) a free 6-week supply of transdermal nicotine replacement therapy.[233] All outcome assessors and caregivers

on the operative day were blinded to group assignment. Smoking cessation occurred in 12 patients (14.3%) in the intervention group as compared with 3 patients (3.6%) in the control group (relative risk, 4.0; 95% CI, 1.2 to 13.7; $P = .03$). The overall rate of combined intraoperative and immediate postoperative complications was not significantly different between intervention and control groups. At follow-up 30 days postoperatively, smoking cessation was reported in 22 patients (28.6%) in the intervention group compared with 8 patients (11%) in controls (relative risk, 2.6; 95% CI, 1.2 to 5.5; $P = .008$).

When Skolnick and co-workers studied 602 children prospectively, exposure to passive smoking (as measured by urinary cotinine, the major metabolite of nicotine) correlated directly with airway complications. Children with the least exposure to passive smoke had the fewest complications.[217] Second-hand smoke may be a model for particulate air pollution with PM 2.5 particles, which have immediate and long-term effects in increasing lung dysfunction and inflammatory stimuli throughout the body.[234,235] In this sense, reducing particulate and diesel exhaust exposure in the 2 weeks before surgical procedures may make sense, but such a hypothesis has not been tested (and outpatient surgery centers located next to busy freeways may prove to be appropriate sites for studying such subtle inhibition of healing secondary to diesel particles).

Celli and associates performed a randomized prospective controlled trial of intermittent positive-pressure breathing (IPPB) versus incentive spirometry and deep-breathing exercises in 81 patients undergoing abdominal surgery.[236] The groups exposed to a respiratory therapist (regardless of the treatment given) had more than a 50% lower incidence of clinical complications (30% to 33% versus 88%) and shorter hospital stays than did the control group. Thus, this third prospective study indicates that outcome improves when any concern about lung function is shown by someone knowledgeable in maneuvers designed to clear lung secretions.

Bartlett and co-workers randomly assigned 150 patients undergoing extensive laparotomy to 1 of 2 groups.[237] One group received preoperative instruction in and postoperative use of incentive spirometry (10 times/hour). The other group received similar medical care but no incentive spirometry. Only 7 of 75 patients using incentive spirometry had postoperative pulmonary complications, as opposed to 19 of 75 in the control group. However, other studies have not shown a benefit for specific treatments or have been too contaminated with bias to have a clear result emerge. Lyager and colleagues randomly assigned 103 patients undergoing biliary or gastric surgery to receive either incentive spirometry with preoperative and postoperative chest physiotherapy or only preoperative and postoperative chest physiotherapy.[238] No difference in the postoperative course or pulmonary complications was found between the groups. Other studies have shown a specific benefit (i.e., greater than that provided by routine care) for chest physiotherapy and IPPB. These studies are usually poorly controlled, not randomized, or retrospective in design (or any combination); these deficiencies probably substantially bias the results toward finding a benefit in reducing postoperative pulmonary complications. Although randomized prospective studies showed no benefit or actual harm from chest physiotherapy and IPPB on the resolution of pneumonia or postoperative pulmonary complications, the studies cited earlier[219,224,236,237] and numerous retrospective studies strongly suggest that preoperative evaluation and treatment of patients with pulmonary disease actually decrease perioperative respiratory complications, even if only by causing a change in anesthetic techniques.

Meta-analyses have suggested a benefit of anesthetic and pain management with respect to respiratory outcomes. Rodgers and associates reviewed 141 trials involving 9559 patients who had been randomized to receive neuraxial blockade or general anesthesia. Overall mortality was significantly less frequent in the neuraxial blockade group (2.1% versus 3.1%) (see also Chapter 56). The relative risk of pneumonia in the neuraxial blockade group was 0.61 (CI, 0.48 to 0.81), and the relative risk of respiratory depression was 0.41 (CI, 0.23 to 0.73).[218] Neuman and colleagues examined a retrospective cohort of 18,158 patients undergoing surgery for hip fracture in 126 hospitals in New York in 2007 and 2008.[239] Patients receiving regional anesthesia experienced fewer pulmonary complications (359 [6.8%] versus 1040 [8.1%]; $P < .005$). Regional anesthesia was associated with a lower adjusted odds of mortality (OR, 0.710; 95% CI, 0.541, 0.932; $P = .014$) and pulmonary complications (OR, 0.752; 95% CI, 0.637, 0.887; $P < .0001$) relative to general anesthesia. In subgroup analyses, regional anesthesia was associated with improved survival and fewer pulmonary complications among patients with intertrochanteric fractures but not among patients with femoral neck fractures (see also Chapter 56).

Not all studies demonstrate beneficial effects of pharmacologic pretreatment. In afebrile outpatient American Society of Anesthesiologists (ASA) class I and II children with no lung disease or findings who underwent noncavitary, nonairway surgery lasting less than 3 hours, neither albuterol nor ipratropium premedication decreased adverse events (see also Chapter 94).[240]

Evaluation of dyspnea is especially useful (see also Chapter 96). Boushy and co-workers found that grades of preoperative dyspnea correlated with postoperative survival.[241] (Grades of respiratory dyspnea are provided in Table 39-9.) Mittman demonstrated an increased risk of

TABLE 39-9 GRADE OF DYSPNEA CAUSED BY RESPIRATORY PROBLEMS (ASSESSED IN TERMS OF WALKING ON A LEVEL SURFACE AT A NORMAL PACE)

Category	Description
0	No dyspnea while walking on a level surface at a normal pace
I	"I am able to walk as far as I like, provided I take my time"
II	Specific (street) block limitation ("I have to stop for a while after one or two blocks")
III	Dyspnea on mild exertion ("I have to stop and rest while going from the kitchen to the bathroom")
IV	Dyspnea at rest

death after thoracic surgery, from 8% in patients without dyspnea to 56% in patients who were dyspneic.[242] Similarly, Reichel found that no patients died after pneumonectomy if they were able to complete a preoperative treadmill test for 4 minutes at the rate of 2 mph on level ground.[243] Other studies have found that the history and physical examination of an asthmatic subject can also predict the need for hospitalization.[208] Wong and colleagues found that the risk index correlated with postoperative pulmonary complications (Table 39-10).[244]

Arozullah and associates developed the first validated multifactorial risk index for postoperative respiratory failure, defined as mechanical ventilation for more than 48 hours after surgical procedures or reintubation and mechanical ventilation after postoperative extubation.[245] In a prospective cohort study of 181,000 male veterans as part of the National Veterans Administration Surgical Quality Improvement Program, 7 factors independently predicted risk (Table 39-11). With increasing numbers of risk factors present, the rate of complications increased from 0.5% (class 1) to 26.6% (class 4). Arozullah and colleagues subsequently developed a risk index for postoperative pneumonia by using data on 160,805 patients undergoing major noncardiac surgery and validated the index by using data on an additional 155,266 patients.[246] Patients were divided into 5 risk classes by using risk index scores (Table 39-12). Pneumonia rates were 0.2% in patients with 0 to 15 risk points, 1.2% in those with 16 to 25 risk points, 4.0% in those with 26 to 40 risk points, 9.4% in those with 41 to 55 risk points, and 15.3% in those with more than 55 risk points.

Gupta and colleagues used the American College of Surgeons NSQIP to develop a risk model for postoperative respiratory failure.[168] On multivariate logistic regression analysis, five preoperative predictors of postoperative respiratory failure were identified: type of surgery, emergency case, dependent functional status, preoperative sepsis, and higher ASA class (Table 39-13).

SPECIFIC DISEASES

Pulmonary Vascular Diseases

Pulmonary vascular diseases include pulmonary hypertension secondary to heart disease (postcapillary disorders), parenchymal lung disease (pulmonary precapillary disorders), pulmonary embolism, and cor pulmonale from COPD.[247] Optimal preoperative management of these conditions requires treatment of the underlying disease.[247-249] Because pulmonary embolism can be particularly difficult to diagnose, it is crucial to be especially alert to the possibility of this disease. The clinical findings of pulmonary emboli are not always present or specific for the diagnosis. The history may include tachypnea, dyspnea, palpitations,

syncope, chest pain, or hemoptysis. Physical examination can reveal a pleural rub, wheezing, rales, a fixed and split second heart sound, right ventricular lift, or evidence of venous thrombosis, none of which are present in most patients. If the ECG shows an S_1Q_3 pattern, spiral CT or lung perfusion scans can be obtained to rule out the diagnosis of pulmonary emboli. A high degree of suspicion is necessary to warrant angiography and anticoagulation or fibrinolytic therapy. If possible, the reactivity of the pulmonary vasculature should be determined because it may be enhanced or decreased by such drugs as nifedipine, hydralazine, nitroglycerin, prazosin, tolazoline, phentolamine, sildenafil citrate, and nitric oxide. Monitoring of pulmonary artery pressure is often required. Preoperative measures should be undertaken to ensure that the patient is not exposed to conditions that elevate pulmonary vascular resistance (e.g., hypoxia, hypercapnia, acidosis, lung hyperinflation, hypothermia)[250] or that decrease blood volume (prolonged restriction of fluid intake) or systemic vascular resistance.

Infectious Diseases of the Lung

Preoperative evaluation and treatment should follow the basic guidelines outlined in the introduction to this section and in Chapter 38. Treatment of the underlying disease should be completed before all but emergency surgery is performed.

Even though elective surgery should be postponed whenever infectious diseases of the lung are present, patients undergoing emergency surgery often have nosocomial infections and immunocompromised systems. The predominant pathogens for nosocomial pneumonia are gram-negative bacilli, *Staphylococcus aureus*, *Haemophilus influenzae*, anaerobes, and pneumococci. Furthermore,

BOX 39-4 *Procedures for Correct Use of a Metered-Dose Inhaler*

Remove the cap and hold the inhaler upright.
Shake the inhaler.
Tilt the head back slightly and exhale steadily to functional residual capacity.
Position the inhaler by using a spacer between the actuator and the mouth.
Press down on the inhaler while taking a slow, deep breath (3 to 5 seconds).
Hold the full inspiration for at least 5 and up to 10 seconds, if possible, to allow the medication to reach deeply into the lungs.
Repeat inhalations as directed. Waiting 1 minute after inhalation of the bronchodilator may permit subsequent inhalations to penetrate more deeply into the lungs and is necessary to ensure proper delivery of the dose. Rinse your mouth and expectorate after using the inhaler.

the incidence of tuberculosis increased rapidly in the late 1980s and in the 1990s, probably because of reactivation in patients infected with HIV. Increased funding and directly observed antituberculosis therapy have more than offset immigrant and travel risk to cause the incidence of tuberculosis to decrease. Tuberculosis leads to chronic pulmonary and systemic symptoms. Affected patients may have malaise, headache, fever, hemoptysis, and extrapulmonary diseases affecting the skin, cervical lymph nodes, kidneys, pericardium, and meninges. Active disease is treated with four-drug therapy: isoniazid, pyrazinamide, ethambutol or streptomycin, and rifampin for 9 months. Therapy should probably be started preoperatively. Management of these emergency patients (many of whom have adult respiratory distress syndrome [ARDS]) before they are brought to the operating room may include initiation of antiinfective therapy, optimization of fluid status and gas exchange, and therapy for the underlying pathophysiologic process.

Chronic Diseases of the Lung

Treatment of COPD (reactive airways) may include the use of β-adrenergic drugs, parasympatholytic agents (especially for exercise-induced asthma), systemic or inhaled corticosteroids, and leukotriene antagonists. An estimated 5% of the population has bronchospasm. Some investigators recommend using inhaled bronchodilators as first-line drugs and reducing the dose of inhaled steroids, such as beclomethasone dipropionate, budesonide, mometasone, and fluticasone, which are inactivated after absorption. However, in large doses, these "inhaled" steroids can suppress adrenal function, and supplemental systemic corticosteroids may be needed at times of stress (see the earlier discussion in the section on adrenocortical malfunction). Preoperative assessment must include gaining knowledge of drug regimens and their effects and education of the patient regarding proper use of an inhaler (Box 39-4), given that these drugs can interact dangerously with anesthetics (see the last section of this chapter) or can be used inappropriately and therefore produce side effects without maximum benefit.[206-216] No known interaction between the inhaled anticholinergic ipratropium bromide and muscle relaxants has been reported. Patients can feel fine at rest but must be tested by exercise or spirometry to document the degree of current bronchospasm. Furthermore, a symptomatic response to bronchodilators in an asymptomatic patient may not predict whether the patient will respond to bronchodilator therapy. An estimated 10% of asthmatic patients exhibit sensitivity to aspirin and may react not only to compounds containing aspirin but also to tartrazine, yellow dye number 5, indomethacin, other nonsteroidal antiinflammatory drugs, and aminopyrine.[251]

Cystic fibrosis is characterized by dilatation and hypertrophy of the bronchial glands, mucous plugging of the peripheral airways, and frequently, bronchitis, bronchiectasis, and bronchiolectasis. For all these conditions, the measures recommended earlier in this section, as well as appropriate hydration to allow mobilization of secretions, constitute optimal preprocedure therapy.

Surgical resection is the primary therapy for non–small cell carcinomas (e.g., adenocarcinoma, squamous cell carcinoma, and large cell carcinoma). These carcinomas account for 75% of all lung carcinomas, 12% of all malignant tumors, and 20% of all cancer deaths in the United States.[252] Success of surgery can be predicted by the stage of the tumor.

The combination of chemotherapy and radiation therapy is the current treatment of choice for small cell carcinomas of the lung.[253] Oat cell (small cell) carcinoma of the lung and bronchial adenomas are known for their secretion of endocrinologically active substances, such as ACTH-like hormones. Squamous cell cancers in the superior pulmonary sulcus produce Horner syndrome, as well as characteristic pain in areas served by the eighth cervical nerves and first and second thoracic nerves. These tumors are now treated with preoperative radiation; surgical resection leads to an almost 30% "cure" rate.

Anaphylaxis, Anaphylactoid Responses, and Allergic Disorders Other Than Those Related to Lung Diseases and Asthma

Anaphylactic and Anaphylactoid Reactions. Anaphylaxis is a severe life-threatening allergic reaction. *Allergic* applies to immunologically mediated reactions, as opposed to those caused by pharmacologic idiosyncrasy, by direct toxicity or drug overdosage, or by drug interaction.[254-256] Anaphylaxis is the typical immediate hypersensitivity reaction (type I). Such reactions are produced by immunoglobulin E (IgE)–mediated release of pharmacologically active substances. These mediators in turn produce specific end-organ responses in the skin (urticaria), the respiratory system (bronchospasm and upper airway edema), and the cardiovascular system (vasodilation, changes in inotropy, and increased capillary permeability). Vasodilation occurs at the level of the capillary and postcapillary venule and leads to erythema, edema, and smooth muscle contraction. This clinical syndrome is called *anaphylaxis*. By contrast, an *anaphylactoid reaction* denotes an identical or very similar clinical response that is not mediated by IgE or (usually) an antigen-antibody process.[255,256]

In anaphylactic reactions, an injected or inhaled (or ingested) substance—usually drugs, food, or insect venom—can serve as the allergen itself. Low-molecular-weight agents are believed to act as haptens that form

immunologic conjugates with host proteins. The offending substance, regardless of whether it is a hapten, may be the parent compound, a nonenzymatically generated product, or a metabolic product formed in the patient's body. When an allergen binds immunospecific IgE antibodies on the surface of mast cells and basophils, histamine and eosinophilic chemotactic factors of anaphylaxis are released from storage granules in a calcium- and energy-dependent process.[255,256] Other chemical mediators are rapidly synthesized and are subsequently released in response to cellular activation. These mediators include the following: slow-reacting substance of anaphylaxis, which is a combination of three leukotrienes; other leukotrienes[255,256]; kinins; platelet-activating factors; adenosine; chemotactic factors; heparin; tryptase; chymase; and prostaglandins, including the potent bronchoconstrictor prostaglandin D_2; eosinophil growth and activating factors; mast cell growth factors; and proinflammatory and other factors that contribute to the IgE isotype switch.

The end-organ effects of the mediators produce the clinical syndrome of anaphylaxis. Usually, a first wave of symptoms, including those caused by vasodilation and a feeling of impending doom, is quickly followed by a second wave as the cascade of mediators amplifies the reactions. In a sensitized patient, onset of the signs and symptoms caused by these mediators is usually immediate but may be delayed 2 to 15 minutes or, in rare instances, as long as 2.5 hours after the parenteral injection of antigen.[257,258] After oral administration, manifestations may occur at unpredictable times.

Mast cell proliferation, together with severe progressive inflammation, contributes to the worsening of symptoms that occurs even after an allergen load is no longer present. The antigen present in cells and lymphocytes, as well as activated mast cells, starts to induce the production of cytokines. These proinflammatory cytokines recruit more inflammatory cells, a process that leads to tissue edema and mediates a second wave of mast cell degranulation. This second wave can promote the recurrence of severe symptoms 6 to 8 hours later and necessitates, some believe, at least 8 hours of continued ICU-like observation.

In addition, biologically active mediators can be generated by multiple effector processes to produce an anaphylactoid reaction. Activation of the blood coagulation and fibrinolytic systems, the kinin-generating sequence, or the complement cascade can produce the same inflammatory substances that result in an anaphylactic reaction. The two mechanisms known to activate the complement system are called classical and alternative. The classical pathway can be initiated through IgG or IgM (transfusion reactions) or plasmin. The alternative pathway can be activated by lipopolysaccharides (endotoxin), drugs (Althesin), radiographic contrast media,[259] membranes (nylon tricot membranes for bubble oxygenators), cellophane membranes of dialyzers, vascular graft material,[260] latex or latex-containing products,[261,262] and perfluorocarbon artificial blood. The most common drugs responsible for intraoperative anaphylaxis are muscle relaxants (see also Chapters 34 and 35).[262] In addition, one of the primary concerns regarding the delayed approval of sugammadex in the United States has been "hypersensitivity reactions," which includes anaphylaxis. However, latex accounts for a significant number of these reactions, and the incidence of intraoperative anaphylaxis caused by latex is increasing. It is now probably the second most important cause of intraoperative anaphylaxis. In addition, histamine can be liberated independent of immunologic reactions.[263] Mast cells and basophils release histamine in response to chemicals or drugs. Most narcotics can release histamine,[263] and they can produce an anaphylactoid reaction, as can radiographic contrast media,[259] *d*-tubocurarine, and thiopental. What makes some patients susceptible to release of histamine in response to drugs is unknown, but hereditary and environmental factors may play a role.

Intravenous contrast material is probably the most frequently used agent that causes anaphylactoid reactions. Because diagnostic (skin and other) tests are helpful only in IgE-mediated reactions, pretesting is not useful for contrast reactions. Pretreatment with diphenhydramine, cimetidine (or ranitidine), and corticosteroids has been reported to be useful in preventing or ameliorating anaphylactoid reactions to intravenous contrast material,[259,264] as well as perhaps to narcotics. Unfortunately, very large doses of steroids (1 g of methylprednisolone intravenously) may be necessary to obtain a beneficial effect.[265] The efficacy of large-dose steroid therapy has not been confirmed. Other common substances associated with anaphylactic or anaphylactoid reactions that may merit preoperative therapy include antibiotics, intravascular volume expanders, and blood products (see also Chapters 61 and 62).[255] The anesthesiologist should always be prepared perioperatively to treat an anaphylactic or anaphylactoid response.

In some cases, a patient with a history of an anaphylactic or anaphylactoid reaction must receive a substance suspected of producing such a reaction (e.g., iodinated contrast material). In addition, some patients have a higher than average likelihood of having a reaction, thus warranting well-planned pretreatment and therapy for possible anaphylactic and anaphylactoid reactions.[259]

Minimizing Risks Preoperatively. Although virtually all evidence on this subject is merely anecdotal, enough consistent thought recurs through the literature to justify proposing an optimal approach to these problems. First, predisposing factors should be sought; patients with a history of atopy or allergic rhinitis should be suspected of being at risk. Because anaphylactic and anaphylactoid reactions to contrast media occur 5 to 10 times more frequently in patients with a previously suspected reaction, consideration should be given to the administration of low-osmotic agents and both H_1- and H_2-receptor antagonists for 16 to 24 hours before exposing these patients to a suspected allergen. H_1-receptor antagonists appear to require this much time to act on the receptor. Volume status can be optimized,[255] and perhaps large doses of steroids (1 g of hydrocortisone) should also be administered before exposing patients to agents associated with a high incidence of anaphylactic or anaphylactoid reactions.[265] Older patients and patients taking β-adrenergic blocking drugs present special problems; they are at higher risk of having complications from both pretreatment (especially vigorous hydration) and therapy for anaphylactic reactions

(glucagon is useful here) and are less responsive to treatment regimens.[266] One approach is to avoid drugs likely to trigger anaphylactic or anaphylactoid reactions or alter the treatment protocol for this group. Drawing blood for later analysis, especially of tryptase, can be useful in clarifying the diagnosis.[267]

With the increasing incidence of latex hypersensitivity, attempts have been made to make much of the operating room environment latex free; however, costs and preferences have resulted in the continued use of latex-containing gloves in many hospitals. Nonetheless, more hospitals are totally latex free. In allergic patients, care should be taken to ensure that no latex-containing products are present in the operating room.

Primary Immunodeficiency Diseases

Primary immunodeficiency diseases usually manifest early in life as recurrent infections. Along with survival achieved with antibiotic and antibody treatment have come new prominent features: cancer and allergic and autoimmune disorders. Hereditary angioneurotic edema is an autosomal dominant genetic disease characterized by episodes of angioneurotic edema involving the subcutaneous tissues and submucosa of the GI tract and airway and often manifested as abdominal pain. These patients have a functionally impotent inhibitor or deficiency of an inhibitor to complement component C1. Treatment of an acute attack is supportive because epinephrine, antihistamines, and corticosteroids often fail to work. Plasma transfusions have been reported to resolve attacks or make them worse (theoretically by supplying either C1 esterase inhibitor or previously depleted complement components). The severity of attacks can be prevented or decreased by drugs that are either plasmin inhibitors (e.g., ε-aminocaproic acid [EACA] and tranexamic acid) or androgens (e.g., danazol). Because trauma can precipitate acute attacks, prophylactic therapy with danazol, intravenous EACA, plasma, or all three is recommended before elective surgery. A partially purified C1 esterase inhibitor has been used in two patients.

Most of the 1 in 700 persons who have selective IgA deficiency (i.e., <5 mg/dL) have repeated serious infections or connective tissue disorders. These infections commonly involve the respiratory tract (e.g., sinusitis, otitis) or GI tract (manifested as diarrhea, malabsorption, or both). If the patient has rheumatoid arthritis, Sjögren syndrome, or systemic lupus erythematosus, the anesthetist should consider the possibility of isolated IgA deficiency. However, patients with this disorder can be otherwise healthy. Because antibodies to IgA may develop in these patients if they were previously exposed to IgA (as could occur from a previous blood transfusion), subsequent blood transfusions can cause anaphylaxis, even when they contain washed erythrocytes. Transfusions should therefore consist of blood donated by another IgA-deficient patient.

Many immunomodulators are now being given to augment cancer treatments[268]; no interactions among these modulators, no effects on the incidence of immune reactions during anesthesia, and no interactions with anesthetic effects have been reported except those regarding immunosuppressant drugs (see the last section of this chapter).

Immunonutrition is increasingly being used preprocedurally by patients and prescribed by providers to decrease inflammatory responses.[261] Whereas excellent data on the benefits of probiotics in changing the intestinal milieu to decrease inflammation can be found, limited data are available on their effects on periprocedural recovery or outcomes.

DISEASES OF THE CENTRAL NERVOUS SYSTEM, NEUROMUSCULAR DISEASES, AND PSYCHIATRIC DISORDERS

Evaluation of a patient with neurologic or psychiatric disease can be found in Chapter 38. Information gathered from the history that warrants further investigation includes a previous need for postoperative ventilation in a patient without inordinate lung disease, which indicates the possibility of metabolic neurologic disorders such as porphyria, alcoholic myopathy, other myopathies, neuropathies, and neuromuscular disorders such as myasthenia gravis. Other historical information warranting further investigation includes the use of drugs such as the following: steroids; guanidine; anticonvulsant, anticoagulant, and antiplatelet drugs; lithium; tricyclic antidepressants; phenothiazines; and butyrophenones.

Although preoperative treatment of most neurologic disorders may not lessen perioperative morbidity, knowledge of the pathophysiologic characteristics of these disorders is important in planning intraoperative and postoperative management. Thus, preoperative knowledge about these disorders and their associated conditions (e.g., cardiac arrhythmias with Duchenne muscular dystrophy or respiratory and cardiac muscle weakness with dermatomyositis) may reduce perioperative morbidity. A primary goal of neurologic evaluation is to determine the site of the lesion in the nervous system. Such localization to one of four levels (supratentorial compartment, posterior fossa, spinal cord, peripheral nervous system) is essential for accurate diagnosis and appropriate management. (Disorders accompanied by increased intracranial pressure and cerebrovascular disorders are discussed in Chapters 17 and 70.)

COMA

Little is known about specific anesthetic or perioperative or periprocedural choices that alter outcome for a comatose patient, but as for all other conditions, the cause of the coma should be known so that drugs can be avoided that may worsen the condition or that may not be metabolized because of organ dysfunction (see also Chapters 96 and 101). First, the patient should be observed. Yawning, swallowing, or licking of the lips implies a "light" coma with major brainstem function intact. If consciousness is depressed but respiration, pupillary reactivity to light, and eye movements are normal and no focal motor signs are present, metabolic depression is likely. Abnormal pupillary responses may indicate hypoxia, hypothermia, local eye disease, or drug intoxication with belladonna alkaloids, narcotics, benzodiazepines, or glutethimide; pupillary responses may also be abnormal, however, after the

use of eye drops. Other metabolic causes of coma include uremia, hypoglycemia, hepatic coma, alcohol ingestion, hypophosphatemia, myxedema, and hyperosmolar nonketotic coma. Except in extreme emergencies, such as uncontrolled bleeding or a perforated viscus, care should be taken to render the patient as metabolically normal as possible before the surgical procedure. This practice and documenting the findings on the chart preoperatively lessen any confusion regarding the cause of intraoperative and postoperative problems. However, too rapid correction of uremia or hyperosmolar nonketotic coma can lead to cerebral edema, a shift of water into the brain as a result of a reverse osmotic effect caused by dysequilibrium of the urea concentration.

The physical examination can be extremely helpful preoperatively in assessing the prognosis. Arms flexed at the elbow (i.e., decorticate posture) imply bilateral hemisphere dysfunction but an intact brainstem, whereas extension of the legs and arms (bilateral decerebrate posture) implies bilateral damage to structures at the upper brainstem or deep hemisphere level. Seizures are often seen in patients with uremia and other metabolic encephalopathies. Hyperreflexia and upward-pointing toes suggest a structural CNS lesion or uremia, hypoglycemia, or hepatic coma; hyporeflexia and downward-pointing toes with no hemiplegia generally indicate the absence of a structural CNS lesion.

EPILEPTIC SEIZURES

Epileptic seizures result from paroxysmal neuronal discharges of abnormally excitable neurons. Six percent to 10% of individuals younger than 70 years old will experience a seizure at some time during their lifetime. Fifty percent to 70% of patients with one seizure will never have another. However, 70% of people with two seizures will have an epileptic focus, be candidates for antiseizure medications, and be subject to withdrawal seizures after anesthesia if such medications are not continued.[269] A *seizure* is the term for the clinical event defined as a paroxysmal alteration in neurologic function caused by a synchronous, rhythmic depolarization of brain cortical neurons. *Epilepsy* is the condition manifested by recurrent, unprovoked seizures. Sometimes syncopal episodes can be mistaken for seizures, especially when interviews are compressed in the short time frame of a preoperative visit. Twenty-five percent of patients with a seizure have a normal electroencephalogram (EEG) when they are interictal. Thus, a negative EEG result does not indicate that someone with a seizure will not have a withdrawal seizure when emerging from anesthesia. Seizures can be generalized (arising from deep midline structures in the brainstem or thalamus, usually without an aura or focal features during the seizure), partial focal motor, or sensory (the initial discharge comes from a focal unilateral area of the brain, often preceded by an aura). As with cerebrovascular accidents and coma, knowing the origin may be crucial to understanding the pathophysiologic processes of the disease and to managing the patient's intraoperative and postoperative course.

Epileptic seizures can arise from discontinuation of sedative-hypnotic drugs or alcohol, use of narcotics, uremia, traumatic injury, neoplasms, infection, congenital malformation, birth injury, drug use (e.g., amphetamines, cocaine), hypercalcemia or hypocalcemia, blood in the ventricle or hypoxia, and vascular disease and vascular accidents. Thirty percent of epileptic seizures have no known cause. Most partial seizures are caused by structural brain abnormalities (secondary to tumor, trauma, stroke, infection, and other causes).

An epileptic patient requires no special anesthetic management other than that for the underlying disease. Most authorities believe that anticonvulsant medications should be given in the therapeutic range,[269-271] and they should be continued through the morning of the surgical procedure, even in pregnant women. They should also be given postoperatively, even in mothers who plan to breastfeed, according to guidelines published by the American Academy of Neurology. Many of the epileptic drugs, including phenytoin, carbamazepine, and phenobarbiturate, alter the hepatic metabolism of many drugs and induce cytochrome P450 enzyme activity. Drug-drug interactions are much less problematic with the newer epileptic drugs such as gabapentin and topiramate.[269] Appropriate treatment of status epilepticus may include general anesthesia.[271] In one controlled trial, phenobarbital was more rapidly effective in controlling status epilepticus than was diazepam followed by phenytoin.[271] The frequency of side effects and of required tracheal intubation was similar for both regimens. Thus, other than the use of current drug therapy and heeding precautions taken for the underlying disease, no known changes in perioperative management seem to be indicated.

INFECTIOUS DISEASES OF THE CENTRAL NERVOUS SYSTEM, DEGENERATIVE DISORDERS OF THE CENTRAL NERVOUS SYSTEM, AND HEADACHE

Many degenerative CNS disorders have been traced to slowly developing viral diseases or even the presence of certain proteins or viral particles ("prions"). No special perioperative anesthetic considerations appear to apply for infectious disorders of the CNS other than those for increased intracranial pressure and avoidance of occupational exposure and transmission of disease to health care workers (see also Chapter 110). The appropriate prophylactic measures to take if one comes in contact with meningococcal disease or other infectious CNS diseases are still not well established. The use of *H. influenzae* type b vaccine has made meningitis an adult disease.[272]

Parkinson disease is a degenerative disorder of the CNS that may or may not be caused by a virus (see also Chapters 38 and 80). Clinically, Parkinson disease, chronic manganese intoxication, phenothiazine or butyrophenone toxicity, Wilson disease, Huntington chorea, traumatic boxing injury, the effects of street drug toxins such as methylphenyltetrahydropyridine (MPTP), and carbon monoxide encephalopathy all have similar initial features: bradykinesia, muscular rigidity, and tremor.

Newer therapies have been developed to arrest or even reverse the progression of Parkinson disease. Therapy is directed at (1) increasing the neuronal release of dopamine

or the receptor's response to dopamine, (2) stimulating the receptor directly with bromocriptine and lergotrile, (3) implanting dopaminergic tissue, or (4) decreasing cholinergic activity. Newer therapies using the monoamine oxidase inhibitor (MAOI) deprenyl or adrenal medullary transplants to slow the progression of disease appear promising,[273,274] and even treatment with high-dose coenzyme Q10 seems to be strikingly beneficial.[28] Experience with deprenyl in the perioperative milieu is insufficient to make proscriptions about its use. Anticholinergic agents have been the initial drugs of choice because they decrease tremor more than muscle rigidity. Dopamine does not pass the blood-brain barrier, so its precursor L-dopa (levodopa) is used. Unfortunately, L-dopa is decarboxylated to dopamine in the periphery and can cause nausea, vomiting, and arrhythmia. These side effects are diminished by the administration of α-methylhydrazine (carbidopa), a decarboxylase inhibitor that does not pass the blood-brain barrier. Refractoriness to L-dopa develops, and it is now debated whether the drug should be used only when symptoms cannot be controlled with other anticholinergic medications. "Drug holidays" have been suggested as one means of restoring the effectiveness of these compounds, but cessation of such therapy may result in marked deterioration of function and need for hospitalization. Therapy for Parkinson disease should be initiated preoperatively and be continued through the morning of the surgical procedure; such treatment seems to decrease drooling, the potential for aspiration, and ventilatory weakness.[275,276] Reinstituting therapy promptly after surgery is crucial,[270,273-277] as is avoiding drugs such as the phenothiazines and butyrophenones (droperidol, and perhaps alfentanil), which inhibit the release of dopamine (and perhaps alfentanil) or compete with dopamine at the receptor.[275] Carbidopa or levodopa in low doses (20 to 200 mg nightly versus the usual 60 to 600 mg/day for Parkinson disease) is commonly used in the nonparkinsonian restless leg syndrome of older adults (present in 2% to 5% of individuals >60 years old). This drug also should be given the night before and the night immediately after the surgical procedure. Clozapine (a benzodiazepine) does not appear to worsen the movement disorders of Parkinson disease and has been used postoperatively to stop levodopa-induced hallucinations. Patients with Parkinson disease may also undergo deep brain stimulation under monitored anesthesia care.

Dementia, a progressive decline in intellectual function, can be caused by treatable infections (e.g., syphilis, cryptococcosis, coccidioidomycosis, Lyme disease, tuberculosis), depression (a trial of antidepressants is indicated in most patients), side effects of medications (digitalis has slowed brain function more than the heart rate), myxedema, vitamin B_{12} deficiency, chronic drug or alcohol intoxication, metabolic causes (liver and renal failure), neoplasms, partially treatable infections (HIV), untreatable infections (Creutzfeldt-Jakob syndrome), or decreased acetylcholine in the cerebral cortex (Alzheimer disease). This last condition occurs in more than 0.5% of Americans.[278-281] Although these patients are often given cholinergic agonists, controlled trials of these drugs have not as yet shown major significant benefit.[279,280,282] Gingko has improved subjective symptoms in 37% of patients versus 23% of those given placebo. Although later controlled trials failed to confirm its benefit in early Alzheimer disease or in healthy older individuals, gingko is still popular. However, the prevalence of Alzheimer disease and the desperation of the patients and their families have now widened such therapies. Cholinergic medications improve functioning in patients with Alzheimer disease.[283] These families often desire surgery, but the interactions of these drugs and therapies with perioperative analgesic and anesthetic drug therapies are not well established. One case report noted intraoperative bradycardia in such patients with two cholinergic drugs.[284] A link may exist among Alzheimer disease, postoperative cognitive dysfunction, and inhaled anesthetics.[285] Deposition of β-amyloid can occur in animals exposed to inhaled anesthetics.[286-288] Whether this link is clinically relevant in humans remains to be determined. Most reversible dementias represent either drug-induced delirium or depression.[279,280,289] At present, early results with stimulation at "threshold testing" are promising and seem to stimulate dendritic regrowth and may reverse some or much of the cognitive decline. Creutzfeldt-Jakob disease has been transmitted inadvertently by surgical instruments and corneal transplants; the causative virus or protein particle is not inactivated by heat, disinfectants, or formaldehyde.

More than 90% of patients with chronic recurring headaches are categorized as having migraine, tension, or cluster headaches. The mechanism of tension or cluster headaches may not differ qualitatively from that of migraine headaches; all may be manifestations of labile vasomotor regulation.[290] A headache is said to be migraine if it is characterized by four of the following five "POUNDing" conditions: if it is Pulsating, if it lasts One day or more, if it is Unilateral, if Nausea occurs, and if it Disturbs daily activities.[291]

Treatment of cluster and migraine headaches centers on the use of serotonin drugs such as sumatriptan or ergotamine and its derivatives.[290-292] Other drugs that may be effective are propranolol, calcium channel inhibitors, cyproheptadine, prednisone, antihistamines, tricyclic antidepressants, phenytoin, and diuretic drugs, as well as biofeedback. Giant cell arteritis, glaucoma, and all the meningitides, including Lyme disease, are other causes of headache that may benefit from preoperative treatment.[293] No other special treatment is indicated preoperatively for a patient who has a well-delineated cause for the headaches. Acute migraine attacks can sometimes be terminated by ergotamine tartrate aerosol or by injection of sumatriptan or dihydroergotamine mesylate intravenously; general anesthesia has also been used. We normally continue all prophylactic headache medicine, although the decision to continue aspirin through the morning of the surgical procedure is usually left to the surgeon.

BACK PAIN, NECK PAIN, AND SPINAL CANAL SYNDROMES

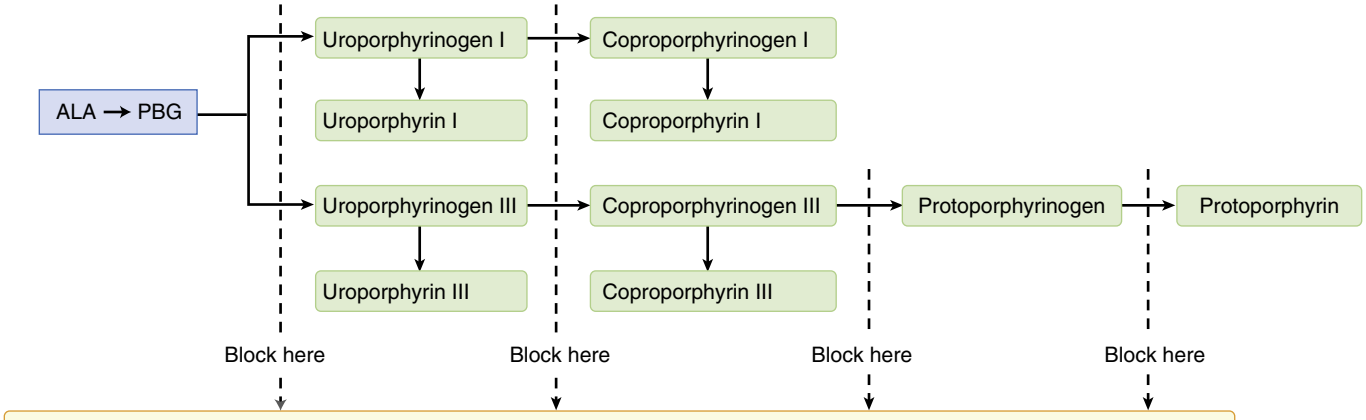
Acute spinal cord injury is discussed earlier in the section on autonomic dysfunction. Although it is a common problem, little is written about the anesthetic

management of syndromes related to herniated disks, spondylosis (usually of advancing age), and the congenital narrowing of the cervical and lumbar spinal canal that gives rise to symptoms of nerve root compression. One report stresses the importance of the vascular component in the mechanism of damage to the spinal cord and hence the theoretic desirability of slight hypertension perioperatively.[294] Another report suggests the use of awake intubation, a fiberoptic bronchoscope, and monitoring of evoked potentials.[295] Other than the commonsense approach of seeking neurologic consultation or, if necessary, using awake positioning of patients in a comfortable position before emergency root decompression procedures, no special procedures appear to be necessary. Patients with back pain may be receiving large doses of narcotics that may influence the anesthetic plan.

DEMYELINATING DISEASES

Demyelinating diseases constitute a diffuse group of diseases ranging from those with uncertain cause (e.g., multiple sclerosis, in which genetic, epidemiologic, and immunologic factors are probably all involved and interferon-β appears to be a promising treatment[296]) to those that follow infection, vaccination (e.g., Guillain-Barré syndrome), or antimetabolite treatment of cancer. Therefore, demyelinating diseases can have very diverse symptoms. Apparently, a risk of relapse of these diseases exists immediately after surgery. Because relapse may occur as a result of rapid electrolyte changes in the perioperative period, such changes may be avoided. In addition, perioperative administration of steroids may be a protective measure.[100] Both spinal anesthesia and epidural anesthesia have been administered without problems.[297,298] Multiple sclerosis and demyelinating diseases in general are the most common causes of nontraumatic disability in young adults. The age-adjusted survival rate is 80% of that of unaffected individuals, or put another way, the average patient with multiple sclerosis ages 1.2 years for every year with the disease. However, the variability of the disease makes this average rate of aging almost meaningless. No treatment alters most of these disease processes, although ACTH, steroids, interferon-β, glatiramer acetate (Copaxone), and plasmapheresis may ameliorate or abbreviate a relapse, or even alter disease progression, especially progression of multiple sclerosis and (if started within 2 weeks of onset) Guillain-Barré syndrome.[299] Such an effect is consonant with the hypothesis of an immunologic disorder as the cause of these diseases. Care should be taken to avoid succinylcholine in these patients because of the risk of hyperkalemia.

METABOLIC DISEASES



Included in the category of metabolic diseases is nervous system dysfunction secondary to porphyrias, alcoholism, uremia, hepatic failure, and vitamin B_{12} deficiency. The periodic paralysis that can accompany thyroid disease is discussed in the later section on neuromuscular disorders.

Alcoholism or heavy alcohol intake is associated with the following: acute alcoholic hepatitis (see also Chapter 73), the activity of which declines as alcohol is withdrawn; myopathy and cardiomyopathy, which can be severe; and withdrawal syndromes. Within 6 to 8 hours of withdrawal, the patient may become tremulous, a state that usually subsides within days or weeks. Alcoholic hallucinosis and withdrawal seizures generally occur within 24 to 36 hours. These seizures are generalized grand mal attacks; when focal seizures occur, other causes should be sought. Delirium tremens usually appears within 72 hours of withdrawal and is often preceded by tremulousness, hallucinations, or seizures. These three symptoms, combined with perceptual distortions, insomnia, psychomotor disturbances, autonomic hyperactivity, and, in a large percentage of cases, another potentially fatal illness (e.g., bowel infarction or subdural hematoma), are components of delirium tremens. This syndrome is now treated with benzodiazepines. Nutritional disorders of alcoholism include alcoholic hypoglycemia and hypothermia, alcoholic polyneuropathy, Wernicke-Korsakoff syndrome, and cerebellar degeneration. In patients with alcoholism (i.e., those who drink at least two six packs of beer or 1 pint of whiskey/day or the equivalent), emergency surgery and anesthesia (despite alcoholic hepatitis) are not associated with worsening abnormalities in liver enzymes. In addition, approximately 20% of patients with alcoholism also have COPD. A patient who has a history of alcohol abuse therefore warrants careful examination of many systems for quantification of preoperative physical status.

Although hepatic failure can lead to coma with high-output cardiac failure, unlike uremia, it does not lead to chronic polyneuropathy. Uremic polyneuropathy is a distal symmetric sensorimotor polyneuropathy that may be improved by dialysis. The use of depolarizing muscle relaxants in patients with polyneuropathies has been questioned (see also Chapter 34). We believe that patients who have neuropathy associated with uremia should not be given succinylcholine because of a possible exaggerated hyperkalemic response.

Pernicious anemia caused by vitamin B_{12} deficiency may result in subacute combined degeneration of the spinal cord; the signs are similar to those of chronic nitrous oxide toxicity. Both pernicious anemia and nitrous oxide toxicity are associated with peripheral neuropathy and disorders of the pyramidal tract and posterior column (which governs fine motor skills and the sense of body position). Combined-system disease can also occur without anemia, as can nitrous oxide toxicity in dentists and nitrous oxide abusers. Patients with vitamin B_{12} deficiency and anemia, if treated with folate, improve hematologically but progress to dementia and severe neuropathy. It may thus be prudent to give an intramuscular injection of 100 μg of vitamin B_{12} or 800 μg orally before giving folate to a patient who has signs of combined-system degeneration.[300]

The porphyrias are a constellation of metabolic diseases that result from an autosomally inherited lack of functional enzymes active in the synthesis of hemoglobin. Figure 39-6 schematically depicts the abnormalities that result from these enzyme deficits. Type 1, 3, and 4 porphyrias can cause life-threatening neurologic abnormalities. These conditions are characterized by the presence of aminolevulinic acid (ALA) or porphobilinogen,

Diagnosis:	Acute intermittent porphyria	Porphyria cutanea tarda	Coproporphyria (hereditary porphyria)	Variegate porphyria
In urine:	ALA PBG	Uroporphyrin	ALA PBG	ALA PBG
Neurologic sequelae:	Yes	No	Yes	Yes
Drug sensitization:	Yes	No	Yes	Yes

Figure 39-6. Schematic depiction of the functional enzyme deficits that occur in some of the porphyrias. *ALA,* Aminolevulinic acid; *PBG,* porphobilinogen.

or both, in urine; these substances do not occur in porphyria cutanea tarda, a disease that does not incur neurologic sequelae.[301] In acute intermittent porphyria, the typical pattern consists of acute attacks of colicky pain, nausea, vomiting, severe constipation, psychiatric disorders, and lesions of the lower motoneuron that can progress to bulbar paralysis. Certain drugs can induce the enzyme ALA synthetase and thereby exacerbate the disease process.[302-304] Such sensitizing drugs include barbiturates, meprobamate, chlordiazepoxide, glutethimide, diazepam, hydroxydione, phenytoin, imipramine, pentazocine, birth control pills, ethyl alcohol, sulfonamides, griseofulvin, and ergotamine preparations. Patients often have attacks during infection, fasting, or menstruation. Administration of glucose suppresses ALA synthetase activity and prevents or ablates acute attacks. Drugs used in anesthetic management that are reported to be safe for patients with porphyria include neostigmine (Prostigmin), atropine, gallamine, succinylcholine, *d*-tubocurarine, pancuronium, nitrous oxide, procaine, propofol, propanidid, etomidate, meperidine, fentanyl, morphine, droperidol, promazine, promethazine, and chlorpromazine.[302-304] Although ketamine has been used, postoperative psychoses attributable to the disease may be difficult to distinguish from those possibly caused by ketamine. In addition, although ketamine and etomidate are reported to be safe in humans, they seem to be porphyrinogenic in rats. Propofol has been used without provoking porphyria in at least two susceptible patients.[302,303]

NEUROMUSCULAR DISORDERS

Neuromuscular disorders consist of conditions affecting any major component of the motor unit: motoneuron, peripheral nerve, neuromuscular junction, and muscle. Neuropathies may involve all components of the nerve, thereby producing sensory, motor, and autonomic dysfunction, or only one component. Myopathies may involve the proximal muscles, the distal muscles, or both.

Myasthenia gravis is a disorder of the muscular system caused by partial blockade or destruction of nicotinic acetylcholine receptors by IgG antibodies (see also Chapters 34, 38, and 80). The severity of the disease correlates with the ability of antibodies to decrease the number of available acetylcholine receptors.[305] Treatment of myasthenia is usually begun with anticholinesterase drugs, but in moderate and severe disease, treatment progresses to steroids and thymectomy.[305,306] Immunosuppressive drugs and plasmapheresis are initiated if the more conservative measures fail, and intravenous immunoglobulin, a rapid-onset therapy, is reserved for acute exacerbations and myasthenic crises.[305,306]

One major problem for the anesthesiologist involves the use of muscle relaxants and their reversal[307] (see also Chapter 35). Because much of the care of patients with myasthenia gravis involves tailoring the amount of anticholinesterase medication to the maximal muscle strength of the patient, derangement of the course of the patient during the surgical procedure could necessitate

reassessment of the drug dosage. For that reason, all anticholinergic drugs may be withheld for 6 hours preoperatively, and medication should be reinstituted postoperatively with extreme caution because the sensitivity of these patients to such drugs may have changed. Small doses of succinylcholine can be used to facilitate endotracheal intubation; extremely small doses of nondepolarizing drugs can be used for intraoperative relaxation not achieved by regional anesthesia or volatile anesthetics. Of prime importance is monitoring neuromuscular blockade as the guide for muscle relaxant administration and their reversal (see Chapter 53). Although controlled ventilation was frequently required for at least 24 to 48 hours postoperatively, immediate extubation has become more common.[306-308] Postoperative ventilation is especially important in patients with myasthenia gravis of more than 6 years' duration, COPD, a daily pyridostigmine requirement of 750 mg in association with significant bulbar weakness, and vital capacity of less than 40 mL/kg.[308] One study in myasthenic patients found rapid recovery of neuromuscular function in patients receiving rocuronium when sugammadex was used for reversal.[309] The authors suggest that the combination could be a rational alternative for myasthenic patients for whom neuromuscular blockade is mandatory during surgical procedures.

Lambert-Eaton syndrome (myasthenic syndrome) is characterized by proximal limb muscle weakness and is associated with antibodies directed against the voltage-gated calcium channels in presynaptic nerve terminals. Strength or reflexes may increase with repetitive effort. Affected patients exhibit decreased release of acetylcholine at the neuromuscular junction. Guanidine therapy enhances the release of acetylcholine from nerve terminals and improves strength. Men with this syndrome generally have small cell carcinoma of the lung or other malignant disease, whereas women often have malignant disease, sarcoidosis, thyroiditis, or a collagen-related vascular disease. In addition, these patients have increased sensitivity to both depolarizing and nondepolarizing muscle relaxants.[310] Lambert-Eaton syndrome is also associated with an autonomic nervous system defect manifested by gastroparesis, orthostatic hypotension, and urinary retention.

Dermatomyositis and polymyositis are characterized by proximal limb muscle weakness with dysphagia. These conditions are associated with malignant disease or collagen-related vascular disease and often involve respiratory and cardiac muscle.

Periodic paralysis is another disease in which sensitivity to muscle relaxants increases. Periodic weakness starts in childhood or adolescence and is precipitated by rest after exercise, sleep, cold, surgery, or pregnancy. Hypokalemic and hyperkalemic forms exist and are associated with cardiac arrhythmias. Like thyrotoxic periodic paralysis, these hypokalemic and hyperkalemic forms usually spare the respiratory muscles. Anesthetic management consists of minimizing stress and maintaining normal fluid and electrolyte status and body temperature.[310-313]

Patients with muscular dystrophy now survive into their late 20s or early 30s. Because the disease involves the muscles themselves and not their innervation, conduction anesthesia cannot produce adequate relaxation of tonic muscles. Gastric dilation is also a problem, as is malignant hyperthermia. As with the other forms of muscular dystrophy, most problems in myotonic dystrophy arise from cardiac arrhythmias and inadequacy of the respiratory muscles.[314] For all the forms of muscular dystrophy, as for all the neuropathies (discussed earlier), problems have been related to exaggerated release of serum potassium after the administration of depolarizing muscle relaxants.

Malignant hyperthermia in the patient or in a relative of the patient merits careful history taking and at least consideration of performing a test for susceptibility to the condition (see also Chapter 43). Prophylaxis with intravenous dantrolene sodium (Dantrium) may also be warranted. In some cases, malignant hyperthermia has been associated with recognizable musculoskeletal abnormalities such as strabismus, ptosis, myotonic dystrophy, hernias, kyphoscoliosis, muscular dystrophy, central core disease, and marfanoid syndrome. Appropriate preparation for a patient with previous masseter spasm, or trismus, is a matter of considerable debate. Malignant hyperthermia occurs most frequently in children and adolescents; the incidence is 1 in 14,000 administrations of anesthesia. The incidence increases to 1 in 2500 patients requiring strabismus (squint) surgery.

DOWN SYNDROME

Down syndrome (trisomy 21) occurs once in 1000 live births. It is associated with congenital cardiac lesions such as endocardial cushion defects (40%), ventricular septal defects (27%), patent ductus arteriosus (12%), and tetralogy of Fallot (8%). Prophylactic antibiotics should be used before predictable bacteremic events. Down syndrome is also associated with upper respiratory infections, with atlanto-occipital instability (in ≈15% of patients,[315-318] in whom it is asymptomatic in most cases, but all patients should be treated as though they have atlanto-occipital instability) and laxity of other joints, with thyroid hypofunction (50%), with an increased incidence of subglottic stenosis, and with enlargement of the tongue (or a decreased oral cavity size for a normal-sized tongue).[317,319] No abnormal responses to anesthetic agents or anesthetic adjuvants have been substantiated. A reported sensitivity to atropine has been disproved, although administration of atropine to any patient receiving digoxin for atrial fibrillation should be done with care.[319] Examination for the conditions associated with Down syndrome should precede surgery.

PREOPERATIVE PREDICTION OF INCREASED INTRACRANIAL PRESSURE DURING NEUROSURGERY

Symptoms and signs of increased intracranial pressure include morning headache or headache made worse by coughing, nausea, vomiting, disturbances in consciousness, history of large tumors, tumors involving the brainstem, neck rigidity, and papilledema. Patients with these signs, large ventricles (as seen on radiography or images of the brain), or edema surrounding supratentorial

tumors should be considered at risk for intraoperative intracranial hypertension. These patients may benefit from preoperative treatment or anesthetic management that assumes this possibility (see also Chapter 70).[320]

Other preoperative considerations for patients with neurologic disease that can cause intracranial hypertension are the associated hypoventilation and hypoxia in patients who have severe hemiplegia and the presence of subarachnoid bleeding or other forms of intracranial hemorrhage (especially likely in women given heparin who have two or more cerebral infarcts noted on CT). Many strokes or transient ischemic attacks have a possible cardiac origin.

MENTAL DISORDERS

Perhaps the most important preoperative consideration for patients with mental disorders, in addition to developing rapport, is understanding their specific drug therapy and its effects and side effects. Lithium, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), other antidepressants that defy classification (e.g., bupropion), phenothiazines, butyrophenones, and MAOIs are used in these patients.[321] These drugs have potent effects and side effects that are discussed in the last section of this chapter, on drug therapy.

RENAL DISEASE AND ELECTROLYTE DISORDERS

The anesthesiologist has an important role to play in preventing the onset and consequences of renal failure and its initiators. The linking of renal failure to electrolyte disorders is more obvious: the kidney is the primary organ for regulating body osmolality and fluid volume and has a major role in excretion of the end products of metabolism. In performing these functions, the kidney becomes intimately involved in the excretion of electrolytes.

A patient with renal insufficiency whose own kidneys are still functioning is distinct not only from a patient with end-stage renal disease whose renal functions are provided by dialysis but also from a patient who has a transplanted kidney. These three groups of patients require very different preoperative preparation. In addition, acute changes in renal function present quite a different problem than do chronic alterations in function. Certain renal diseases require different preoperative preparation than others, but generally, renal disease of any origin presents the same preoperative problems (see also Chapters 23, 38, and 52).

RENAL DISEASE

Causes and Systemic Effects of Renal Disorders

Nephrotic syndrome may develop in patients with glomerular diseases without disturbing tubular function. The soundness of tubular function is an important consideration because tubular dysfunction with attendant uremia presents problems quite different from those presented by glomerular disease with only nephrotic syndrome. This is not to minimize the adverse effects of glomerular disease; nephrotic syndrome consists of massive proteinuria and consequent hypoalbuminemia. The resulting reduction in plasma oncotic pressure diminishes plasma volume and calls forth compensatory mechanisms that result in retention of sodium and water. As a result, a common clinical finding in nephrotic syndrome is edema. Thus, patients with nephrotic syndrome may have excess total-body water and decreased intravascular volume. In addition, diuretics are often given in an attempt to decrease edema. Although serum creatinine and creatinine clearance estimations have limitations as indices of the GFR (inulin clearance is still the gold standard), these measurements are, for now, the most readily available to the anesthesiologist. Plasma creatinine levels reflect endogenous muscle catabolism and dietary intake, as well as urinary excretion. Urinary excretion depends on both filtration and secretion by the kidney. Drugs that are commonly used in the preoperative and perioperative periods can distort this measure of glomerular filtration. Moreover, the commonly used methods for measuring creatinine have a 95% confidence limit of greater than 20% for a GFR higher than 30 mL/minute. Thus, a normal creatinine level of 1.3 mg/dL may give a measured value ranging from 1.0 to 1.5 mg/dL.

Furthermore, in patients with nephrotic syndrome in whom renal tubular function has been preserved, hypovolemia appears to be a significant cause of deteriorating tubular renal function.[322-324] No randomized study has shown that close control of intravascular volume status in these groups of patients preserves renal tubular function (or any other measure of perioperative morbidity) to a greater degree than does less rigid control.

Uremia, the end result of renal tubular failure (i.e., failure of the concentrating, diluting, acidifying, and filtering functions) manifests in many ways. Changes occur in the cardiovascular, immunologic, hematologic, neuromuscular, pulmonary, and endocrine systems, as well as in bone. These alterations are ascribed either to the toxic end products of protein metabolism or to an imbalance in functioning of the kidney. As the number of functioning nephrons diminishes, the still-functioning nephrons attempt to increase some solute and body composition preservation functions at the expense of other functions, such as excretion of phosphate. The accumulation of phosphate increases PTH levels, which in turn produce osteodystrophy. Osteodystrophy can be managed by (1) restriction of dietary phosphate, (2) the use of gels (e.g., aluminum hydroxide or carbonate) that bind with intestinal phosphate, (3) calcium supplementation, or (4) parathyroidectomy.

Certain alterations in patients with uremia, such as neuropathy, are most logically attributed to an accumulation of toxic metabolites. Peripheral neuropathy is most often sensory and involves the lower extremities, but it may also be motor; peripheral neuropathies are frequently improved with hemodialysis and can be dramatically reversed with renal transplantation. The use of depolarizing muscle relaxants in patients with peripheral neuropathy is controversial and is discussed in the section on neuropathies. Tubular function is commonly

assessed by acidifying and concentrating capabilities.[325] Although such tests are crude, these capabilities are usually readily evaluated by measuring urine pH and specific gravity. Better assessment of renal blood flow, for the purpose of improving renal blood flow and its distribution, is promised by the use of contrast-enhanced ultrasound in the operating room.[326] Along with the altered volume status and cardiac complications in uremic patients, autonomic neuropathy may contribute to hypotension during anesthesia. Atherosclerosis is often accelerated in uremic patients; hypertension, with its attendant consequences, is very common.

Cardiac failure (especially episodic failure) frequently occurs in uremic patients because of the presence of many adverse conditions: anemia with increasing myocardial work, hypertension, atherosclerosis, and altered volume status. Pericarditis can manifest by pericardial rub alone or by pain (with or without hemorrhage). Cardiac tamponade should be ruled out on the basis of clinical features and by echocardiography if this diagnosis is seriously suspected preoperatively. In addition, cardiac tamponade should be treated or planned for preoperatively.

If anemia is present, its severity generally parallels the degree of uremia; chronically uremic patients seem to adapt well to anemia. No hard data have substantiated the need to give a preoperative blood transfusion to a chronically uremic patient, even when the preoperative hematocrit is as low as 16% to 18%. Even in nonuremic patients in an ICU, a randomized trial was unable to demonstrate improved outcome with a liberal transfusion strategy,[327] and transfusions increase the risk for immune system compromise (see also Chapter 61).[328] Thus, one of the major historical reasons for not transfusing blood in patients with end-stage renal disease has been disproved by this finding: data show that the more blood transfusions a transplant recipient receives before transplantation, the greater is the chance that the transplant will function successfully.[329] In uremic patients, coagulation and platelet adhesiveness may be abnormal and factor III activity may be decreased. Even uremic patients who are not given corticosteroids or immunosuppressive drugs may demonstrate abnormal immunity, perhaps warranting increased attention regarding procedures that lessen patient cross-contamination.

Uremic patients exhibit a wide variety of metabolic and endocrinologic disorders in addition to hyperparathyroidism, including impaired carbohydrate tolerance, insulin resistance, type IV hyperlipoproteinemia, autonomic insufficiency, hyperkalemia, and anion-gap acidosis (caused by an inability of the kidneys to reabsorb filtered bicarbonate and excrete sufficient ammonium into urine). Furthermore, the excretion and pharmacokinetics of drugs are different in uremic patients than in normal patients. In addition, complications of hemodialysis include nutritional deficiencies, electrolyte and fluid imbalances, and mental disorders. Because these conditions can lead to serious perioperative morbidity, they should be evaluated preoperatively. No data, however, have substantiated the hypothesis that preoperative optimization of these metabolic and endocrinologic disorders reduces perioperative risk in uremic patients.

As with uremic patients, preoperative optimization of volume status is paramount in patients with kidney stones, and both are affected by carbohydrate intolerance.[330,331] Seventy-five percent of all kidney stones are composed of calcium oxalate. Patients with these stones frequently take diuretic drugs, consume calcium- and citrate-rich foods, and restrict salt intake. Prevention of dehydration by institution of intravenous fluid therapy along with restricted oral intake of protein may be as important for these patients as it is for patients with struvite or uric acid stones. Struvite stones often result from urinary infection. Uric acid stones can be prevented by treatment with allopurinol, by preoperative hydration, or by alkalinization of urine. Acidosis may contribute to stone formation. Again, optimal intravascular volume status is important in preventing stones and preserving renal function. More thorough discussion of renal function and physiology is provided in Chapter 23. Chapter 72 deals with the complexities of managing patients for renal surgery and other urologic procedures.

Creatinine clearance in conjunction with free water clearance appears to be the most accurate way of quantifying, for pharmacokinetic purposes, the degree of decreased renal function (see also Chapter 23).[331] For a patient with stable renal function, creatinine clearance, which is a rough estimate of GFR, can be approximated by noting the serum creatinine level: a doubling of the creatinine level represents a halving of the GFR. Thus, a patient with a stable serum creatinine level of 2 mg/dL would have a GFR of approximately 60 mL/minute. A stable serum creatinine level of 4 mg/dL would accompany a GFR of approximately 30 mL/minute, and a stable serum creatinine level of 8 mg/dL would accompany a GFR of 15 mL/minute or less. When pregnancy and considerable edema are not present and the serum creatinine level is stable, the following formulas can be used to estimate creatinine clearance and free water clearance.[331-333]

$$\text{Creatinine clearance} = \frac{(140 - \text{Age [yr]}) \times \text{Body weight (kg)}}{72 \times \text{serum creatinine}\left(\frac{\text{mg}}{\text{dL}}\right)}$$

$$\text{Free water clearance} = \text{Urine flow (mL/hour)} - \frac{\text{Urine osmolality}\left(\frac{\text{mOsm}}{\text{L}}\right) \times \text{Urine flow}\left(\frac{\text{mL}}{\text{hour}}\right)}{\text{Plasma osmolality}\left(\frac{\text{mOsm}}{\text{L}}\right)}$$

Note that renal function must be stable. Unstable renal function is often associated with changes in serum creatinine levels that lag by several days. Although knowing the serum creatinine level is more useful than knowing the BUN level, the BUN value provides some information, as discussed in the next section.

Free water clearance is a measure of renal concentrating ability, and it is normally –25 to +100 mL/hour; it becomes more positive in renal insufficiency states. It may also become more positive in patients who have a head injury or high blood alcohol levels or in those undergoing aggressive fluid infusion or administration of diuretics.[332]

Patients With Insufficient but Functioning Kidneys

One of the greatest challenges for the anesthesiologist is presented by patients with insufficient renal function whose renal function must be preserved during surgical procedures. Additionally, the presence of chronic renal failure is associated with higher rates of perioperative cardiac morbidity, which may warrant further evaluation for the presence of occult CAD.[333] The many uremic symptoms and great perioperative morbidity associated with uremia can probably be avoided by attention to detail in the preoperative and perioperative management of patients with insufficient, but still functioning kidneys.[322-324]

First, studies demonstrate that acute postoperative renal failure is associated with an extremely high mortality rate.[334] The development of perioperative renal dysfunction has multiple risk factors, the most important of which include preexisting renal disease, heart surgery involving cardiopulmonary bypass or aortic surgery involving cross-clamping of the thoracic or abdominal aorta, and ongoing sepsis.

Moreover, acute perioperative renal failure is most likely to occur in patients who have renal insufficiency before the surgical procedure, are older than 60 years, and have preoperative left ventricular dysfunction.[332,334] Proper preoperative hydration probably decreases mortality after acute renal failure induced by radiocontrast agents.[324] Clues to the presence of hypovolemia or hypervolemia should be sought from the history and physical examination (e.g., weight loss or gain, thirst, edema, orthostatic hypotension and tachycardia, flat neck veins, dry mucous membranes, decreased skin turgor). In seriously ill patients, insertion of a pulmonary artery catheter permits more precise monitoring of intravascular fluid volume. Other causes of deterioration in function in chronic renal insufficiency are low cardiac output or low renal blood flow (in prerenal azotemia, whether because of cardiac failure or fluid depletion from diuretic drugs, BUN often increases disproportionately to increases in creatinine), urinary tract infection, use of nephrotoxic drugs, hypercalcemia, and hyperuricemia. These conditions and drugs should be avoided; if any of these conditions exist, they should be treated preoperatively.

Management of patients with renal disease is discussed in Chapter 72.

Patients Undergoing Dialysis

Patients with chronic (and at times acute) renal failure require renal replacement therapy, including conventional intermittent hemodialysis, peritoneal dialysis, and continuous renal replacement therapy (CRRT). CRRT includes a wide variety of techniques whose perioperative management has been reviewed (Table 39-14).[335] Although the primary indication for CRRT is acute renal failure, it can also be used for fluid clearance, correction of electrolyte abnormalities, and management of metabolic acidosis. It can be used in surgical patients without significant hemodynamic abnormalities. These patients may return to the operating room, and their assessment and management may be complicated by the underlying disease and the use of systemic anticoagulation to prevent filter and circuit clotting. In patients undergoing intermittent treatment with hemodialysis or peritoneal dialysis, the procedure is discontinued before entering the operating room. For CRRT, the anesthesiologist must determine the appropriateness of discontinuing the therapy. With short procedures, the therapy can almost always be stopped and the arterial and venous ends of the circuit connected and run in the bypass mode. CRRT can also be used to manage fluids during the surgical procedure by changing the dialysate. If CRRT is continued, its effect on drug dosing must be recognized. In addition to effects on renal elimination of drugs, CRRT has effects resulting from changes in protein binding and volume of distribution, as well as drug removal effects from membrane permeability, membrane surface area, the ultrafiltration rate, and the dialysate flow rate.

Because a patient undergoing dialysis has already lost natural renal functioning, the emphasis in preoperative assessment shifts toward protecting other organ systems and optimally maintaining vascular access sites for cannulation. Usually, this does not require invasive monitoring. Emphasis is placed on intravascular fluid volume and electrolyte status, which can be ascertained by knowing when the patient last underwent dialysis, how much weight was normally gained or lost with dialysis, whether the fluid loss was peritoneal or intravascular, and what electrolyte composition the blood was dialyzed against. Although preoperative dialysis may benefit patients who have hyperkalemia, hypercalcemia, acidosis, neuropathy, and fluid overload, the resulting dysequilibrium between fluid and electrolytes can cause problems. Because hypovolemia induced by dialysis can lead to intraoperative hypotension, we try to avoid weight and fluid reduction in patients undergoing preoperative dialysis. In addition, hypopnea

TABLE 39-14 **CHARACTERISTICS OF RENAL REPLACEMENT THERAPY**

Renal Replacement Therapy	Blood Pump	Replacement Fluid (RF)/ Dialysate (D)	Intraoperative Use
Conventional intermittent hemodialysis	Yes	D	No
Peritoneal dialysis	No	D	No
Slow continuous ultrafiltration	Yes/ no	None	Yes
Continuous arteriovenous hemodialysis	No	D	No
Continuous arteriovenous hemodiafiltration	No	RF/D	No
Continuous venovenous hemofiltration	Yes	RF	Yes
Continuous venovenous hemodialysis	Yes	D	Yes
Continuous venovenous hemodiafiltration	Yes	RF/D	Yes

From Petroni KC, Cohen NH: Continuous renal replacement therapy: anesthetic implications, Anesth Analg *94:1288-1297, 2002.*

has been found to occur during and after dialysis when the dialysate contained acetate. Avoiding an acetate bathing solution may prevent this cause of hypoventilation.

When renal transplant recipients have subsequent surgical procedures, the status of their renal function must be determined (i.e., whether they have normal renal function, insufficient but still functioning kidneys, or end-stage renal disease requiring hemodialysis) (see also Chapter 74). Descriptions of side effects of immunosuppressive drugs should also be sought. The drugs used preoperatively and intraoperatively to prevent acute rejection themselves have serious side effects that encourage close monitoring of blood glucose and cardiovascular function.[329,336] Because renal transplantation greatly increases the risk of infection, it is very important to avoid invasive monitoring and prevent patient cross-contamination.

Drugs in Patients With Renal Failure

Patients with renal azotemia have a threefold or higher risk of having an adverse drug reaction than do patients with normal renal function.[337-339] The risk is increased by two conditions. First, excessive pharmacologic effects result from high levels of a drug or its metabolite (e.g., the metabolite of meperidine) in blood because of physiologic changes in target tissues induced by the uremic state. An example is excessive sedation in a uremic patient with standard blood levels of sedative-hypnotic drugs. Second, excessive administration of electrolytes with drugs also increases the risk of having an adverse drug reaction. Administration of standard doses of drugs that depend on renal excretion for their elimination can result in drug accumulation and enhanced pharmacologic effect. In one report, patients with end-stage renal disease required significantly higher propofol doses to achieve the clinical endpoint of hypnosis than did patients with normal renal function.[339]

INFECTIOUS DISEASE

Sepsis is a leading cause of postoperative morbidity,[324,340] probably through a decrease in systemic vascular resistance related to activation of the complement system and other mediators. Thus, attention to the effects of antibiotic drugs must be supplemented by attention to intravascular volume status.[322-324,340-342] The degree of impairment of the infected organ and its effect on anesthesia should be assessed. For instance, endocarditis merits examination of the following: intravascular volume status; antibiotic and other drug therapy and side effects[343]; myocardial function; and renal, pulmonary, neurologic, and hepatic function—organ systems that can be affected by endocarditis.

Although all surgery except emergency or essential operations is proscribed when an acute infectious disease is present, many such diseases (e.g., influenza and pneumococcal pneumonia) and even inflammatory conditions are becoming less frequent because of successful immunization recommendations and programs.[344] Furthermore, even though acute infections are less common, surgery in patients with chronic viral diseases such as hepatitis and HIV infection is more frequent. Many of these patients may also harbor opportunistic infections such as tuberculosis or may have other systemic problems. Whether anesthesia or surgery, or both, exacerbates these infections or their systemic manifestations is not clear.

ELECTROLYTE DISORDERS

Disorders of calcium, magnesium, and phosphate balance are discussed in the earlier section on diseases involving the endocrine system and disorders of nutrition (see also Chapters 38 and 60).

Hyponatremia and Hypernatremia

Electrolyte disorders are usually detected by determining the levels of electrolytes in serum. These concentrations reflect the balance between water and electrolytes. The osmolality of all body fluids is normally maintained within the narrow physiologic range of 285 to 290 mOsm/kg H_2O by integration of three key processes: thirst, release of ADH, and responsiveness of the medullary collecting ducts to ADH. Because of the permeability of biologic membranes, intracellular osmolality and extracellular osmolality are almost always equal and can be estimated by the following formula:

$$2\left[Na^{2+}\right](\text{mEq/L}) + \frac{[\text{Glucose}]\,(\text{mg/dL})}{18} + \frac{[\text{BUN}]\,(\text{mg/dL})}{2.8} = \text{mOsm/kg}$$

This formula will become easier to calculate when we convert fully to the International System of Units (SI units; metric system) because millimoles (mmol) can be substituted for mg/(factor) in the foregoing formula to read

$$2\left[Na^{2+}\right] + [\text{Glucose}] + [\text{BUN}] = \text{mOsm/kg}$$

with concentrations expressed in millimoles per liter (mmol/L). Although secretion of ADH is tightly controlled by osmotic stimuli at 285 to 290 mOsm/kg, the osmotic threshold for thirst is high (300 mOsm/kg), thus making this sign an important guide to volume deficiency.

Hyponatremia is perhaps the third most common fluid electrolyte abnormality in hospitalized patients. (Magnesium deficiency occurs in as many as 25% [see Chapter 59], and potassium deficiency, discussed later in this section, occurs in as many as 10%.) Hyponatremia can occur in isotonic, hypertonic, or hypotonic forms. For example, isotonic hyponatremia can develop in protein or liquid accumulation states such as myeloma. Hypertonic hyponatremia can be present with hyperglycemia or with infusions of glycine (as in the TURP syndrome). Hypotonic hyponatremia is the largest classification and is subdivided according to the status of the extracellular fluid into hypovolemic, isovolumic, or hypervolemic hypotonic hyponatremia. All three types require that excretion of renal water be impaired despite continued intake of dilute fluid. Common causes of hypovolemic hypotonic hyponatremia are GI losses (vomiting, diarrhea), third-space losses (diuretics or salt-wasting nephropathy), and

BOX 39-6 *Types and Causes of Hypotonic Hyponatremia**

HYPOVOLEMIC
- Gastrointestinal losses
  - Vomiting
  - Diarrhea
- Skin losses
- Third-space losses
- Lung losses

  - Diuretics
  - Renal damage
  - Urinary tract obstruction
- Adrenal insufficiency

ISOVOLUMIC
- Syndrome of inappropriate secretion of antidiuretic hormone
- Renal failure
- Water intoxication
- Hypokalemia
- Dysfunctional osmostat

HYPERVOLEMIC
- Congestive heart failure
- Nephrosis
- Liver dysfunction

*Serum osmolality less than 280 mOsm/L.

adrenal insufficiency (Box 39-6). Hypervolemic hypotonic hyponatremic states complicate severe cardiac failure, cirrhosis, nephrotic syndrome, and renal failure and are characterized by retention of sodium with disproportionately larger amounts of water.

The more common isovolumic hypotonic hyponatremia is caused by retention of water without sodium. Because edema is not usually clinically apparent, such patients appear isovolumic. Edema is most often caused by SIADH, which in turn may be caused by CNS or pulmonary tumors or dysfunction. Secretion of ADH increases with age, thus rendering older adults more prone to hyponatremia. Drugs that potentiate the secretion of ADH (tricyclic antidepressants and vincristine) or its effects on the medullary collecting duct system in the kidney (nonsteroidal antiinflammatory drugs and chlorpropamide) or that have similar effects (oxytocin) may be more likely to cause hyponatremia in older adults. To establish the diagnosis of SIADH, the physician should determine that the patient is free of renal and cardiac dysfunction, has normal adrenal and thyroid function, and is normovolemic. Urine osmolality would then be found to exceed 100 mOsm/kg, serum osmolality would be low, and urine sodium excretion would be higher than 20 mEq/L (20 mOsm/L).

Disturbances in serum sodium therefore reflect alterations in glucose metabolism, renal function, or accumulation of body water. The last can be affected by disturbances in thirst, release of ADH, and renal function. Thus, hyponatremia reflects a relative excess of free water and can occur when total-body sodium increases (as in edematous disorders), when total-body sodium is normal (as in excess of free water because of SIADH), or when total-body sodium decreases (as occurs with too aggressive use of diuretic drugs). Definition of the cause defines the treatment. For instance, water restriction is the mainstay of therapy for SIADH. Administration of demeclocycline is another option that corrects SIADH by inducing a reversible nephrogenic diabetes insipidus. The anesthesiologist is faced with the question of what levels of electrolytes require treatment before anesthesia. Although slowly developing hyponatremia usually produces few symptoms, the patient may be lethargic and apathetic. Chronic hyponatremia is better tolerated than acute hyponatremia because of mechanisms regulating intracellular fluid volume that alleviate brain edema; the loss of other solutes from cells decreases the osmotic movement of water into cells. Nonetheless, severe chronic hyponatremia (i.e., serum sodium levels <123 mEq/L) can cause brain edema.

By contrast, acute hyponatremia may be manifested by severe symptoms requiring emergency treatment: profound cerebral edema with obtundation, coma, convulsions, and disordered reflexes and thermoregulatory control.[100,101,345] Depending on the cause and relative total sodium and water content, treatment can range from the administration of hypertonic saline or mannitol (with or without diuretic drugs) to restriction of fluids or administration of other drugs.[100,101,345] Because neurologic damage may develop if the serum sodium concentration is increased too rapidly, the rate of increase should not exceed 1 mEq/L/hour.[100,101,345] After the serum sodium concentration has reached 125 mEq/L, therapy may consist of water restriction; more rapid correction may result in CNS demyelination.[100,101,345] In hyponatremic patients who have excess total-body water secondary to SIADH, serum levels can be corrected by giving furosemide, 1 mg/kg, and hypertonic saline to replace the loss of electrolytes in urine.[100,101,345] The diagnosis of SIADH is discussed earlier in this chapter (see the section on pituitary abnormalities).

Neither acute nor chronic hyponatremia necessitates restoration of serum sodium to normal levels; brain swelling usually disappears at a serum sodium level of 130 mEq/L.

Hypernatremia occurs much less commonly than hyponatremia. It is often iatrogenic (e.g., it can be caused by failure to provide sufficient free water to a patient who is unconscious or who has had a recent stroke-induced deficit of the thirst mechanism) and can occur in the presence of low, normal, or excess total-body sodium. The primary symptoms of hypernatremia relate to brain cell shrinkage. Because too rapid correction of hypernatremia can lead to cerebral edema and convulsions, correction should be made gradually. Again, with no data to support this stance, we believe that all patients undergoing surgical procedures should have serum sodium concentrations of less than 150 mEq/L before anesthesia.

Hypokalemia and Hyperkalemia

Hypokalemia and hyperkalemia are also discussed in Chapters 38 and 59. The relationship between the measured potassium concentration in serum and total-body potassium stores can best be described with a scattergram. Only 2% of total-body potassium is stored in plasma (4200 mEq in cells and 60 mEq in extracellular fluid). In

normal persons, 75% of the 50 to 60 mEq/L of total-body potassium is stored in skeletal muscle, 6% in red blood cells, and 5% in the liver. Thus, a 20% to 25% change in potassium levels in plasma could represent a change in total-body potassium of 1000 mEq or more if the change were chronic or as little as 10 to 20 mEq if the change were acute.

As with serum sodium levels,[100,101,345] acute changes in serum potassium levels are less well tolerated than chronic changes. Chronic changes are relatively well tolerated because of the equilibration of serum and intracellular stores that takes place over time to return the resting membrane potential of excitable cells to nearly normal levels.

Hyperkalemia can result from the following: factitious increase of potassium administration (as in red blood cell hemolysis); excessive exogenous potassium from sources such as salt substitutes or, in large amounts, bananas; cellular shifts in potassium (as a result of metabolic acidosis, tissue and muscle damage after burns, use of depolarizing muscle relaxants, or intense catabolism of protein); and decreased renal excretion (as occurs in renal failure, renal insufficiency with trauma, and therapy with potassium-sparing diuretic drugs, especially when combined with ACE inhibitors or mineralocorticoid deficiency).[346-348] Factitious hyperkalemia can occur when a tourniquet is left on too long or even by simple fist clenching.[349]

The major danger in anesthetizing patients who have disorders of potassium balance appears to be abnormal cardiac function (i.e., both electrical disturbance[346] and poor cardiac contractility). Hyperkalemia lowers the resting membrane potential of excitable cardiac cells and decreases the duration of the myocardial action potential and upstroke velocity. This decreased rate of ventricular depolarization, in addition to the beginning of repolarization in some areas of the myocardium while other areas are still undergoing depolarization, produces a progressively widening QRS complex that merges with the T wave into a sine wave on the ECG.

At a potassium level greater than 6.7 mEq/L, the degree of hyperkalemia and the duration of the QRS complex correlate well.[346] This correlation is even better than the correlation between the serum potassium level and T-wave changes. Nevertheless, the earliest manifestations of hyperkalemia are narrowing and peaking of the T wave. Although not diagnostic of hyperkalemia, T waves are almost invariably peaked and narrow when serum potassium levels are 7 to 9 mEq/L. When serum potassium levels exceed 7 mEq/L, atrial conduction disturbances appear, as manifested by a decrease in P-wave amplitude and an increase in the PR interval. Supraventricular tachycardia, atrial fibrillation, PVCs, ventricular tachycardia, ventricular fibrillation, or sinus arrest may all occur.

The ECG and cardiac alterations associated with hyperkalemia are potentiated by low serum levels of calcium and sodium. Intravenous administration of saline, bicarbonate, glucose with insulin (1 unit/2 g glucose), and calcium can reverse these changes by shifting some extracellular potassium into the cell.

β-Adrenergic stimuli also cause redistribution of potassium into the cell. Indeed, the plasma potassium concentration measured in samples immediately before surgical procedures is usually 0.2 to 0.8 mEq/L lower than that measured during the less stressful period 1 to 3 days before surgery.[350] β-Adrenergic receptor blocking drugs can be used to prevent such an effect preoperatively. A β-adrenergic receptor stimulating agent (20 mg of nebulized albuterol for a 70-kg patient) can be used to treat hyperkalemia when it occurs; it decreases potassium levels 1.0 mEq/L within 30 minutes, and its effect lasts 2 hours.[351] Although nebulized β_2-agonists effectively lower plasma potassium concentrations by stimulating sodium- and potassium-dependent adenosine triphosphatase, this therapy should be used as an adjunct to rather than a substitute for more established measures. Kayexalate (sodium polystyrene sulfonate) enemas can be given to bind potassium in the gut in exchange for sodium. Dialysis against a hypokalemic solution also decreases serum potassium levels. However, in a hyperkalemic patient, hypoventilation can be dangerous during anesthesia because each 0.1 change in pH can produce a 0.4 to 1.5 mEq/L change in serum potassium levels in the opposite direction. For example, if pH decreases from 7.4 to 7.3, serum potassium levels could increase from 5.5 to 6.5 mEq/L.

Hypokalemia can be caused by inadequate intake of potassium, excessive GI loss (through diarrhea, vomiting, nasopharyngeal suctioning, long-term use of laxatives, or ingestion of cation exchange resins, as in certain wines), excessive renal loss (because of the use of diuretic drugs, renal tubular acidosis, chronic chloride deficiency, metabolic alkalosis, mineralocorticoid excess, excessive ingestion of licorice, use of antibiotics, ureterosigmoidostomy, and diabetic ketoacidosis), and shifts of potassium from extracellular to intracellular compartments (as occurs in alkalosis, insulin administration, administration of a β-adrenergic agonist or stress, barium poisoning, and periodic paralysis). As with hyperkalemia, knowledge of the cause of the potassium deficiency and appropriate preoperative evaluation and treatment of that cause may be as important as treatment of the deficiency itself. Also like hyperkalemia, hypokalemia may reflect small or vast changes in total-body potassium. Acute hypokalemia may be much less well tolerated than chronic hypokalemia. The major worrisome manifestations of hypokalemia pertain to the circulatory system, both the cardiac and peripheral components. In addition, chronic hypokalemia results in muscle weakness, hypoperistalsis, and nephropathy.

Cardiovascular manifestations of hypokalemia include the following: autonomic neuropathy, which results in orthostatic hypotension and decreased sympathetic reserve; impaired myocardial contractility; and electrical conduction abnormalities, which can result in sinus tachycardia, atrial and ventricular arrhythmias, and disturbances in intraventricular conduction that can progress to ventricular fibrillation. In addition to arrhythmias, the ECG shows widening of the QRS complex, ST-segment abnormalities, progressive diminution of the T-wave amplitude, and a progressive increase in the U-wave amplitude. Surawicz found these changes to be invariably present when serum potassium levels decreased to less than 2.3 mEq/L.[346] Although U waves are not specific for

hypokalemia, they are sensitive indicators of the condition. Replenishing the total-body potassium deficit for a depletion reflected by a serum deficit of 1 mEq/L (e.g., from 3.3 to 4.3 mEq/L) may require 1000 mEq of potassium. Even if this amount could be given instantaneously (and it should not be replenished at a rate exceeding 250 mEq/day), it would take 24 to 48 hours to equilibrate in all tissues. Potassium-depleted myocardium is unusually sensitive to digoxin, calcium, and most important, potassium. Rapid potassium infusion in a hypokalemic patient can produce arrhythmias as severe as those produced by hypokalemia itself.[352] One potential strategy to prevent hypokalemia from anxiety and stress includes premedication with clonidine.[353]

Thus, the decision to proceed with surgery and anesthesia in the presence of acute or chronic depletions or excesses of potassium depends on many factors.[354-359] The cause and treatment of the underlying condition creating the electrolyte imbalance and the effect of that imbalance on perioperative risk and physiologic processes must be known. The urgency of the operation, the degree of electrolyte abnormality, the medications given, the acid-base balance, and the suddenness or persistence of the electrolyte disturbance are all considerations. For example, a small study of patients undergoing vascular access procedures with preoperative potassium levels of higher than 6 mmol/L demonstrated no adverse outcomes.[357] Similarly, in a cohort study in which 38 patients had a preoperative potassium level higher than 5.5 mEq/L, no dysrhythmias or major morbidity were associated with the use of succinylcholine.[358]

Retrospective epidemiologic studies attribute significant risk to the administration of potassium (even long-term oral administration).[354] In one study, 1910 of 16,048 consecutive hospitalized patients were given oral potassium supplements. Of these 1910 patients, hyperkalemia contributed to death in 7, and the incidence of complications of potassium therapy was 1 in 250. Armed with such data, many internists do not prescribe oral potassium therapy for patients given diuretic drugs. Yet these patients frequently become moderately hypokalemic.[360] Modest hypokalemia occurs in 10% to 50% of patients given diuretic drugs. Should surgery be delayed to subject such patients to the risks of potassium therapy?

Three studies investigated whether modest hypokalemia was a problem by prospectively seeking arrhythmias on the ECGs of patients who had various preoperative levels of potassium.[355,356,359] No difference in the incidence of arrhythmias occurred in 25 normokalemic ($K^+ > 3.4$ mEq/L) patients, 25 moderately hypokalemic ($K^+ = 3$ to 3.4 mEq/L) patients, and 10 severely hypokalemic ($K^+ < 2.9$ mEq/L) patients.[355] Wahr and coauthors studied 2402 patients undergoing elective CABG and concluded that a serum potassium level less than 3.5 mmol/L was a predictor of serious perioperative arrhythmia (OR, 2.2; 95% CI, 1.2 to 4.0), intraoperative arrhythmia (OR, 2.0; 95% CI, 1.0 to 3.6), and postoperative atrial fibrillation/flutter (OR, 1.7; 95% CI, 1.0 to 2.7).[359] The inability of the eye to pick up these changes—or even the inability of Holter recordings for short periods (which seem not to have been used in this study)—points to the need for confirming studies.

Modest hypokalemia can have severe consequences.[360,361] Holland and co-workers treated 21 patients with 50 mg of hydrochlorothiazide twice a day for 4 weeks.[361] These patients had a history of becoming hypokalemic during diuretic therapy; no patients had cardiac disease or were taking other medications. Before and after diuretic therapy, 24-hour ambulatory ECGs were recorded. This study is also subject to the limitations of Holter monitoring. Ventricular ectopy, including complex ventricular ectopy (multifocal PVCs, ventricular couplets, ventricular tachycardia), developed in 7 of the 21 patients (33%). Potassium repletion decreased the number of ectopic ventricular beats per patient from 71.2 to 5.4/hour. Apparently, some patients are sensitive to even minor potassium depletion. In the Multiple Risk Factor Intervention Trial involving 361,662 patients, more than 2000 of whom were treated for hypertension with diuretics, the reduction in serum potassium after diuretic therapy was greater in patients with PVCs.[360]

GASTROINTESTINAL AND LIVER DISEASES

GASTROINTESTINAL DISEASE

Preoperative Search for Diverse Associated Disorders in Gastrointestinal Disease

Although preoperative preparation of the GI tract is usually the responsibility of the surgeon, GI disease can and often does cause derangements in many or all other systems (see also Chapter 38). Such disturbances can affect the safety of anesthesia for the patient. Preoperative preparation should include knowledge of disease processes and their effects to guide the patient smoothly through the perioperative period. The major advances of correcting fluid and electrolyte disorders and optimizing nutritional status preoperatively allow surgical procedures to be performed in patients with GI disease previously deemed to be at too great a risk and may have lessened the risk for others.[45-47,362] Nonetheless, in patients with GI disease, thorough assessment of intravascular fluid volume, electrolyte concentrations, and nutrition is essential, including an evaluation of the supervening side effects of these therapies (e.g., hypophosphatemia from parenteral nutrition, hyperkalemia or cardiac arrhythmias from too vigorous treatment of hypokalemia, and CHF from too rapid or too vigorous treatment of hypovolemia).

In addition to the vast alterations in fluids, electrolytes, and nutrition that can occur with such diverse GI diseases as neoplasms and pancreatitis, patients with GI disorders can have gastroesophageal reflux disease,[363] bowel obstruction, vomiting, or hypersecretion of acid. These effects may merit rapid induction of anesthesia with the application of cricoid pressure or endotracheal intubation with the patient unanesthetized (awake), preoperative nasogastric suctioning, or preoperative use of histamine receptor blocking drugs. Clotting abnormalities may need to be corrected because fat-soluble vitamin K (often malabsorbed) is necessary for the synthesis of factors II, VII, IX, and X in the liver (see also Chapter 62). Liver disease is often associated with GI disease and, if

severe enough, can also result in a deficiency of clotting factors synthesized by the liver.

Other factors should be remembered in the perioperative management of any patient with GI disease. First, closed spaces containing gas expand by absorbing nitrous oxide. Such expansion can lead to ischemic injury, rupture of GI viscera, or both. Second, GI surgery predisposes the patient to sepsis; sepsis and decreased peripheral vascular resistance can lead to massive fluid requirements, cardiac failure, and renal insufficiency. The surgical site infection rate has been declining. This decrease may be attributable to the use of better technique, more appropriate prophylactic timing and use of antibiotics, better nutrition, less invasive (laparoscopic and endoscopic) surgery, maintenance of normothermia, and surgical resection of even tumors.[364-368] Third, patients with GI disease may have many other associated disorders not directly related to the GI tract. For example, they may be anemic from deficiencies in iron, intrinsic factor, folate, or vitamin B_{12}. They may also manifest neurologic changes from combined-system disease. Respiration may be impaired because of heavy cigarette smoking, peritonitis, abscess, pulmonary obstruction, previous incisions, aspiration, or pulmonary embolism (as occurs with ulcerative colitis or with thrombophlebitis in bedridden patients). These patients may also have hepatitis, cholangitis, side effects from antibiotic drugs or other medications, massive bleeding with anemia and shock, or psychological derangements.

Because GI disease can be accompanied by so many diverse associated disorders, the clinician must clearly search for involvement of other systems and preoperatively assess and treat such disorders appropriately. Discussion of two specific diseases, ulcerative colitis and carcinoid tumor, highlights the importance of involvement of other systems in GI disease.

Ulcerative Colitis and Carcinoid Tumors as Examples of Gastrointestinal Disease Affecting Other Systems

Patients with ulcerative colitis often have psychological problems. They may also have the following: phlebitis; deficiencies in iron, folate, or vitamin B_{12}; anemia; or clotting disorders caused by malabsorption. They may be malnourished or dehydrated or have electrolyte abnormalities. In addition, ulcerative colitis can be accompanied by massive bleeding, bowel obstruction or perforation or toxic megacolon causing respiratory compromise, hepatitis, arthritis, iritis, spondylitis, or diabetes secondary to pancreatitis.

The site of origin of carcinoid tumors in more than 75% of patients is the GI tract. Within the GI tract, carcinoid tumors have been documented to occur from the esophagus to the rectum. The most frequent site is the appendix, but carcinoids in this location rarely, if ever, metastasize or produce carcinoid syndrome. Tumors arising in the ileocecal region have the highest incidence of metastases. Carcinoid tumors originating from sites other than the GI tract, such as the head and neck, lung, gonads, thymus, breast, and urinary tract, have also been reported. Cardiac involvement, although frequently reported, is usually limited to right-sided valvular and myocardial plaque formation.[369]

Not all patients with carcinoid tumors have symptoms attributable to secretion of hormone by the tumor. Some do, however, and unexpected carcinoid can manifest intraoperatively by hypersecretion of gastric fluid. The most comprehensive series in the literature indicates that only 7% of patients have carcinoid syndrome, which typically consists of flushing, diarrhea, and valvular heart disease. Of those patients with the syndrome, approximately 74% have cutaneous flushing, 68% have intestinal hypermotility, 41% have cardiac symptoms, and 18% have wheezing. Factors influencing symptoms include the location of the tumor and the specific hormones produced and secreted. Although it is generally believed that if patients do not exhibit carcinoid syndrome, the tumors are not producing serotonin (5-hydroxytryptamine [5-HT]), such may not be the case. Approximately 50% of patients with carcinoid tumors of the GI tract demonstrate evidence of 5-HT production as manifested by elevated urinary levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolic product of 5-HT. Carcinoid syndrome is usually associated with ileal carcinoid tumors that have metastasized to the liver. Presumably, the liver clears mediators released from the tumor. Impairment of this clearing ability by the metastatic tumor results in carcinoid syndrome.

Most patients with carcinoid tumors and increased urinary 5-HIAA levels have typical carcinoid tumors originating from the midgut (ileum or jejunum). These patients excrete only small amounts of 5-hydroxytryptophan (5-HTP). Patients with atypical carcinoid tumors that originate in the foregut (bronchus, stomach, and pancreas) excrete large amounts of 5-HT and 5-HTP, as well as moderately higher amounts of 5-HIAA.

Although it is generally agreed that 5-HT is responsible for the diarrhea experienced by patients with carcinoid tumors, other neurohumoral agents may contribute to the flushing and hypotension, including dopamine, histamine, and some of the neuropeptides such as substance P, neurotensin, vasoactive intestinal peptide, and somatostatin.

The net physiologic effect of circulating 5-HT represents a composite of both direct action (mediated by 5-HT receptors) and indirect action (mediated through modulation of adrenergic neurotransmission). The existence of several subtypes of 5-HT receptors may account for the different effects of 5-HT on various serotonin-sensitive tissue beds. Indirect actions are effected through alterations in catecholamine release and depend on the level of circulating 5-HT.

5-HT has little if any direct effect on the heart. With increased levels, however, positive chronotropic and inotropic myocardial effects may occur, mediated by the release of noradrenaline (norepinephrine). Effects of serotonin on the vasculature include both vasoconstriction and vasodilation.

Alterations in GI function attributed to 5-HT include increased motility and net intestinal secretion of water, sodium chloride, and potassium. 5-HT reportedly causes bronchoconstriction in many animals, but rarely in humans. Patients with asthma are a possible exception. Carcinoid tumors frequently manifest as diarrhea with fluid and electrolyte abnormalities. Because these tumors secrete vasoactive substances, patients can exhibit

hyspotension or hypertension along with the flush associated with release of vasoactive substances. Vasoactive substances can be released from the tumor by any number of substances, including catecholamines. Until the 1990s, management of patients with this tumor was a real challenge for the anesthesiologist. Thus, anesthesiologists of that era had to tread a fine line between avoiding substances known to release 5-HT (e.g., *d*-tubocurarine and morphine) and inducing anesthesia so light that painful stimuli activated a sympathetic stress response.[370] The anesthesiologist also needed to be ready and able to treat hypotension, decreased peripheral vascular resistance, bronchospasm, and hypertension. α-Adrenergic receptor blockade with the phenothiazines, butyrophenones, or phenoxybenzamine and β-adrenergic receptor blockade with propranolol have been advocated to prevent catecholamine-mediated release of vasoactive substances. These practices, however, can lead to hypotension. Nevertheless, the difficulty in managing carcinoid syndrome seemed to change with the availability of a somatostatin analogue. In fact, somatostatin is now such a powerful inhibitor of the release of peptides from carcinoid tumors and an inhibitor of the peptic effects on receptor cells that it is the therapy of choice for preoperative, intraoperative, and postoperative management of carcinoid symptoms and crises.[370,371] In cardiac surgical patients, mortality has declined over time, and vasopressors have been shown to be safe in conjunction with octreotide.[372] However, the ease of management of most patients[370,371,373-376] should not lull the anesthesiologist into being unprepared—in fact, somatostatin has caused problems of its own and has failed to prevent severe hypotension and bronchospasm.[377,378]

In patients with severe hypotension that is not treatable with somatostatin, the drug of choice is either angiotensin or vasopressin. (Angiotensin is not commercially available in the United States.) However, the vasoactive substances released by carcinoid tumors cause fibrosis of the heart valves that often results in pulmonic stenosis or tricuspid insufficiency. To increase cardiac output in a patient with tricuspid insufficiency, the anesthesiologist should avoid drugs or situations that increase pulmonary vascular resistance (e.g., angiotensin, vasopressin, acidosis, hypercapnia, hypothermia). In addition, the production of large amounts of 5-HT (equal to 200 mg/day of 5-HIAA) can lead to the development of niacin deficiency with pellagra (as occurs with diarrhea, dermatitis, and dementia).

Acute increase of plasma kinin activity in patients with carcinoid tumors has been the explanation for the symptoms of carcinoid syndrome. The physiologic effects of kinins are known to include vasodilation of smaller resistance vessels and stimulation of the release of histamine from mast cells. The latter action potentiates their own vasodilating properties and further reduces systolic and diastolic blood pressure. In addition, increases in vascular permeability may lead to edema. Kinins do not affect the myocardium directly.

Steroids have been effective in treating the symptoms of bronchial carcinoid tumors. Although prophylactic preoperative administration and intraoperative therapeutic use have been described, controlled studies of beneficial effects are lacking. Aprotinin, like steroids, inhibits the kallikrein cascade. This drug is capable of blocking the proteinase activity of kallikrein, and some reports have described a dramatic clinical response.

A subset of patients with symptoms of carcinoid syndrome excretes histamine at increased levels in their urine. Histamine causes vasodilation of small blood vessels, which leads to flushing and decreased total peripheral resistance. Histamine is known to cause bronchoconstriction, particularly in patients with bronchial asthma and other pulmonary diseases. Its role in carcinoid bronchospasm, if any, is uncertain. Histamine receptor blocking drugs have been used with some success in alleviating the flushing associated with carcinoid syndrome. H_2 antagonism alone was found to be just as effective as combination therapy in preventing symptoms; pure H_1 antagonism, however, was ineffective. These therapies have been relegated to a second-line defense since the use of somatostatin.

Catecholamines aggravate the symptoms of carcinoid syndrome, presumably by stimulating release of hormone by the tumor. The mechanism by which this release occurs remains obscure. Adrenergic receptors have not been demonstrated in carcinoid tumors, nor do these tumors usually have neural innervation. Perhaps adrenergic stimuli work through their mechanical effects on the gut and vessels to stimulate the release of tumor products. Treatment of patients with carcinoid tumors by means of α- and β-adrenergic antagonists has been beneficial in ameliorating flushing in some instances but ineffective in others.

The results of prospective studies on somatostatin to ameliorate the symptoms of carcinoid syndrome have been dramatic. Somatostatin appears to be a major advance in the treatment of carcinoid syndrome.

Bronchospasm with or without flushing also develops in many patients when vasoactive substances are released. Thus, a patient with carcinoid tumor may be well or may be severely incapacitated by pulmonary, neurologic, nutritional, fluid, electrolytic, or cardiovascular disturbances. Therefore, although the GI system in itself may not require extensive preoperative preparation, GI disease can cause disturbances in any or all other systems that require extensive preoperative preparation to optimize the patient's condition in addition to preoperative knowledge of physiology and the effects of diseases to guide patients through the perioperative period smoothly. In addition, the anesthesiologist's understanding of the nature of the surgical procedure probably aids in determining the system involvement caused by the GI disorder.

Another perioperative consideration is that patients with GI diseases (perhaps even more so than those with other diseases) have had to endure the psychosocial trauma of having to live with their disease for long periods or the necessity of facing such a prospect.[379] They need emotional support and holistic kindnesses as much as, if not more than, other patients without sacrificing scientific rigor in the treatment of their condition. Obtaining relevant psychological data while gathering medical information, sitting (not standing) while taking the history, and empathizing with the patient about how difficult it must be to accomplish tasks with this disease (stressing

accomplishments, we have found) legitimize the physician's interests in and support of the patient's pain and other psychosocial issues. The time spent sitting and talking with the patient also allows the anesthesiologist to discuss options for pain therapy with the patient, why systemic morphine may be avoided in a patient with a fresh bowel anastomosis,[380] and other issues that show the anesthesiologist to be both a competent physician and particularly concerned with that patient's well-being. In addition to an appreciation of the organic effects of the disease, attention to emotional support of these patients perioperatively presents opportunities to use one's full skills as a physician to bring about healing.

LIVER DISEASE

What are the risks of giving anesthesia to patients with acute liver disease who require emergency surgery? What are the risks of giving anesthesia to patients with chronic impairment of liver function? What can be done to minimize these risks? Although one may think that the experiences gained from providing anesthesia for liver transplantation would answer many of these questions, a substantial difference exists between optimizing cardiovascular function to meet the needs of a new liver (e.g., supply of nutrients) and maintaining liver function in a diseased liver. Hepatic physiology and pathology are discussed in Chapter 22.

HEMATOLOGIC DISORDERS AND ONCOLOGIC DISEASE

HEMATOLOGIC DISORDERS

Sickle Cell Anemia and Related Hemoglobinopathies

The sickle cell syndromes constitute a family of hemoglobinopathies caused by abnormal genetic transformation of amino acids in the heme portion of the hemoglobin molecule. The sickle cell syndromes arise from a mutation in the β-globin gene that changes the sixth amino acid from valine to glutamic acid. A major pathologic feature of sickle cell disease is the aggregation of irreversibly sickled cells in blood vessels. The molecular basis of sickling is the aggregation of deoxygenated hemoglobin B molecules along their longitudinal axis.[381] This abnormal aggregation distorts the cell membrane and thereby produces a sickle shape. Irreversibly sickled cells become dehydrated and rigid and can cause tissue infarcts by impeding blood flow and oxygen to tissues.[381-384] Some investigators have challenged this hypothesis, with several studies showing enhanced adhesion of sickled erythrocytes to vascular endothelium.[385] Some other abnormal hemoglobins interact with hemoglobin S to various degrees and give rise to symptomatic disease in patients heterozygous for hemoglobin S and one of the other hemoglobins such as the hemoglobin of thalassemia (hemoglobin C).

Three tenths of 1% of the African American population in the United States have sickle cell–thalassemia disease (hemoglobin SC); these patients also have end-organ disease and symptoms suggestive of organ infarction. For these patients, perioperative considerations should be similar to those for patients with sickle cell disease (hemoglobin SS).

Whereas 8% to 10% of African Americans have the sickle cell trait (hemoglobin AS), 0.2% are homozygous for sickle cell hemoglobin and have sickle cell anemia. Sickle cell trait is a heterozygous condition in which the individual has one βS globin gene and one βA globin gene, which results in the production of both hemoglobin S and hemoglobin A, with a predominance of hemoglobin A. Sickle cell trait should not be considered a disease because hemoglobin AS cells begin to sickle only when the oxygen saturation of hemoglobin is less than 20%. No difference has been found between physiologically normal persons (those with hemoglobin AA) and those with hemoglobin AS regarding survival rates or the incidence of severe disease, with one exception: patients with hemoglobin AS have a 50% increase in pulmonary infarction. However, single case reports of a perioperative death and a perioperative brain infarct in two patients with hemoglobin AS disease do exist, as does a report of death believed to be caused by aortocaval compression during general anesthesia that resulted in a sickling crisis.[386] The need for exchange transfusion before cardiac surgery has been debated.[387,388] Frequent measurement of oxygen saturation (pulse oximetry) in multiple areas of the body is recommended, including the ear and toe in pregnant patients.[386]

The pathologic end-organ damage that occurs in sickle cell states is attributable to three processes: the sickling or adhesion (or both) of cells in blood vessels, which causes infarcts and subsequent tissue destruction secondary to tissue ischemia; hemolytic crisis secondary to hemolysis; and aplastic crises that occur with bone marrow exhaustion, which can rapidly result in severe anemia. Logic dictates that patients currently in crisis not undergo surgery except for extreme emergencies, and then only after an exchange transfusion.[383,385-389]

Because sickling is increased with lowered oxygen tensions, acidosis, hypothermia, and the presence of more desaturated hemoglobin S, current therapy includes keeping the patient warm and well hydrated, giving supplemental oxygen, maintaining high cardiac output, and not creating areas of stasis with pressure or tourniquets. Meticulous attention to these practices in periods when we do not usually pay most careful attention (i.e., waiting in the preinduction area) or when gas exchange may be most unmatched to the cardiovascular-metabolic demands (early postoperative period) may be important in lessening morbidity. Even following these measures routinely, with no special emphasis placed on the periods described, succeeded in reducing mortality to 1% in several series of patients with sickle cell syndromes.[386,389,390] Retrospective review of patients' charts led the authors of those studies to conclude that, at most, a 0.5% mortality rate could be attributed to the interaction between sickle cell anemia and anesthesia.

Several investigators have advocated using partial exchange transfusions perioperatively. In children with sickle cell anemia and acute lung syndromes, partial exchange transfusion improved clinical symptoms and blood oxygenation. In addition, serum bilirubin levels

decreased in patients with acute liver injury. Clinical improvement of pneumococcal meningitis and cessation of hematuria in papillary necrosis also accompanied exchange transfusion.[382] The goal of exchange transfusion is to increase the concentration of hemoglobin A to 40% and the hematocrit to 35%. The 40% figure is an arbitrary one because no controlled studies have established a threshold ratio of hemoglobin A to hemoglobin S that would render blood unable to sickle in vivo. To achieve the 40% ratio in a 70-kg adult, approximately 4 units of washed erythrocytes would have to be exchanged; the system is inexpensive but efficient.

The possible decrease in perioperative morbidity after partial exchange transfusion has not been compared with the risks of exchange, except in 2 studies,[384,391] in which the risks of exchange were found to exceed the benefits. In the first study, a retrospective review of 82 surgical procedures performed between 1978 and 1986 in 60 patients, no advantage was noted for preoperative exchange transfusion as measured by a decrease in postoperative complications.[391] (However, only the sickest patients may have received exchange transfusions because patients were not randomly allocated to exchange or nonexchange groups.) A slight increase in postoperative atelectasis requiring treatment was seen in patients given preoperative transfusions. More than 50% of the patients given transfusions had a postoperative complication. Patients who began with a hematocrit higher than 36% had a lower rate of complications.[391] In the second study, a randomized comparison of aggressive versus conservative transfusion practices in 551 patients (604 operations), perioperative sickling complications were not different between groups, and transfusion-related complications were substantially less in the conservatively treated group.[384] A more recent retrospective review of 14 patients with sickle cell anemia who were undergoing total hip revision supports the decision to perform a simple transfusion preoperatively only if the patient's hemoglobin is significantly lower than their steady-state hemoglobin level.[392] Transfusion can be used intraoperatively according to hemoglobin level or blood loss volume. Other conditions are common in sickle cell syndromes: pulmonary dysfunction with increased shunting, renal insufficiency, gallstones, small MIs, priapism, stroke, aseptic necrosis of bones and joints, ischemic ulcers, retinal detachment as a result of neovascularization, and complications of repeated transfusions.

In thalassemia, globin structures are normal, but because of gene deletion, the rate of synthesis of either the α or β chains of hemoglobin (α- and β-thalassemia, respectively) decreases.[393-395] Two copies of the gene that codes for the α-globin chain are located on chromosome 16. Deletion of all four of these genes causes cell death in utero, and three deletions cause severe chronic hemolysis and a shortened life span. α-Thalassemia-1 (trait) occurs when two genes have been deleted and mild anemia results; α-thalassemia-2 (silent) occurs when the two genes have been deleted but no mild anemia or microcytosis results. In α-thalassemia trait, the hemoglobin A_2 level is normal. β-Thalassemia is associated with an excess of α chains, which denature developing erythrocytes, thereby leading to their premature death in marrow or to shortened survival in the circulation. An elevated hemoglobin A_2 level is the hallmark of β-thalassemia trait, a common cause of mild anemia and microcytosis. Bone marrow transplantation and pharmacologic manipulation of hemoglobin F synthesis are being tried in these hemoglobinopathies, as is direct gene replacement therapy. These therapies seem to be promising in even reversing liver failure from previous iron overload.[396] These syndromes are common in Southeast Asia, India, and the Middle East and in people of African descent.

In thalassemia, facial deformity from erythropoietin-stimulated ineffective erythropoiesis (ineffective because of a genetic inability to produce useful hemoglobin) was reported to make endotracheal intubation difficult.[393,394] This one case report has not been amplified,[394] and no reports of this complication in patients with sickle cell anemia have been published. However, the anemia associated with these syndromes often produces compensatory hyperplasia of the erythroid marrow, which in turn is associated with severe skeletal abnormalities.[393-395]

Cytoskeletal Anemias (Hereditary Spherocytosis and Elliptocytosis), Enzyme-Deficient Anemias, and Autoimmune Hemolytic Anemias

Congenital abnormalities of the erythrocyte membrane are becoming better understood. In elliptocytosis and hereditary spherocytosis, the membrane is more permeable to cations and is more susceptible to lipid loss when cell energy is depleted than is the membrane of a normal red blood cell. Both hereditary spherocytosis (present in 1 in 5000 people) and hereditary elliptocytosis are inherited as autosomal dominant traits. In both disorders, defects in the membrane are thought to result from a mutation of spectrin, a structural protein of the membrane cytoskeleton.[397] Although the therapeutic role of splenectomy in these diseases is not fully defined, in severe disease, splenectomy is known to improve the shortened life span of the red blood cell 100% (from 20 to 30 days to 40 to 70 days). Because splenectomy predisposes the patient to gram-positive septicemia (particularly pneumococcal), perhaps patients should be given pneumococcal vaccine preoperatively before predictable bacteremic events. No specific problems related to anesthesia have been reported for these disorders.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency (a gender-linked recessive trait) is also reported to occur in approximately 8% of African American men.[398] Young cells have normal activity, but older cells are grossly deficient when compared with normal cells. A deficiency in G6PD results in hemolysis of the erythrocyte and the formation of Heinz bodies. Red blood cell hemolysis can also occur with intercurrent infections or after the administration of drugs that produce substances requiring G6PD for detoxification (e.g., methemoglobin, glutathione, and hydrogen peroxide). Drugs to be avoided are sulfa drugs, quinidine, prilocaine, lidocaine, antimalarial drugs, antipyretic drugs, nonnarcotic analgesics, vitamin K analogues, and perhaps sodium nitroprusside.

The autoimmune hemolytic anemias include cold antibody anemia, warm antibody anemia (idiopathic), and drug-induced anemia.[399-401] Cold antibody hemolytic

anemias are mediated by IgM or IgG antibodies, which at room temperature and lower temperatures cause red blood cells to clump. When these patients are given blood transfusions, the cells and all fluid infusions must be warm, and body temperature must be meticulously maintained at 37° C if hemolysis is to be prevented. Warm antibody (or idiopathic) hemolytic anemia is a difficult management problem characterized by chronic anemia, the presence of antibodies active against red blood cells, a positive Coombs test, and difficulty crossmatching blood. For patients undergoing elective surgery, autologous transfusions, predeposit of blood with or without erythropoietin stimulation,[402] and blood from rare Rh-negative red blood cell donors or the patient's first-degree relatives (or both) can be used. In emergency situations, the possibility of autotransfusion, splenectomy, or corticosteroid treatment should be discussed with a hematologist knowledgeable in this area.

Drug-induced anemias have three mechanisms. In receptor-type hemolysis, a drug (e.g., penicillin) binds to the membrane of the red blood cell, and the complex stimulates the formation of an antibody against the complex. In "innocent bystander" hemolysis, a drug (e.g., quinidine, sulfonamide) binds to a plasma protein, thereby stimulating an antibody (IgM) that cross-reacts with an erythrocyte. In autoimmune hemolysis, the drug stimulates the production of an antibody (IgG) that cross-reacts with the erythrocyte. Drug-induced hemolytic anemias generally cease when therapy with the drug ends. In emergency situations, the least incompatible cells available should be used for blood transfusion.

Granulocytopenia

Granulocyte mechanisms have undergone experimental elaboration since 2000, partly because of the molecular biologic revolution: in addition to erythropoietin (discussed earlier), more than 14 hemolymphopoietic growth factors or cytokines have been characterized biochemically and cloned genetically. These growth factors interact with cell-surface receptors to produce their major actions (Table 39-15).[403] Use of the colony-stimulating factors has permitted more intense oncologic treatment. The few reports related to their perioperative effects detail the unfavorable adverse consequences that such therapies can have on gas exchange when adverse immunologic effects occur.[404]

In patients who have fewer than 500 granulocytes/mL of blood and established sepsis, the use of growth factor and granulocyte transfusion has been shown to prolong life.[405-407] Although bone marrow transplantation is being used increasingly, complications usually occur after transplantation, not on harvesting of cells (at which time the anesthesiologist who is not involved in critical care is most frequently involved). Abnormal results on pulmonary function testing before bone marrow transplantation seem to predict complications after transplantation, but not so strongly as to preclude transplantation.[408]

Platelet Disorders

Although inherited platelet disorders are rare, acquired disorders are quite common and affect at least 20% of all patients in medical and surgical ICUs, with infections and drug therapies being the leading causes (see also Chapter 61).[409] Both acquired and inherited platelet conditions cause skin and mucosal bleeding, whereas defects in plasma coagulation produce deep tissue bleeding or delayed bleeding. Perioperative treatment of inherited platelet disorders (e.g., Glanzmann thrombasthenia, Bernard-Soulier syndrome, Hermansky-Pudlak syndrome) consists of platelet transfusions. EACA has been used successfully (experimentally, 1 g/70 kg four times daily) to decrease perioperative bleeding in thrombocytopenic patients. The much more common acquired disorders may respond to one of several therapies (see Chapter 61). Immune thrombocytopenias, such as those associated with lupus erythematosus, idiopathic thrombocytopenic purpura, uremia, hemolytic-uremic syndrome, platelet transfusions, heparin, and thrombocytosis, may respond to steroids, splenectomy, plateletpheresis, eradication of *Helicobacter pylori*, or alkylating agents or may require platelet transfusions, plasma exchange, whole blood exchange, or transfusion; sometimes these disorders do not respond to anything.[185,410,411] Traditionally, splenectomy is performed when steroid therapy fails or reaches a dosage that poses unacceptable risks of toxicity. Newer agents such as anti-D immune globulin and rituximab may induce desirable remissions in idiopathic thrombocytopenic purpura without splenectomy.

Thrombotic thrombocytopenic purpura is a rare disorder of unknown cause. Despite various therapies, this disorder carries a very high mortality rate. However, the introduction of plasmapheresis has improved response rates dramatically in patients with this disease. One uncontrolled study implies that the benefit lies not only in improvement of the hematologic picture but also in prevention of ARDS, a leading cause of death in these patients.[411] In that study, early institution of plasmapheresis improved oxygenation.

By far the largest number of platelet abnormalities consists of drug-related defects in the aggregation and release of platelets. Aspirin irreversibly acetylates platelet cyclooxygenase, the enzyme that converts arachidonic acid to prostaglandin endoperoxidases. Because cyclooxygenase is not regenerated in the circulation within the life span of the platelet and because this enzyme is essential for the aggregation of platelets, one aspirin tablet may affect platelet function for a week. All other drugs that inhibit platelet function (e.g., vitamin E, indomethacin, sulfinpyrazone, dipyridamole, tricyclic antidepressant drugs, phenothiazines, furosemide, steroids) do not inhibit cyclooxygenase function irreversibly; these drugs disturb platelet function for only 24 to 48 hours. If emergency surgery is needed before the customary 8-day period for platelet regeneration after aspirin therapy or if the 2-day period for other drugs has not elapsed, administration of 2 to 5 units of platelet concentrate will return platelet function in a 70-kg adult to an adequate level and platelet-induced clotting dysfunction to normal. Only 30,000 to 50,000 normally functioning platelets per milliliter are needed for normal clotting. Because low-dose aspirin therapy (<650 mg/day) allows aspirin to be gone from the body 24 hours after the last dose and because the body makes 70,000 platelets/mL blood per day, a 48-hour

TABLE 39-15 **MAJOR EFFECTS OF HEMOLYMPHOPOIETIC GROWTH FACTORS AND CYTOKINES**

Cytokine	Other Names	Biologic Effects
Erythropoietin		Erythrocyte production
Interleukin-3 (IL-3)	Multicolony-stimulating factor Stem cell–activating factor Persisting cell-stimulating factor Hemopoietin-2	Stimulates proliferation and differentiation of granulocyte, macrophage, eosinophil, mast cell, megakaryocyte, and T- and B-cell lineage and early myeloid stem cells Interacts with erythropoietin to stimulate erythroid colony formation, stimulates proliferation of AML blasts, and stimulates histamine release by mast cells
Granulocyte colony-stimulating factor (G-CSF)	Differentiation factor MGI-2	Stimulates granulocyte lineage proliferation and differentiation Acts on early myeloid stem cells, especially in association with other factors; synergizes with IL-3 to stimulate megakaryocyte colony formation Increases neutrophil phagocytes and antibody-dependent cell-mediated cytotoxicity Releases neutrophils from bone marrow and is chemotactic for neutrophils and monocytes Enhances phagocytosis and antibody-dependent cell-mediated cytotoxicity and oxidative metabolism of neutrophils Stimulates monocyte killing of *Mycobacterium avium-intracellulare* and *Candida* species, tumoricidal activity of monocytes, antibody-dependent cell-mediated cytotoxicity, and expression of cell-surface proteins
Granulocyte-macrophage colony-stimulating factor (GM-CSF)		Stimulates granulocyte, macrophage, and megakaryocyte proliferation and differentiation, early myeloid stem cells, and—in the presence of erythropoietin—erythropoiesis Enhances the cytotoxic and phagocytic colony-stimulating factor activity of neutrophils against bacteria, yeast, parasites, and antibody-coated tumor cells Increases surface expression of neutrophil adhesion proteins and enhances eosinophil cytotoxicity, macrophage phagocytosis, and basophil histamine release Amplifies IL-2–stimulated T-cell proliferation and stimulates B-cell lines to proliferate
Colony-stimulating factor-1	Macrophage colony-stimulating factor	Stimulates predominantly macrophage-monocyte proliferation and differentiation with lesser effects on granulocytes Acts synergistically with other factors on earlier myeloid stem cells Stimulates macrophage phagocytosis, killing, migration, antitumor activity, and metabolism Stimulates secretion of plasminogen activator, G-CSF, interferon, IL-3, or tumor necrosis factor by peritoneal macrophages
Interleukin-1 (α and β)	Endogenous pyrogen Hemopoietin-1 Osteoclast-activating factor Lymphocyte-activating factor	Induces synthesis of acute-phase proteins by hepatocytes Activates resting T cells, cofactor for T- and B-cell proliferation Chemotactic for monocytes and neutrophils Induces production of growth factors, including G-CSF, GM-CSF, IL-6, CSF-1, IL-3, and interferon by many cells Radioprotective in mice
Interleukin-2	T-cell growth factor	Growth factor for T cells, activates cytotoxic T lymphocytes, promotes synthesis of other cytokines, enhances natural killer cell function
Interleukin-4	B-cell–stimulating factor-1 (BSF-1) B-cell differentiation factor (BCDF) IgG induction factor	Enhances antibody production (IgG and IgE) and up-regulates class II MHC molecules and Fc receptors on B cells Costimulant with anti-IgM antibodies for induction of DNA synthesis in resting B cells Stimulates growth of activated T cells In the presence of IL-3, enhances mast cell growth; with G-CSF, enhances granulocytes of GM colony formation; and with erythropoietin and/or IL-1, stimulates erythroid and megakaryocyte colony formation
Interleukin-5	Eosinophil differentiation factor (EDF) T-cell–replacing factor (TRF) B-cell growth factor-II (BCGF-II) B-cell differentiation factor (BCDF)	Enhances antibody production (IgA) Promotes proliferation and IgG secretion by B-cell lines and induces hapten-specific IgG secretion in vitro by in vivo–primed B cells Promotes differentiation by normal B cells Stimulates eosinophil production and differentiation (GM-CSF and IL-3 act synergistically with IL-5 to stimulate eosinophil proliferation and differentiation) Enhances synthesis of IL-2 receptors
Interleukin-6	B-cell–stimulating factor-2 (BSF-2) Interferon-β_2 T-cell activation factor Hybridoma growth factor	B-cell differentiation and IgG secretion T cells activated to cytotoxicity Synergizes with IL-3 on early marrow myeloid stem cells and stimulates proliferation and differentiation of granulocytes, macrophages, eosinophils, mast cells, and megakaryocytes, as well as platelet production (may be a thrombopoietin)

TABLE 39-15 **MAJOR EFFECTS OF HEMOLYMPHOPOIETIC GROWTH FACTORS AND CYTOKINES—cont'd**

Cytokine	Other Names	Biologic Effects
Interleukin-7	Lymphopoietin-1	Stimulates pre–B-cell production Stimulates T-cell proliferation
Interleukin-8*	Neutrophil-activating factor T-cell chemotactic factor	Inflammatory mediator; stimulates activation of neutrophils
Interleukin-9		Stimulates erythroid colony formation and proliferation of a megakaryocyte cell line
Interleukin-10	Cytokine synthesis–inhibiting factor	Inhibits cytokine production by T_H1 cells
Interleukin-11		Stimulates B-cell, megakaryocyte, and mast cell lineages
C-kit ligand	Mast cell factor Stem cell factor Hemolymphopoietic growth factor-1	Acts on relatively early stem cells synergistically with other cytokines Stimulates pre-B cells

AML, Acute myeloblastic leukemia; *IgA,* immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *MHC,* major histocompatibility complex; *T_H1,* first of the thymus-derived cells.
*Not considered a true growth factor but included here for completeness.

period after the last aspirin in minidose therapy should be sufficient time for platelet aggregation to become normal. This may be the period that must pass to avoid platelet transfusions and their associated risks. One platelet transfusion will increase the platelet count from 4000 to 20,000/mL blood; the platelet half-life is approximately 8 hours.

Heparin-induced thrombocytopenia can develop within hours on reexposure to heparin in a previously sensitized patient. Lepirudin and argatroban are direct thrombin inhibitors effective as therapy for heparin-induced thrombocytopenia.[412]

Major risk factors for thrombosis include factor V Leiden and prothrombin 20210A mutations, elevated plasma homocysteine, and the antiphospholipid antibody syndrome.[413,414] Clinicians facing these challenging patients may seek expert local consultation for help with management. This issue is discussed more fully in Chapter 62.

Hemophilia and Related Clotting Disorders

Abnormalities in blood coagulation as a result of defects in plasma coagulation factors are either inherited or acquired. Inherited disorders include X-linked hemophilia A (a defect in factor VIII activity), von Willebrand disease (defect in the von Willebrand component of factor VIII), hemophilia B (a sex-linked deficiency of factor IX activity), and other less common disorders. The sex-linked origin of some of these disorders means that hemophilia occurs almost exclusively in the male children of female carriers; men do not transmit the disease to their male children.

In elective surgery, levels of the deficient coagulation factor should be assayed 48 hours preoperatively and the level restored to 40% of normal before the surgical procedure. One unit of factor concentrate per kilogram of body weight normally increases the factor concentration by 2%. Thus, in an individual essentially devoid of activity, administration of 20 units/kg body weight would be required as an initial dose. Because the half-life is 6 to 10 hours for factor VIII and 8 to 16 hours for factor IX, approximately 1.5 units/hour/kg of factor VIII or 1.5 units/2 hours/kg of factor IX should be given. Additional administration of factors VIII and IX should be guided by the activity of the clotting factors for approximately 6 to 10 days postoperatively.[415-417]

These factors are available in various preparations; the newer genetically engineered von Willebrand factor, cryoprecipitate, which contains 20 units/mL, is obtained from regular donors (the risk of hepatitis being 1 in 200 for 5-mL lots) or from fresh frozen plasma (which contains 1 unit/mL). Some risk of transmitting hepatitis virus and HIV (the agent of acquired immunodeficiency syndrome [AIDS]) accompanies transfusion but, with better testing, much less than formerly.[418-421] Current screening of blood for aspartate or alanine aminotransferase levels is believed to result in a much lower risk of hepatitis C and even AIDS from transfusion. Theoretically, antigenic testing for HIV should further decrease the risk of transmission by blood products. Heat treatment is also reported to reduce the risk substantially. Factor IX, but not factor VIII, is contained in prothrombin complex concentrates; however, these concentrates may contain activated clotting factors, which can lead to disseminated intravascular coagulation (DIC) and a high risk for hepatitis. In addition, although EACA or tranexamic acid is sometimes administered as a fibrinolytic inhibitor, these substances carry with them a significant risk for DIC. Additional hazards of modern therapy include acute and chronic hepatitis, AIDS, hypersensitivity reactions, psychic trauma, chronic pain with narcotic addiction, and inhibition of factors, especially VIII.

An antibody that inactivates factor VIII or IX (fresh frozen plasma fails to increase clotting factor activity after incubation with the patient's plasma) develops in approximately 10% of patients with either hemophilia A or B. These acquired anticoagulants are usually composed of IgG, are poorly removed by plasmapheresis, and are variably responsive to immunosuppressive drugs. The use of prothrombin complex concentrates can be lifesaving but carries the risk of DIC and hepatitis.

Vitamin K deficiency is discussed in the section on liver disease. To review, vitamin K–dependent clotting factors (II, VII, IX, and X) require vitamin K for the post-synthetic addition of γ-carboxyl groups to glutamate residues; administration of vitamin K or fresh frozen plasma can correct these deficiencies.

Patients who come to the operating room after having received many units of blood (as in massive GI bleeding) may have deficient clotting. This impaired clotting is initially caused by depletion of platelets, which occurs after administration of approximately 10 to 15 units of blood and, later, by depletion of coagulation factors (see Chapter 62). Treatment of these deficiencies can be corrected with platelet concentrates—each concentrate is normally suspended in 50 mL of fresh plasma; thus, coagulation factors are also replaced.

Urokinase, streptokinase, and tissue-type plasminogen activator (t-PA) have been used to treat pulmonary embolism, deep vein thrombosis, stroke, and arterial occlusive disease. These drugs accelerate the lysis of thrombi and emboli, in contrast to heparin, which may prevent, but not dissolve a thrombus. Bleeding complications associated with these fibrinolytic agents are the result of dissolution of hemostatic plugs and can be quickly reversed by discontinuing the medication and replenishing plasma fibrinogen with cryoprecipitate or plasma. However, cryoprecipitate and plasma are seldom needed preoperatively because the fibrinolytic activity of urokinase and streptokinase usually dissipates within 1 hour of discontinuing their administration. Nonetheless, insufficient data have accumulated to prescribe the ideal preoperative preparation and intraoperative management of hemostasis in patients recently treated with urokinase, streptokinase, or t-PA. Postponing surgery for three half-lives of the drug (increases in plasmin activity in blood can be assayed for ≥4 to 8 hours) may not be possible, and meticulous observation of the operative field for hemostasis may not suffice.[422,423] The process may be even more complex in a patient with a vascular or cardiac condition who requires heparin administration intraoperatively. To correct the fibrinogen deficiency in these patients, some clinicians administer fibrinogen preoperatively and EACA at heparin administration.

DDAVP has been used in operations associated with high blood loss as a routine measure to decrease bleeding and transfusion requirements. DDAVP therapy began as treatment of platelet dysfunction in von Willebrand disease but has since expanded to routine use in patients undergoing cardiovascular surgery and to frequent use in other high–blood loss operations. A meta-analysis of cardiac surgery concluded that DDAVP was not associated with a clinically significant reduction in exposure to blood transfusion in unselected patients, and therefore the authors were unable to recommend the routine use of DDAVP in patients exposed to CPB.[424] However, DDAVP may reduce postoperative bleeding in patients who have received preoperative aspirin within 7 days of surgery, patients with CPB times in excess of 140 minutes, and patients with demonstrable platelet dysfunction. The authors suggested that DDAVP could be used selectively in these subgroups.

ONCOLOGIC DISEASE

Patients with malignant tumors may be otherwise healthy or may be desperately ill with nutritional, neurologic, metabolic, endocrinologic, electrolyte, cardiac, pulmonary, renal, hepatic, hematologic, or pharmacologic disabilities. Thus, determining the other disabilities accompanying malignant tumors requires evaluation of all systems. Abnormalities frequently accompanying such tumors include hypercalcemia either by direct bone invasion or by ectopic elaboration of PTH or other bone-dissolving substance, uric acid nephropathy, hyponatremia (especially with small cell, or oat cell, carcinoma of the lung), nausea, vomiting, anorexia and cachexia, fever, tumor-induced hypoglycemia, intracranial metastases (10% to 20% of all cancers), peripheral nerve or spinal cord disorders, meningeal carcinomatosis, toxic neuropathies secondary to anticancer therapy, and paraneoplastic neurologic syndromes (dermatomyositis, Eaton-Lambert syndrome, myopathies, and distal neuropathies).

Many patients with malignant tumors are given large doses of analgesics and should be kept comfortable during the perioperative period. Avoiding drug dependence is of no practical importance in terminally ill patients.[425] Marijuana (tetrahydrocannabinol) depresses the CNS vomiting center and may be more effective than the phenothiazines or butyrophenones in suppressing the nausea associated with cancer and its therapy; marijuana decreases anesthetic requirements 15% to 30%. Immunomodulators, stimulating factors or cytokines, gene identification,[426,427] and drugs for treating side effects (e.g., midazolam or ondansetron) have given new hope for safer, more effective therapy with fewer limiting side effects. The effect of ondansetron in preventing vomiting and the effect of midazolam in preventing memory-stimulated vomiting have been important additions. The neurokinin-1 (NK-1) antagonists have also been approved for treatment in oncologic patients.

The toxicity of cancer chemotherapy is related to the drugs used and the dose. For radiation therapy, damage occurs when the following doses are exceeded: lungs, 1500 rad; kidneys, 2400 rad; heart, 3000 rad; spinal cord, 4000 rad; intestine, 5500 rad; brain, 6000 rad; and bone, 7500 rad. The toxicities of biologic and immunomodulating therapies are related to the change in immune function that they cause. Alkylating agents cause bone marrow depression, including thrombocytopenia, as well as alopecia, hemorrhagic cystitis, nausea, and vomiting. The alkylating agents, including cyclophosphamide and mechlorethamine, can act as an anticholinesterase and prolong neuromuscular blockade.[428] The antineoplastic alkaloid vincristine produces peripheral neuropathy and SIADH, and vinblastine produces myelotoxicity. Cisplatin is also associated with peripheral neuropathy and severe nausea. Nitrosoureas can produce severe hepatic and renal damage, as well as bone marrow toxicity, myalgia, and paresthesia. Folic acid analogues such as methotrexate have been linked to bone marrow depression, ulcerative stomatitis, pulmonary interstitial infiltrates, GI toxicity, and occasionally, severe liver dysfunction. Fluorouracil

and floxuridine, both pyrimidine analogues, cause bone marrow toxicity, megaloblastic anemia, nervous system dysfunction, and hepatic and GI alterations. Purine analogues (mercaptopurine, thioguanine) have bone marrow depression as their primary toxic effect. Anthracycline antibiotics (doxorubicin, daunorubicin, mithramycin, mitomycin C, bleomycin) can all cause pulmonary infiltrates, cardiomyopathy (especially doxorubicin and daunorubicin), myelotoxicity, and GI, hepatic, and renal disturbances.

The wisdom of anesthetizing patients given bleomycin has been questioned. A retrospective study by Goldiner and coauthors reported postoperative deaths in 5 consecutive patients given bleomycin.[429] All 5 patients died of postoperative respiratory failure. Using the same anesthetic technique, Goldiner and coauthors then anesthetized 12 patients, limited the inspired oxygen concentration to 22% to 25% perioperatively, and replaced much of the blood loss with colloids rather than crystalloids.[429] None of the 12 patients died. These investigators postulated that bleomycin caused epithelial cell edema that progressed to necrosis of type I alveolar cells, leakage of fluid into the alveolar space, and the formation of hyaline membranes similar to those associated with oxygen toxicity. Goldiner and coauthors believe that this pathophysiologic similarity indicates a possible synergistic relationship between oxygen and bleomycin.[429] However, LaMantia and co-workers retrospectively analyzed the changes in 16 patients undergoing surgery after bleomycin therapy.[430] Thirteen patients were given oxygen at inspired concentrations of 37% to 45%. No instances of postoperative respiratory failure occurred. Using data from the Mayo Clinic registry, the incidence of postoperative ARDS after major surgery with general anesthesia is approximately 1.3% (95% CI, 0.6% to 2.6%).[431] The authors found a history of smoking as a major risk factor. Therefore, general anesthesia appears safe with appropriate perioperative management.

PATIENTS GIVEN DRUG THERAPY FOR CHRONIC AND ACUTE MEDICAL CONDITIONS

A steadily increasing number of potent drugs are being used to treat disease, and the average hospitalized patient receives more than 10 drugs (see also Chapter 38). Many drugs have side effects that may make anesthesia more risky or patient management more difficult. Knowing the pharmacologic properties and potential side effects of commonly used drugs helps the anesthesiologist avoid pitfalls during anesthesia and surgery.

ANTIHYPERTENSIVE DRUGS

ACE inhibitors (captopril, enalapril, lisinopril, enalaprilat, and ramipril) and angiotensin II receptor blockers are being used increasingly as first-line drugs and appear to improve the quality of life of patients taking antihypertensive drugs. One of the angiotensin II receptor blockers—valsartan—when combined with a diuretic, actually increases libido in both men and women while decreasing arterial blood pressure. However, ACE inhibitors and angiotensin II receptor blockers may be associated with more peripheral vasodilation and hypotension on induction of anesthesia than are sympatholytic agents. Added to this group are the ACE receptor blocking agents. Both ACE inhibitors and ACE receptor blocking agents are associated with such severe hypotension with standard anesthetic induction that we discontinue or at least consider discontinuing the use of these drugs preoperatively (see earlier).

Catecholamine or sympathetic receptor blocking drugs affect the three major types of catecholamine receptors: α-adrenergic, β-adrenergic, and dopaminergic. The existence of subdivisions (e.g., β_1 and β_2) suggested the possibility that some drugs would be found to affect only one set of receptors. For example, terbutaline is used more frequently than isoproterenol because terbutaline is said to exert a preferential effect on α_2 receptors (i.e., dilation of bronchial smooth muscle), thereby avoiding the cardiac stimulation produced by drugs that stimulate β_1-receptors. In fact, the selectivity is dose related. At a certain dose, a direct β_2-receptor stimulating drug affects only those receptors but, at a higher dose, stimulates both β_1 and β_2 receptors. The effect of a given dose varies with each patient. A certain dose may stimulate β_1 and β_2 receptors in one patient but neither receptor in another patient. More and more selective blocking drugs are being developed in hope of widening the margin among β_1-, β_2-, and α-adrenergic effects. Ultimately, however, even more selectivity is desired. It would be advantageous to be able to decrease the heart rate without changing myocardial contractility or to increase contractility without changing the heart rate. Such is the goal of much drug research and the development of dobutamine and fenoldopam. However, to date, all such selectivity appears to be dose related, even for dobutamine.

Metoprolol (Lopressor) and atenolol (Tenormin) (both β_1-adrenergic receptor blocking drugs) and propranolol, betaxolol, timolol, esmolol, pindolol, oxprenolol, acebutolol, carteolol, penbutolol, and nadolol are widely available β-adrenergic receptor blocking drugs used for long-term therapy in the United States. Because nadolol has poor lipid solubility, it has a long elimination half-life (17 to 24 hours) and does not cross the blood-brain barrier readily. Although selective β-adrenergic receptor blocking drugs should be more appropriate in patients with increased airway resistance or diabetes, this advantage is apparent only when low doses are used. The use of β-adrenergic receptor blocking drugs has become widespread because these drugs treat everything from angina and hypertension to priapism and stage fright. These drugs appear to decrease morbidity and mortality in patients who have initially survived MI,[432,433] and they may increase perioperative survival in selected patients.

When administration of β-adrenergic receptor blocking drugs is terminated, sympathetic stimulation often increases, as though the body had responded to the presence of these drugs by increasing sympathetic neuron activity. Thus, propranolol and nadolol (to name just two) withdrawal can be accompanied by a hyper–β-adrenergic condition that increases myocardial oxygen demands. Administering propranolol or metoprolol can cause bradycardia, CHF, fatigue, dizziness, depression, psychoses,

bronchospasm, and Peyronie disease. The POISE study emphasized the concerns that inadequate titration of these agents can lead to stroke or increased mortality.[111] Side effects of dopaminergic receptor blocking drugs are discussed later. Prazosin (Minipress), terazosin, and oxazocin are α_1-adrenergic receptor blocking drugs used to treat hypertension, ischemic cardiomyopathy, receding hairlines, and benign prostatic hypertrophy because they dilate both veins and arteries and reduce sphincter tone. These drugs are associated with vertigo, palpitations, depression, dizziness, weakness, and anticholinergic effects.

Some sympathomimetic drugs stimulate α-adrenergic receptors in the brainstem. Clonidine (Catapres), a drug with a half-life of 12 to 24 hours, guanabenz, and guanfacine (Tenex) are α_2-adrenergic receptor stimulants. Presumably, α_2-adrenergic agonists, including clonidine, guanabenz, and guanfacine, lower arterial blood pressure on a long-term basis through the central brainstem adrenergic stimulation referred to previously. They may also be used on a long-term basis to treat opiate, cocaine, food, and tobacco withdrawal. Occasionally, withdrawal from clonidine can precipitate a sudden hypertensive crisis, analogous to that occurring on withdrawal from propranolol, and it can cause a hyper–β-adrenergic condition. The degree of hypertensive crisis after clonidine withdrawal is now being debated. (Although intravenous clonidine is not available in the United States, a skin patch of clonidine is used preoperatively to ablate sympathomimetic responses perioperatively.) Tricyclic antidepressant drugs and presumably phenothiazines and the butyrophenones interfere with the action of clonidine. Although administration of a butyrophenone (e.g., droperidol) to a patient taking clonidine, guanabenz, or guanfacine on a long-term basis could theoretically precipitate a hypertensive crisis, this has not been reported. Clonidine administration can be accompanied by drowsiness, dry mouth, orthostatic hypotension, bradycardia, and impotence. Acute clonidine or dexmedetomidine administration decreases anesthetic requirements by at least 40% to 60%; long-term administration decreases requirements by 10% to 20%.[434,435] Because of the relative safety of these drugs and their ability to decrease anesthetic requirements, block narcotic-induced muscle rigidity, and provide pain relief, their popularity preoperatively, intraoperatively, and in ICU sedation is increasing dramatically.[434-438]

Three other classes of antihypertensive drugs affect the sympathetic nervous system indirectly: diuretics, arteriolar dilators, and slow-(calcium) channel blocking agents. Thiazide diuretic drugs are associated with hypochloremic alkalosis, hypokalemia, hyperglycemia, hyperuricemia, and hypercalcemia. The potassium-sparing diuretic drug spironolactone is associated with hyperkalemia, hyponatremia, gynecomastia, and impotence. All diuretic drugs can cause dehydration. The thiazide diuretics and furosemide appear to prolong neuromuscular blockade. The arteriolar dilator hydralazine can cause a lupus-like condition (usually with renal involvement), nasal congestion, headache, dizziness, CHF, angina, and GI disturbances. Such a syndrome is nonexistent with the other direct vasodilator on the U.S. market, minoxidil.

The slow-channel calcium ion antagonists (calcium channel blocking drugs) inhibit the transmembrane influx of calcium ions into cardiac and vascular smooth muscle. Such inhibition reduces the heart rate (negative chronotropy), depresses contractility (negative inotropy), decreases conduction velocity (negative dromotropy), and dilates coronary, cerebral, and systemic arterioles (Fig. 39-7).[439] Verapamil, diltiazem, and nifedipine all

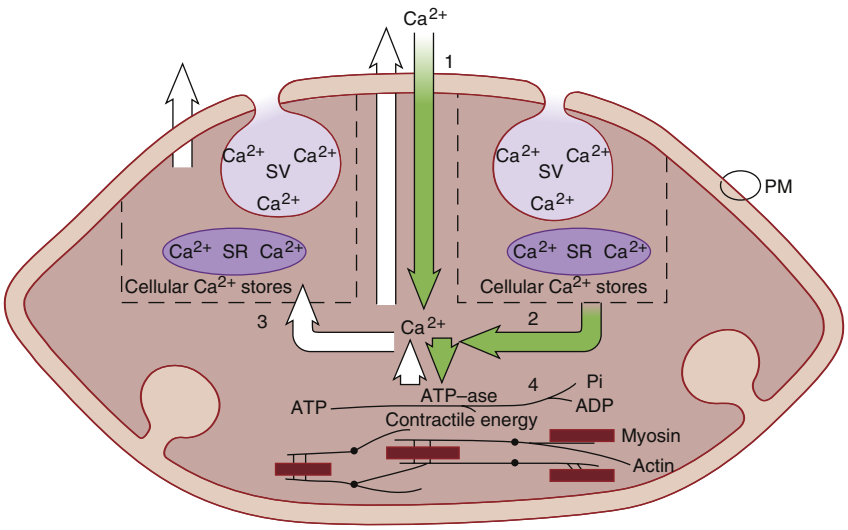

Figure 39-7. Schematic drawing of a smooth muscle cell showing calcium (Ca^{2+}) flux and possible sites of interference by halothane and nifedipine. The concentration of calcium in the cytoplasm increases *(green arrows)* because of entry through the plasma membrane (PM) and release from surface vesicles (SV) or the sacroplasmic reticulum (SR). When the concentration of cytoplasmic Ca^{2+} is sufficiently high, adenosine triphosphate (ATP) is activated. Splitting of ATP by adenosine triphosphatase (ATPase) into phosphatidylinositol (Pi) and adenosine diphosphate (ADP) provides the interaction and contraction of actin filaments and myosin particles constituting muscle fibers. The concentration of cytoplasmic Ca^{2+} decreases *(white arrows)* with the return of Ca^{2+} to cellular stores and the extracellular transport of Ca^{2+}. Both halothane and nifedipine probably (1) inhibit the entry of Ca^{2+} and (2) may also interfere with cytoplasmic Ca^{2+} flux by reducing the release of Ca^{2+} by the SR, by (3) reducing storage and reuptake, or by (4) blocking ATPase or the contractile mechanism (or both). *(Redrawn from Tosone SR, Reves JG, Kissin I, et al: Hemodynamic responses to nifedipine in dogs anesthetized with halothane,* Anesth Analg *62:903, 1983.)*

produce such effects, but to varying degrees and apparently by similar, but different mechanisms. These mechanisms relate to the three different classes of calcium channel antagonists that they represent: the phenylalkyl amines, the benzothiazepines, and the dihydropyridines, respectively. Nifedipine is the most potent of the three as a smooth muscle dilator, whereas verapamil and diltiazem have negative dromotropic and inotropic effects and vasodilating properties. Diltiazem has weak vasodilating properties when compared with nifedipine and has less of an AV conduction effect than does verapamil. Thus, verapamil and diltiazem can increase the PR interval and produce AV block. In fact, reflex activation of the sympathetic nervous system may be necessary during the administration of diltiazem, and especially during verapamil therapy, to maintain normal conduction. Clearly, verapamil and diltiazem must be titrated very carefully when a patient is already taking a β-adrenergic receptor blocking drug or when adding β-blocking drugs to a patient already taking verapamil or diltiazem.

The use of calcium channel blocking drugs has several important implications for anesthetic management.[439-441] First, the effects of inhaled and narcotic anesthetics and nifedipine in decreasing systemic vascular resistance, arterial blood pressure, and contractility may be additive. Similarly, verapamil and anesthetics (inhaled anesthetics, nitrous oxide, and narcotics) increase AV conduction times and additively decrease arterial blood pressure, systemic vascular resistance, and contractility. Second, verapamil and presumably the other calcium channel blocking drugs have been found to decrease anesthetic requirements by 25%. These drugs can produce neuromuscular blockade, potentiate both depolarizing and nondepolarizing neuromuscular blocking drugs, and, in at least one type of myopathy (Duchenne muscular dystrophy), even precipitate respiratory failure. Finally, because slow-channel activation of calcium is necessary to cause spasms of cerebral and coronary vessels, bronchoconstriction, and normal platelet aggregation, these drugs may have a role in treating ischemia of the nervous system, bronchoconstriction, and unwanted clotting disorders perioperatively. All three drugs are highly protein bound and may displace or be displaced by other drugs that are also highly protein bound (e.g., lidocaine, bupivacaine, diazepam, disopyramide, and propranolol). Adverse consequences can be minimized by titrating the inhaled or narcotic drug to the hemodynamic and anesthetic effects. Hemodynamic, but not electrophysiologic, changes can usually be reversed by administering calcium. Reversal of the electrophysiologic effects may occur if "industrial" doses of β-adrenergic agonists are given.

MOOD-ALTERING DRUGS

Mood-altering drugs are the most frequently prescribed medications in the United States.[442,443] They include MAOIs, SSRIs, phenothiazines, tricyclic antidepressant drugs, other antidepressants that do not fall into previous drug category classifications such as bupropion, and drugs of abuse such as cocaine. MAOIs, which include isocarboxazid (Marplan), phenelzine (Nardil), pargyline (Eutonyl), tranylcypromine (Parnate), and deprenyl, bind irreversibly to the enzyme MAO, thereby increasing intraneuronal levels of amine neurotransmitters (serotonin, norepinephrine, dopamine, epinephrine, octopamine). This increase is associated with an antidepressant effect, an antihypertensive effect, an antinarcoleptic effect, elevation of liver enzymes, and delayed onset of Parkinson disease (deprenyl). Because two forms of the enzyme (MAO-A and MAO-B) are selective in vitro for substrate (MAO-A is selective for serotonin, dopamine, and norepinephrine; MAO-B for tyramine and phenylethylamine), presumably MAOIs selective for MAO-A or MAO-B would have different effects.[444] This is not known for certain inasmuch as deprenyl (selegiline [Eldepryl]), an MAO-B–selective drug, improves a dopamine deficiency state, parkinsonism.

Interactions between MAOIs and a variety of foods and drugs containing indirect-acting sympathomimetic substances such as ephedrine or tyramine (found especially in aged cheeses) can occur for as long as 2 weeks after the last dose of MAOI is given. The most serious effects of this interaction are convulsions and hyperpyrexic coma (particularly after narcotics).

Anesthetic management of a patient given an MAOI can be chaotic; for this reason it is widely accepted practice to discontinue MAOIs at least 2 to 3 weeks before any planned operation.[442-448] An alternative point of view has been expressed regarding severely psychotic patients or emergency surgery.[444,449-451] Clearly, the risk of discontinuing MAOIs must be weighed against the risk of suicidal tendencies in some patients deprived of MAOIs. No reported experiences of interactions between narcotics and deprenyl have been published, so judgments about possible worsening of Parkinson disease and continuing MAOIs have no basis in data. Severe reactions have occurred when too short an interval existed between the administration of MAOIs and tricyclic antidepressants. Emergency surgery in patients given MAOIs can be punctuated by hemodynamic instability. A regional block can be attempted as treatment of postoperative pain to avoid having to give narcotics. Cases of hyperpyrexic coma after the administration of most narcotics have been reported in humans, and animal studies document a 10% to 50% incidence of hyperpyrexic coma in animals pretreated with MAOIs and then given a variety of narcotics.[442-448] These reactions appear to be treated best by therapy supporting vital functions.

Alternative drugs for the treatment of severe depression include the tricyclic antidepressant drugs: amitriptyline (Elavil, Endep), imipramine (Tofranil, Presamine), desipramine (Norpramin), doxepin (Adapin, Sinequan), nortriptyline (Aventyl), fluoxetine (Prozac), trazodone (Desyrel), and others.[442,443] Tricyclic antidepressant drugs also block the reuptake of neurotransmitters and cause their acute release. Given on a long-term basis, these drugs decrease stores of noradrenergic catecholamines. Tricyclic antidepressant drugs also produce side effects similar to those of atropine (dry mouth, tachycardia, delirium, urinary retention) and can cause changes on the ECG (changes in the T wave, prolongation of the QRS complex, bundle branch block or other conduction abnormalities, or PVCs). Although arrhythmias induced by tricyclic antidepressants have been treated

successfully with physostigmine, bradycardia has sometimes occurred.[442,443] Drug interactions with tricyclic antidepressants include those related to blockade of the reuptake of norepinephrine (e.g., interference with the action of guanethidine) and fatal arrhythmias after halothane and pancuronium.[452,453] Such interactions, although predictable for a population of patients, may not alter a patient's threshold for arrhythmias. The newer antidepressants (the SSRIs) can also have serious side effects. Fluoxetine, a tricyclic antidepressant that also has an SSRI effect, causes nausea, vomiting, headaches, nervousness, and possibly paranoia and ideas of suicide more commonly than do the other tricyclics[442,443]; however, it is less likely to cause anticholinergic effects or orthostatic hypotension. Bupropion, which is fundamentally different than the SSRIs, may cause nausea, vomiting, seizures, agitation, tremor, excitement, and increased motor activity, but it only rarely causes anticholinergic effects or orthostatic hypotension. Discontinuing drugs can cause withdrawal symptoms or precipitate recurrence of psychiatric illness. Switching among drugs for depression can cause hyperpyrexia and coma. Thus, switching drugs preoperatively should not be requested casually.[442,443]

The effectiveness of phenothiazines and butyrophenones in schizophrenia suggests a dopamine receptor blocking action. In addition, these drugs possess varying degrees of parasympathetic stimulation and ability to block α-adrenergic receptors. The phenothiazines include chlorpromazine (Thorazine, Chlor-PZ), promazine (Sparine), triflupromazine (Vesprin), fluphenazine (Prolixin), trifluoperazine, prochlorperazine (Compazine), and many others. The butyrophenones include droperidol and haloperidol (Haldol). Both the phenothiazines and butyrophenones produce sedation, depression, and antihistaminic, antiemetic, and hypothermic responses. They are also associated with cholestatic jaundice, impotence, dystonia, and photosensitivity. Other side effects associated with phenothiazines include orthostatic hypotension (partly as a result of α-adrenergic blockade) and abnormalities on the ECG such as prolongation of the QT or PR intervals, blunting of T waves, depression of the ST segment, and on rare occasion, PVCs and torsades de pointes.[442,443,452,453] Although few data are available on the antidepressant drugs selective for serotonin (the SSRIs), occasional case reports of severe hypotension and cardiac arrest with severe bradycardia have been presented in abstract form.

Several important drug interactions are noteworthy for the phenothiazine derivatives. The effects of CNS depressants (especially narcotics and barbiturates) are enhanced by the concomitant administration of phenothiazines. In addition, the CNS seizure threshold is lowered by the administration of phenothiazines, which should be avoided in patients who are epileptic or withdrawing from any drug that depresses the CNS. The antihypertensive effects of guanethidine and guanadrel are blocked by tricyclic antidepressant drugs and the phenothiazines.[454] Lithium carbonate is used to treat manic depression, but it is more effective in preventing mania than in relieving depression. In excitable cells, lithium mimics sodium and decreases the release of neurotransmitters both centrally and peripherally. Lithium prolongs neuromuscular blockade and may decrease anesthetic requirements because it blocks brainstem release of norepinephrine, epinephrine, and dopamine.

Psychoactive drugs such as the amphetamines (including methamphetamines and their smokable derivative in crystal form known as "ice") and cocaine acutely release norepinephrine, epinephrine, and dopamine and block their reuptake. Taken on a long-term basis, they deplete nerve endings of these neurotransmitters.

Drugs that appear to increase central α-adrenergic release increase anesthetic requirements, whereas drugs that appear to decrease central α-adrenergic release decrease anesthetic requirements. (This may not be the mechanism by which they alter anesthetic requirements, but it is a convenient way of remembering the alteration.) Drugs that affect only the β-adrenergic receptors do not alter anesthetic requirements.

ANTIARRHYTHMIC DRUGS

Antiarrhythmic drugs include local anesthetics (lidocaine, procaine), anticonvulsant (phenytoin) or antihypertensive (propranolol) drugs, calcium channel blocking drugs, or primary antiarrhythmic drugs (see also Chapters 67 and 68). These drugs are classified into five major categories: local anesthetics that alter phase 0 and phase 4 depolarization (quinidine, procainamide, and flecainide), local anesthetics that affect only phase 4 depolarization (lidocaine, tocainide, phenytoin, encainide), β-adrenergic receptor antagonists, antiadrenergic drugs (bretylium, disopyramide, amiodarone), and calcium entry blockers. These drugs are discussed elsewhere in this chapter. A lack of adverse reports does not indicate that all these drugs should be continued through the time of surgery; pharmacokinetic studies have not yet determined whether anesthesia (or anesthesia with specific agents) alters the volume of distribution or clearance of these drugs to an extent sufficient to warrant changing the dosage or dosage schedule in the perioperative period. The dearth of reports on this subject may reflect a lack of significant drug interaction or a lack of awareness that untoward events could be caused by such an interaction.

The pharmacologic characteristics of the various antiarrhythmic drugs can affect anesthetic management. Disopyramide is similar to quinidine and procainamide in its antiarrhythmic effectiveness. Disopyramide is excreted mainly by the kidneys, but hepatic disease increases its half-life. This drug often produces anticholinergic effects, including tachycardia, urinary retention, and psychosis. Hepatitis has also been reported to have occurred after its use.[455] Little is known of the interaction of bretylium with anesthetic agents. Because bretylium blocks the release of catecholamines, long-term therapy with this drug has been associated with hypersensitivity to vasopressors.[455] Quinidine depends on the kidneys for excretion, can produce vagolytic effects that can decrease AV block, and is associated with blood dyscrasias and GI disturbances.[455] Most of the antiarrhythmic drugs enhance nondepolarizing neuromuscular blockade. Reports have confirmed this enhancement for quinidine, phenytoin, lidocaine, procainamide, and propranolol.[456-464] No data document such an effect for depolarizing muscle relaxants. Amiodarone, an antiadrenergic drug used to treat

recurrent supraventricular and ventricular tachycardia, causes thyroid dysfunction as a result of the large amount of iodine in its structure (see the section on thyroid disorders earlier in this chapter), as well as peripheral neuropathy, and has been associated with hypertension, bradyarrhythmias, and reduced cardiac output during anesthesia.[465] The drug has a half-life of 29 days, and its pharmacologic effects persist for more than 45 days after discontinuance.[466]

ANTIBIOTICS

Many antibacterial drugs are nephrotoxic or neurotoxic, or both, and many prolong neuromuscular blockade (see also Chapters 34 and 35).[458-464] The only antibiotics devoid of neuromuscular effects appear to be penicillin G and the cephalosporins.[463] Most enzyme-inducing drugs do not increase the metabolism of enflurane or isoflurane. However, isoniazid induces the microsomal enzymes responsible for the metabolism of at least enflurane and thereby increases the possibility of fluorine-associated renal damage after enflurane administration.[467] Appropriate antibiotic prophylaxis for surgery requires a knowledge of the probability of infection for that type of surgical procedure and, if the incidence of infection warrants, the use of a drug regimen directed against the most likely infecting organisms.[468]

MEDICATIONS FOR GLAUCOMA

Medications for glaucoma include two organophosphates: echothiophate and isoflurophate (see also Chapter 84). These drugs inhibit serum cholinesterase, which is responsible for the hydrolysis and inactivation of succinylcholine and ester-type local anesthetics such as procaine, chloroprocaine, and tetracaine (see also Chapters 34 and 36).[469,470] These ester-type local anesthetics should be avoided in patients treated with eye drops containing organophosphate. Table 39-16 lists other medications related to anesthesia and their side effects (from the National Registry for Drug-Induced Ocular Side Effects,

TABLE 39-16 **COMMON OPHTHALMOLOGIC DRUGS AND THEIR ANESTHETICALLY IMPORTANT INTERACTIONS**

Drug (Trade Name)	Toxicities and Specific Treatments
Glaucoma: Primary Goal Is to Reduce IOP By Miotics and epinephrine: increase outflow of aqueous humor β-Blockade and carbonic anhydrase inhibitors: reduce production of aqueous humor Osmotic drugs: transiently decrease volume	
Miotics Parasympathomimetics Pilocarpine (Adsorbocarpine, Isopto Carpine, Pilocar, Pilocel) Carbachol	
Acetylcholinesterase Inhibitors Physostigmine Demecarium Isoflurophate (Floropryl) Echothiophate (Echodide, Phospholine)	Tox: Hypersalivation, sweating, N/V, bradycardia, hypotension, bronchospasm, CNS effects, coma, respiratory arrest, death Rx: Atropine, pralidoxime (Protopam) Ix: Succinylcholine—prolonged apnea (drugs must be discontinued 4 wk before)
Epinephrine (Epitrate, Murocoll, Mytrate, Epifrin, Glaucon, Epinal, Eppy)	Tox: (rare) Tachycardia, PVCs, HTN, headache, tremors Ix: Avoid drugs that sensitize to catecholamines (e.g., halothane)
β-Blockers Timolol (Timoptic) Betaxolol (Betoptic) Levobunolol (Betagan)	Tox: β-Blockade with bradycardia, exacerbation of asthma, CNS depression, lethargy, confusion Synergy noted with systemic drugs
Carbonic Anhydrase Inhibitors Acetazolamide (Diamox) Dichlorphenamide (Daranide, Oratrol) Ethoxzolamide (Cardrase, Ethamide) Methazolamide (Neptazane)	Tox: Anorexia, GI disturbances, "general miserable feeling" and malaise, paresthesias, diuresis, hypokalemia (transient), renal colic and calculi, hyperuricemia, thrombocytopenia, aplastic anemia, acute respiratory failure in patients with COPD
Osmotic Drugs Glycerin (Glyrol, Osmoglyn) Isosorbide (Ismotic) Urea (Urevert, Ureaphil) Mannitol (Osmitrol)	Tox: Dehydration, hyperglycemia, nonketotic hyperosmolar coma (rare); fatalities with mannitol secondary to CHF or intracranial bleeding; urea may cause thrombosis
Intraocular acetylcholine (Miochol)	Tox: Hypotension, bradycardia Rx: Atropine
Mydriatics and Cycloplegics: Provide Pupillary Dilatation and Paralysis of Accommodation Anticholinergics block muscarinic receptors; paralyzing in iris α-Adrenergics contract the dilator of the iris
