Chapter 93

Pediatric Anesthesia

CHARLES J. COTÉ

Key Points

- During the first few weeks of life, neonates are vulnerable to a phenomenon, the *flip-flop circulation*; that is, going from an adult type of circulation to a fetal type. Factors such as hypoxia, hypercapnia, acidosis, infection, hypothermia, and prematurity increase the potential for sudden increases in pulmonary artery pressure and subsequent shunting of blood past the lungs through a patent foramen ovale or the ductus arteriosus, which may reopen, particularly during the first 10 days of life.
- The reduced cellular mass of the neonatal heart devoted to contractility results in less compliant ventricles. This leads to a sensitivity to excessive intravascular volume, poor tolerance of afterload (i.e., the development of biventricular failure), and rate-dependent cardiac output. In addition, the reduced cardiac calcium stores produce increased susceptibility to myocardial depression by potent anesthetics and also make neonates dependent on exogenous (i.e., blood-ionized) calcium values and vulnerable to the negative inotropic effects of ionized hypocalcemia, particularly that caused by infusion of citrated blood products such as fresh frozen plasma.
- The neonatal airway differs from the adult airway in four ways: the larynx is located higher in the neck, the glottis is shaped differently and angled over the laryngeal inlet, the vocal cords are angled, and the narrowest portion is the subglottic region at the level of the cricoid cartilage. Accordingly, straight blades are more useful than curved blades in neonates, and uncuffed endotracheal tubes are commonly used.
- Glomerular filtration and tubular function are immature but rapidly develop during the newborn period; adult levels are achieved at approximately the age of 2 years. The frequency with which medications excreted by the kidneys (e.g., antibiotics) can be administered during the first month of life rapidly changes. Particular attention is required in this period to avoid drug-induced toxicity (e.g., ototoxicity) caused by excessive plasma levels of antibiotics.
- Hepatic metabolic capacity is immature at birth. Some cytochrome P450 enzymes (phase I reactions) are fully developed, whereas others are approximately 50% of adult values. Phase II reactions, that is, reactions that make a drug more water soluble, are usually impaired in neonates. Some of these reactions do not achieve maturity until the age of 1 year. This hepatic immaturity can have important clinical implications regarding a neonate's ability to excrete some medications, such as benzodiazepines, morphine, and caffeine.
- Cardiac dysfunction from anesthetic overdose is a particular danger for neonates and infants because of a combination of factors, including immaturity of the myocardium, decreased calcium stores of the neonatal myocardium, and the "systems issue" of the vaporizers for halothane and sevoflurane having different maximum minimum alveolar concentration (MAC) delivery capability; that is, nearly 6 MAC multiples of halothane may be delivered to a newborn, whereas only ~2.5 MAC multiples of sevoflurane can be delivered. Thus anesthetic drug–induced cardiac arrest is a function of both vaporizer design and the vulnerability of the neonatal myocardium to anesthetic-induced cardiac depression, especially on changing from spontaneous to controlled respirations.

KEY POINTS—cont'd

- Remifentanil is a unique potent opioid in neonates. Unlike other medication used in newborns, remifentanil's context sensitive half-life is similar to older children and adults. Therefore remifentanil can rapidly induce or terminate an intense opioid effect even in neonates. However, opioid-induced bradycardia and chest wall rigidity can occur.
- Former preterm infants younger than 60 weeks of age and/or who are anemic are at risk for postoperative apnea (i.e., hemoglobin <10 gm/dL). Both gestational age and postconceptual age at the time of surgery are independent risk factors. The use of regional anesthesia in these children may reduce the incidence of postanesthesia apnea. Postoperative apnea can occur from all inhaled anesthetics, including desflurane and sevoflurane.
- Preoperative laboratory testing (also see Chapter 38) is usually minimal for most children. Routine hemoglobin measurements should be determined in infants younger than 6 months of age to assess the severity of the physiologic hemoglobin nadir (especially former preterm infants with a potential risk for apnea) and in older children expected to experience significant blood loss. Preoperative chest radiographs are not generally indicated. Children who have undergone chemotherapy with anthracycline chemotherapy have congenital heart disease, and neonates at risk for associated cardiac anomalies may require a preoperative echocardiogram. Children undergoing chemotherapy should usually have a complete recent hematology profile, including platelet counts. Children with a history of seizures should have a preoperative assessment including a confirmation that therapeutic blood levels of antiseizure medications exist.
- Temperature regulation (also see Chapter 54) is especially important for neonates and infants. Because of the large body surface-to-weight ratio, they are vulnerable to intraoperative hypothermia. Efforts to maintain a warm surgical unit, to use warming devices such as hot air mattresses, to apply warm surgical skin preparation solutions, and to transport the neonate or infant in an appropriate transport device, as well as keeping the infant covered during transport, all help prevent dangerous hypothermia.
- Intraoperative fluid therapy has changed from the classic 4-2-1 rule of Holliday and Segar to the perioperative administration of 20 to 40 mL/kg of an isotonic solution (lactated Ringer solution). In the postoperative period, the new 2-1-0.5 rule applies (2 mL/kg for the first 10 kg, 1 mL/kg for 10 to 20 kg, and 0.5 mL/kg for each kg above 20 kg in weight). This therapy now recognizes the common dysregulation of antidiuretic hormone secretion after surgery and prevents hyponatremia. If the child has not been able to convert to oral intake after 12 hours, then D5 0.45% saline should be given using the 4-2-1 rule.

The physiologic, pharmacologic, and psychologic differences between children and adults must be understood. Special consideration must be given to preterm infants and those with congenital malformations. Anesthetic-induced neurotoxicity is a concern, but it is not as important as the fundamental issues of maintaining oxygenation, perfusion, and adequate analgesia/anesthesia. This chapter describes how the unique characteristics of children influence the safe conduct of anesthetic procedures.

DEVELOPMENTAL CONSIDERATIONS

Organogenesis takes place within 8 weeks of conception; organ function develops during the second trimester; and the infant gains weight, primarily muscle and fat, during the third trimester. Any physiologic or pharmacologic injury or stress during the first trimester may cause abnormal organogenesis; during the second trimester, functional development of organs may be abnormal; and during the third trimester, organs may be smaller or muscle and fat mass may be reduced. Injuries and stress take the form of congenital viral infections, exposure to drugs (therapeutic or recreational), nutritional insufficiency (caloric or vascular), or maternal illness. A genetic predisposition to developmental malformations can also produce adverse effects. Such interruptions in normal growth and development may cause a variety of physiologic abnormalities ranging from simple preterm birth to a constellation of congenital malformations.

A preterm infant is one born before 37 weeks' gestation; a postmature infant is one born after 42 weeks' gestation. Any infant born weighing less than 2500 g is considered a low–birth-weight infant. Plotting weight

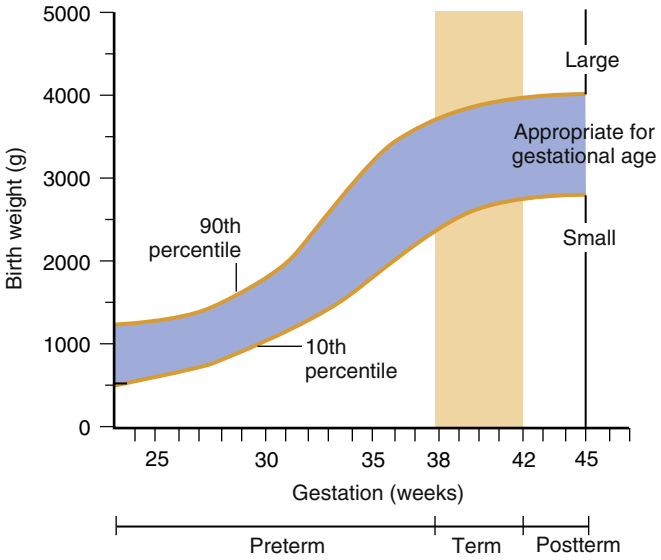

Figure 93-1. Plotting birth weight against gestational age for neonates determines whether infants are small, appropriate, or large for gestational age. Babies who are either small or large for gestational age are particularly likely to have a variety of problems such as metabolic, developmental, infectious, or structural abnormalities, as well as drug addiction and withdrawal. *(Modified from Battaglia FC: Intrauterine growth retardation,* Am J Obstet Gynecol *106:1103-1114, 1970. Used with permission.)*

against gestational age allows classification into three general categories: small for gestational age, appropriate for gestational age, or large for gestational age (Figure 93-1). Infants who are small or large for gestational age often have developmental problems or difficulties associated with maternal disease (Table 93-1). Careful physical and neurologic examination at birth allows a fairly accurate estimate of gestational age. The anesthesiologist should be aware of this type of evaluation to ensure that potential problems can be anticipated. Obtaining a perinatal history of problems during pregnancy (e.g., maternal drug abuse, maternal infection, eclampsia, diabetes) or during and after delivery (e.g., fetal distress, meconium aspiration, prematurity, postdelivery intubation) is also valuable for assessing possible anesthetic implications that may require specific considerations during and after anesthetic management. In the weeks after birth, measurements of weight, height, and head circumference are plotted on standard developmental curves; deviations from normal (i.e., crossing developmental lines) usually indicate a severe physiologic insult. The anesthesiologist should examine the growth chart to evaluate how the child is developing.

THE CARDIOVASCULAR SYSTEM

The cardiovascular system undergoes dramatic physiologic and maturational changes during the first year of life. In utero, most of the cardiac output is directed from the placenta across the foramen ovale into the ascending aorta (oxygenated blood), whereas superior vena cava blood (deoxygenated) is directed to both the pulmonary artery and the ductus arteriosus. This pattern of circulation results in minimal intrauterine pulmonary blood flow. At birth, a number of events change hemodynamic interactions such that the fetal circulation becomes an adult type of circulation. Specifically, the placenta is removed from the circulation; portal blood pressure falls, which causes the ductus venosus to close; and blood becomes oxygenated through the

TABLE 93-1 COMMON NEONATAL PROBLEMS ASSOCIATED WITH WEIGHT AND GESTATIONAL AGE

Gestation	Relative Weight	Neonatal Problems at Increased Incidence
Preterm (<37 weeks)	SGA	Respiratory distress syndrome Apnea Perinatal depression Hypoglycemia Polycythemia Hypocalcemia Hypomagnesemia Hyperbilirubinemia Viral infection Thrombocytopenia Congenital anomalies Maternal drug addiction Fetal alcohol syndrome
	AGA	Respiratory distress syndrome Apnea Hypoglycemia Hypocalcemia Hypomagnesemia Hyperbilirubinemia

lungs. Exposure of the ductus arteriosus to oxygenated blood induces ductal closure. As a result of the combined effects of lung expansion, exposure of blood to oxygen, and loss of low resistance through placental blood flow, pulmonary vascular resistance decreases while peripheral vascular resistance rapidly rises. The decrease in pulmonary vascular resistance occurs on the first day of life and continues to decrease gradually during the next several years as the architecture of the pulmonary vessels changes. An increase in pressure on the left side of the heart (caused by the increase in peripheral vascular resistance) induces mechanical closure of the foramen ovale. Thus all three connections between the right and left sides of the circulation close. Although closure of the ductus arteriosus probably occurs primarily from an increase in arterial oxygen concentration, successful completion requires arterial muscular tissue; that such tissue is less prevalent in preterm infants may partly account for the frequent incidence of patent ductus arteriosus in preterm infants. True mechanical closure by fibrosis does not occur until 2 to 3 weeks of age.

During this critical period, the infant readily reverts from the adult type of circulation to a fetal type of circulation; this state is called *transitional circulation*. Many factors (e.g., hypoxia, hypercapnia, anesthesia-induced changes in peripheral or pulmonary vascular tone) can affect this precarious balance and result in a sudden return to the fetal circulation. When such a *flip-flop* occurs, pulmonary artery pressure increases to systemic levels, blood is shunted past the lungs via the patent foramen ovale, and the ductus arteriosus may reopen and allow blood to shunt at the ductal level. A rapid downhill spiral may occur and lead to severe hypoxemia, which explains why hypoxemic events may be prolonged, despite adequate pulmonary ventilation with 100% oxygen. In most cases, simple hyperventilation will cause the increased pulmonary artery pressure to return to normal in response to a decreased arterial partial pressure of carbon dioxide ($Paco_2$).

Risk factors increasing the likelihood of prolonged transitional circulation include prematurity, infection, acidosis, pulmonary disease resulting in hypercapnia or hypoxemia (aspiration of meconium), acidosis, hypothermia, and congenital heart disease. Care must be directed to keeping the infant warm, normal arterial oxygen and carbon dioxide tensions, and minimal anesthetic-induced myocardial depression.

The myocardial structure of the heart, particularly the volume of cellular mass devoted to contractility, is significantly less developed in neonates than in adults. These differences, as well as developmental changes in contractile proteins, produce a leftward displacement of the cardiac function curve and less compliant ventricles. This developmental immaturity of myocardial structures accounts for the tendency toward biventricular failure, sensitivity to volume loading, poor tolerance of increased afterload, and heart rate–dependent cardiac output.[1,2] Another issue is that cardiac calcium stores are reduced because of the immaturity of the sarcoplasmic reticulum; consequently, neonates have a greater dependence on exogenous (blood-ionized) calcium and probably increased susceptibility to myocardial depression by volatile anesthetics that have calcium channel–blocking activity.

THE PULMONARY SYSTEM

The pulmonary system is not capable of sustaining life until both the pulmonary airways and the vascular system have sufficiently matured to allow the exchange of oxygen from air to the bloodstream across the pulmonary alveolar-vascular bed. Independent life is not generally possible until a gestational age of 24 to 26 weeks, although survival of infants of 22 to 24 weeks' gestational age is possible but with a high percentage of neurocognitive impairment.[3] Alveoli increase in number and size until the child is approximately 8 years old. Further growth is exhibited as an increase in size of the alveoli and airways. At term, complete development of surface-active proteins helps maintain patency of the airways. If a child is prematurely born and these proteins are insufficient, then respiratory failure (e.g., respiratory distress syndrome) may follow.

Respiration is less efficient in infants. The small diameter of the airways increases resistance to airflow; resistance is inversely proportional to the radius raised to the fourth power for laminar flow and to the fifth power for turbulent flow. The airway of infants is highly compliant and poorly supported by the surrounding structures. The chest wall is also highly compliant, therefore the ribs provide little support for the lungs; that is, negative intrathoracic pressure is poorly maintained. Thus functional airway closure accompanies each breath. Dead space ventilation is proportionally similar to that in adults; however, oxygen consumption is two to three times higher. In preterm infants, the work of breathing is approximately three times that in adults, and this work can be significantly increased by cold stress (i.e., increased metabolic demand for oxygen) or any degree of airway obstruction. Another important factor is the composition of the diaphragmatic and intercostal muscles. These muscles do not achieve the adult configuration of type I muscle fibers until the child is approximately 2 years old (Figure 93-2).[4] Because type I muscle fibers provide the ability to perform repeated exercise, any factor that increases the work of breathing contributes to early fatigue of the respiratory muscles of infants; this partially explains why the infant's respiratory rate and hemoglobin desaturation is so rapid, and their propensity to develop fatigue and apnea with airway obstruction.

Differences in airway anatomy explain the more likely potential for technical airway difficulties in infants than in teenagers or adults. Typically, the airway of infants differs from adults in five ways[5]: (1) The relatively large size of the infant's tongue, in relation to the oropharynx, increases the likelihood of airway obstruction and technical difficulties during laryngoscopy. (However, magnetic resonance imaging [MRI] studies have called this into question).[6] (2) The larynx is located higher (more cephalic) in the neck, thus making straight blades more useful than curved blades. (3) The epiglottis is shaped differently, being short, stubby, omega shaped, and angled over the laryngeal inlet. Control with the laryngoscope blade is

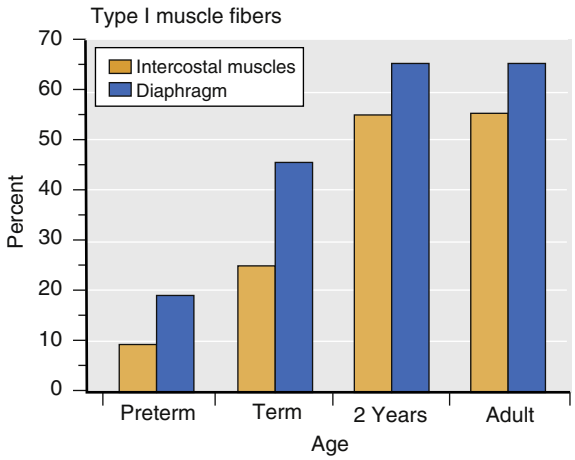

Figure 93-2. The composition of the diaphragm and intercostal muscles significantly changes during the first 2 years of life. The number of type I muscle fibers is inversely related to age and may account, in part, for the ease of inducing respiratory fatigue as the work of breathing increases. *(Data from Keens TG, Bryan AC, Levison H, et al: Developmental pattern of muscle fiber types in human ventilatory muscles,* J Appl Physiol *44:909-913, 1978.)*

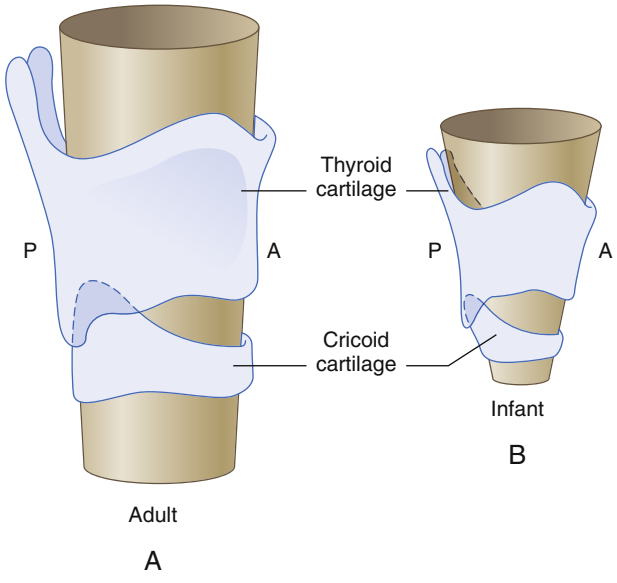

Figure 93-3. The narrowest part of the adult larynx and the pediatric larynx is at the level of the cricoid cartilage. Traditionally, the adult larynx was thought to be cylindrically shaped, but autopsy data suggest that the narrowing in adults (**A**) is not as pronounced as it is in infants (**B**). The narrowest part of the infant larynx occurs at the level of the cricoid cartilage; the normal adult configuration of the larynx is not achieved until the teenage years. This anatomic difference is one of the reasons uncuffed tracheal tubes have been traditionally preferred for children younger than 6 years of age. *A,* Anterior; *P,* posterior. *(From Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

therefore more difficult. (4) The vocal cords are angled; consequently, a *blindly* passed tracheal tube may easily lodge in the anterior commissure rather than slide into the trachea. (5) Finally, the infant larynx is funnel shaped, the narrowest portion occurring at the cricoid cartilage (Figure 93-3). Classic teaching has been that the adult larynx is cylindrical and the infant larynx is funnel shaped.

Figure 93-4. The Microcuff tracheal tube (Microcuff; PET; I-MPEDC, Microcuff GmbH, Weinheim, Germany, Kimberly-Clark USA) (*right*) has a soft polyurethane cuff that symmetrically inflates and is located more distally than standard tracheal tubes (*left*). This configuration results in more even pressure applied to the mucosa of the trachea, less potential for edema formation in the subglottic region because the cuff is located below the cricoid cartilage, and a reduced risk for ventilator-associated pneumonia.

However, it is now known that the narrowest portion in approximately 70% of adults is also in the subglottic region at the level of the cricoid cartilage. The opening is so large in adults that commonly used tracheal tubes are usually easy to advance past the glottic opening.[7] In infants or young children, a tracheal tube that easily passes the vocal cords may be tight in the subglottic region because of the relatively greater proportional narrowing at the level of the cricoid cartilage. Thus uncuffed tracheal tubes were in the past preferred for children younger than 6 years of age. However, the development of better tracheal tube design and several prospective studies have combined to allow the more common use of cuffed tracheal tubes, even in infants.[8,9] Nonetheless, a leak should be maintained around the cuff (with or without inflation) because injury to the tracheal mucosa is still possible. The Microcuff tube may improve the safety of cuffed tracheal tubes[10]; the new material is very soft, the shape of the cuff is more uniform (allowing a more uniform distribution of lateral sealing pressure), and the cuff, itself, is located more distally and thus perhaps beyond the cricoid cartilage (Figure 93-4).[11] These more expensive tracheal tubes are usually reserved for children with anticipated prolonged tracheal intubation (reduced ventilator-associated pneumonia),[12] and the lower-cost tracheal tubes are still used for short-term intraoperative tracheal intubation.

Although infants are obligate nasal breathers, approximately 8% of preterm neonates (31 to 32 weeks' postconceptual age [PCA]) and 40% of term infants can convert to oral breathing if the nasal airway is obstructed. Almost all infants can easily convert to oral breathing by 5 months of age; most convert to oral breathing if the obstruction lasts longer than 15 seconds.

THE KIDNEYS

Renal function is diminished in neonates and even more in preterm infants because of small perfusion pressures and immature glomerular and tubular function (Figure 93-5). Nearly complete maturation of glomerular filtration and tubular function occurs by approximately 20 weeks after birth, although delayed in preterm infants. Complete maturation of renal function occurs at approximately 2 years of age. Thus the ability to excrete free water and solute loads may be impaired in neonates, and the half-life of medications excreted by means of glomerular filtration will be prolonged (e.g., antibiotics, hence the longer intervals between doses in neonates).

THE LIVER

At term, the functional maturity of the liver is incomplete. Most enzyme systems for drug metabolism are developed but not yet induced (stimulated) by the material that they metabolize. As the infant grows, the ability to metabolize medications rapidly increases for two reasons: (1) hepatic blood flow increases and more drug is delivered to the liver, and (2) the enzyme systems develop and are induced.[13] The cytochrome P450 system is responsible for phase I drug metabolism of lipophilic compounds. This system reaches approximately 50% of adult values at birth, thus the capacity for drug metabolism (e.g., caffeine) is reduced. However, this is not true for all lipophilic medications, and the ability of neonates to metabolize some drugs is dependent on specific individual drug cytochromes. CYP3A (cytochrome P450, family 3, subfamily A) is generally present at adult values at birth,[14] whereas other cytochromes are absent or reduced.[15] Phase II reactions involve conjugation, which makes the drug more water soluble to facilitate renal excretion.[16] These reactions are often impaired in neonates and result in jaundice (decreased bilirubin breakdown) and long drug (and their active metabolites) half-lives (e.g., the half-life of morphine and benzodiazepines is several days). Some of these reactions do not achieve adult activity until after 1 year of age. Thus quantitative measurements of some medications is important.[17,18]

A preterm infant's liver has minimal glycogen stores and is unable to manage large protein loads. This accounts for the neonate's tendency toward hypoglycemia and acidemia and for the failure to gain weight when the diet contains too much protein. Additionally, plasma levels of albumin and other proteins necessary for the binding of drugs are lower in full-term newborns (and are even lower in preterm infants) than in older infants (Figure 93-6). This condition has clinical implications regarding neonatal coagulopathy (e.g., need for vitamin K at birth), as well as for drug binding and its pharmacodynamic effects; the lower the albumin value, the less protein binding of some drugs with resultant greater levels of unbound drug (i.e., unbound drug is the portion available to cross biologic membranes). In addition, the binding of some drugs to albumin may be altered in the presence of hyperbilirubinemia in the

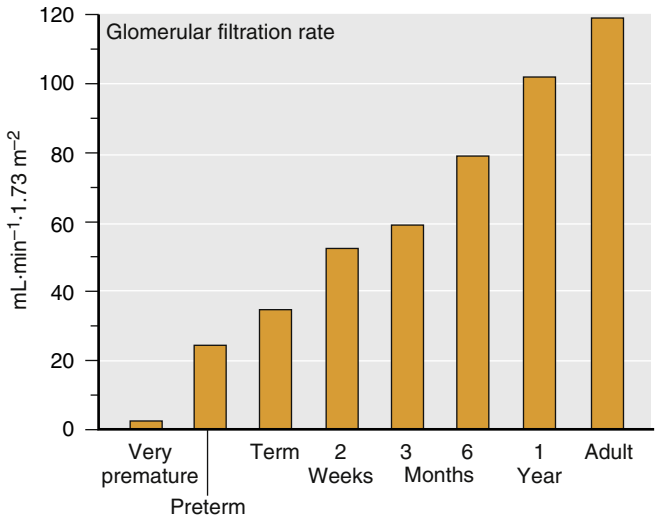

Figure 93-5. Glomerular filtration is significantly impaired at birth but develops rapidly during the first year of life. The ability of the kidney to regulate large amounts of solutes and water is also limited during the first several months of life. These developmental changes have significant implications for drug excretion and fluid therapy, particularly during the first 4 weeks of life. Maturation of renal function may be delayed in sick and preterm neonates. *(Data from McCrory WW:* Developmental nephrology, *Cambridge, Mass, 1972, Harvard University Press.)*

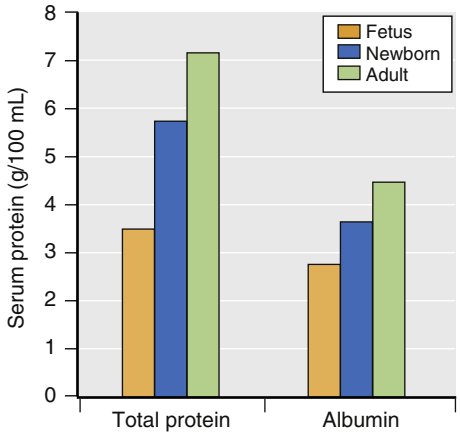

Figure 93-6. Total serum protein and albumin values change with maturation. Total protein and albumin are less in preterm infants than in term infants and less in term infants than in adults. The result may be pharmacokinetic and pharmacodynamic alterations for drugs with a high degree of protein binding because less drug is protein bound and more is available for clinical effect. *(Abstracted from Ehrnebo M, Agurell S, Jalling B, et al: Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults,* Eur J Clin Pharmacol *3:189-193, 1971. From Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

neonatal period; this effect is more important for drugs with high protein binding because a greater fraction of unbound drug will occur.

THE GASTROINTESTINAL SYSTEM

At birth, gastric pH is alkalotic; by the second day of life, pH is in the normal physiologic range for older children. The ability to coordinate swallowing with respiration does not fully mature until infants are 4 to 5 months of age, thus resulting in a high incidence of gastroesophageal reflux, particularly in preterm newborns. If a developmental problem occurs within the gastrointestinal system, then symptoms will occur within 24 to 36 hours of life. Upper intestinal abnormalities are exhibited as vomiting and regurgitation, whereas lower intestinal abnormalities produce abdominal distention and a failure to pass meconium.

THERMOREGULATION (Also See Chapter 54)

Infants are especially vulnerable to hypothermia because of the large ratio of body surface area to weight, the thinness of the skin, and a limited ability to cope with cold stress. Cold stress causes increased oxygen consumption and a metabolic acidosis, particularly in preterm infants because of even thinner skin and limited fat stores. The infant compensates by shivering and nonshivering (cellular) thermogenesis (metabolism of brown fat); however, the minimal ability to shiver during the first 3 months of life makes cellular thermogenesis the principal method of heat production. Addressing all aspects of possible perioperative heat loss is vital. Placing the baby on a warming mattress and warming the surgical unit (80° F or warmer) will reduce heat lost by conduction. Keeping the infant in an incubator and covered with blankets minimizes heat lost through convection. The head should also be covered. Heat lost from radiation is decreased with the use of a double-shelled isolette during transport. Heat lost through evaporation is lessened by humidification of inspired gases, the use of plastic wrap to decrease water loss through the skin, and warming of skin disinfectant solutions. Hot air blankets are the most effective means of warming children; however, especially in neonates, overheating must be avoided. Anesthetics alter many thermoregulatory mechanisms, particularly nonshivering thermogenesis in neonates.

PHARMACOLOGIC AND PHARMACODYNAMIC RESPONSES

DEVELOPMENTAL PHARMACOLOGY

The response of infants and children (particularly neonates) to medications is modified by many factors: body composition, protein binding, body temperature, distribution of cardiac output, functional organ (heart, liver, kidneys) maturity, maturation of the blood-brain barrier, the relative size of the liver and kidneys, and the presence or absence of elevated intraabdominal pressure (gastroschisis or omphalocele closure) or congenital malformations.[13]

The body compartments (e.g., fat, muscle, water) change with age (Figure 93-7). Total body water content is significantly higher in preterm infants than in term infants and in term infants than in 2 year olds. Fat and muscle content increases with age. These alterations in body composition have several clinical implications for neonates: (1) a drug that is water soluble has a large volume of distribution and usually requires a large initial dose (mg/kg) to achieve the desired blood level (e.g., most antibiotics, succinylcholine); (2) because the neonate has less fat, a drug that depends on the redistribution into fat for the termination of its action will have a long clinical effect; and (3) a drug that redistributes into muscle may have a long clinical effect (e.g., fentanyl, for which, however, saturation of muscle tissue has not been demonstrated).

In addition to these very basic concepts, other important factors play a role in the neonate's response to medications and include the following: (1) delayed excretion secondary to the larger volume of distribution, (2) immature hepatic and renal function, and (3) altered drug excretion caused by lower protein binding. Further perturbations in drug pharmacodynamic and pharmacokinetic effects occur with extreme prematurity and with factors such as sepsis, congestive heart failure, increased intraabdominal pressure, controlled ventilation, need for vasoactive infusions, and poor nutritional state.[13] All of these factors lead to clinically important neonatal patient-to-patient pharmacokinetic and pharmacodynamic variabilities.

Older children tend to have mature renal and hepatic function, with normal adult values for protein, fat, and muscle content. A larger fraction of cardiac output is diverted to the liver and kidneys—which also weigh more in relation to body mass—in older children than in infants. These factors usually mean that the half-life

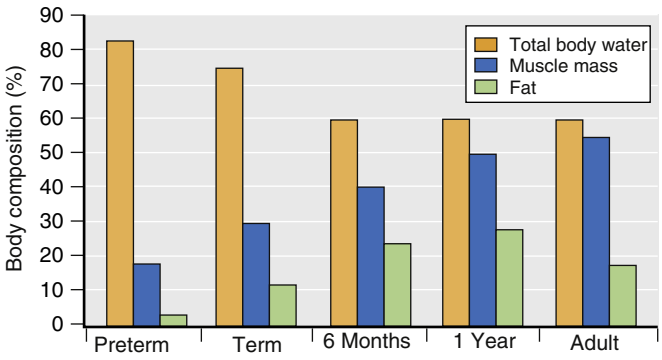

Figure 93-7. Body composition rapidly changes in preterm and term infants during the first 12 months of life. Their high water content provides a large volume of distribution for water-soluble medications, whereas their low fat and muscle content provides a small reservoir for drugs that depend on redistribution into these tissues for the termination of the drug effect. Thus body composition may significantly affect pharmacokinetics and pharmacodynamics. *(Data from Friis-Hansen B: Body composition during growth. In vivo measurements and biochemical data correlated to differential anatomical growth,* Pediatrics *47:264, 1971. From Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

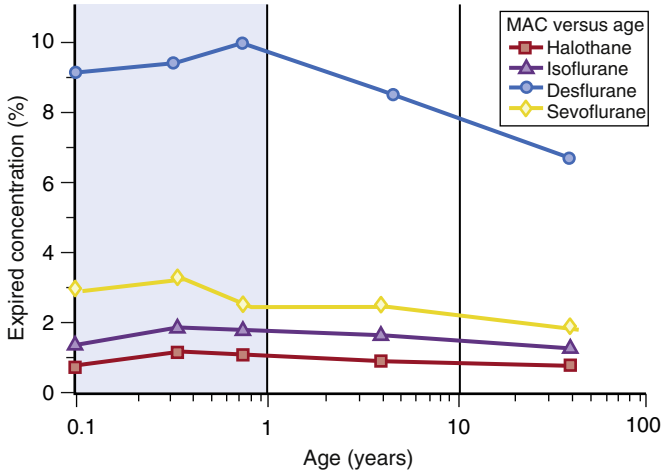

Figure 93-8. The minimum alveolar concentrations (MACs) of four commonly used inhaled anesthetics are plotted versus age. MAC is highest in infants 3 to 6 months of age. The reasons for this are not clear. *(Extracted from data from references 19 through 26.)*

of most medications in children older than 2 years of age is shorter than in adults or is equivalent. As the child approaches adulthood, the half-life of many drugs lengthens. In general, most medications will have a prolonged elimination half-life in preterm and term infants, a shortened half-life in children older than 2 years of age up to the early teenage years, and a lengthening of half-life in those approaching adulthood.

INHALED ANESTHETICS

The expired minimum alveolar concentration (MAC) of an inhaled anesthetic required in children changes with age (Figure 93-8). Anesthetic requirement is smaller for preterm than for term neonates and smaller for term neonates than for 3 month olds. Infants have a higher MAC than that of older children or adults; the reasons for these age-related differences in MAC are not known. This fact, combined with the need for deeper planes of anesthesia to achieve satisfactory conditions for tracheal intubation, places the infant in a precarious position because the safety margin between anesthetic overdose (from a cardiovascular standpoint) and inadequate depth of anesthesia (for tracheal intubation) is small. Avoiding controlled respirations until an intravenous line is inserted, rapidly reducing the delivery of inspired anesthetic drug, especially with the initiation of controlled respirations after the administration of a muscle relaxant, and, in some cases, substituting opioids for an inhaled anesthetics are practices that may improve safety.

Uptake of volatile anesthetics is more rapid in children because of an increased respiratory rate and cardiac index and a greater proportional distribution of cardiac output to vessel-rich organs. This rapid rise in blood anesthetic levels, combined with functional immaturity of cardiac development, probably explains, in part, why delivering an inhaled anesthetic overdose to infants and toddlers is so easy. Age-related differences in blood-gas partition coefficients may also facilitate a more rapid rise in alveolar concentration in infants. Other factors include the

TABLE 93-2 **MINIMUM ALVEOLAR CONCENTRATION MULTIPLES FOR A NEONATE ALLOWED BY CURRENT VAPORIZERS**

Agent	Maximum Vaporizer Output (%)	MAC (%)	Maximum Possible MAC Multiples
Halothane	5	0.87	5.75
Isoflurane	5	1.20	4.2
Sevoflurane	8	3.3	2.42
Desflurane	18	9.16	1.96

MAC, *Minimum alveolar concentration.*

state of hydration (e.g., excessive fasting would make a small infant relatively dehydrated) and the type of anesthesia circuit used. For example, a Mapleson D has a smaller volume than a circle system; therefore less volume is needed to achieve equilibration when the concentration of anesthetic agent exiting the vaporizer increases. With a Mapleson D circuit (rarely used in modern anesthetic practices), the fresh gas flow is introduced into the system at the airway and directly enters the child's lungs. Perhaps the most important factor influencing the potential for anesthetic overdose in neonates is the number of MAC multiples that can be delivered by the vaporizer; for example, a halothane vaporizer can deliver up to 5.75 MAC multiples versus 2.42 MAC multiples for a sevoflurane vaporizer (Table 93-2).

Sevoflurane

Sevoflurane has a gas partition coefficient similar to that of nitrous oxide (also see Chapters 25 and 26). Sevoflurane is less pungent than isoflurane and desflurane; it may be superior or equivalent to halothane for inhaled induction of anesthesia. As with all volatile anesthetics, the MAC is highest in young patients: 3.3% for neonates, 3.2% for infants 1 to 6 months old, and 2.5% for children older than 6 months.[19,20] Sevoflurane and halothane are approximately equivalent in terms of airway complications during induction of anesthesia (laryngospasm, bronchospasm, breath holding), but the rate of induction is more rapid with sevoflurane. The incidence of coughing during induction with sevoflurane (~6% versus ~10%) is smaller and a 33% more frequent incidence of excitement occurs during emergence (~21% versus ~15%) (Table 93-3). Both sevoflurane and halothane produce dose-related respiratory depression; however, halothane produces a decrease in tidal volume and an increase in respiratory rate, whereas sevoflurane decreases both the respiratory rate and the tidal volume. Respirations may need to be assisted during the early induction stage in sevoflurane-anesthetized children. Unless the inspired concentration is significantly reduced (usually to ~3%), such assistance then increases the potential for anesthetic overdose while attempts are made to establish intravenous access.[27]

Sevoflurane and halothane also have different cardiovascular profiles. Children older than 3 years of age usually experience an increase in heart rate and no change in systolic blood pressure with sevoflurane, whereas with

TABLE 93-3 **SUMMARY STATISTICS FOR 17 STUDIES COMPARING THE CHARACTERISTICS OF SEVOFLURANE AND HALOTHANE**

	Sevoflurane			Halothane

Data from References 19-26.

halothane, the heart rate does not change but systolic blood pressure decreases. The children most vulnerable to anesthetic overdose are the age groups that have the least increase in heart rate and the largest decrease in systolic blood pressure (34% ± 16% and 26% ± 20%, respectively, for neonates and infants younger than 6 months of age).[19] These changes in systolic blood pressure are comparable with those produced by equi-MAC concentrations of halothane.[20] As described in the Pediatric Perioperative Cardiac Arrest (POCA) registry, the use of controlled ventilation is related to cardiac arrest; generally, arrest occurs before the establishment of intravenous access.[27] Even sevoflurane can cause catastrophic effects on the infant's cardiovascular system. Although sevoflurane causes less myocardial depression than that of halothane, a difference in safety has not been established. Alternatively, the use of a neuromuscular blocker to facilitate tracheal intubation (also see Chapter 34) and an avoidance of high inspired concentrations of sevoflurane could be a safer approach in this age group.

The safety of all potent anesthetics probably relates to how the drugs are used, the experience of the person administering the anesthesia, and other less obvious factors. When inducing anesthesia with sevoflurane with resultant apnea, the inspired concentration of sevoflurane should be reduced while gently assisting respirations. After intravenous access is established, a decision must be made regarding continued management with just a face mask, with a supraglottic airway device (e.g., laryngeal mask airway [LMA]), or with a tracheal tube. If a supraglottic device is inserted, then propofol (1 mg/kg) can be administered and the device inserted 30 to 45 seconds later. Most children maintain spontaneous respirations from this dose of propofol, whereas others will become apneic and require assisted ventilation for several minutes. If an endotracheal intubation is to be performed, then two techniques seem reasonably safe: (1) For a brief procedure, the inspired concentration of sevoflurane is increased to 8% and controlled ventilation is instituted for a brief period (usually 1 to 2 minutes) to rapidly deepen the plane of anesthesia. When spontaneous respirations cease, propofol (1 to 2 mg/kg) is then administered, the vaporizer is shut off (to ensure that the 8% sevoflurane is not accidentally continued), and then the tracheal tube is inserted. (2) If muscle relaxation is necessary, then sevoflurane can be administered with an inspired concentration of 3.5% to 4% (lower for a neonate). An appropriate muscle relaxant is administered (also see Chapter 34), and the tracheal tube is then inserted. At this point, the inspired concentration of sevoflurane can be reduced or changed to an appropriate concentration of halothane or isoflurane for maintenance. Changes in *time to discharge* (i.e., "street readiness") do not seem significantly different, based on the choice of volatile anesthetic.

Several other issues related to sevoflurane are worthy of mention. The most important is the risk of exothermic reactions with dry desiccant,[28-31] which has resulted in fires and explosions (sevoflurane and Baralyme) (see also Chapter 109); this reaction should no longer be a risk since Baralyme is no longer marketed.[32-34] These incidents are associated with high flows of oxygen through the circuit for extended periods and then the use of high inspired sevoflurane concentrations (e.g., the first procedure on a Monday morning). Another issue is the production of toxic metabolites as a result of an interaction with the carbon dioxide absorbent.[35,36] Compound A appears to be nephrotoxic in animal models, the clinical implications of which are not clear. Low-flow (2 L/minute) and prolonged anesthesia have not altered the usual markers of renal function. Sevoflurane appears to be a safe anesthetic, even for prolonged surgical procedures. Fresh gas flows (less than 1 L/minute) are not recommended. The use of new carbon dioxide absorbents that do not contain a strong base seems to eliminate most of these issues.

A major concern is the more frequent incidence of emergence agitation with sevoflurane than with halothane (see Table 93-3). This response during emergence from sevoflurane anesthesia is not related to pain and is especially frequent in children 5 years of age or younger. The incidence of emergence agitation can be reduced with midazolam and/or the administration of clonidine (orally or epidurally), ketorolac, fentanyl, or dexmedetomidine.[37] When the data from many studies are combined, the true difference in emergence agitation is quite small (~21% with sevoflurane and ~15% with halothane). This issue is usually a problem when patients arrive in the postanesthesia care unit (PACU) in an agitated state. With halothane, children generally arrive in the PACU still partially anesthetized, the nurses are able to chart their initial vital signs, and then the children become agitated. In either case, this condition responds to small doses of fentanyl or propofol and is generally short-lived

(~5 to 10 minutes).[37] Another issue is the report of seizurelike activity during induction with sevoflurane. At least one careful electroencephalographic (EEG) study has not documented seizure activity, thus suggesting that these abnormal movements are not central in origin.[38]

Airway reflexes are usually inadequately suppressed from volatile anesthetic for the performance of bronchoscopy during spontaneous respirations. Supplementation with any combination of intravenous propofol, small-dose remifentanil, or a muscle relaxant is usually required with sevoflurane. Halothane is a superior inhaled anesthetic for this procedure but is not always available. The longer elimination half-life and maintenance of spontaneous respirations with halothane also contribute to its advantage for procedures in which the face mask is intermittently applied, such as during bronchoscopy or suture removal after a cleft lip repair.

Halothane

The use of halothane in the United States has decreased dramatically; however, it is still widely used in other parts of the world. Halothane does not have a noxious smell and is commonly used for the gaseous induction of anesthesia in places where budgetary concerns limit the availability of sevoflurane. A statistically significant but clinically unimportant difference in the rapidity of awakening (usually 3 to 5 minutes) nearly always occurs when comparing halothane with either desflurane or sevoflurane. Most important, airway-related problems during induction occur less frequently with halothane and sevoflurane than with isoflurane or desflurane. Halothane and sevoflurane are the anesthetics of choice for the gaseous induction of anesthesia in children.

A 1987 report describing seven cases (one fatal) of *halothane hepatitis* concluded that children should not undergo repeated exposure to halothane (also see Chapter 26).[39] However, this report must be placed in its proper perspective. Millions of children have been anesthetized with halothane. Perhaps a dozen instances of halothane hepatitis—and one or two deaths—have been reported in children. This is a remarkable safety record for any medication. Because halothane hepatitis appears to be primarily an adult issue, the use of other anesthetics or techniques in teenage patients may make sense. Halothane will probably remain the most commonly used potent anesthetic in undeveloped countries because of cost. Furthermore, hepatic dysfunction has been reported in children after all potent anesthetics, including sevoflurane and desflurane.

Sensitization of the myocardium to arrhythmias because of exogenous and endogenous catecholamines is another concern with halothane. Most arrhythmias associated with halothane anesthesia in children are caused by either hypercapnia or an inadequate depth of anesthesia.[40] Up to 10 μg/kg of epinephrine may be used with minimal risk of cardiac arrhythmias in children. The heart rate is generally stable or slightly decreased. If tachycardia develops in a halothane-anesthetized child, then inadequate anesthesia or hypovolemia is usually the cause. This development is distinctly different from isoflurane, desflurane, and sevoflurane, all of which can directly cause tachycardia.

Halothane is a potent myocardial depressant that can have profound effects on neonates and children with congenital heart disease. Such depression is responsible for the occasional inability to give critically ill children sufficient concentrations of halothane to provide *anesthesia* without inducing severe hypotension. In this circumstance, the liberal use of short-acting opioids with low concentrations of halothane generally provides the desired response. The POCA study reported a more frequent incidence of anesthetic-induced cardiac arrests with halothane; the use of controlled ventilation (probably without reducing the inspired concentration of the anesthetic agent) was a common observation.[27] Although both halothane and sevoflurane depress cardiac function, sevoflurane is less of a myocardial depressant.[41,42] However, at both 1 and 1.5 MAC in children, no significant difference in mean arterial blood pressure has been reported[41]; in infants, no difference has been observed at 1 MAC, but a difference at 1.5 MAC was reported. The simple administration of atropine would abolish these differences.

Isoflurane

Isoflurane may have some advantages over halothane: less myocardial depression, preservation of the heart rate, and a larger reduction in the cerebral metabolic rate for oxygen (also see Chapters 25 and 26). These properties may be beneficial in selected children. The major disadvantages of isoflurane are its noxious smell, which is unacceptable to many children, and a more frequent incidence of airway-related events (e.g., laryngospasm, coughing). Hypertension is also occasionally observed, especially in teenagers, when the inspired concentration is rapidly increased or when the change from sevoflurane to isoflurane is sudden. The probable mechanism is similar to that of desflurane—stimulation of pulmonary irritant receptors, causing increased sympathetic activity and stimulation of the renin-angiotensin system. Occasionally, a diffuse rash appears, primarily on the torso. All signs and symptoms regress with the decrease of the inspired concentration of isoflurane.

Desflurane

Desflurane has a gas partition coefficient similar to that of nitrous oxide (also see Chapter 26). Unfortunately, it causes an unacceptable incidence of laryngospasm (~50%) during the gaseous induction of anesthesia in children.[43] Gaseous induction of anesthesia with halothane or sevoflurane and then changing to desflurane for maintenance and wake-up may be reasonable. This changeover, unlike a similar change to halothane or isoflurane, may be clinically important in that the gas partition coefficient clearly favors rapid excretion. However, changing to desflurane for long procedures makes more sense than for brief cases, during which such accumulation is less likely. The more rapid awakening may be advantageous for neurosurgical and spinal fusion procedures, for which early assessment of mental and neurologic status is important. One study of pediatric patients undergoing adenoidectomy found a more rapid wake-up with desflurane than with sevoflurane or halothane, yet desflurane was also associated with the most frequent rate of emergence agitation.[44] Nasally

administered fentanyl (2 μg/kg) reduces the incidence of emergence agitation, but it also increases the incidence of postoperative vomiting.[45]

The MAC for desflurane is dependent on age: 9.2% for neonates, 9.4% for infants 1 to 6 months of age, 9.9% for infants 6 to 12 months of age, 8.7% for 1 to 3 year olds, and 8% for 5 to 12 year olds.[22] Interestingly, nitrous oxide does not contribute to the MAC of desflurane to the same degree as it does with other volatile anesthetics.[46] Desflurane, unlike other volatile anesthetics, has virtually no hepatic metabolism. Concern for the potential for carbon monoxide poisoning with desflurane as a result of dry carbon dioxide absorbent (also possible with isoflurane) can be prevented by rehydration before use. New carbon dioxide absorbents that do not contain a strong base may offer improved safety.

DRUGS USED TO INDUCE ANESTHESIA

Propofol

Propofol is highly lipophilic and promptly distributes into and out of vessel-rich organs; its rapid redistribution, hepatic glucuronidation, and high renal clearance account for the short duration of its effect (also see Chapter 30). As with barbiturates, the induction dose is larger in younger children (2.9 mg/kg for infants younger than 2 years of age) than in older children (2.2 mg/kg for children 6 to 12 years of age). The central volume is large and the clearance is rapid in young children.[47] The major drawback of propofol is pain on intravenous administration, particularly through small veins. As little as 0.2 mg/kg of lidocaine (mixed with the propofol) is effective in reducing but not eliminating this discomfort. Placing a tourniquet on the child and administering 1 mg/kg (up to 40 mg) of lidocaine 15 to 20 seconds before administering the propofol helps; propofol is then administered with the intravenous line running, and the tourniquet is then let down. This *mini–Bier block* technique is quite effective in reducing pain. Another method for minimizing pain is to use a small (22- to 24-gauge) catheter and to administer the drug through a large antecubital vein. Propofol is particularly useful for the brief and repeated sedation needed for radiotherapy in children with central venous lines. A constant infusion is useful for sedating children undergoing radiologic procedures and as a means of maintaining anesthesia during transport from one location to another, for example, from radiology to the surgical unit. A modest reduction in systolic blood pressure often accompanies a bolus administration. Propofol reduces the incidence of postoperative vomiting. Because propofol contains egg and soy products, it should be used with caution in children with egg or soy anaphylactic allergies[48,49]; however, a study of children with known egg allergy reported only one nonanaphylactoid reaction.[50] It should be avoided in children with anaphylactic reactions to eggs.

The major concern with propofol is the potential for propofol infusion syndrome (e.g., lactic acidosis, rhabdomyolysis, cardiac and renal failure), which is generally associated with high-dose infusions for an extended period (usually days in an intensive care unit [ICU] environment)[51] (also see Chapter 30). Although no such cases have been reported in healthy children during routine anesthesia care, one child with a genetic defect in lipid metabolism who received approximately 150 μg/kg/min (~9 mg/kg/hr) for 6.5 hours during scoliosis repair was reported. This case report along with one other[52] suggests caution in the use of propofol in children with known defects in lipid metabolism,[53,54] which may include some forms of mitochondrial disease. Yet, propofol has been safely used in many children with mitochondrial disease; this caution applies only to those with defects in lipid metabolism.[55]

Methohexital

Methohexital is generally administered intravenously at a concentration of 1% and a dose of approximately 1 to 2 mg/kg (also see Chapter 30). Problems associated with intravenous administration include burning, hiccups, apnea, and extrapyramidal-like movements. Methohexital has a shorter elimination half-life than thiopental. It is also useful for providing sedation during radiologic procedures by rectal administration (10% solution). Usually, 25 to 30 mg/kg produces light sleep within 8 to 10 minutes that lasts for 20 to 40 minutes. Obstructive or central apnea may occasionally occur. Therefore a means of ventilating the child must be available, and appropriate monitoring with pulse oximetry is important. Because it can cause seizures, methohexital is contraindicated in children with temporal lobe epilepsy. Children receiving seizure medications generally require larger doses.

Thiopental

Intravenous bolus administration of 2.5% thiopental (5 to 6 mg/kg) is sufficient to induce anesthesia in most healthy, unpremedicated children (also see Chapter 30). Termination of effect occurs through redistribution into muscle and fat; thiopental should be used in reduced doses (2 to 4 mg/kg) in children who have low fat stores, such as neonates or malnourished infants. Limiting the total dose to 10 mg/kg or less in older children minimizes the possibility of prolongation of anesthesia caused by residual barbiturate sedation. Thiopental (30 mg/kg in a 10% solution) may also be rectally administered if methohexital is contraindicated; thiopental is no longer available in the United States.

Ketamine

Ketamine causes central dissociation of the cerebral cortex while providing analgesia and amnesia (also see Chapter 30). In addition to the intravenous and intramuscular routes, ketamine may be administered rectally (10 mg/kg), orally (6 to 10 mg/kg), or intranasally (3 to 6 mg/kg). The combination of oral ketamine (4 to 6 mg/kg), oral midazolam (0.5 mg/kg), and oral atropine (0.02 mg/kg) provides a deeply-sedated child. Intravenous administration of doses as low as 0.25 to 0.5 mg/kg may be used to provide sedation and analgesia for painful procedures, whereas doses of 1 to 2 mg/kg produce sedation sufficient for a smooth transition to general anesthesia. Larger doses (up to 10 mg/kg intramuscularly) provide sufficient analgesia for the insertion of invasive monitoring devices before the induction of anesthesia (cardiac surgery) or in children with limited venous access. Ketamine is useful

for the induction of anesthesia in hypovolemic children. Patient-to-patient variability in response to this drug is relatively large, however. A major side effect, increased production of secretions, usually requires the administration of an antisialagogue agent. Other undesirable side effects include vomiting and postoperative "dreaming" or hallucinations; the incidence of dreaming may be reduced by the concomitant administration of a benzodiazepine. Although spontaneous respirations and a patent airway are usually maintained, apnea and laryngospasm may occur.

Contraindications to the use of ketamine in children include the presence of an active upper respiratory infection (URI), increased intracranial pressure, open-globe injury, and a psychiatric or seizure disorder. Ketamine does not preserve the gag reflex and thus should not be used as the sole anesthetic for children with a full stomach or a hiatal hernia. Ketamine has also been used as an adjunct for epidural analgesia.[56] However, *because the preservative in most ketamine preparations is neurotoxic, only preservative-free ketamine must be administered in the epidural space* (also see Chapter 30).

Etomidate

Etomidate is a steroid-based hypnotic drug used for induction of anesthesia (also see Chapter 30). As with propofol, the incidence of pain on intravenous administration is frequent. Concerns regarding anaphylactoid reactions and suppression of adrenal function have limited widespread use of this anesthetic. Etomidate is extremely useful in children with a head injury and those with an unstable cardiovascular status, such as children with a cardiomyopathy, because of the virtual absence of adverse effects on the cardiovascular system.[57,58] This drug has gained increasing popularity for airway management in the emergency department setting.[59] Usual doses are 0.2 to 0.3 mg/kg given before the administration of a small-dose opioid and a muscle relaxant. Etomidate is often used to facilitate tracheal intubation in children who are critically ill. Because a high proportion of critically ill children, particularly those resistant to vasopressors, suffer from relative adrenal insufficiency, steroid supplementation may be indicated in such children in whom etomidate is deemed necessary for their safe airway management.[60,61] A new ultrashort-acting etomidate analogue (cyclopropylmethoxycarbonyl metomidate) may avoid adrenal suppression while allowing a continuous infusion.[62]

SEDATIVES AND ANXIOLYTIC AGENTS

Diazepam

Oral absorption of diazepam is more rapid in children than in adults, with 0.1 to 0.3 mg/kg usually providing excellent peak sedation within 1 hour (also see Chapter 30). Intravenous administration is painful and not well tolerated; diazepam may also be rectally administered. Because the liver is the main site of degradation, this medication should be given with caution to any child with hepatic disease. Diazepam has an extremely long half-life in neonates (80 hours) and may not be indicated until the infant is 6 months of age or until hepatic metabolic pathways have matured.

Midazolam

Midazolam is water soluble and therefore not generally painful on intravenous administration (also see Chapter 30). Because of its water solubility, *it takes three times longer to reach a peak EEG effect than the more fat-soluble diazepam*. The clinician waits at least 3 minutes between intravenous doses to avoid *stacking* of effect.[63] The shorter elimination half-life (~2 hours) of midazolam than diazepam (~18 hours) offers an advantage for use as a premedication in children. Midazolam is the only benzodiazepine approved by the U.S. Food and Drug Administration for use in neonates; the half-life is significantly longer (6 to 12 hours) in this population.[64] Severe hypotension has occurred in neonates after bolus administration, and the potential for this problem is apparently increased in neonates also receiving fentanyl. Midazolam is rapidly absorbed after intramuscular (0.1 to 0.15 mg/kg, maximum of 7.5 mg), oral (0.25 to 1.0 mg/kg, maximum of 20 mg), rectal (0.75 to 1.0 mg/kg, maximum of 20 mg), nasal (0.2 mg/kg), or sublingual (0.2 mg/kg) administration.[65] Nasal administration is uncomfortable for most children. Midazolam probably augments the respiratory depressant effects of opioids. One important interaction is that erythromycin, calcium channel blockers, protease inhibitors, and even grapefruit juice produce a clinically important delay in midazolam metabolism because of inhibition of cytochrome P450. In this circumstance, either midazolam should be avoided or the dose reduced by 50%.[66] Nasal administration may increase the possibility of central nervous system (CNS) toxicity as a result of drug entering the CNS along the olfactory nerves.[67] Because neurotoxicity has never been examined and most children cry with nasal administration, this author believes that this route should generally be avoided.

Dexmedetomidine

Dexmedetomidine is a selective α_2-adrenergic agonist with anxiolytic, sedative, and analgesic properties (also see Chapter 30). The role of this drug for the care of children awaits further investigation to clarify its exact advantages and disadvantages. Very limited well-controlled pediatric studies have been conducted. A pharmacokinetic trial involving 36 children, 2 to 12 years of age, revealed a terminal elimination half-life of approximately 110 minutes with both heart rate (≤15%) and systolic blood pressure (≤25%) decreasing over time as the dose is increased; these observations are similar to those in adults.[68] Infusions of 2, 4, or 6 μg/kg for 10 minutes (total dose 0.33 to 1.0 μg/kg) found no significant effect on the respiratory rate or oxygen saturation during the 1-hour period of observation before induction of anesthesia. Only one child initially demonstrated an increase in blood pressure, but it was unclear whether it was drug related. Transient sedation occurred in all children, and the authors recommend slow intravenous infusion to minimize possible adverse hemodynamic events that might occur with bolus administration. The use of dexmedetomidine as a sole drug or combined with other sedatives has been described in children undergoing cardiac catheterization and a variety of radiologic procedures.[69,70] Dexmedetomidine facilitates fiberoptic intubation,[71] provides sedation for a child undergoing an awake craniotomy,[72] reduces

the incidence of emergence agitation,[73,74] and facilitates withdrawal from opioids.[75] In addition, this medication can provide prolonged sedation in children who are critically ill.[76] Thus the indications in children would seem to be the same as in adults. Large dose dexmedetomidine (2 to 3 μg/kg initial dose, followed by 1 to 2 μg/kg/hr) infusion has been associated with severe bradycardia (heart rate, 40 beats/minute),[77,78] but treatment with glycopyrrolate resulted in severe and persistent hypertension of unknown cause.[79] Given these potentially serious adverse effects, large dose dexmedetomidine cannot be recommended. In general, an initial dose of 0.7 to 1.0 μg/kg administered over 10 minutes is followed by an infusion of 0.5 to 1 μg/kg/hr; further sedation can be accomplished with opioid, benzodiazepines, or other sedating medications.[80]

OPIOIDS (Also See Chapter 31)

Morphine

Morphine is the oldest commonly used long-acting opioid. Its use in neonates (those younger than 10 days) remains controversial because it may cause more respiratory depression than meperidine. Higher brain levels of morphine were found in neonatal rats than in adult rats, thus implying that permeability of the blood-brain barrier may account, in part, for the apparent sensitivity of the human neonate to morphine.[81] This rationale led to the common belief that infants are sensitive to the effect of opioids. More recent studies have found age-dependent pharmacokinetics. Newborns have slower clearance of morphine, and therefore a smaller dose will result in higher plasma values because of a longer elimination half-life.[82] Term infants older than 10 days may clear morphine more rapidly and at a similar rate as adults.

The issue of respiratory sensitivity and the age at which it decreases in humans has yet to be resolved; a difference between morphine and fentanyl may exist that may not relate to the transport of drug into the brain.[83] If so, then changes in pharmacodynamics rather than simply maturation of the blood-brain barrier are dominant. Morphine should be administered with caution to neonates and preterm infants who are not in a monitored setting. Infants older than 6 months probably have a normal adult response to morphine.

Meperidine

Meperidine received great attention when it was thought to cause less respiratory depression than morphine in newborns (also see Chapter 31).[84] This difference may be related, in part, to the fact that meperidine is significantly more lipophilic than morphine. Unlike morphine, the fraction of drug that enters the brain of neonates is similar to that entering the brain of older children. As with all drugs administered to neonates, a large patient-to-patient variability in metabolism and response exists. Meperidine is not appropriate for long-term or repeated administration because of the accumulation of the toxic metabolite normeperidine; this drug has been removed from the formulary of many children's hospitals.

Fentanyl

Fentanyl is the most commonly used opioid in infants and children (also see Chapter 31). Its major advantages relate to its rapid onset and brief duration of action. This opioid is more lipophilic than meperidine; the potential effects of the blood-brain barrier are of no importance with fentanyl. Termination of the effect of low doses of fentanyl primarily results from redistribution, whereas termination of the effect of high doses depends on elimination. Large doses of fentanyl achieve the properties of long-acting opioids.

Fentanyl induces a very stable cardiovascular response while providing an anesthetic state. The dosage required to produce anesthesia varies considerably, depending on the child's age, the surgical procedure, the health of the child, and the use of anesthetic adjuvants.[85] Neonates undergoing abdominal surgery have a longer fentanyl half-life than do those undergoing other procedures; hepatic blood flow, and factors that greatly increase or decrease hepatic blood flow, such as positive end-expiratory pressure (PEEP) or the use of vasopressors, may alter the pharmacokinetic response. Impaired hepatic function may also play a role in the altered kinetics with increased intraabdominal pressure.[86] Therefore the pharmacokinetic and pharmacodynamic profile is very different and more variable for neonates than it is for older children. A dose of 12.5 μg/kg produces anesthesia in full-term neonates undergoing abdominal surgery,[85] whereas larger doses (30 to 100 μg/kg) are used for cardiac surgery (also see Chapter 94). These doses are safe in children whose ventilation will be controlled postoperatively; much smaller doses (2 to 10 μg/kg) should be used with other anesthetics if ventilation is not to be controlled postoperatively. Because the cardiac output of neonates is determined by the heart rate, fentanyl-induced bradycardia may require the administration of a vagolytic drug, such as atropine or even pancuronium during long procedures.

Alfentanil

Alfentanil is more rapidly eliminated than fentanyl; its pharmacokinetic effects are independent of dose (also see Chapter 31), which may provide a margin of safety because the greater the administered dose, the greater the elimination. Clearance of alfentanil may be increased in children, compared with adults. As with any opioid, important patient-to-patient variability in pharmacokinetics and pharmacodynamics occurs in neonates and in children with impaired hepatic blood flow.

Sufentanil

Sufentanil has been primarily used for cardiac anesthesia; age-dependent kinetics are also evident, particularly in the first month of life (also see Chapters 31 and 94). Children are able to clear sufentanil more rapidly than adults. This drug must be administered with caution because severe bradycardia and asystole have been reported when a vagolytic drug was not simultaneously administered.[87] Sufentanil may be nasally administered as a premedicant or analgesic (2 μg/kg); however, desaturation may follow.

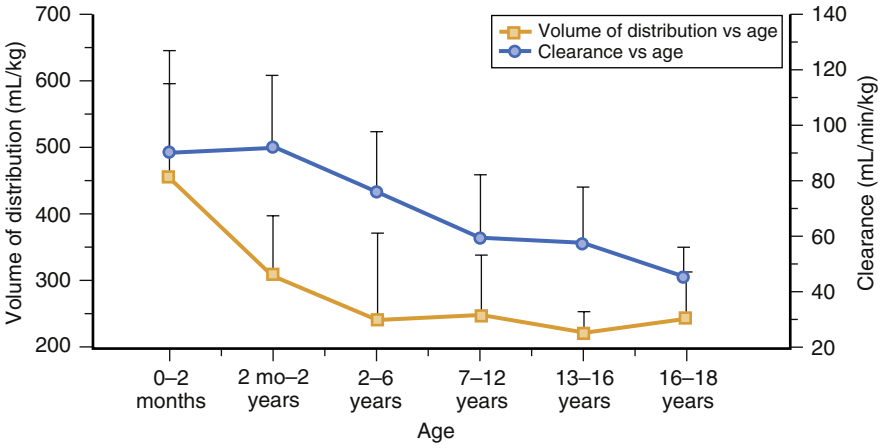

Figure 93-9. Remifentanil is the newest potent opioid available for the care of neonates. Unlike virtually all other medications, its clearance is more rapid in neonates than it is in older children, probably because of elimination of remifentanil by nonspecific plasma and tissue esterases, as well as the larger volume of distribution in neonates. The importance of this observation is that developmental immaturity of liver and renal function does not affect the pharmacokinetics of remifentanil. *(Data abstracted from Ross AK, Davis PJ, del Dear G, et al: Pharmacokinetics of remifentanil in anesthetized pediatric patients undergoing elective surgery or diagnostic procedures,* Anesth Analg *93:1393-1401, 2001.)*

Remifentanil

Remifentanil is the most recent addition to the opioids available for the care of children (also see Chapter 31).[88] The main advantage of this opioid is its extremely brief half-life. Studies in adults have found that even after prolonged infusions, the time to a 50% reduction in effect-site concentration (i.e., effect on respiration) is approximately 4 minutes. One study examined its pharmacokinetic effects in children and found age-related differences in the volume of distribution and clearance but not in half-life (Figure 93-9).[89] Contrary to the pharmacokinetics of most drugs, neonates are able to clear the drug more rapidly than older children! Of further interest is the very small patient-to-patient variability in pharmacokinetic parameters when compared with similar studies examining other opioids, particularly in infants and neonates. Because remifentanil is degraded by nonspecific plasma and tissue esterases, the importance of maturation of renal and hepatic function is minimal; the differences in remifentanil's half-life among neonates, infants, and adults are minimal. Therefore this drug has great utility in infants with hepatic or renal failure. The particularly favorable pharmacokinetics in neonates allows the provision of a deep opioid-induced plane of anesthesia while avoiding cardiovascular depression and the need for postoperative ventilation. One multicenter study of infants undergoing pyloromyotomy found no difference in intraoperative hemodynamic parameters, time to tracheal extubation, PACU discharge times, need for pain medications, or adverse events when compared with halothane anesthesia.[90,91] In older children, remifentanil is extremely helpful in the anesthetic management of those in whom neurologic status must be rapidly assessed. This drug is also very useful for cardiac surgery in children as a means of providing adequate opioid analgesia, cardiovascular stability, and early extubation while transitioning to longer-acting low dose opioids (also see Chapter 94).

Several studies have examined bolus doses of remifentanil as an alternative to succinylcholine.[92,93] One study found that 1.25 μg/kg of remifentanil combined with 4 mg/kg of propofol allowed all children (2 to 16 years of age) to have their tracheas successfully intubated, but more coughing was observed. In addition, the duration of apnea was longer in the remifentanil group than in those who received an equivalent dose of propofol combined with succinylcholine (1 mg/kg); none of the children in the remifentanil group developed chest wall rigidity.[92] Another study of infants 2 to 12 months old and children 1 to 6 years of age determined the 98% effective dose (ED_{98}) for successful intubation to be similar in both age groups (~2.9 μg/kg).[93] The second half of that study compared remifentanil, 3 μg/kg, combined with propofol, 4 mg/kg, in 2- to 12-month-old infants succinylcholine (2 mg/kg) combined with propofol (4 mg/kg) and found similar tracheal intubating conditions; the duration of apnea was similar in both groups. Data are currently insufficient to support the routine substitution of remifentanil for succinylcholine for rapid sequence tracheal intubation. Because bolus doses of remifentanil are associated with hypotension and bradycardia, a vagolytic drug should also be administered.

In neonates and toddlers, the use of a more dilute concentration (e.g., 5 μg/mL) of remifentanil and bypassing the dead space of the injection port with a needle (or priming the dead space) are necessary to ensure that the onset of drug effect is not delayed.[94,95] In older children, a standard solution of 50 μg/mL may be used. In general, a starting bolus dose is not necessary and an infusion of 0.1 μg/kg/min may be increased or decreased as indicated. Two studies have compared the somatic and autonomic responses to skin incision during continuous remifentanil infusion in adults and children.[96,97] The infusion rates to block somatic and autonomic responses in 50% of children were significantly higher (approximately twofold greater) than in adults. The reason for such a disparity in drug requirement between adults and children is not clear. However, this observation is certainly clinically important because it suggests the possible need to (1) start at higher initial infusion rates, (2) rapidly increase infusion rates after an initial assessment of responses, (3) supplement the anesthetic with nitrous oxide or a volatile anesthetic, or (4) add another analgesic. This author has used a fixed combination of 100 μg of remifentanil combined with 18 mL of propofol (final concentration, 5 μg/mL of remifentanil) for children younger than 10 years of age and a lower fixed combination of 50 μg of remifentanil in 19 mL of propofol (final concentration of 2.5 μg/mL) for older children and started the infusion rate equivalent to 150 μg/kg/min of propofol; this combination

provides excellent conditions for upper and lower endoscopic procedures. The smaller dose of remifentanil for the older children is to avoid bradypnea. One study has demonstrated adequate stability of this mix for 6 hours.[98]

For practical purposes and safety, remifentanil should be administered by continuous infusion. It should also be carried into the vein by a second continuous infusion because variations in drug delivery related to differences in intravenous fluid delivery can have profound effects on the rate of opioid administration.[94,95] For neonates and small children, this author has generally used a continuous infusion pump for administering the maintenance intravenous fluid at half the hourly requirement and *piggyback* the remifentanil infusion as close to the intravenous catheter as possible. In complex procedures, this author uses a separate intravenous line for all other anesthetic management issues. A further extremely important concern is the need to provide analgesia once the remifentanil is discontinued. This author usually accomplishes this with morphine (0.05 to 0.2 mg/kg, depending on the severity of the expected pain) or with a regional nerve block administered well before the discontinuation of the remifentanil. This author has also used remifentanil as a means of producing profound analgesia while taking advantage of its vagotonic effects to reduce blood pressure in children undergoing spinal instrumentation. This strategy avoids interference of evoked motor or sensory potentials because a low-dose inhaled volatile anesthetic and a propofol infusion may be used for anxiolysis and amnesia. Acute tolerance has been reported in this setting.[99]

MUSCLE RELAXANTS (Also See Chapter 34)

Depolarizing Muscle Relaxants

Succinylcholine is highly water soluble and rapidly redistributes into the extracellular fluid volume. For this reason, the dose required for intravenous administration of this depolarizing muscle relaxant in infants (2.0 mg/kg) is approximately twice that for older children (1.0 mg/kg). Succinylcholine is the only short-acting relaxant that is effective when given intramuscularly; reliable muscle relaxation occurs within 3 to 4 minutes after 5 mg/kg in infants and 4 mg/kg in children older than 6 months. The skeletal muscle relaxation produced by intramuscular administration may last up to 20 minutes; more rapid onset is not achieved by splitting the dose into two injections or by changing the concentration. In an emergency situation, succinylcholine may be administered intralingually (via a submental approach), which will further speed the onset of relaxation because the drug is more rapidly absorbed from the tongue than from peripheral skeletal muscle.

Cardiac arrhythmias frequently follow intravenous administration, especially during halothane anesthesia. Prior intravenous administration of atropine (but not intramuscular administration of atropine as a premedication) reduces the incidence of arrhythmias. Cardiac sinus arrest may follow the first dose of succinylcholine but is more common after repeated bolus administrations; such arrest may occur in children of any age. Although the incidence of bradycardia is infrequent in older children, this author has observed one 13-year-old child in whom asystole developed for approximately 30 to 45 seconds after a single dose of succinylcholine administered with thiopental but not atropine; the asystole occurred before intubation and with 100% oxygen saturation and immediately responded to the administration of atropine and several chest compressions to circulate the atropine. Therefore a vagolytic drug should probably be intravenously administered just before the first dose of succinylcholine in all children, including teenagers, unless a contraindication to tachycardia (e.g., a cardiomyopathy) exists.

Succinylcholine has received significant attention because of the severity of its possible complications. The potential for rhabdomyolysis and hyperkalemia (particularly in boys younger than 8 years of age who have unrecognized muscular dystrophy), as well as the risk for masseter spasm and malignant hyperthermia, suggests that succinylcholine should not be routinely used in children.[100,101] Increased jaw muscle tone (masseter spasm) after succinylcholine has been observed, which may be a normal variant. However, masseter tetany ("jaws of steel"), which prevents any mouth opening, represents an extreme variation in increased masseter muscle tone and may be the reaction associated with malignant hyperthermia. This author has observed this effect two times; malignant hyperthermia did not develop in either child, but one child had creatine kinase (CPK) values larger than 20,000 International Units (IU) the next morning.

With the foregoing cautions in mind, succinylcholine remains valued because it is the only commercially available ultrashort-acting muscle relaxant that provides a dependable, rapid onset of action. Intravenous use of this drug should be limited to children who have a full stomach or to treat laryngospasm; intramuscular or submental (intralingual) administration is indicated for children with difficult intravenous access when control of the airway is deemed essential.

Hope is on the horizon for a safer alternative for rapid-sequence intubation of the trachea and for treatment of laryngospasm (i.e., large-dose rocuronium, 1.2 mg/kg).[102] If the new reversal drug, sugammadex, is demonstrated to be safe and effective in children (see later discussion) and its ability to antagonize profound neuromuscular blockade is confirmed in children, the vast majority of life-threatening adverse effects associated with succinylcholine will disappear. In many countries all over the world, sugammadex has proven to be an excellent reversal of neuromuscular blockade.

Nondepolarizing Muscle Relaxants

A comparison of infants with older children or adults regarding their responses to nondepolarizing muscle relaxants shows that infants are generally more sensitive to these drugs and that their responses vary to a greater degree (also see Chapter 34). Although the initial dose per kilogram needed for neuromuscular blockade is often similar for children of all ages, the greater volume of distribution and reduced renal or hepatic function of neonates result in a slower rate of excretion and hence a

TABLE 93-4 COMMONLY USED MUSCLE RELAXANTS AND REVERSAL AGENTS IN PEDIATRICS

Drug	Average Intubation Dose (mg/kg)	Category	Approximate Duration (minutes)
Muscle relaxants*			
Pancuronium	0.1	Long acting	~45-60
Cisatracurium	0.1	Intermediate acting	~30
Vecuronium	0.1	Intermediate acting	~30
Rocuronium		Dose related:	
	0.3	Short acting	~15-20
	0.6	Intermediate acting	~30-45
	1.2	Long acting	~45-75
Reversal agents†			
Edrophonium	0.3-1.0 mg/kg + atropine, 0.02 mg/kg		
Neostigmine	0.02-0.06 mg/kg + atropine, 0.02 mg/kg		

*The response of preterm and term neonates (who may be more sensitive to the drugs) to muscle relaxants varies greatly from patient to patient. Therefore all doses should be titrated to response. The recommended tracheal intubation doses may be reduced 30% to 50% in the presence of a potent inhaled agent.

†The dose of the reversal agent given to antagonize nondepolarizing neuromuscular blockade should be determined by the degree of residual neuromuscular blockade (i.e., the dose should be titrated to clinical effect).

prolongation of effect. Neuromuscular blockade occurs at a lower blood concentration in infants.

The choice of nondepolarizing muscle relaxant depends on the side effects and the duration of the desired muscle relaxation. If tachycardia is desired (e.g., with fentanyl anesthesia), then pancuronium may be an appropriate choice. Vecuronium, atracurium, rocuronium, and cisatracurium are useful for shorter procedures in infants and children; they may also be administered as a constant infusion. The method of excretion of atracurium and cisatracurium (Hofmann elimination and ester hydrolysis) makes these relaxants particularly useful in newborns and children with immature or abnormal hepatic or renal function. Vecuronium is valuable because no histamine is released; however, its duration of action is prolonged in newborns, which makes it similar to pancuronium.

Rocuronium has a clinical profile similar to that of vecuronium, cisatracurium, and atracurium but offers the advantage that it can be administered intramuscularly. One study observed that acceptable conditions for intubation are produced by rocuronium within 3 to 4 minutes after 1 mg/kg intramuscularly in infants and 1.8 mg/kg intramuscularly in children older than 1 year of age; these effects were more dependable with deltoid than with quadriceps muscle injection.[103] This onset time is similar to that produced with intramuscular succinylcholine; however, the duration of action is approximately 1 hour, which could be a distinct disadvantage for a brief procedure. The onset of neuromuscular blockade with intravenous rocuronium (1.2 mg/kg) is also virtually the same as intravenous succinylcholine (1.5 mg/kg), and intubation conditions are identical.[102] The author has used this intravenous rocuronium dose with propofol (3 to 4 mg/kg) for rapid-sequence induction after administering oxygen in children in whom succinylcholine might present an added risk; even better intubating conditions are achieved with the addition of intravenously administered lidocaine (1 mg/kg). The tracheas of most children can be intubated at 45 seconds. The disadvantage is that the duration of action is 45 to 75 minutes, thus limiting its usefulness to either long procedures or accepting the fact that prolonged neuromuscular blockade may result. Conversely, at small doses of rocuronium (0.3 mg/kg), satisfactory conditions for tracheal intubation occur at approximately 3 minutes when combined with a volatile anesthetic, but successful reversal of neuromuscular blockade can usually be achieved within 15 to 20 minutes.

Table 93-4 provides commonly recommended guidelines for doses. Because of the extreme variability in response, the doses of long-acting muscle relaxants used for infants should be carefully titrated, starting with one third to one half of the usual dose administered to older children. This author recommends routine pharmacologic antagonism of neuromuscular blockade in all neonates and small infants, even if they have clinically recovered, because any increase in the work of breathing may cause fatigue and respiratory failure. Useful signs of reversal are the ability to lift the legs and arms and recovery of the train-of-four response to peripheral nerve stimulation.

Sugammadex

Sugammadex is a cyclodextrin whose endoskeleton forms a water-soluble complex with the exoskeleton of rocuronium; it was specifically designed to antagonize the effects of rocuronium[104,105] (also see Chapter 35). The purported advantage of sugammadex is that antagonism occurs as a result of covalent bonding, and because sugammadex is made of sugars, the potential for adverse side effects would appear to be minimal.[105,106] This drug also reverses the other steroidal relaxants, vecuronium and pancuronium, probably to a lesser extent. The mechanism of reversal is a lowering of the plasma concentration and thus reversing the concentration gradient and encapsulating the rocuronium for transport away from the myoneural junction.[105,107] The result is a more rapid antagonism than with a neostigmine-atropine mixture.[108] Furthermore, sugammadex has no cardiovascular effects; therefore it does not require a drug such as atropine. The importance of this new approach to antagonism of neuromuscular

TABLE 93-5 **APPROXIMATE COST FOR REVERSAL OF ROCURONIUM BY WEIGHT AND DENSITY OF BLOCK***

	Weight (kg)			
Depth of Block	**3**	**10**	**20**	**70**
Mild (4 twitches with fade) 2 mg/kg	$1.4625	$9.75	$19.50	$67.90
Moderate (1-2 twitches) 4 mg/kg	$1.95	$19.50	$39.00	$135.80
Profound (no twitches) 8 mg/kg	$3.90	$39.00	$78.00	$271.60
Wasted drug (single-patient use; profound blockade)	$93.60	$58.50	$19.50	$68.025†

*Rocuronium is not yet approved by the U.S. Food and Drug Administration; therefore the above prices are based on the United Kingdom costs.

†Assumes one 200-mg vial and one 500-mg vial for complete dosing:
Cost per 200 mg vial: £60 or ~$97.50 ($0.4875/mg)
Cost per 500 mg vial: £149 or ~$242.125 ($0.4843/mg)

blockade is the ability to avoid all the side effects of neostigmine and anticholinergic medications, as well as the ability to antagonize profound neuromuscular blockade. This very exciting development could virtually eliminate the need for succinylcholine in pediatric practice, except perhaps for intramuscular use in children without intravenous access. Even in this circumstance, intramuscular rocuronium would be antagonized by sugammadex, provided that adequate doses are administered. Certainly, the adult data are very promising, and if sugammadex has a minimal adverse event profile, then it may completely change the approach to anesthesia in children. Data also suggest a more rapid recovery from anaphylaxis related to rocuronium when sugammadex is administered as a rescue medication.[109,110] Unfortunately, the manufacturer has established a price so high that its routine use is inhibited and usually not financially practical (Table 93-5). Therefore at the time of this writing, it appears that sugammadex will be administered as a rescue drug only.

ANESTHETIC CONSIDERATIONS

PREOPERATIVE PREPARATION

The preoperative visit and preparation of the child for surgery are more important than the choice of premedication (also see Chapter 38). During this time the anesthesiologist evaluates the medical condition of the child, the needs of the planned surgical procedure, and the psychological makeup of the child and family. The anesthesiologist also formulates the approach to induction of anesthesia, explains the possibilities regarding induction, and helps soothe family concerns. Because the anxiety felt by the parents may be transferred to the child, any practice that reduces anxiety in the parents may also reduce anxiety in the child. Therefore the anesthesiologist should explain in great detail what the child and family can expect and what will be done to ensure their own and their child's utmost safety. The more information that the parents and child have, the more easily they will deal with the stress of surgery and hospitalization. Presurgical programs such as videotapes, literature, and hospital tours also help. Play therapy can also relieve stress; it is amazing to observe children so enthralled with their iPad video game that they fall asleep while playing the game.

After chart review, physical examination, and furnishing information regarding the approximate time and length of surgery, the anesthesiologist should describe to the child what anesthesia is and what will be done to ensure good care. The purpose of all monitoring devices should be explained to both the child and family. Children need to understand that none of these devices will hurt and that they can watch during their application. If an intravenous line will be started, then the child needs to be told that "numbing" medicine will be used. Any special monitoring devices, such as an arterial line, central venous line, nasogastric tube, or urine catheter, should also be described to the parents, with assurances that these devices will be inserted after the induction of anesthesia. Part of this informed consent is also a description of the anesthesiologist's role in the operating room. It is vital to assure parents that the "anesthetic prescription" will be tailored to meet their child's medical, as well as surgical, needs. This author uses the phrase "anesthetic prescription" because anesthesiologists are physicians, as is the surgeon or a pediatrician, and it is important for families to clearly understand this.

Children think in very concrete terms, therefore care must be taken to avoid misunderstandings. Explaining to children that the "sleep" caused by anesthetic drugs differs from normal sleep is important. They should know that the anesthesia medicines keep them from awakening during surgery and from remembering the operation. It should also be explained that the anesthesia medicines will be removed at the end of surgery and that they will then wake up and return to their parents. This kind of explanation does not require a significant amount of time and goes a long way toward reassuring the child and family about the quality of care provided.

The issue of pain must not be avoided. Children need to be reassured that everything possible will be done to minimize pain on awakening. Therefore it should be stressed that pain medications will be administered and that local infiltration nerve blocks, continuous epidural or caudal infusions, child-controlled epidural analgesia, or patient/parent/nurse-controlled analgesia will be used (see also Chapters 92 and 98). The PACU or ICU must also be described to ensure that no surprises occur.

THE FEARFUL CHILD

Because of either a past experience or a general lack of understanding, some children are terrified to come to the operating room. When a child breaks into tears and if the child is old enough to talk with, then the anesthesiologist should stop whatever is happening at the moment, sit on the bed next to the child, and ask what exactly is concerning them. Sometimes the child does not respond. In this situation, such children should be asked if they are afraid to go to sleep, afraid of feeling their "operation," or

afraid of pain afterward. Generally, they are able to verbalize their concern; however, even with no response, at this point the anesthesiologist should reiterate that "*the sleep from anesthesia is different from sleep at home. At home, if mom or dad shakes you, you would wake up. In the operating room, no matter what we do, you will not feel it, you will not remember it, and then at the end I will take the medicine away. You will breathe it all back out again, and then you will wake up and return to your family.*"

This explanation usually ends the tears. Sometimes the tears flow because they want a parent present for induction, even some of the older children. This request is easy to grant, and it also usually ends the tears. If, on the other hand, a specific event in the past is causing concern, then determining whether something was misunderstood or whether something can be carried out differently to avoid the issue is important. For some children with previous anesthetic experience, simply allowing them to hold the anesthesia mask themselves provides them with sufficient control of the situation to stop the tears. I once had a 7 year old who wrote a will: "*Leave my doll to.... Leave my blanket to....*" When I asked what this was all about, she responded that she was "*going to sleep today and that sometimes when people go to sleep they do not wake up.*" Because she had suffered a burn injury and need many procedures, I explained to her that, yes, people can go to sleep and not wake up, but usually that happened to an older person with a problem with the heart or the brain and that I had not seen this in someone her age having this operation. I asked her if she would feel better if she held the mask herself, and she, in fact, held the mask for a smooth anesthetic induction. In recovery, she later thanked me as "*the first doctor that ever explained anything to me!*" This brief anecdotal experience emphasizes the importance of directly talking to children, regardless of their age. Finally, other children cannot be consoled, and finding the source of their concern is not always possible. It is these children who will benefit from heavy premedication, such as the combined oral midazolam, ketamine, and atropine (see earlier discussions).

FASTING

No difference is observed in gastric residual volume or pH in children allowed to ingest unlimited clear liquids (e.g., water, apple juice) up until 2 to 3 hours before anesthetic induction versus standard fasting. Being able to drink appropriate fluids is a more humane approach for both children and their parents without increasing the risk for pulmonary aspiration of gastric contents. Infants and young children have a higher metabolic rate and a larger body surface area-to-weight ratio than adults and more easily become dehydrated than adults. The major advantage of the liberalized fasting guidelines may be a reduced incidence of hypovolemia at the time of anesthesia induction. This author's approach is to restrict milk and solids after midnight but allow unlimited clear fluids up to 3 hours before induction; even if the surgical schedule changes, this author still feels comfortable with 2 hours of fasting (Table 93-6). Infants who are breast-fed may have their last breast milk 4 hours before induction of anesthesia. Breast milk should be considered equivalent to formula because the fat content varies with maternal diet, and delayed gastric emptying may result. The American Society of Anesthesiologists (ASA) guideline also allows a "light meal" of toast and clear liquids up to 6 hours before induction of anesthesia, but parents frequently confuse this guideline to mean any type of meal, including eggs and bacon![111]

TABLE 93-6 PREOPERATIVE FASTING RECOMMENDATIONS IN INFANTS AND CHILDREN

Type	Fasting Time (hrs)
Clear liquids*	2
Breast milk	4
Infant formula	6†
Solid (fatty or fried) foods	8

*Includes only fluids without pulp; clear tea or coffee without milk products.
†The American Society of Anesthesiologists guideline allows a "light breakfast" (tea and plain toast) 6 hours before anesthesia; however, determining what a "light breakfast" means for a child is difficult.

PREMEDICATION

Almost all sedatives are effective. The important issue is local effectiveness at a given institution. The need for premedication must be individualized according to the underlying medical conditions, the length of surgery, the desired induction of anesthesia, and the psychologic makeup of the child and family. Premedication is not normally necessary for the average 6-month-old infant but is warranted for a 10- to 12-month-old who is afraid to be separated from his or her parents. Oral midazolam is the most commonly administered premedication in the United States. An oral dose of 0.25 to 0.33 mg/kg (maximum, 20 mg) generally results in a very compliant child who will separate from parents without crying[65] (also see Chapter 38). A review of previous anesthetic records is particularly helpful in ascertaining how the child has responded in the past.

Premedications may be administered orally, intramuscularly, intravenously, rectally, sublingually, or nasally. Although most of these routes of administration are effective and reliable, each one has its drawbacks. Oral or sublingual premedication does not hurt but may have a slow onset or can be spit out; drug taste and child cooperation are the main determinants of success. Oral ketamine (4 to 6 mg/kg) combined with atropine (0.02 mg/kg) and midazolam (0.5 mg/kg, maximum of 20 mg) will result in a deeply sedated child. Intramuscular medications hurt and may result in a sterile abscess. Intravenous medications may be painful during injection or at the start of infusion. Rectal medications sometimes make the child feel uncomfortable, cause defecation, and occasionally burn. Nasal medications can be irritating, although absorption is rapid. A midrange dose of *intramuscular* ketamine (2 to 4 mg/kg) combined with atropine (0.02 mg/kg) and midazolam (0.05 mg/kg) is generally reserved for children who refuse oral premedication or those in whom lighter premedication regimens have failed in the past. Larger doses of intramuscular ketamine (up to 10 mg/kg) combined with atropine and midazolam may be administered

to children with anticipated difficult venous access or in whom an intravenous line is necessary for induction (e.g., infants with congenital heart disease) to provide better conditions for the insertion of an intravenous line.

Anticholinergic drugs are not routinely administered intramuscularly to children because they are painful on administration and do not significantly reduce laryngeal reflexes during induction of anesthesia.

THE CHILD WITH AN UPPER RESPIRATORY INFECTION

A child with a URI is a major concern because the anesthetic implications can be quite important. Unfortunately, data regarding URIs and the anesthetic implications are difficult to ascertain for many reasons, including the definition of what a URI is, which varies from study to study. The decision whether to proceed with surgery and anesthesia is dependent on a number of factors. The URI may represent a prodrome of a much more serious illness, or it may simply be the usual viral infection so common in children, particularly in the wintertime. A child with a URI likely has an irritable airway and is at increased risk for laryngospasm, bronchospasm, postintubation croup, atelectasis, pneumonia, and episodes of desaturation. The incidence of airway-related problems in children who are passively exposed to tobacco smoke is increased.[112-115] These complications can be reduced by avoiding tracheal intubation or using a supraglottic device such as an LMA. However, the incidence of adverse airway-related events is not reduced by the administration of anticholinergics or bronchodilators.[116,117] Because bronchial hyperreactivity may last for up to 6 weeks after a URI, cancellation will make a difference only if surgery is delayed for this length of time or longer.[118,119] The same incidence of airway-associated complications occur in children who are recovering from a URI as for those in the acute phases of a URI.[112,119,120] If the child is acutely ill and obviously getting worse, then the procedure should probably be canceled. If the child has rhonchi and a productive cough, then the procedure is canceled. If the child is stable and afebrile and has had the URI for several days, then this author usually proceeds. The main concern is a child who is going to have a very long procedure or will be admitted to the hospital postoperatively, which may in turn result in exposure of other hospitalized children who may be immunocompromised. When faced with this dilemma for a child who will be going home postoperatively, the family and the surgeon should be informed of the increased risks; they generally make the decision to proceed. Tools are available to manage the reasonably common complications successfully. Oxygen is used to treat hypoxemia, albuterol and inhaled anesthetics can treat bronchospasm, muscle relaxants are available to treat laryngospasm, and usually a way is found to avoid intubation of the trachea for simple procedures. Cancellation of a procedure at the last minute is unfair to the family and upsets the surgical unit schedule. On the other hand, one should not place the child at risk merely for economic or social concerns. The best way to avoid last-minute cancellations is a telephone call by the nursing staff the day before to inquire about the child's health. If the child has a URI, then the anesthesiologist can call the family and take a history to determine how best to proceed. In this way, wasted trips to the hospital are avoided and the father or mother, or both, do not unnecessarily take off a day of work. Physicians are really left to their own best clinical judgment for an individual child on a particular day undergoing a specific procedure. If the decision is made to proceed, then writing a note in the chart documenting the discussion is helpful and recommended.

INDUCTION OF ANESTHESIA

The method of inducing anesthesia is determined by a number of factors: the medical condition of the child, the surgical procedure, the level of anxiety of the child, the child's ability to cooperate and communicate (because of age, developmental delay, or language barrier), and the presence or absence of a full stomach, among others.

Infants

Induction of anesthesia via a mask without premedication is generally used in infants younger than 10 to 12 months because this age group readily separates from their parents. Induction via a mask is accomplished most easily by holding the end of the anesthesia circuit in a cupped hand over the infant's face or by holding the mask just off the surface of the face; the other hand can adjust the concentration of anesthetic. Allowing neonates and small infants to suck on a rubber nipple or on a gloved finger generally prevents crying during the induction of anesthesia. As the infant loses consciousness, the anesthesia mask is adjusted to improve delivery and decrease operating room pollution. This phase is the most dangerous time because misjudging the depth of anesthesia and depressing the heart are very easy. Once anesthesia has been induced, it is critical to reduce the inspired concentration of halothane (down to 1.0% to 1.5%) or sevoflurane (down to 3% to 4%) and maintained at this level or less until an intravenous line is in place. After the intravenous line is inserted, the plane of anesthesia may be deepened or a muscle relaxant may be added. Directly proceeding to a deep plane of anesthesia without having an intravenous line in place is dangerous; without this precaution, resuscitation would be difficult.

The second most dangerous point occurs immediately after tracheal intubation. If the vaporizer has not been closed before laryngoscopy, then forgetting that a relatively high inspired concentration is being delivered and perhaps giving an overdose of inhaled anesthetic while checking for breath sounds are both easy. Therefore the prudent clinician will discontinue all anesthetics until laryngoscopy and tracheal intubation have been completed. With a Mapleson D circuit, a high concentration of anesthetic can more easily be delivered because the anesthetic enters directly at the airway. In contrast, changes made at the vaporizer of a circle system take a longer time to achieve equilibration with the circuit; therefore the inspired concentration of anesthetic more gradually increases (or decreases) unless a high fresh gas flow is being used. Particular caution should be used when changing from halothane or sevoflurane to isoflurane because the myocardial depressant effects of these drugs are additive.

Older Pediatric Patients

Successful, psychologically atraumatic induction of anesthesia by mask in an older child requires that the child understand and cooperate. Premedication is particularly helpful in the 1- to 4-year-old age group. Several different techniques may be used. One method is to play a game. For example, a younger child may be asked to *"blow up the balloon."* A slightly older child (4 years of age and older) may be receptive to hypnotic suggestions during induction. A young child may be susceptible to a suggestion that the anesthesia mask is an *"airplane pilot's mask"* and that the smell of halothane or sevoflurane is *"oxygen"* or *"aviation fuel."* Stating that the *"faster and higher the plane goes, the stronger the aviation fuel will smell"* is one means of distracting the child. During this type of induction, the operating room must be free of distractions, and the anesthesiologist must be able to communicate with the child. The use of constant conversation and incremental increases in the inspired concentration of anesthetic every third or fourth breath usually produce a smooth transition to general anesthesia. In many places, a "play therapist" has educated the child about what to expect and may even have a video game to distract him or her during the induction of anesthesia. If so, then another person must hold the video game so that it does not strike the child in the face as she or he falls asleep. Often the child will breath hold. If so, then the anesthesiologist should not attempt to assist respirations because this action often elicits coughing or laryngospasm. The anesthesiologist must be certain that airway obstruction and laryngospasm can be differentiated from breath holding. Observing the chest wall and abdomen helps identify airway obstruction, which creates a rocking-type movement of the chest and abdomen (when the diaphragm descends, the abdomen appears to expand but the chest does not). As soon as the child loses consciousness, the inspired concentration of anesthetic can be reduced and an intravenous line can be inserted. Should partial laryngospasm or upper airway obstruction occur, closing the pop-off valve to create approximately 5 to 10 cm water (H_2O) of PEEP, while allowing the child to breathe spontaneously, often facilitates gas exchange. If this procedure is not effective, then administration of rapid positive-pressure breaths, while avoiding inflation of the stomach, often disrupts the laryngospasm. Obviously, administration of a muscle relaxant will also break the laryngospasm; succinylcholine remains the agent of choice in an emergency situation.

A third method of induction involves the use of flavored masks. A variety of flavored scents and lip balms are available to reduce the noxious smell of anesthetics; the child can select a favorite scent.

A fourth method, the single-breath technique, requires a very cooperative child who can follow instructions. Using an unattached anesthesia mask, the anesthesiologist should demonstrate the procedure to the child, who then rehearses the following steps: (1) take a big breath in and hold at full inspiration; (2) exhale completely, hold at full expiration, and place the mask on the child's face at exactly the end of expiration; (3) take another full inspiration, hold as long as possible; (4) and then resume normal breathing. Before induction, the anesthesia circuit is filled with either 5% halothane or 8% sevoflurane in 60% nitrous oxide. The circuit bag must be emptied and filled several times so that the entire circuit is filled with 5% halothane or 8% sevoflurane. Steps 1 through 4 are then repeated with the mask attached to the Y-piece of the anesthesia circuit. When placing the face mask, care should be taken to not direct the gas toward the eyes (flutters the eyelashes), which can frighten the child. If the child fully cooperates, then this method generally produces loss of the eyelid reflex in less than 1 minute. Occasionally, a child does not take a full breath or becomes frightened, or the application of the face mask is not complete. If the child is partially anesthetized, then induction takes slightly longer, but the child does not usually remember the induction. If the child panics before inhalation of anesthetic, then induction should not be forced, and an alternative plan should be undertaken.

Parents in the Operating Room

It is very common for parents to request to be present during induction of anesthesia. This author welcomes their participation in this process (usually limited to one parent) because on some occasions, the security of having a parent present and avoiding separation allows the anesthesiologist to omit premedication. *Parental presence should not be substituted for premedication if the child needs premedication.* In other situations, parental presence sufficiently reduces anxiety so that light premedication is adequate. Decisions regarding parental presence must, however, take into consideration the developmental level of the child and the reason for parental presence. It serves no purpose to have a parent present during induction of anesthesia in a newborn or a 6-month-old infant who is completely trusting of strangers. Likewise, parental presence is unlikely to benefit a child who has been heavily premedicated. Certainly, parents must not be present for rapid induction in the presence of a full stomach. Parents are present for the benefit of their child, and if the child does not benefit or if a parent makes the physicians uncomfortable, then he or she should not be present. The safety and care of the child are the priority. This author sometimes explains that their participation in this process is a privilege but not a right. Each physician and each institution must determine what works and what does not work for them. If this author makes a decision to allow a parent to be present, then explaining what they might see is vital to ensure no surprises. The explanation may include, *"When anyone goes to sleep, their eyes roll upward,"* which is a normal response; and the parent might see his or her child's eyes do this a few times. The anesthesiologist should assure the parents that they should expect this and not to think that something is wrong. Next, the explanation should include the warning that as children fall asleep, *"they often make noises from their throat"* (e.g., snoring) and that this is also normal and that they might hear noises from their child's throat as their child falls asleep. (The author does not explain that these noises might be airway obstruction or developing laryngospasm). Third, the author points out that the *"brain often gets excited before it goes to sleep"*; thus after their child breathes the anesthesia medicine for a brief period, it is common for the child to suddenly become restless and to move the arms and legs or look from side to side. This response is expected, and, shortly afterward, the child will be completely anesthetized. Further, although

the child appears to be awake, the parent is assured that the child will not remember any of these responses. Thus the eye rolling, possible airway obstruction, and excitement are all explained, and the parent is not frightened should any of these events occur. The author also makes certain that the parent is sitting in a chair and explains that as soon as their child looses consciousness, they should kiss their child and then leave the operating room so that anesthesia team can completely focus on the care of their child.

For smaller children, this author likes to anesthetize them on a parent's lap. The child faces straight forward with the parent's arms wrapped around the child, helping to hold the child's arms near his or her side to reduce the potential for them to reach up and grab the mask. The author explains to the parent that he or she is going to be able to hug their child as he or she goes to sleep. I also explain that the child will become limp and could fall unless the parent holds on tight. Finally, as the child loses consciousness, the anesthesiologist will pick up the child and place him or her on the surgical table. The parent can then kiss the child and proceed to the family waiting area. If a language barrier exists, then the author will ask a translator to help explain this process and allow the translator in the surgical unit to assist in the communication that is needed to perform an atraumatic mask induction. For these children, usually only a pulse oximeter is applied before induction.

Rectal Induction of Anesthesia

A number of medications may be rectally administered for induction and premedication of anesthesia, but this method is rarely used in current practice. The main advantage of this approach is that the child falls asleep in the parent's arms or, as is the case with midazolam, atraumatically separates from the parents. This technique is no more intimidating than taking a rectal temperature but is generally reserved for children still in diapers. Care must be taken to not allow the child to see the rectal catheter or syringe, which would appear very large to the child. Rectal administration of 10% methohexital (20 to 30 mg/kg) reliably induces anesthesia within 8 to 10 minutes in 85% of young children and toddlers. Oxygen desaturation is not usually a problem unless the child's head is allowed to flex forward and cause obstruction of the airway. The main disadvantage of this technique is that drug absorption can be either significantly delayed or very rapid. Other drugs rectally administered include 10% thiopental (20 to 30 mg/kg), midazolam (1 mg/kg up to 20 mg), and ketamine (6 mg/kg).

Intramuscular Induction of Anesthesia

Many medications, such as methohexital (10 mg/kg), ketamine (2 to 10 mg/kg combined with atropine [0.02 mg/kg] and midazolam [0.5 mg/kg]), or midazolam alone (0.15 to 0.2 mg/kg), are intramuscularly administered for premedication or induction of anesthesia. The main advantage of this route of administration is its reliability; its main disadvantage is that it is painful.

Intravenous Induction of Anesthesia

Intravenous induction of anesthesia is the most reliable and rapid technique. The main disadvantage is that starting an intravenous line can be painful and threatening for the child. Intravenous induction may be preferable when induction by mask is contraindicated (e.g., in the presence of a full stomach). Older children will often allow insertion of an intravenous catheter after the administration of 50% nitrous oxide and a local anesthetic; topical anesthetic creams (e.g., eutectic mixture of local anesthetics [EMLA] or ELA-Max) are also well received. Emphasizing to the child that this procedure will not be excessively painful is important. Occasionally, children will cry with the infiltration of a local anesthetic and become hysterical when they see the intravenous catheter. Two maneuvers help minimize this response: (1) Do not allow the child to see the catheter. (2) Puncture the anesthetized area with a needle, ask the child to look at the needle, and then ask if there is any sensation. Frequently the child is astounded at the lack of pain and stops crying.

PEDIATRIC AIRWAY MANAGEMENT

Endotracheal Tubes

For most children, the proper size of endotracheal tube and the proper distance of insertion relative to the alveolar ridge are moderately constant (also see Chapter 55). Published formulas are estimates that may need to be modified, based on physical examination or unusual child size. Table 93-7 provides a guide for selecting the proper size endotracheal tube and the recommended distance for insertion from the alveolar ridge. Uncuffed endotracheal tubes were traditionally preferred for children younger than 6 years of age (see earlier discussion). A new cuffed endotracheal tube (see Figure 93-4) may offer specific advantages over traditional cuffed endotracheal tubes. If a cuffed endotracheal tube is used, then a half-size smaller tube should be selected, rather than an uncuffed endotracheal tube, and cuff pressure should be adjusted to ensure that a small leak around the cuff is at a peak inflation pressure of 20 to 30 cm H_2O. Cuff pressure should be periodically checked during anesthesia involving nitrous oxide. If an uncuffed endotracheal

TABLE 93-7 RECOMMENDED SIZES AND DISTANCE OF INSERTION OF ENDOTRACHEAL TUBES AND LARYNGOSCOPE BLADES FOR USE IN PEDIATRIC PATIENTS

Age of Patient	Internal Diameter of Endotracheal Tube (mm)	Recommended Size of Laryngoscope Straight Blade	Distance of Insertion* (cm)
Preterm (<1250 g)	2.5 uncuffed	0	6-7
Full term	3.0 uncuffed	0-1	8-10
3 mo - 1 yr	3.5-4.0 cuffed	1	11
2 yr	4.5-5.0 cuffed	1-1.5	12
6 yr	5.0-5.5 cuffed	1.5-2	15
10 yr	6.0-6.5 cuffed	2-3	17
18 yr	7.0-8.0 cuffed	3	19

*Inserting the endotracheal tube these distances from the alveolar ridge of the mandible or maxilla usually places the distal end of the tube in the midtrachea.

Assessment of Percent Airway Obstruction Using Leak Around The Uncuffed Endotracheal Tube (Size ETT–mm ID)

Age	ETT	2	2.5	3	3.5	4	4.5	5	5.5	6
Preterm	No detectable lumen	40								
Preterm		58	30			No obstruction				
0–3 months		68	48	26						
3–9 months		75	59	41	22					
9 months–2 years		80	67	53	38	20				
2 years		84	74	62	50	35	19			
4 years		86	78	68	57	45	32	17		
6 years		89	81	73	64	54	43	30	16	
	Grade IV	Grade III			Grade II		Grade I			

Figure 93-10. Method of determining the percentage of airway obstruction. After easy passage of an uncuffed endotracheal tube (ETT), a stethoscope is placed over the larynx and the circuit slowly pressurized. The pressure at which a leak is auscultated is matched with the age of the child and the size of the ETT to assess the degree of laryngeal narrowing. It should be noted that this chart is based on only one institution's experience and that the manufacturer of the ETTs was not described; therefore the actual external diameter of the ETTs used is unknown. *ID,* Internal diameter. *(Reproduced and modified with permission from Myer CM 3rd, O'Connor DM, Cotton RT: Proposed grading system for subglottic stenosis based on endotracheal tube sizes,* Ann Otol Rhinol Laryngol *103:319-323, 1994.)*

tube is used, then the appropriate size allows a small gas leak at peak inflation pressures of 20 to 30 cm H_2O. If an uncuffed endotracheal tube (or a cuffed tube without the cuff inflated) does not leak at 40 cm H_2O, then the author will replace it with the next smaller size and recheck for a leak. Making this leak assessment to determine the size of the larynx is always important. On average in the author's practice, several children per year have undiagnosed subglottic stenosis detected by the anesthesiologist at the time of intubation (Figure 93-10).

Laryngoscope Blades

Any hospital that cares for children must have a full selection of laryngoscope blades to ensure that the blade most appropriate for the child is readily available. In general, straight blades are used in neonates and toddlers because of anatomic differences from older children (see "The Pulmonary System" discussion); the Wis-Hippel 1.5 is a particularly versatile blade because its surface is flat. Older children can be managed with either curved or straight blades. In some children, a straight blade may offer advantages over curved blades because of midfacial hypoplasia or other anatomic deformity (see Table 93-7). A laryngoscope blade with built-in oxygen delivery is available in sizes 0 and 1 and offers specific advantage for awake or sedated intubation of neonates (Figure 93-11).

The Child With a Full Stomach

A child with a full stomach must be treated the same as an adult with a full stomach; that is, both should undergo rapid-sequence induction of anesthesia with the application of cricoid pressure (also see Chapters 34 and 55). Because oxygen consumption is significantly greater, hemoglobin desaturation occurs more rapidly in a child than in an adult and more rapidly in an infant than in a child. Additionally, a child may be uncooperative and

Figure 93-11. The oxyscope (Heine Optotechnik, D-82211, Herrsching, Germany) is a Miller 1 laryngoscope blade with an insufflation channel along its length so that it may be attached to an oxygen source. An oxyscope provides increased fraction of inspired oxygen concentration *(*FiO_2) and is particularly useful for intubation in a conscious neonate whose oxygen consumption is high and in whom desaturation rapidly may develop.

refuse to breathe oxygen (i.e., refuse preoxygenation) before induction of anesthesia. In this circumstance, the best that can be done is to enrich the environment with a high flow of oxygen because upsetting the child further is not desirable. Additional equipment that should be available includes two suction catheters (if one becomes blocked, another would be immediately available) and two appropriately sized laryngoscope blades (e.g., Macintosh 2, Miller 2) with two handles (if the bulb, contact, or battery fails, another would be immediately available). While the child is breathing oxygen, atropine (0.02 mg/kg)

TABLE 93-8 **SUGGESTED EQUIPMENT FOR A DIFFICULT-AIRWAY CART**

Equipment Category	Recommended Equipment
Airways	Oral and nasopharyngeal (trumpet) airways in all sizes for preterm infants to adults
Endotracheal tubes	Cuffed and uncuffed endotracheal tubes of various sizes (uncuffed down to size 2 mm ID)
Stylets	Stylets in several sizes
Laryngoscopy	Laryngoscope blades in multiple sizes and configurations Several handles and extra batteries Oxyscope (Heine Optotechnik, D-82211, Herrsching, Germany)
Laryngeal mask airways (LMAs)	All sizes (1 to 6) of ProSeal LMAs for patients with a full stomach or for those who require higher peak inflation pressure for successful ventilation Large-volume syringes for the larger masks
Fiberoptic intubation	Several sizes of fiberoptic scopes, including one that will fit through a 2.5-mm ID endotracheal tube Light source Teeth protectors Oral airways designed for fiberoptic intubation Silicone lubricant
Retrograde equipment	Retrograde intubation equipment (needle with guide wire)
Optical stylet or videolaryngoscope*	Optical stylet or videolaryngoscope in a variety of sizes, including one that will fit through a 2.5-mm ID endotracheal tube (Storz, Karl Storz GmbH & Co. KG, Tuttlingen, Germany) or a 3.0-mm ID endotracheal tube (Shikani, Clarus Medical, Minneapolis, Minn.) or a GlideScope Videolaryngoscope (Verathon Inc., Bothell, Wash.)
Endotracheal tube exchangers	Endotracheal tube exchangers in various sizes for the full array of pediatric patients
Cricothyrotomy equipment	Percutaneous cricothyrotomy kits designed for older and larger children (e.g., needles, guide wire, dilator) Jet ventilation–type device, which is similar to an intravenous catheter (18, 14, and 13 gauge) and is useful in infants
Jet ventilation equipment	Jet ventilation stylets and jet injector with an appropriate hookup for wall oxygen
Carbon dioxide detector	For use in nonsurgical venues

ID, Internal diameter.
*Many devices are available and the mention of these devices should not be taken as an endorsement.

is intravenously administered to prevent reflex- or succinylcholine-induced bradycardia and to delay the bradycardia of hypoxemia should any of these events occur. Because of its rapid onset of neuromuscular blockade, succinylcholine is still the muscle relaxant of choice in this circumstance and should be administered at a dose of 1 to 2 mg/kg immediately after thiopental (5 to 6 mg/kg) or propofol (3 mg/kg). Cricoid pressure is gently applied after the child loses consciousness. Children should be told that they may *"feel someone touching you on the neck"* as they fall asleep and that this is *"normal."* In children, the head-up position does not significantly increase protection from pulmonary aspiration of acid gastric contents. If succinylcholine is contraindicated, then rocuronium (1.2 mg/kg) will provide conditions for intubation similar to those provided with succinylcholine within 30 seconds of administration.[89] However, the duration of neuromuscular blockade will be 45 to 75 minutes (also see earlier discussion of rocuronium and Chapter 34). In the hypovolemic child, ketamine (2 mg/kg) may be used for induction, whereas etomidate (0.2 to 0.3 mg/kg) may be a better choice in a child with hemodynamic instability (e.g., cardiomyopathy).

Difficult Airway

The terminology *difficult airway* refers to certain situations or conditions during which maintaining a patent airway may be so technically difficult that hypoxia or difficulty with endotracheal tube placement may occur. The approach to a difficult airway depends, in part, on whether the difficult airway is known and previous records are available for review or whether the child has an unexpectedly difficult airway. In the former situation, a difficult-airway cart with age- and size-appropriate airway equipment (Table 93-8) is brought into the operating room, and the assistance of a colleague with pediatric airway skills is arranged. In the latter situation, the difficult-airway cart may need to be urgently brought into the operating room and skilled help summoned. The most common errors that this author has observed in several malpractice cases are the lack of equipment or inappropriately sized equipment, inadequate skilled help, the failure or delay in calling for help, and the failure of the anesthesiologist to attempt cricothyrotomy early enough. Accordingly, the importance of having a dedicated pediatric difficult-airway cart, the need to be familiar with its contents and how to use the devices that it contains, and the availability of skilled help are essential.

A child facing a potentially difficult laryngoscopic procedure should receive, at most, light sedation before induction of anesthesia by mask to maintain spontaneous respirations. In this way the airway can be secured before "burning bridges" by administering a muscle relaxant and losing the help of spontaneous respirations. With the child spontaneously breathing, breath sounds can be used to guide successful tracheal intubation. When normal airway anatomy cannot be visually confirmed, placing a stylet in the tracheal tube and acutely bending the tip of the tracheal tube (90-degree bend) allows the placement of the tip of the tracheal tube in the midline just posterior to the epiglottis (Figure 93-12, *A*). One can then listen for breath sounds exiting from the end of the tracheal tube; once good air exchange is heard, the tracheal tube is advanced off the stylet (not inserted with the stylet) (Figure 93-12, *B*).

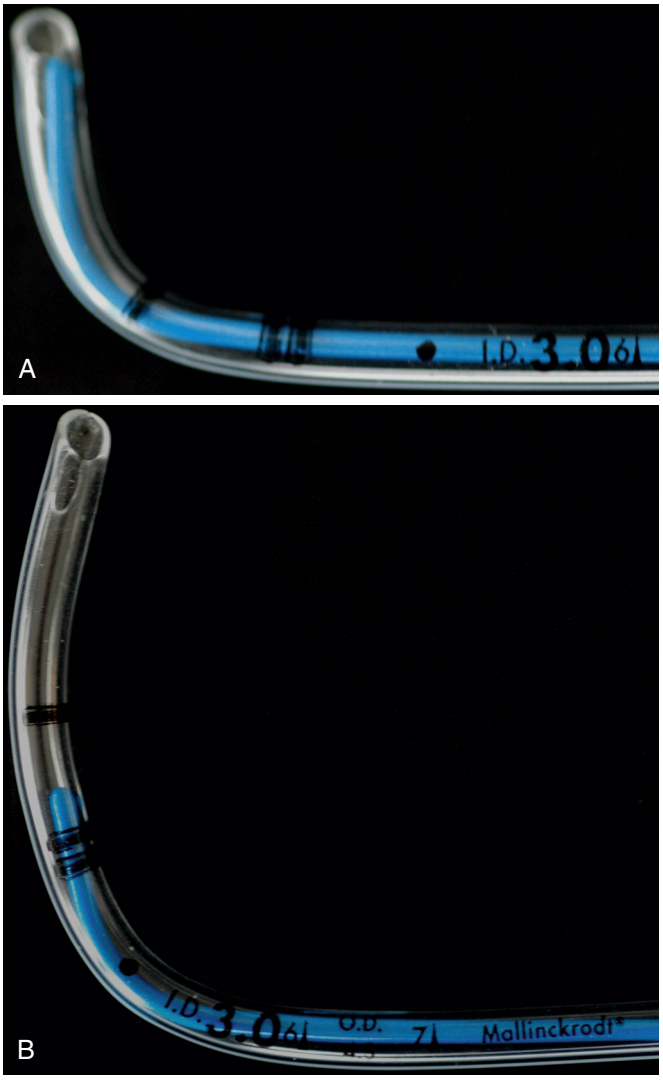

Figure 93-12. In patients with midfacial hypoplasia or in those in a cervical collar, making a nearly 90-degree bend around the base of the tongue to enter the larynx is necessary. If one inserts a stylet into an endotracheal tube with a 90-degree bend **(A)**, listens for breath sounds emerging from the proximal end of the endotracheal tube, and threads the endotracheal tube off the stylet (not advancing the stylet) when good breath sounds are heard, then the tube will make the bend around the base of the tongue and pass into the trachea **(B)**.

This technique allows advancement of the tracheal tube at an acute angle without causing trauma to anatomic structures. If the child is not spontaneously breathing, then this advantage may be lost. Spontaneous respiration with a face mask designed to allow fiberoptic intubation is another approach (Frie endoscopy mask, VBM Medical, Noblesville, Ind. 46060). Having a skilled assistant pull the tongue forward out of the mouth with a dry gauze, plastic retractor, or full suction applied to the tip of the tongue will also aid visualization of the glottic opening (Figure 93-13).[121]

Fiberoptic intubation of the trachea via an LMA requires the use of two tracheal tubes threaded on the fiberoptic scope (the second to hold the first in position while removing the LMA). The LMA is perhaps the most important adjunct to airway management because it can establish a patent airway before the airway is secured more definitively

Figure 93-13. In this child with facial burn and severely restricted mouth opening, suction was applied to the tip of the tongue to facilitate pulling it forward to improve glottic visualization. This technique is particularly useful when the tongue is slippery, attributable to secretions or if the mouth opening is small and prevents direct grasping of the tongue with a dry gauze. *(Reproduced with permission from Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

TABLE 93-9 LARYNGEAL MASK SIZE VERSUS PATIENT WEIGHT*

with a tracheal tube or a cricothyrotomy (Table 93-9). In neonates with difficult airways such as those with Goldenhar, Treacher Collins, or Pierre Robin syndrome, topicalization of the airway with lidocaine (1% nebulized to avoid excessive doses) with the patient awake, followed by the placement of an LMA is very helpful in guiding awake-sedated fiberoptic intubation. A skilled assistant who can hold the head in the proper position and assist is critical to the success of most of these approaches to a difficult airway. In children, the ProSeal LMA will allow ventilation at significantly higher peak inflation pressures (~25 cm H_2O) than possible with the classic LMA (~15 cm H_2O); thus this device may be preferable in a difficult airway situation, especially since the stomach can be suctioned.[122] Another useful adjunct is the air-Q laryngeal mask airway (Mercury Medical, Clearwater, Fla.) when used as a conduit for fiberoptic intubation. It has a wide airway tube that accommodates cuffed tracheal tubes and has a shorter length that facilitates the removal of the LMA after successful fiberoptic intubation. One should always check before insertion that the selected tracheal cuffed tube will pass through this device. A special tracheal tube introducer in three pediatric sizes is used to hold the tracheal tube in position while the LMA is removed (Figure 93-14). Many other new airway

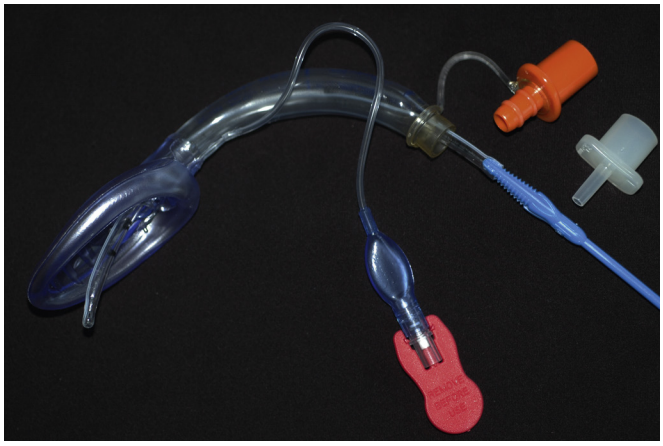

Figure 93-14. The air-Q laryngeal mask airway is short and has a large airway conduit to facilitate fiberoptic intubation. A tube introducer is used to maintain advancing pressure on the tracheal tube as the LMA is removed. *(Reproduced with permission from Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

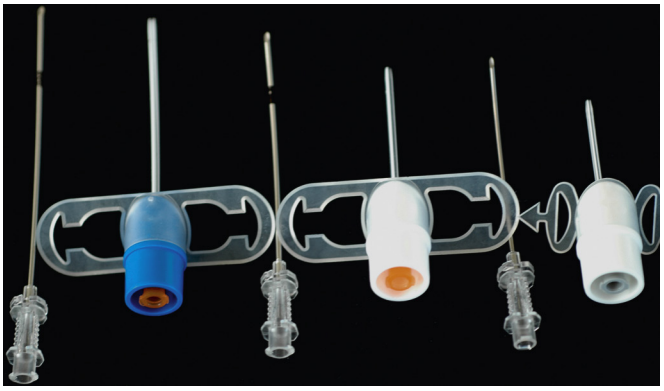

Figure 93-15. This preformed device is designed for transtracheal ventilation and provides one of the best systems for emergency airway management in a child with a "cannot ventilate, cannot intubate" airway situation (Ventilation-Catheter, VBM Medical, Noblesville, Ind.). The design is similar to that of an intravenous catheter but with lateral side holes, which means that the principles for use are familiar to all anesthesiologists, and the device is small enough to allow use even in neonates. In addition to a secure 15-mm adapter for interface with any standard bag ventilation device, a Luer-Lok connection allows jet ventilation. Three sizes are available: 16 gauge (infant), 14 gauge (child), and 13 gauge (adult). An initial fresh gas flow of 0.5 L/min is recommended and then adjusted up as needed once chest expansion and exhalation (deflation) are confirmed.

adjuncts are available, such as the Storz video laryngoscope (Karl Storz GbmH, Tuttlingen, Germany), the GlideScope (Verathon, Bothell, Wash.), MultiView scope (Medical Products International, Tokyo), Airtraq optical laryngoscope (Prodol Meditec, S.A., Vizcaya, Spain), and others too numerous to detail in this chapter.

If the child should progress to a "cannot ventilate, cannot intubate" situation, then a surgical airway must be established. The child should be positioned with a roll of towels under the shoulders to force the larynx anteriorly so that the best access to the larynx and trachea is provided. A variety of cricothyrotomy devices should be available; some are appropriate for infants, whereas others are appropriate only for older children and teenagers. Devices appropriate for older children include some using the Seldinger technique (cricothyroid puncture, passing a guide wire, skin incision, then passing a dilator-catheter over the wire) (e.g., Arndt and Melker kits, Cook Medical, Bloomington, Ind.) or use of an armored transtracheal catheter (Cook Medical). Intravenous catheters are the simplest cricothyrotomy devices that can be used in children of all ages, including infants, and can then be interfaced with the 15-mm connector of a 3-mm internal diameter (ID) tracheal tube.[123] The author believes a preformed device designed exactly like an intravenous catheter but with a built-in 15-mm connector and lateral side holes is the most useful. This device comes in three sizes (16, 14, and 13 gauge) and also has a Luer-Lok connection to allow transtracheal jet ventilation (Figure 93-15) (Ventilation-Catheter, VBM Medical, Noblesville, Ind.). Other emergency airway devices include a styletted tracheal tube changer (used as a bougie) that has both 15-mm and Luer-Lok adapters (Cook Medical, Bloomington, Ind.) (Figure 93-16). A simple method for administering oxygen to the Luer-Lok without the high pressure of a jet ventilator is to use standard oxygen tubing with a hole cut in the side; occlusion and unocclusion of the hole will direct oxygen (0.5 L/min and adjusted up as needed) through the catheter. Whenever such a technique is applied, the catheter must be correctly positioned within the trachea to avoid barotrauma and the chest must deflate between breaths. A review of emergency airway devices is available elsewhere.[124]

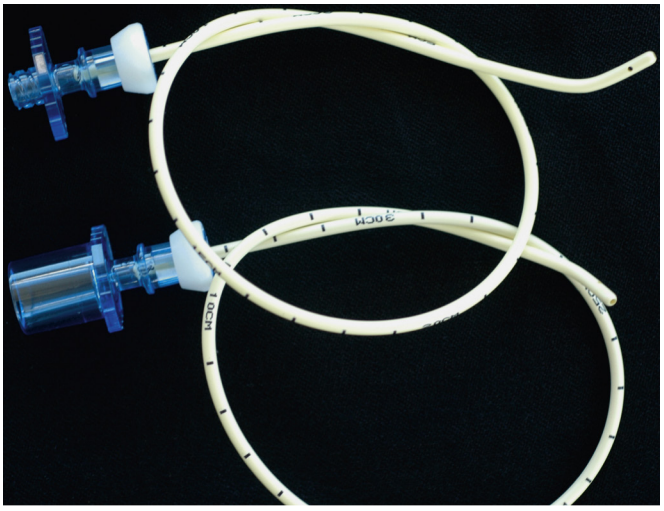

Figure 93-16. Tracheal tube exchangers are available that have side holes at the tip that allow delivery of oxygen and may be attached to either a jet ventilation system or standard adaptors with a 22-mm outside diameter. This device is also available with a stylet and slight bend to be used as an intubation bougie.

The Child With Stridor

A child with intrathoracic airway obstruction has expiratory stridor and prolonged expiration (e.g., bronchiolitis, asthma, intrathoracic foreign body). In contrast, a child with extrathoracic upper airway obstruction has inspiratory stridor (e.g., epiglottitis, laryngotracheobronchitis, laryngeal, subglottic foreign body). When agitated or

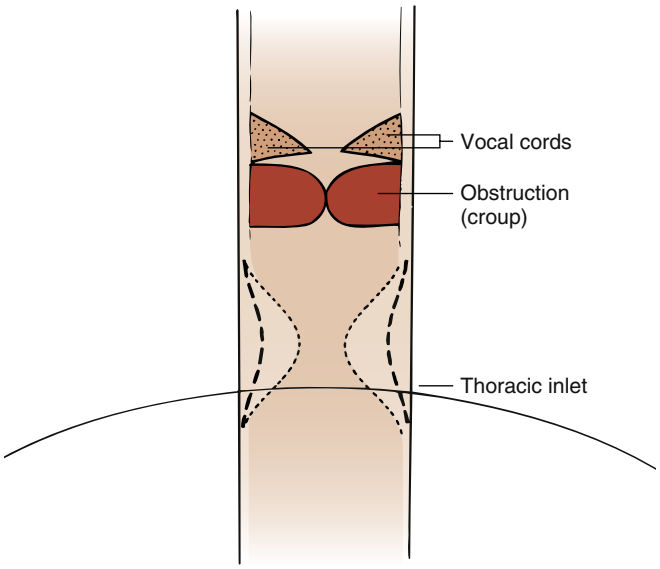

Figure 93-17. Infants and young children have highly compliant airway structures. With normal respiration, some dynamic collapse of the extrathoracic upper airway occurs (*broken line*). When a child has upper airway obstruction, as in epiglottitis, laryngotracheobronchitis, or extrathoracic foreign body (*dark brown*), and struggles to breathe against this obstruction, dynamic collapse of the trachea increases. This increase in dynamic collapse (*dotted line*) augments the mechanical obstruction of the airway. Therefore until the airway is secured, avoiding procedures that will upset the child is important. *(Modified from Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

crying, such children exhibit dynamic collapse of the airway (Figure 93-17), which can significantly worsen airway obstruction and lead to respiratory failure and hypoxemia. Therefore events that can upset the child such as drawing of blood for analysis of gases, venipuncture for blood tests, and separation from parents, must be minimized. The difficult-airway cart should also be present. The surgical team should be mobilized and prepared to perform an emergency tracheotomy should total airway obstruction occur and mask ventilation or tracheal intubation not be possible.

This author has found the following procedure to be effective for inducing anesthesia in a child with stridor. To minimize upsetting the child, the child is brought to the operating room with the mother or father, who holds the child during induction (preferably lying down in a semi-upright position). Induction of anesthesia with halothane or sevoflurane in oxygen by mask is the preferred method because maintaining spontaneous respirations is critical. As soon as the child loses consciousness, the child is gently moved off the parent's chest to the operating room table and the parent is escorted out of the unit. With the child lightly anesthetized and after infiltration of local anesthetic, an intravenous line is inserted. This allows withdrawal of blood samples if indicated. Intravenous hydration is begun with lactated Ringer solution (20 to 40 mL/kg), and atropine (0.02 mg/kg) or glycopyrrolate (0.01 mg/kg) is given. At this point, the plane of anesthesia can be deepened with greater safety. If the stridor worsens or mild laryngospasm occurs, then the pop-off valve is sufficiently closed to develop 10 to 15 cm H_2O of PEEP. This procedure relieves most instances of airway obstruction caused by dynamic collapse of the airway and loss of pharyngeal muscle tone when the child attempts to inspire against an obstructed airway (Figure 93-18). As the level of anesthesia deepens, gentle assistance with ventilation may be necessary; however, maintaining spontaneous respiratory effort is important if possible.

Any child with airway obstruction will have a long, slow induction of anesthesia before becoming sufficiently anesthetized to permit laryngoscopy and tracheal intubation. Because a sevoflurane vaporizer allows only ~2.5 MAC to be delivered, whereas a halothane vaporizer allows nearly 6 MAC, halothane would be the author's drug of choice in this circumstance (if available). In addition, the slower excretion of halothane than of sevoflurane would also provide better conditions for airway manipulation for a longer time. The issue of a full stomach is secondary to the airway problem. **Rapid induction of anesthesia and paralysis is contraindicated in these children**. A child with laryngotracheobronchitis or epiglottitis usually requires an uncuffed tracheal tube that is 0.5 to 1.0 mm ID smaller than normal (see Table 93-7); the use of a stylet facilitates its insertion. (Management of a difficult airway is also discussed in Chapter 55).

INTRAVENOUS FLUID AND TRANSFUSION THERAPY

Intravenous Fluids

The approach to intravenous fluid therapy in children must consider their high metabolic demands and high ratio of body surface area to weight (also see Chapter 59). The basis for calculating maintenance fluids derives from data by Holliday and Segar,[125] who found that daily fluid requirements directly depend on metabolic demand—specifically, that 100 mL of water is required for each 100 calories of expended energy. Relating this to weight produces hourly fluid requirements of 4 mL/kg for children up to 10 kg, an additional 2 mL/kg for each kilogram above 10 kg up to 20 kg, and an additional 1 mL/kg for each kilogram above 20 kg (Table 93-10) (4-2-1 rule). Thus a 25-kg child would require 65 mL/hr:

$$(10 \times 4) + (10 \times 2) + (5 \times 1) = 65 \text{ mL}$$

This amount does not include fluid deficits, third-space losses, modifications because of hypothermia or hyperthermia, or requirements caused by unusual metabolic demands. Third-space losses are replenished according to the surgical procedure and may vary from 1 mL/kg/hr for a minor surgical procedure to as much as 15 mL/kg/hr for major abdominal procedures (e.g., surgical repair of gastroschisis). The original Holliday and Segar approach was revisited, and it was concluded that their original formula would be problematic for children who are acutely ill or for those with significant cardiac or renal dysfunction. They now recommend a simpler and likely more accurate method of fluid management, which is to administer 20 to

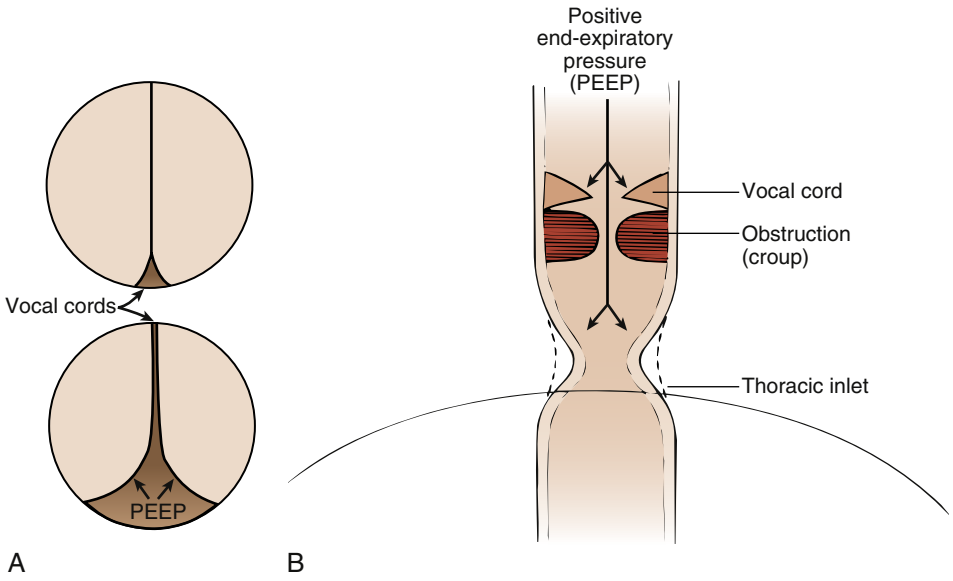

Figure 93-18. When a child has upper airway obstruction caused by laryngospasm **(A)** *(top)* or mechanical obstruction **(B)**, application of approximately 10 to 15 cm H_2O of positive end-expiratory pressure (PEEP) (*arrows*) during spontaneous breathing often relieves the obstruction. PEEP helps keep the vocal cords separated **(A)** *(bottom)* and the airway open **(B)** *(broken lines)*. If this simple maneuver does not relieve the obstruction, then more vigorous positive-pressure ventilation may be necessary. Airway obstruction caused by the tongue requires insertion of an appropriately sized oral airway.

40 mL/kg of a balanced salt solution during the course of the anesthetic. Postoperative fluid management should be reduced to a 2, 1, 0.5 rule; that is, 2 mL/kg for the first 10 kg, 1 mL/kg for the next 10 kg, and 0.5 mL/kg for each kg above 20 kg with an isotonic fluid.[126-128] If after 12 hours the child is unable to convert to oral intake, then a standard hypotonic solution (D5 0.45% saline) is initiated at the 4-2-1 rule rate to avoid hypernatremia (see Table 93-10).

Because greater hypoxic brain damage occurs in animals with high blood glucose levels, the routine use of glucose-containing solutions, especially for brief surgical procedures, is no longer recommended. However, a concern about unrecognized hypoglycemia was the motivating factor regarding the routine use of glucose-containing solutions in children, particularly in those who have not had food or fluids for a longer time than usual or for those who have diminished glycogen stores. Data are inadequate to eliminate glucose completely because the relevance of the animal data is not clear and the true incidence of hypoglycemia is not known in all populations of food-restricted children. This issue is further complicated by the fact that different values are used to define hypoglycemia, depending on the child's age.

If a child is thought to be at risk for hypoglycemia, 5% dextrose in 0.45% normal saline should be administered by piggyback infusion at maintenance rates. This minimizes the chance of a bolus administration of glucose and satisfies the concern for unrecognized hypoglycemia or accidental hyperglycemia. The routine use of 5% dextrose or 5% dextrose in 0.45% normal saline as the initial replacement for fluid deficit, third-space losses, and blood loss is discouraged. For most children, lactated Ringer solution is the only fluid required. Children receiving intravenous alimentation present a special problem (also see Chapter 106). Transition to 10% glucose is often recommended to avoid intraoperative hyperglycemia with continuation of the current alimentation fluid and to avoid hypoglycemia if it is suddenly stopped. However, this change to 10% glucose has not been adequately studied. The author reduces the established intravenous alimentation fluid infusion rate by 33% to 40% (to account for the reduced metabolic rate under anesthesia) and periodically checks blood glucose values for long procedures. This approach, then, does not waste the current alimentation fluid and involves only a simple change in infusion rate. Another population of children who require specific intravenous fluid management consists of those with mitochondrial disease. In general, glucose-containing solutions are administered at maintenance rates, and lactate-containing solutions are avoided. Some children with mitochondrial disease have enormous glucose requirements that may necessitate the use of 10% glucose. Management of such patients must be individualized with their pediatrician.

Fluid management of term and preterm infants must take into account other variables. The amount of insensible water loss is inversely proportional to gestational age. The younger and more physically immature the infant,

TABLE 93-10 **CALCULATION OF MAINTENANCE FLUID REQUIREMENTS FOR PEDIATRIC PATIENTS***

Weight (kg)	First 12 Hours After Surgery (mL)†	If No Oral Intake (mL)‡
<10	2 mL/kg	4 mL/kg
11-20	1 mL/kg	40 mL + 2 mL/kg for each kilogram above 10 kg
>20	0.5 mL/kg	60 mL + 1 mL/kg for each kilogram above 20 kg

*This approach avoids postoperative hypernatremia.
†Hourly fluid requirements for the first 12 hours after surgery.
‡Hourly fluid requirement for 12 hours after surgery if no oral intake occurs.

the higher the skin permeability, the ratio of body surface area to weight, and the metabolic demand. In addition, the use of radiant warmers and phototherapy increases insensible water loss. On the other hand, preservation of body heat with warming devices reduces insensible water loss.

The fact that the neonatal kidney is unable to excrete large amounts of excess water or electrolytes must also be considered. As described earlier, the volume of extracellular fluid in a newborn is extremely large. During the first days of life, some of this excess water is excreted. Therefore term newborns have reduced fluid requirements for the first week of life. The daily fluid requirements for a term newborn in the days after birth are estimated to be 70 mL/kg on day 1, 80 mL/kg on day 3, 90 mL/kg on day 5, and 120 mL/kg on day 7. Daily fluid requirements would be slightly higher for preterm infants. Sodium and potassium concentrations are usually kept at 2 to 3 mEq/100 mL. Newborns are generally started on 10% glucose to prevent hypoglycemia. This fluid is continued for the first several days of life until glucose values are stable. Infants of diabetic mothers or infants whose mother was given large amounts of glucose just before delivery may require greater concentrations of glucose for protection against rebound hypoglycemia. Infants unable to tolerate oral feeding may continue to receive 10% glucose solutions and may even require peripheral or central alimentation. A number of infants have been transferred to the author's institution with severe and potentially life-threatening hyperglycemia (i.e., blood glucose levels of 700 to 900 mg/dL) as a result of overzealous use of this type of glucose therapy. This solution should only be administered with a rate-limiting device and be used with caution if infants require surgery; every effort should be made to reduce bolus administration of glucose. Blood sugar levels should be periodically monitored and the solution infused at only maintenance rates unless a glucose bolus is indicated.

Packed Red Blood Cells

Historically, the use of blood products in pediatric surgical patients has greatly diminished because of the fear of transmission of disease—particularly human immunodeficiency virus (HIV). Because HIV, hepatitis B virus (HBV), hepatitis C virus (HCV), and a number of other disease-causing viruses can be transmitted with as little as 10 mL of packed red blood cells (PRBCs), the administration of any blood product requires clear, medically defensible clinical indications that are preferably recorded on the anesthetic record (also see Chapters 61 and 62). In the past 10 years, transmission of disease has become an increasingly rare event. The current estimated risk for transmission is 1 in 2,300,000 units for HIV, 1 in 250,000 units for HBV, and 1 in 1,800,000 units for HCV (see Chapter 61). Although the safety of blood transfusions has significantly increased, blood should still be given with precise and documented indications. It is still recommended for families to donate blood for their child or relative; in this situation the blood product should be irradiated to prevent possible graft-versus-host disease.

When caring for children, the emphasis should be on blood volumes and portions of blood volumes lost, rather than units, because a unit of blood may constitute several blood volumes in a preterm infant but only a fraction of the blood volume of a robust teenager. These considerations govern the calculation of the maximal allowable blood loss (MABL) resulting in an acceptable hematocrit. MABL takes into account the effect of patient age, weight, and starting hematocrit on blood volume. In general, blood volume is approximately 100 to 120 mL/kg for a preterm infant, 90 mL/kg for a full-term infant, 70 to 80 mL/kg for a child 3 to 12 months old, and 70 mL/kg for a child older than 1 year of age. These volumes are merely estimates of blood volume. The individual child's blood volume is calculated by simple proportion by multiplying the child's weight by the estimated blood volume (EBV) per kilogram. Although several formulas are available, a simple relationship is easiest to remember:

$$\text{MABL} = \text{EBV} \times \frac{(\text{Starting hematocrit} - \text{Target hematocrit})}{\text{Starting hematocrit}}$$

Thus if a 3-year-old child weighs 15 kg and has a starting hematocrit of 38% and if clinical judgment estimates the desired postoperative hematocrit to be 25%, then the calculation would be as follows:

$$\text{MABL} = (15 \times 70) \times [(38 - 25) \div 38] = 1050 \div 38 = \sim 360\text{mL}$$

The MABL would be replaced with 3 mL of lactated Ringer solution per milliliter of blood loss; that is, 3 mL of lactated Ringer solution times the 360 mL of blood loss equals approximately 1080 mL of lactated Ringer solution. If blood loss is less than or equal to the MABL and no further significant blood loss occurs or is anticipated in the postoperative period, then there is no need for transfusion of PRBCs. If, however, significant postoperative bleeding occurs or is anticipated, then a discussion of potential transfusion needs with the surgeon is very important. Normally, a child who has had adequate replacement of intravascular volume deficits will tolerate anemia very well. There is sufficient time to make the decision to transfuse by observing postoperative urinary output, heart rate, respiratory rate, and overall cardiovascular stability. Unfortunately, no one formula permits a definitive decision. The development of lactic acidosis is a late sign of inadequate oxygen-carrying capacity.

If the child has reached the MABL and significantly more blood loss is expected during surgery, then the child should receive PRBCs in sufficient quantity to maintain the hematocrit in the 20% to 25% range. The entire loss of red cell mass should not be replaced unless clinically indicated if these additional PRBCs would expose the child to additional units of blood products. Hematocrit values in the low 20% range are generally well tolerated by most children, the exception being preterm infants, term newborns, and children with cyanotic congenital heart disease or those with respiratory failure in need of high oxygen-carrying capacity (also see Chapters 61 and 94). Because the incidence of apnea is high in neonates and preterm infants who have hematocrit values less than 30%, the minimal target

hematocrit should be discussed with the surgeon and neonatologist.[129] Older children with a history of sickle cell disease may require preoperative transfusion and should be managed in conjunction with their attending hematologist. As an example, the following simple formula may be used for intraoperative or postoperative estimation of the volume of PRBCs needed in a 15-kg child with a hematocrit (Hct) of 20%:

$$\text{Volume of PRBCs to be transfused} = \frac{[\text{Desired Hct (35)} - \text{Present Hct (20)} \times \text{EBV (70mL/kg} \times \text{15kg)}]}{\text{Hct of PRBCs}(\sim 60\,\%)}$$

$$\frac{(35-20) \times (70 \times 15)}{60} = \sim 262 \text{ mL PRBCs}$$

Fresh Frozen Plasma

Fresh frozen plasma (FFP) is administered to replenish clotting factors lost during massive blood transfusion (usually defined as blood loss exceeding 1 blood volume), for disseminated intravascular coagulopathy, or for congenital clotting factor deficit. The anesthesiologist initiates and guides therapy with FFP during massive blood loss, whereas the hematologist's advice is sought when either of the other two conditions exists.

Children with known clotting factor deficits, such as those with massive thermal injury or coagulopathy, may require transfusion of FFP before blood loss exceeds 1 blood volume. In contrast, healthy children who do not have coagulation factor deficits at the beginning of surgery do not need FFP until blood loss exceeds 1 blood volume.[130,131] Despite the loss of 1 blood volume, prolongation of the prothrombin time (PT) and the partial thromboplastin time (PTT) will only be minor. This generalization applies to children given PRBCs; children given whole blood will not need FFP, even when blood loss exceeds several blood volumes.

Blood loss exceeding 1 to 1.5 blood volumes (replaced entirely with PRBCs and crystalloid, albumin, or other non–blood-related products) often necessitates a transfusion of FFP. However, the decision to administer FFP should be based on observed coagulopathy or documented prolongation of the PT and PTT values. Obtaining these test results from the laboratory often takes longer than desired. In this circumstance, a note should be written that blood loss has exceeded 1 blood volume and that abnormal oozing has occurred in the surgical field. A child should never be given FFP to correct bleeding that is surgical in nature.

No studies on children have yet clearly defined what values of PT and PTT are associated with pathologic bleeding requiring a transfusion of FFP to replace clotting factors. However, if the clotting factor deficit is associated with abnormal oozing, then a PT exceeding 15 seconds (international normalized ratio [INR] >1.4) or a PTT greater than 60 seconds (>1.5 times baseline) warrants close observation. Usually an INR <2 does not warrant correction. If these abnormalities exist but oozing does not occur and the surgical field is relatively safe from the complications of hematoma formation, as in orthopedic surgery versus neurosurgery, then it seems appropriate to observe the child and withhold the transfusion of FFP.

The volume of FFP required to correct prolongation of the PT and PTT values depends on the severity of the clotting factor deficit and the presence or absence of consumptive coagulopathy. In general, FFP therapy may require replacement of 30% or more of the child's blood volume. Transfusion of FFP at rates exceeding 1 mL/kg/min is sometimes followed by severe ionized hypocalcemia and cardiac depression with hypotension, especially if FFP is administered during anesthesia with a potent inhaled anesthetic (Figure 93-19).[132,133] Therefore exogenous calcium chloride (2.5 to 5 mg/kg) or calcium gluconate (7.5 to 15 mg/kg) should be administered, preferably through a separate IV, during rapid transfusion of FFP.[134] Ionized hypocalcemia occurs very frequently in neonates given FFP, possibly because of their decreased ability to mobilize calcium and metabolize citrate. Children undergoing liver transplantation or those with compromised hepatic function or perfusion may also be at increased risk because of a decreased ability to metabolize citrate.

Platelets

Thrombocytopenia may occur as a result of disease processes (e.g., idiopathic thrombocytopenic purpura, chemotherapy, infection, disseminated intravascular coagulopathy) or dilution during massive blood loss. Children whose platelet count has decreased because of idiopathic thrombocytopenic purpura or chemotherapy generally tolerate platelet counts as low as 15,000/mm^3 without a need for platelet transfusion. In contrast, children whose platelet count has decreased because of dilution (massive blood loss) generally require platelet transfusion when the count is ~50,000/mm^3 (also see Chapters 61 and 62). The reason for this disparity is not known. However, in the author's experience, the preoperative platelet count has been extremely valuable in predicting intraoperative platelet requirements.[135] Children who begin surgery with increased platelet counts may not require platelet transfusion, despite blood loss of four or more blood volumes. Conversely, children who begin surgery with low platelet counts (~100,000/mm^3) may require platelet transfusion when blood loss is one or two blood volumes. Children who begin surgery with a normal platelet count (150,000 to 350,000/mm^3) usually do not require platelet transfusion until two blood volumes or more are lost (Figure 93-20).

Whenever platelets are administered, the anesthesia record should document the reason for the transfusion, and every effort should be made to obtain a platelet count before transfusion. Clinical oozing is the typical indication for platelet transfusion, unless the potential for bleeding would be critical to survival, such as during neurosurgery, cardiac surgery, or major organ transplantation. The initial volume of platelets transfused is approximately 0.1 to 0.3 U/kg; the increase in platelet count achieved with this amount of transfusion varies considerably and depends on the presence or absence of platelet antibodies and the rate of platelet consumption.

Blood Warmers

A fluid and blood warmer is essential for any child who might require rapid correction of intravascular volume.

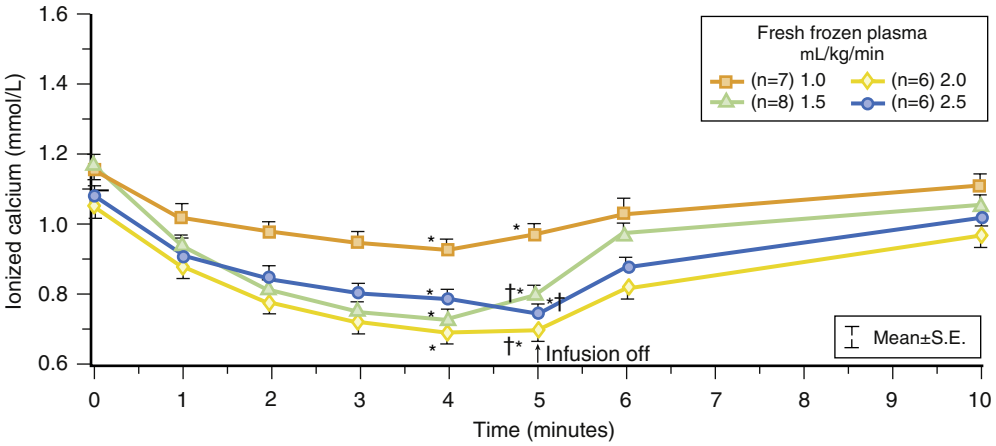

Figure 93-19. Ionized hypocalcemia always accompanies the administration of citrated blood products (e.g., fresh frozen plasma, citrated whole blood). Fresh frozen plasma has the highest concentration of citrate per unit volume of any blood product and is the most likely to cause ionized hypocalcemia during rapid infusion. Studies in children with thermal injuries suggest that rates exceeding 1 mL/kg/min produce severe ionized hypocalcemia. If no further citrated blood products are administered, then this abnormality corrects itself because of metabolism of the citrate. However, children with impaired hepatic blood flow—infants, patients undergoing liver transplantation, patients with trauma—may need exogenous calcium therapy. **P*, < .001; †*P*, < .0021 versus baseline; *S.E.*, standard error. *(From Coté CJ, Drop LJ, Hoaglin DC, et al: Ionized hypocalcemia after fresh frozen plasma administration to thermally injured children: effects of infusion rate, duration, and treatment with calcium chloride,* Anesth Analg *67:152-160, 1988. Used with permission.)*

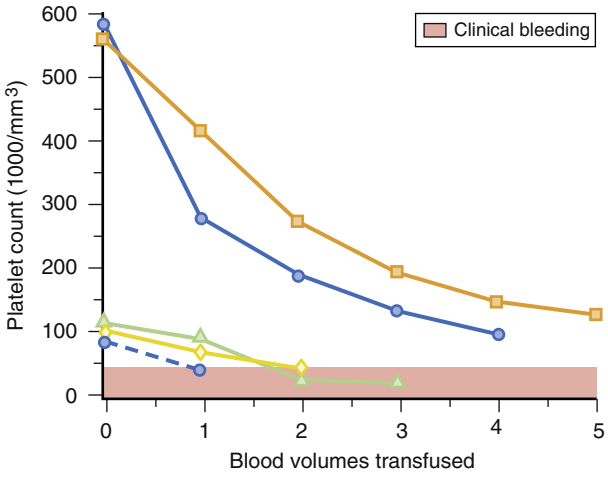

Figure 93-20. Dilutional thrombocytopenia occurs whenever massive blood loss takes place. The need for platelet transfusion, however, depends on the starting platelet count. In children who began surgery with low platelet counts, dilutional thrombocytopenia developed after blood loss of one or two blood volumes, whereas children who began surgery with high platelet counts did not require transfusion of platelets. The *blue dashed, solid yellow,* and *solid green lines* represent three children with initial low platelet counts; the *blue* and *orange lines* represent two children with initial high platelet counts. *(Data from Coté CJ, Liu LM, Szyfelbein SK, et al: Changes in serial platelet counts following massive blood transfusion in pediatric patients,* Anesthesiology *62:197-201, 1985.)*

Using such devices for maintenance intravenous fluid therapy provides no benefit because the rate of infusion is so slow that the intravenous fluid returns to room temperature between the times that it exits the warmer and enters the child. New warming devices that use countercurrent or microwave warming methods are superior to the older water bath coiled tubing devices. Low-capacity passive flow through devices such as the Hotline fluid warmer (Level 1 Technologies, Inc., Rockland, Mass.) are useful but not for warming a patient with maintenance rate administration. The Belmont Buddy Fluid Warmer (Belmont Instrument Corp., Billerica, Mass.) claims a warming capacity of "cold fluids to 38° C at flow rates as low as keep vein open (KVO) and as high as 100 mL/min." High-capacity systems such as the Level 1 System 1000 (Level 1 Technologies, Inc.), which uses countercurrent warming technology, is capable of warming blood starting at 5° C to 6° C to 33° C at rates as high as 250 mL/min. Another high-capacity blood warmer, the Belmont FMS (Belmont Instrument Corp.) uses microwave warming and is capable of fluid delivery at rates of 10 to 750 mL/min. A comparison of several devices used with pediatric intravenous catheters found that technology similar to the Belmont FMS was superior to the Level 1 for maintaining temperature and high-volume transfusions through intravenous catheters larger than 18 gauge.[136] Thus the Hotline or Belmont Buddy fluid warmer seem appropriate for neonates and infants, the Level 1 would appear to be appropriate for massive rapid transfusion in children weighing less than 30 kg, but the Belmont FMS would be superior for larger children.

MONITORING AND SAFETY ISSUES FOR PEDIATRIC PATIENTS

The complexity of monitoring applied to children must be consistent with the severity of the underlying medical condition and the planned surgical procedure. The author's philosophy is that if an arterial line or central venous line is placed in an adult undergoing a particular surgical procedure, then the same should be carried out for a child or an infant.

Routine Monitoring and Safety Issues (Also See Chapter 44)

Minimal monitoring during anesthesia should include a blood pressure cuff, an electrocardiogram, a temperature

probe, a pulse oximeter, an end-tidal carbon dioxide monitor, and, if possible, an anesthetic agent analyzer. The noninvasive blood pressure cuff (NIBP) is particularly useful because frequent blood pressure measurements can be made even when the anesthesiologist is preoccupied with other tasks. The end-tidal carbon dioxide monitor, NIBP, and pulse oximeter all provide an early warning of impending disaster that may go unobserved until the appearance of late clinical signs such as cyanosis, bradycardia, severe hypotension, or absence of breath sounds. The simultaneous loss of the pulse oximeter signal and an inability to measure blood pressure usually indicate low or no cardiac output. If the pulse oximeter continues to function but the NIBP has changed from measuring to nonmeasuring, then the likelihood of hypovolemia or anesthetic overdose must be immediately addressed, but one can have some assurance that perfusion is still taking place.

Capnography is the gold standard for confirmation of successful endotracheal intubation. However, the capnograph is useful in a number of other ways as well. Changes in the shape or magnitude of the carbon dioxide waveform may indicate bronchospasm, endobronchial intubation, a kinked endotracheal tube, or low pulmonary blood flow. One of the main drawbacks of capnography in small children is the inaccuracy of the recording obtained with the use of nonrebreathing circuits. The best method of avoiding artifacts is to sample the expired gases at some point within the tracheal tube or to use a circle system, even in small infants but at lower fresh gas flow rates. In general, the concentration of carbon dioxide in expired gas is within 2 to 3 mm Hg of that in arterial blood. However, severe pulmonary disease or atelectasis may produce a large difference in these values. In this type of child, the gradient between arterial and expired carbon dioxide values may be used to estimate the severity of the shunting. When such shunts exist, the measurement of expired carbon dioxide values may be used only to monitor trends. Ultimately, the most important monitors are the eyes, ears, and hands of the anesthesiologist, who must gather all the information provided by observation of the child and by the monitors applied to the child, consolidate the information into an accurate picture, and respond accordingly.

New monitors capable of noninvasive continuous cardiac output assessment via changes in impedance are now being introduced (Cardiotronic, Osypka Medical, La Jolla, Calif.).[137,138] Although some limitations exist, such as not functioning during electrocautery or with an open chest, the simplicity of placing four electrocardiographic electrodes and entering the height, weight, age and gender, outweigh the limitations. This device has been used in children as small as 1 kg, and trend monitoring seems to correlate with clinical assessments and the usual anesthetic monitors. This type of technology will likely be the next advancement in improving safety for children under anesthesia by providing an early warning of developing cardiovascular dysfunction or the immediate assessment of response to vasoactive medications. Other devices which use end-tidal carbon dioxide assessment pulse contour analysis or the Fick principle are limited to children who are intubated or have an arterial line in place.[139,140]

Prospective studies have shown that children younger than 6 months of age have a high incidence of critical events.[27,141-144] The incidence of critical events is greater in children with ASA physical status 3 and 4 than in ASA physical status 1 and 2. A number of factors may account for these results: the high metabolic rate of small children, the technical difficulty of caring for infants, the difficulty of estimating actual delivered ventilation when a variety of circuit configurations are available, and unfamiliarity with the care of small children. The POCA registry, a voluntary reporting system, estimated that the incidence of pediatric cardiac arrest was 1.4 ± 0.45 per 10,000 cases. Of the 289 cases, 83 occurred in children younger than 12 months of age. Emergency procedures and ASA physical status 3 or greater were predictive of death. It should be noted that two incidents of pediatric cardiac arrest were associated with sevoflurane and that the data were collected at the time when sevoflurane was not widely used in the United States. The use of high inspired concentrations of halothane (~3%) accounted for 14 of the arrests, and other associated factors were controlled ventilation ($n = 18$) and difficult intravenous access ($n = 4$). The most common preceding events were bradycardia and hypotension ($n = 25$). Three infants had an unrecognized cardiomyopathy and one had congenital heart disease. Airway-related events accounted for only 20% of cases, and most involved airway obstruction and laryngospasm. Several lessons can be taken from these data: (1) Children younger than 1 year of age are particularly vulnerable to adverse events in the perioperative period. (2) The combination of high inspired concentrations of an inhaled volatile anesthetic and controlled ventilation contribute to the critical event. (3) High inspired concentrations of an inhaled volatile anesthetic should be avoided until intravenous access is established. (4) The way the anesthetic is used, not the inhaled volatile anesthetic, is most likely the major contributing factor to these arrests. (5) Particular attention should be paid to frequent monitoring of blood pressure and heart rate during induction. (6) Monitoring with pulse oximetry and capnography may have reduced the incidence of airway-related events that were avoidable when compared with earlier studies. (7) Lastly, children with congenital heart disease are particularly vulnerable to the cardiac depressant effects of volatile anesthetic (also see Chapter 94). One study that supports these conclusions compared remifentanil-based anesthesia and halothane-based anesthesia for pyloromyotomy.[90,91] No cases of significant bradycardia, no differences in hemodynamic variables, and no differences in extubation times, PACU time, or rate of adverse events occurred. Basically, no difference between halothane (a slow-onset, slow-offset potent anesthetic) and remifentanil (a potent opioid with rapid onset and rapid offset) was observed. This study suggests that when anesthesiologists pay careful attention to details, adverse outcomes and severe adverse events can be avoided. The presence of an intravenous line before induction of anesthesia also probably provided an additional measure of safety. The most recent POCA data suggest that the rate of cardiac arrest is frequent in children with single

ventricle structure (Fontan), in children with Williams syndrome (supravalvular aortic stenosis, abnormal coronary vessels, pulmonary stenosis), and in infants receiving rapid blood transfusions who develop pathologic hyperkalemia.[145,146]

Invasive Monitoring

Arterial and central venous catheters should be used in children whenever such monitors contribute to the management of safe anesthesia. The placement of these monitors should not be avoided simply because the child is small or the anesthesiologist is uncomfortable applying the technique to a child. A variety of manufactured kits are available, most often using a thin-walled needle and a guide wire for venous access. If these monitors are indicated, then the anesthesiologist, surgeon, cardiologist, or neonatologist should insert them. Peripherally inserted central catheters (PICCs) offer a less invasive procedure that can provide accurate measures of central venous pressure.

Multilumen catheters are extremely valuable in the care of children who are critically ill. These devices facilitate the simultaneous intravenous administration of a variety of fluids, vasopressors, and antibiotics. However, these catheters can also lead to a false sense of security created by having three intravenous ports. Specifically, if a rapid infusion of PRBCs, colloid, or even crystalloid is necessary, then the long, narrow lumen severely limits the rate of infusion. If the need for rapid volume expansion is anticipated, then a separate large-bore intravenous catheter should be inserted; short-term cannulation of the femoral or brachiocephalic vein is reasonable and may be lifesaving.

PEDIATRIC EQUIPMENT

Dedicated Pediatric Equipment Cart

Anesthesiologists caring for children must be prepared for the unexpected, particularly an undiagnosed congenital malformation or difficult endotracheal intubation. Having designated pediatric carts containing pediatric equipment is a convenient way of providing optimal care in a variety of locations inside and outside of the operating room. These carts contain pediatric-specific intravenous administration sets, intravenous catheters of various sizes, butterfly needles (scalp vein needles), electrocardiographic pads, various infant- to adult-sized blood pressure cuffs, precordial stethoscopes, adult and pediatric esophageal stethoscopes, arm boards, intravenous fluids in pediatric-size containers, preterm infant– to adult-sized laryngoscope blades and handles, preterm infant– to adult-sized oral airways, tracheal tubes (2.0 to 2.5 mm ID uncuffed and 3.0 to 7.0 mm ID cuffed), stylets, face masks in preterm to adult size, size 1 to 5 LMAs, tape, drugs for resuscitation and commonly administered medications, and syringes, especially tuberculin syringes, for more precise administration of drugs. In addition, an interface that allows the administration of albuterol down an endotracheal tube should be readily available and preferably in the drug drawer (Figure 93-21).

Figure 93-21. Adaptor allows the administration of albuterol through a tracheal tube, and the timing of the dose with inspirations provides maximum delivery. The use of a long intravenous catheter that extends beyond the tip of the tracheal tube may further improve drug delivery. Up to 20 puffs may be required to deliver adequate drug distally. *(From Coté CJ, Lerman J, Anderson BJ, editors:* A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.)*

An intraosseous needle can be a lifesaving means of establishing emergency venous access for the administration of a drug or crystalloid. The Easy-IO is a relatively new battery-powered, drill-like device that provides rapid intraosseous access.[147,148] This device is a major new advance for pediatric care and should be readily available for emergent use.

Anesthesia Circuits

Much has been written about the advantages and disadvantages of various anesthesia circuits for use in children (also see Chapter 29).[149] Most of the attention has been directed to neonates and ways of reducing the work of breathing while preventing rebreathing. Nonrebreathing circuits provide the advantage of minimal work of breathing because they have no valves to be opened by the child's respiratory effort. The rate of induction of anesthesia may be more rapid because the volume of the nonrebreathing circuit is less, no equilibration with the carbon dioxide canister is required, anesthetic gases are immediately delivered at the airway, and the compression and compliance volume will be low.[149] These advantages improve the ability to observe respiratory effort, as reflected by movement of the anesthesia bag, as well as the ability to estimate pulmonary compliance. Thus the actual delivered ventilation, when used in conjunction with a ventilator, may be greater with a Mapleson D system than with a circle system if no compensatory adjustment in tidal volume is made (Figure 93-22). The most recent generation of ventilators are less susceptible to these types of issues because they automatically compensate for changes in fresh gas flow and circuit compliance.

A pediatric circle system can be safely used in neonates as long as the clinical implications are understood: large

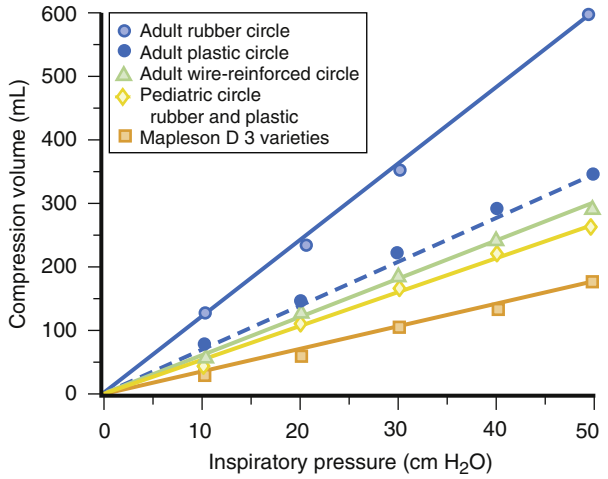

Figure 93-22. Eight types of anesthesia circuits were compared regarding ventilatory losses (circuit efficiency) as a result of compression of anesthetic gases (compression volume) and stretching of the circuit (compliance volume). Compression volume and compliance volume losses vary by as much as a factor of 5, depending on the volume of the circuit and the material from which it is constructed. Low-volume, low-compliance circuits (Mapleson D systems) are the most efficient and give the anesthesiologist the greatest amount of tactile feedback on tidal volume and lung compliance in small children. Most current practitioners use pediatric circle systems with assisted or controlled ventilation, which reduces environmental pollution and is more economical. *(From Coté CJ, Petkau AJ, Ryan JF, et al: Wasted ventilation measured in vitro with eight anesthetic circuits with and without inline humidification,* Anesthesiology *59:442-446, 1983. Used with permission.)*

compression volume losses, slightly longer time to equilibrate, and perhaps a decreased ability to determine changes in compliance. The author has exclusively used pediatric circle systems for the past 20 years; as long as pressure-limited ventilation with the same peak inflation pressure is used, the same tidal volume is delivered as with a non-rebreathing system.[150-152] Perhaps the greatest advantage of the circle system is the ability to use reduced fresh gas flow, which saves money and reduces air pollution.

CONSIDERATIONS FOR NEONATAL ANESTHESIA

The neonate has unique requirements for equipment, intravenous access, fluid and drug therapy, anesthetic dosage, and environmental control (see also Chapters 94 and 95). The many possible neonatal procedures are too numerous to describe in this limited space. However, the basic anesthetic management is the same for all neonates. An understanding of the basic differences in physiologic function, pharmacologic and pharmacodynamic responses, and the underlying pathologic surgical problem is essential for the development of a safe anesthesia plan. Most of the complications are attributable to a lack of understanding of these special considerations before the induction of anesthesia. Care of neonates is fraught with danger, sudden changes, unexpected responses, and unknown congenital problems. If anesthesiologists are to deliver optimal pediatric anesthesia care, then they must always be prepared for the unexpected, have the proper size and variety of equipment available, and obtain the most intense level of support, both in the operating room and in the ICU. If the anesthesiologist only occasionally cares for infants, then the likelihood of a problem dramatically increases.

Children younger than 1 year of age have a more frequent incidence of complications than older children.[27,141-144,153,154] These complications relate to oxygenation, ventilation, airway management, and response to anesthetic medications; complications also occur more frequently in children with ASA physical status 3 and 4. Neonates, particularly preterm infants, function on a marginal basis; therefore any type of stress is usually poorly tolerated. This vulnerability may relate to the technical difficulty of taking care of small children, the immaturity of their organ systems (especially the cardiovascular, pulmonary, renal, hepatic, and nervous systems), their high metabolic rate, the large ratio of body surface area to weight, and the ease of miscalculating a drug dose.

When caring for infants and neonates, special attention must be paid to all aspects of anesthesia and surgical management. The anesthesiologist must devote particular care to the calculation of drug dose and dilution of drugs. Prevention of paradoxical air emboli requires that all air be vented from intravenous devices and syringes before use; each intravenous injection port is aspirated to remove air trapped at these junctions, and some drug is ejected before intravenous administration to clear air from the dead space of the needle. A volume of air that is clinically unimportant in an adult may prove catastrophic in an infant. Warming of skin preparation solutions and irrigation fluids before applying minimizes heat loss. Intravenous fluids should be administered with volume-limiting devices; infusion pumps are particularly helpful in preventing over administration of intravenous fluid. The composition and infusion rate of flush solutions should be noted and calculated into maintenance fluid therapy. In neonates and small infants, a basal infusion rate of balanced salt solution with a pump is most useful, and third space losses and fluid boluses can be given via piggyback or a three-way stopcock.

Every effort must be made to maintain the infant's temperature to minimize thermal stress. The surgical environment should be warmed to ensure that the entire room constitutes a giant incubator. Heated air mattress devices are particularly useful for maintaining temperature.

Monitoring expired concentrations of carbon dioxide can be less accurate in small infants but is still extremely useful for diagnosing changes over time and for issues such as bronchospasm, a kinked endotracheal tube, or endobronchial intubation. Pulse oximetry is useful not only for the usual data that it provides but also for preventing extreme hyperoxia. Maintaining oxygen saturation at 93% to 95% keeps preterm infants on the steep side of the oxygen-hemoglobin dissociation curve. This consideration may be important to infants still susceptible to retinopathy of prematurity (ROP), that is, those younger than 44 weeks' PCA, although a multicenter trial of tight control of supplemental oxygen failed to show any change in risk for the development of ROP.[155] However, because these infants have the highest oxygen

consumption, oxygen saturation in the 93% to 95% range can change to severe hypoxemia within seconds. When managing such a delicate balance and in view of the slight inaccuracies of these monitors, the anesthesiologist must be extremely vigilant and prepared to respond rapidly to changes in oxygen saturation. Keeping arterial carbon dioxide values within the normal range (35 to 45 mm Hg) may also be important in preventing ROP. Many other factors well beyond the control of the anesthesiologist contribute to the development of this condition.

APOPTOSIS

One very important concern is the theoretic risk of apoptosis caused by medications used to provide sedation, analgesia, and anesthesia for infants and toddlers (particularly those younger than 3 years of age), a population still undergoing rapid brain growth. Anesthesiologists must be up to date on this issue because with the current widespread use of the Internet, more and more parents are asking *"Is it safe for my baby to have anesthesia?"* and specifically mention apoptosis! All of the potent inhaled anesthetics—nitrous oxide, ketamine, propofol, etomidate, barbiturates, benzodiazepines, chloral hydrate, ethanol, and others—have been associated with an increased rate of apoptosis in laboratory animals.[156-159] The majority of animal studies have examined drug doses far outside the clinical range. Others have not controlled for blood pressure, ventilation, or oxygenation. To further confound the issue, the period of rapid brain growth is different in each animal species, and the time of exposure (i.e., area under the curve exposure) in some is far longer than what would occur in clinical practice. For example, a 3-hour exposure to a neonatal monkey is equivalent to nearly 8 hours for a human; a neonatal rat exposed to 6 hours of anesthesia is equivalent to 222 hours of human exposure. In addition, many of the doses used far exceed those used in humans. The following questions need to be answered: Do apoptotic anesthetic drugs kill normal cells, leading to abnormal neurocognitive development? Do they simply accelerate death of cells already destined for programmed cell death with no sequelae? Does the human brain have so much plasticity that these potential adverse effects are overcome?

Data in primates (monkeys) are limited, and perhaps these observations are not transferable to humans. In fact, the preliminary data that have focused on ketamine "suggest that there might be a margin of safety for the use of ketamine in vivo over other anesthetics currently used in the clinical setting."[157] A 3-hour ketamine infusion in primates found no apoptosis in 5- and 35-day-old neonatal monkeys. Human data are virtually nonexistent. A retrospective questionnaire pilot study using the 120-item Child Behavior CheckList found an odds ratio of 1.38 to 1.19 for greater behavioral disturbances in children exposed to anesthesia during the first 6 years of life. The authors concluded that to refute or confirm an anesthetic effect would require "at least 2268 children."[160] The Mayo Clinic examined the school records of children who had no exposure, one exposure, two exposures, or more than two exposures to anesthesia during the first 4 years of life.[161] They found no difference in learning disabilities in children who had no exposure or one exposure; however, children with two exposures had an odds ratio of 1.59 (confidence interval 1.06 to 2.37) and those with three or more exposures had an odds ratio of 2.6 (confidence interval 1.6 to 4.24) for having a learning disability. At the time of their anesthetic exposure, pulse oximetry and capnography were not standards of care; the number of infants who suffered unrecognized hypoxic events or extreme hyperventilation or hypoventilation, each of which can also cause apoptosis, is unknown.[162] This same group examined a case controlled retrospective study of 350 infants exposed to anesthesia younger than the age of 2 years, compared with 700 children not exposed to anesthesia. They specifically examined several factors: learning disability, receipt of an "individualized educational program for emotion/behavior disorder," and scores for "group-administered achievement tests."[163] They concluded that multiple but no single exposures to anesthesia increased the risk of developing a learning disability (hazard ratio 2.12, confidence range 1.26 to 3.54); however, no difference in individualized interventions regarding emotional or behavioral issues was observed. Once again, this cohort of patients was anesthetized between 1976 and 1982, which is before pulse oximetry and capnography were introduced as the standard of care; thus this study suffers from the same flaws. Another paper of 1143 pairs of monozygotic twins examined the relationship of learning disabilities to exposure to anesthesia in the first 3 years of life.[164] Educational achievement and cognitive problems were assessed at 12 years of age. When both twins were exposed to anesthesia, the rates of cognitive problems and lower achievement scores increased; however, when only one twin was exposed to anesthesia, no difference was observed in these scores. The authors concluded that no evidence suggests a causal relationship of exposure to anesthesia, that is, other factors were contributory to later learning-related outcomes. An important animal study compared rats exposed to 4 hours of sevoflurane. At 4 weeks, all of the animals demonstrated some evidence of cognitive dysfunction.[165] They were then divided into two groups such that one half of the rats had "normal cage care" and the other half had a "stimulated cage environment." They were again examined for evidence of cognitive dysfunction 4 weeks later. Those who were stimulated had complete reversal of their cognitive dysfunction, thus indicating for the first time that the apparent problem is reversible. Certainly, children are not pushed into a corner and then ignored; therefore this assumption, in fact, fits the human condition and the author's assessment of this issue as a clinician. Given the fact that thousands of infants and toddlers undergo general anesthesia for diagnostic and therapeutic procedures each year, certainly if cognitive dysfunction were a major issue for humans, by now we would have evidence that our most vulnerable children, neonates, infants, and toddlers, would demonstrate adverse developmental outcomes consistent with the animal models. In addition, many preterm and term infants receive these same medications for days and often weeks in the neonatal ICU and these children have many other problems that could contribute to neurocognitive deficits.[158]

At present, the issue of drug-induced apoptosis appears to be a valid concern and an area of research that must

be vigorously pursued.[166,167] It appears that dexmedetomidine, opioids, and xenon are not associated with this phenomenon, but further studies are certainly required before changing anesthesia practice is advocated. What is quite unclear is at what age or developmental level that apoptosis is no longer a concern. Is it just preterm infants, full-term infants, toddlers, teenagers, or even adults? Is the plasticity of the human brain able to overcome a (potential) short-term insult? What other factors besides drug exposure contribute to this possible association with learning disability or cognitive dysfunction? If the drugs thought to be a concern in animal models are removed from our armamentarium, how are adequate amnesia, analgesia, and anxiolysis to be provided? Until more convincing data are available, continuing the current level of care with the drugs now available is prudent. Parents must be assured that their children will be adequately oxygenated, skillfully ventilated, well perfused, and that their pain will be well managed.[168,169] It would not make sense and would be irresponsible to change current practice without adequate science to support drastic changes in anesthesia practice.

THE STRESS RESPONSE

Little doubt exists that neonates, even extremely preterm infants, are capable of feeling pain and will respond to painful stimuli; however, what actually constitutes a state of anesthesia has yet to be proven. No child should be denied analgesia or anesthesia because of size or age. Clearly, the cardiovascular system of a preterm infant rarely tolerates the cardiovascular depressant effects of potent inhaled anesthetics. However, the synthetic opioids (e.g., fentanyl, sufentanil, alfentanil, remifentanil) are usually well tolerated by even infants who are critically ill. These potent opioids must be carefully titrated to a defined response, and anesthesiologists must remain cautious of opioid-induced bradycardia and its consequences on cardiac output. Low concentrations of potent inhaled anesthetics can be used with opioids to provide a means of controlling hemodynamic responses without significantly depressing the myocardium. The relative merits of one anesthetic technique over another are not well defined. Opioids and inhaled anesthetics suppress the hormonal responses to pain. The important result of the provocative studies undertaken to clarify this issue is that they have heightened everyone's awareness of the need to provide adequate anesthesia and analgesia to neonates. As stated earlier, outcomes are mostly determined by the skill of the clinician and not the specific anesthetic chosen.

SPECIFIC NEONATAL AND SURGICAL PROCEDURES

MENINGOMYELOCELE

Meningomyelocele, the hernial protrusion of a part of the meninges and spinal cord through a defect in the vertebral column, is a relatively common neonatal abnormality. The following should be considered in addition to the usual concerns for the management of neonates: (1) special positioning for tracheal intubation (i.e., the defect is placed on a "doughnut" and towels are placed under the head); (2) possibility of underestimating fluid and blood loss; (3) high association of meningomyelocele with hydrocephalus; (4) possibility of cranial nerve (vocal cord) palsy, resulting in inspiratory stridor; and (5) potential for brainstem herniation. The anesthesiologist must establish adequate intravenous access and invasive monitoring (rarely indicated) if appropriate; replace all fluid deficits, including loss from the defect (usually with normal saline); and ensure that crossmatched blood is available. Latex allergy precautions should be used with these children for their first and all subsequent anesthetics.

OMPHALOCELE AND GASTROSCHISIS

Omphalocele and gastroschisis are major defects in the closure of the abdominal wall that result in exposure of viscera that are either covered (omphalocele) or not covered (gastroschisis) by peritoneum (Figure 93-23; Table 93-11). The major problems with these defects include the following: (1) severe dehydration and massive fluid

Figure 93-23. A, Gastroschisis malformation. The viscera have herniated outside the peritoneum. **B,** Omphalocele malformation. The viscera are still covered by peritoneum.

TABLE 93-11 **COMPARISON OF GASTROSCHISIS AND OMPHALOCELE MALFORMATIONS**

	Gastroschisis	Omphalocele
Pathophysiologic characteristics	Occlusion of the omphalomesenteric artery	Failure of gut migration from the yolk sac into the abdomen
Incidence	~1 in 15,000 births	~1 in 6000 births
Incidence of associated anomalies	~10%-15%	~40%-60%
Location of defect	Periumbilical	Within the umbilical cord
Problems associated with defect	Inflammation of exposed gut Edema Dilated and foreshortened gut (chemical peritonitis)	Congenital heart disease (~20%) Exstrophy of the bladder Beckwith-Wiedemann syndrome (macroglossia, gigantism, hypoglycemia, hyperviscosity)

From Coté CJ, Lerman J, Anderson, BA, editors: A practice of anesthesia for infants and children, *ed 5, Philadelphia, 2013, Saunders.*

loss from the exposed visceral surfaces (gastroschisis, chemical peritonitis) and from third-space losses caused by partial bowel obstruction; (2) heat loss; (3) difficulty of surgical closure; and (4) high association of this condition with prematurity and other congenital defects, including cardiac abnormalities (with omphalocele, ~20%). These children should not be rushed to surgery without an echocardiogram before anesthesia; postoperative ventilation is nearly always necessary with tight closures; in some cases, a staged repair is needed.

Infants with omphalocele or gastroschisis must be expeditiously cared for to reduce the potential for infection and compromise of bowel function and to minimize the loss of fluid and heat; optimizing fluid and electrolyte balance before surgery is recommended. Adequate intravenous access must be ensured, and invasive monitoring is occasionally necessary, particularly if an associated cardiac defect is present. The liberal use of muscle relaxants provides optimal surgical conditions for closure of the defect; hypotension secondary to tension on a major organ (liver) or caval compression is common. If the surgeon is unable to close the defect in one procedure, then a staged procedure is planned, usually in the neonatal ICU. In either situation, postoperative ventilation will be necessary until the abdominal wall has had time to stretch to accommodate the viscera. Intravenous alimentation may also play a vital role in the rapid recovery of these children. It should be noted that increased abdominal pressure after a tight closure (abdominal compartment syndrome) may compromise hepatic and renal function and significantly alter drug metabolism. Staged closure with a premade spring-loaded silastic silo is being used with increasing frequency, thus minimizing repeat trips to the operating room. A small percentage of children with omphalocele will also have Beckwith-Wiedemann syndrome, a condition characterized by profound hypoglycemia, hyperviscosity syndrome, congenital heart disease, and associated visceromegaly.

TRACHEOESOPHAGEAL FISTULA ANOMALY

A tracheoesophageal fistula anomaly can have five or more configurations, most of which are demonstrated as an inability to swallow because of esophageal atresia (the esophagus ends in a blind pouch). The characteristic diagnostic test is an inability to pass a suction catheter into the stomach. Neonates may have aspiration pneumonitis from a distal fistula connecting the stomach to the trachea through the esophagus or from a proximal connection of the esophagus with the trachea. Additionally, this anomaly may be part of a larger constellation of anomalies known as the VATER association (**V**, vertebral; **A**, anal; **TE**, tracheoesophageal; **R**, renal) or the VACTERL association (VATER and **C**, cardiac; and **L**, limb). Any child with a tracheoesophageal fistula or esophageal atresia should be suspected of having the other anomalies described. An echocardiogram to examine for a right-sided aortic arch and the presence of congenital heart disease should be performed before anesthesia.[170]

The major anesthetic issues include (1) evaluation for aspiration pneumonia; (2) overdistention of the stomach from entry of air directly into the stomach through the fistula; (3) inability to ventilate the child because of the large size of the fistula; (4) problems associated with other anomalies, particularly a patent ductus arteriosus (shunting) and other forms of congenital heart disease; and (5) the need for postoperative intensive care.[171]

For management of anesthesia, the infant's feedings are withheld, a catheter is placed in the esophagus to drain saliva, and the infant is placed prone in a head-up position. If the infant has pneumonia, then treatment should be initiated. Surgery may be postponed until the pneumonitis improves or clears. The infant may be a candidate for gastrostomy to provide a means of nutrition during recovery from pneumonitis. Anesthesia evaluation centers on the pulmonary and cardiovascular systems. Generally, an *awake-sedated* intubation is performed. The author usually administers 0.5 to 1 μg/kg of fentanyl and 25 to 50 μg/kg of midazolam and topicalizes the tongue, larynx, and vocal cords with no more than 5 mg/kg of lidocaine (1.0%). The tracheal tube is intentionally passed into the right main bronchus and then slowly withdrawn until breath sounds are heard on the left. Often this technique ensures that the tip of the tracheal tube is placed beyond the origin of the fistula, thus avoiding massive distention of the stomach. Care must be taken to avoid rupturing the stomach; therefore spontaneous and gently assisted ventilation may be appropriate until the fistula is ligated or a gastrostomy is completed. A change in the distance of insertion of the tracheal tube of as little as 1 to 2 mm may determine whether the anesthesiologist is ventilating both lungs, one lung, or the fistula. Because a change in oxygen saturation may be the first indication that all is not well, the pulse oximeter is one of the most

useful monitors in managing these children. A preductal and postductal location (two pulse oximeters) will diagnose intracardiac shunting. Taping the stethoscope to the left side of the chest in the axilla also decreases the possibility of unrecognized endobronchial intubation. Some surgeons prefer that the infant remain intubated postoperatively, whereas others prefer an attempt at extubation of the trachea; approximately 30% of those extubated in the operating room will require reintubation to clear secretions.

Postoperative pain may be managed with a caudal catheter threaded up to the thoracic level and either intermittent bupivacaine (1 to 2 mL of 0.125% with epinephrine 1:200,000) administered every 6 to 8 hours or a continuous infusion of chloroprocaine (1.5%) with fentanyl (0.4 μg/mL) infused at 0.3 to 0.8 mL/kg/hr. Such management may be undertaken only with the full support of a pediatric pain service (also see Chapter 92).

DIAPHRAGMATIC HERNIA

A diaphragmatic hernia is usually revealed on the first day of life by respiratory distress and a scaphoid abdomen. The abnormality consists of herniation of the abdominal viscera through a defect in the diaphragm, most commonly the foramen of Bochdalek on the left side. Almost all of the abdominal viscera, including the liver and spleen, may be above the diaphragm. The gestational age at which herniation occurs may determine the degree of lung hypoplasia.

Anesthesia concerns include the following: (1) hypoxemia and hypotension caused by overdistention of the stomach and herniation of the mediastinum across the midline, (2) hypoxemia attributable to primary pulmonary hypoplasia, (3) hypoxemia attributable to pulmonary hypertension, (4) pneumothorax of the contralateral lung during attempts at high-pressure ventilation, and (5) systemic hypotension caused by kinking of major blood vessels, particularly those of the liver. In general, the anesthesiologist's ability to control $Paco_2$ reflects the severity of the lung pathologic presentation and therefore survival. An inability to reduce $Paco_2$ is associated with a poor prognosis. Extracorporeal membrane oxygenation (ECMO) and the use of nitric oxide have slightly reduced the mortality associated with this condition, and the urgency for surgical intervention has diminished and given way to a desire to stabilize the infant and minimize stress. Anesthetic management of children with a diaphragmatic hernia includes the following: (1) Awake endotracheal intubation without bag-and-mask ventilation prevents overdistention of the stomach and herniation across the midline (now uncommon because the child generally does not come to the surgical department for several days). (2) Insertion of an arterial line for heartbeat-to-heartbeat blood pressure monitoring and close observation of the surgical field are most helpful in diagnosing impairment of venous return or cardiac output. (3) Blunting of the stress response is accomplished by providing analgesia with opioids (usually high-dose fentanyl, 25 μg/kg or more) and by controlling respirations with a muscle relaxant (usually pancuronium). (4) Careful control of ventilation and oxygenation prevents sudden increases in pulmonary artery pressure ($Paco_2$ is maintained less than 40 mm Hg and arterial partial pressure of oxygen [PaO_2] more than 100 mm Hg); pulse oximetry is helpful in diagnosing subclinical episodes of hypoxemia. (5) Hypothermia is avoided to decrease the oxygen consumption needed for thermogenesis. (6) Volatile anesthetics that might depress the myocardium are avoided until the chest is decompressed. (7) To prevent bowel distention, nitrous oxide is not administered. (8) Awareness for the development of barotrauma-induced pneumothorax on the ipsilateral or contralateral side should be heightened. (9) Adequate intravenous access for the maintenance of a constant circulating blood volume should be ensured. (10) Postoperative intensive care is necessary (also see Chapter 95).

In most centers, the approach to these children has changed to supportive care initially with permissive hypercapnia, ECMO, high-frequency ventilation, and inhaled nitric oxide[172,173] (also see Chapter 104). The infant is no longer rushed to the operating room soon after birth, and this approach appears to have only slightly reduced mortality.[173-176] In some centers, the closure is accomplished at the bedside in the neonatal ICU.

PYLORIC STENOSIS

Pyloric stenosis is normally revealed in the first 3 to 6 weeks of life. The anesthesiologist has the following major concerns: (1) a full stomach, rarely filled with contrast material; (2) metabolic alkalosis with hypochloremia and hypokalemia; and (3) severe dehydration.

This procedure is never a surgical emergency. Children should be carefully evaluated, and severe metabolic imbalance should be corrected before surgery. Even if the child arrives with a nasogastric tube in place and although the diagnosis is now most commonly made by ultrasound rather than barium swallow, the stomach should still be immediately suctioned with a wide-bore vented catheter in the supine and the right and left lateral positions before induction of anesthesia. This suctioning technique will remove 98% of the gastric contents![177] Children with pyloric stenosis can be managed with awake intubation, followed by low-dose cisatracurium (0.1 mg/kg) or rapid-sequence induction of anesthesia with cricoid pressure after atropine (0.02 mg/kg), propofol (3 mg/kg), and succinylcholine (2 mg/kg) administration. The actual selection of a specific anesthetic approach primarily depends on the skill and familiarity of the anesthesiologist with the technique. However, one study demonstrated fewer attempts and one half the time for successful intubation of the trachea when a muscle relaxant was used.[178] Postoperative analgesia is generally provided by local infiltration of the skin incision with bupivacaine (maximum dose, 1 mL/kg of 0.25% bupivacaine) and rectal acetaminophen (40 mg/kg initial dose followed by 10 to 15 mg/kg by mouth every 4 to 6 hours for a total 24-hour dose of ~75 mg/kg). Reports of apnea events after pyloromyotomy have been conflicting.[179,180] One well-controlled clinical trial described new-onset apnea after halothane anesthesia in 3 of 13 children.[91] Until larger studies are performed, these children should be observed with apnea monitors and pulse oximetry postoperatively.

FORMER PRETERM INFANTS

A frequent incidence of postoperative apnea occurs in former preterm infants (gestational age less than 37 weeks). The majority of infants in whom postanesthesia apnea develops are younger than 46 weeks' PCA; however, apnea occurs up to 60 weeks' PCA.[181] The conclusions reached by a number of studies were limited by the relatively small number of children. This author had the opportunity to obtain and analyze the original data from eight prospective studies. A combined analysis examining the risk for apnea included only children undergoing inguinal hernia repair and not receiving special treatment such as caffeine or regional anesthesia.[129] The only two risk factors that stood out across all ages were gestational age and PCA. The incidence of apnea was inversely related to both PCA and gestational age. For example, if two infants were now 45 weeks' PCA yet one was born at 28 weeks' and the other at 36 weeks' gestational age, then the 28 weeks' gestational age infant would have approximately twice the potential for apnea (Figure 93-24). In addition, the younger the child at the time of surgery (e.g., 45 versus 55 weeks' PCA), the higher the incidence of apnea. The incidence of apnea was more frequent in institutions that collected data with continuous recording devices than in those that relied on impedance pneumography or nursing observations. Anemia (hematocrit <30%) is an independent risk factor associated with apnea in former preterm infants (see Figure 93-24). What makes this risk factor unique is the fact that the risk for apnea in anemic former preterm infants is not apparently altered by PCA or gestational age; that is, the risk for apnea appears to be the same for an anemic 60-weeks' PCA infant as for an anemic 45-weeks' PCA infant. Even after eliminating infants with an obvious apnea spell in recovery and infants who were anemic, the risk for apnea does not decrease to less than 1% (with 95% statistical confidence) until a PCA of 56 weeks with a gestational age of 32 weeks or until a PCA of 54 weeks with a gestational age of 35 weeks. In general, all former preterm infants younger than 60 weeks' PCA should be admitted to monitored beds, and the clinicians should be aware that anemic former preterm infants are at particular risk.

Although the risk of apnea may be less with regional anesthesia, apnea may still occur and may even be increased if regional anesthesia is combined with sedation (ketamine, midazolam).[182-187] The numbers of well-controlled studies of regional versus general anesthesia to determine whether the risk is significantly reduced are insufficient.[188] Apnea still clearly occurs even with sevoflurane or desflurane anesthesia; therefore the newer volatile anesthetics have not eliminated this concern.[189]

Part of the problem of how to treat these children is the fact that the clinical importance of brief apnea associated with bradycardia spells that do not require intervention is not known. Because cerebral blood flow is significantly reduced at heart rates less than 80 beats per minute, even brief apnea associated with bradycardia may have adverse effects.[190] Pulse oximetry would help define the severity of desaturation, and electrocardiographic monitoring would help define episodes of bradycardia, which may reduce cerebral blood flow. The combination of desaturation and bradycardia is of more physiologic importance than simple documentation of pauses in respiration.

If appropriate monitoring facilities are not available postoperatively, then a preterm infant who is younger than 60 weeks' PCA should be referred to an institution that has such facilities. High-dose caffeine (10 mg/kg) has been recommended,[191] which may be an effective therapy. However, the half-life of caffeine in older former preterm infants is only 6 hours, and the first apnea spells after anesthesia may not be expressed until 12 hours.[129] Therefore one cannot administer caffeine and then send the infant home and assume that the problem has been treated.

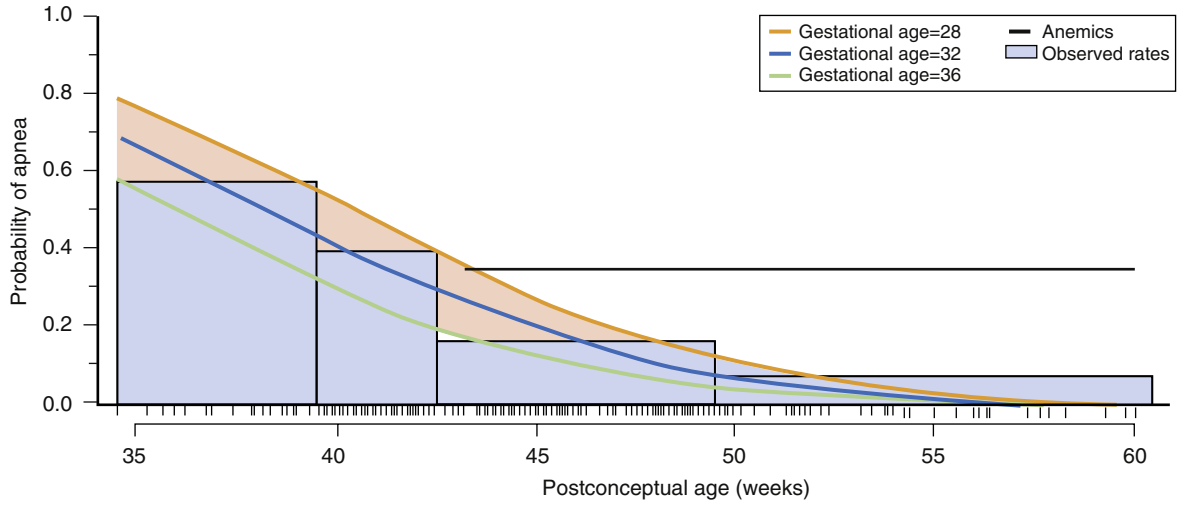

Figure 93-24. Predicted probability of apnea for all children by gestational age and weeks postconceptual age. Children with anemia are shown as the *horizontal solid black line*. *Bottom marks* indicate the number of data points by postconceptual age. The risk for apnea diminishes in infants born at a later gestational age. The *shaded boxes* represent the overall rates of apnea for infants within that gestational age range. The probability of apnea was the same, regardless of postconceptual age or gestational age, for infants with anemia (*horizontal solid black line*). *(Reproduced with permission from Coté CJ, Zaslavsky A, Downes JJ, et al: Postoperative apnea in former preterm infants after inguinal herniorrhaphy. A combined analysis,* Anesthesiology *82:809-802, 1995.)*

To make the issue even more complex, this author has a full-term infant who became apneic after general anesthesia. This infant had periodic breathing, which is distinctly unusual in a full-term infant and suggestive of a problem with control of respirations.[192] Which full-term neonates can be safely anesthetized on an outpatient basis is still not known with certainty. Because most organ systems are still rapidly developing during the first month of life (44 weeks' PCA), elective surgery should be delayed during the first month of life, and postoperative admission and apnea monitoring should be considered even in full-term infants younger than 1 month.

CHILDREN WITH REPAIRED HEART DISEASE

One should not assume that children have normal cardiac function after *correction* of congenital heart defects. Although the circulation may be normal, there is never assurance that cardiac function is normal. Any child who has undergone a ventriculotomy may have some ventricular dysfunction caused by the incision; there is less potential for dysfunction if the surgical approach was through an atriotomy. Likewise, even relatively benign procedures such as open closure of ventricular or atrial septal defects can be associated with the later development of dysrhythmias. Some children, particularly those with repaired single-ventricle physiology, have a significant predisposition to sudden death as a result of pathologic arrhythmias; a careful history is particularly important in these children. Should an arrhythmia develop intraoperatively, consultation with the child's cardiologist is essential because this development may be the first indication of a serious underlying arrhythmogenic focus. A radiofrequency ablation procedure may be lifesaving.

Children with a single-ventricle physiology (Fontan) require very specific anesthetic management. Because blood flow to the lungs is passive (i.e., no pumping chamber and no valves), high venous pressure is required (full hydration). PEEP is avoided and, the use of higher respiratory rates with low peak inflation pressure is recommended. The avoidance of anything that will increase pulmonary artery pressure (e.g., hypercarbia, further desaturation from baseline) is essential.[193] Children with Fontan physiology are poor candidates for laparoscopic procedures because of the required increases in intraabdominal pressure (compromised respirations, leading to hypercarbia and raised pulmonary artery pressure), carbon dioxide absorption from the pneumoperitoneum (raising pulmonary artery pressure), and extremes of head up or head down positions that also adversely affect passive blood return to the pulmonary circuit. These children often have other major issues such as protein-losing enteropathy and *plastic* bronchitis, and they are at significant anesthetic risk if one is unfamiliar with this unique physiologic abnormality.[194]

Another pediatric population at high risk for sudden death related to anesthesia is children with Williams syndrome (aortic stenosis, abnormal coronary arteries, pulmonic stenosis).[195] Children who have undergone cardiac transplantation also need particular attention to rule out small vessel coronary artery disease.[196] A full discussion of congenital heart disease is beyond the scope of this chapter, but the following three problems are the most common that a nonpediatric anesthesiologist may face for an appendectomy or the treatment of a forearm fracture (see also Chapter 94).

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) is defined as a "disorder of breathing during sleep characterized by prolonged upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep." These children also have an altered response to carbon dioxide.[197] Children at particular risk include those with craniofacial abnormalities, neuromuscular disorders, obesity, and adenotonsillar hypertrophy.[198,199] The increasing number of obese children is a major contributing factor.[200-202] The difficulty that anesthesiologists face is determining which children are at risk because not all children will undergo formal polysomnogram evaluation, which is considered the gold standard.[198] Abnormal sleep oximetry values (clusters of desaturation) also correlate with the severity of OSA.[203,204] Even children undergoing surgery in the afternoon may be at greater risk compared with those undergoing surgeries in the morning.[205] The apnea index (AI) and the respiratory disturbance index are measurements of the presence and severity of OSA syndrome. These indices reflect the frequency of occlusive and partially occlusive respiratory events per hour of sleep. OSA syndrome is present if the AI is 1 or greater (i.e., one or more apnea events per hour of sleep) and can be classified as mild if the AI is between 1 and 5, moderate if the AI is between 5 and 10, and severe if the AI is greater than 10 events per hour of sleep. Of particular concern are children in whom cardiac dysfunction (cor pulmonale) has developed and those in whom postobstructive pulmonary edema could develop. These children may require overnight ventilation in an ICU. In general, risk factors for postoperative complications include the following: (1) age younger than 3 years; (2) abnormal coagulation values; (3) evidence of OSA; (4) systemic disorders that place the child at increased perioperative risk (e.g., cor pulmonale, metabolic diseases); (5) presence of craniofacial or other airway abnormalities; (6) performance of the procedure for peritonsillar abscess; (7) child living a long distance from an adequate health care facility, adverse weather conditions, or home conditions not consistent with close observation, cooperativeness, and ability to return quickly to the hospital (e.g., substance-abusing parents, teenage mother); (8) obesity (>95% body mass index [BMI] or >95% weight for gender and age), and (9) African-American ethnicity.[206,207] The main problems that anesthesiologists face are determining when it is safe to send these children home and what should be done to provide postoperative analgesia.[202] Some day-surgery centers immediately send children home after tonsillectomy; others hold the children for at least 4 hours (the interval during which bleeding or respiratory compromise will most likely occur). Hospitals tend to admit the children to a 23-hour unit (to avoid the 24-hour hospital admission), thus observing the child for an extended time (usually not the full 23 hours) while minimizing the expense to the insurance provider. Analgesia is generally provided with a combination of oral acetaminophen preoperatively or rectally

administered after induction and low-dose morphine (33-50 μg/kg). Some anesthesiologists prefer short-acting opioids such as fentanyl to minimize respiratory depression and then supplement the analgesia with an additional longer-acting opioid in the PACU. Ketorolac provides analgesia without adverse respiratory effects, but it is associated with an increased incidence of postoperative bleeding if given before achieving hemostasis.[208] Postoperative nausea and vomiting are generally treated with serotonin 5-HT_3 antagonists, whereas postoperative swelling (plus vomiting) is treated with dexamethasone (0.0625 to 0.15 mg/kg).[209]

The most common at-home analgesic is acetaminophen with codeine. One issue that requires further evaluation is the possibility of alteration of opioid receptors (upregulation of μ opioid–receptors) in response to repeated minor hypoxemic events, as well as an altered response to carbon dioxide.[197,210-212] These altered responses result in increased sensitivity to the respiratory depressant effect of opioids.[213] These children are analgesic at one half the normal dose of opioid, thus a normal dose may, in fact, be a relative overdose for children with severe OSA.[214] In addition to these factors, children with OSA have a structurally narrowed airway because of an increased propensity for upper airway collapsibility.[215] These factors explain, in part, why children with OSA are at significantly increased risk for postoperative respiratory complications. A further concern is the recent reports of deaths after tonsillectomy related to altered conversion of the prodrug codeine to morphine.[216,217] Approximately 2% to 10% of children are slow metabolizers attributable to the deficiency of CYP2D6 genes (cytochrome P450, family 2, subfamily D, polypeptide 6), thus making codeine an ineffective analgesic. However, a more worrisome variant is children with duplicated CYP2D6 genes, resulting in ultraextensive conversion to morphine.[218,219] Thus the combination of OSA-induced opioid sensitivity and rapid metabolism can lead to fatal outcomes.[216-219] The FDA has added a **black box** warning strongly recommending that codeine not be administered to children for posttonsillectomy analgesia, particularly to those with obstructive sleep apnea.[220]

Independent of this genetic variant, children with severe OSA are at very high risk. If the child has not had a formal sleep polysomnogram or an overnight pulse oximeter study, then the practitioner must have a high index of suspicion if the child is obese (>95% weight for gender and age); has loud snoring, daytime somnolence, observed pauses or gasps, or exhibits a new onset of enuresis; is syndromic; or is African American.[221,222] These children are not candidates for same-day outpatient surgery and should be admitted to the safety net of medical supervision overnight. Unfortunately, this author has reviewed several medical misadventures during which children with known OSA died at home within hours of their tonsillectomy attributable to apnea.

REGIONAL ANESTHESIA AND ANALGESIA

Most regional anesthesia techniques used in adults can be safely administered to children as long as strict attention is paid to the dose of the local anesthetic, the dose of epinephrine, the route of administration, and the use of proper equipment. Perhaps the greatest advance in pediatric anesthesia has been the development of methods producing postoperative analgesia (also see Chapters 92 and 98). Caudal anesthesia, caudal opioids, regional blocks, and child-parent-nurse–controlled analgesia have all been accepted by anesthesiologists and children. Recent advances in ultrasound equipment have further improved the accuracy of nerve blocks and reduced the dose of drug needed to provide a successful block. Even pediatric patient–controlled epidural analgesia has been successfully used in children as young as 5 years of age.[222] Each institution and practitioner must decide which method works best, given each particular practice setting. Obviously, until dosage guidelines and safety standards for monitoring are well established, some of these techniques must be limited to medical centers familiar with their use in children (also see Chapter 92).

Regional nerve blocks and direct local infiltration of surgical wounds with long-acting local anesthetics are simple yet very effective and safe methods of providing pain relief for all children.[224,225] In most institutions, it is now rare for a child to awaken from anesthesia without some form of regional block. This practice has been especially helpful in the outpatient population; parents are encouraged to start analgesics when they observe their child becoming irritable but before the complete dissipation of the block. This approach usually provides a smooth transition from general anesthesia and a pain-free child. (Chapters 56 through 58 discuss regional anesthesia and analgesia in detail, and Chapter 92 places a special emphasis on pediatrics.)

Chapter 94

Anesthesia for Pediatric Cardiac Surgery

WILLIAM J. GREELEY • †CHAD C. CRIPE • ARUNA T. NATHAN

Acknowledgment: The editors and the publisher would like to thank Dr. Darryl H. Berkowitz, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Organ system maturation, from birth through adolescence (e.g., cardiovascular, central nervous system [CNS], pulmonary, renal, hematologic), affects physiologic function and therefore anesthetic and surgical management and outcome.
- Physiologic understanding of congenital heart disease (CHD) and consequent anesthetic management are based on the pathophysiologic determinants of four categories of defects: shunts, mixing lesions, stenotic lesions, and regurgitant lesions.
- The chronic sequelae of CHD—repaired, palliated, or unrepaired—affect anesthetic management: ventricular failure, residual hemodynamic effects (e.g., valve stenosis), arrhythmias, and pulmonary blood flow changes (e.g., pulmonary artery hypertension).
- Preoperative assessment of cardiac status (e.g., review of history and physical examination, echocardiography, and catheterization data and consulting with the patient's cardiologist) and planning are the keys to a successful anesthesia outcome.
- Intraoperative transesophageal echocardiography and CNS monitoring enhance surgical outcome and reduce morbidity.
- Selecting an induction technique depends on the degree of cardiac dysfunction, the cardiac defect, the degree of sedation provided by the premedication, and the presence or absence of an indwelling venous catheter. Other factors to be considered are the presence of pulmonary hypertension, electrical rhythm disorders, and other comorbidities. The maintenance of anesthesia depends on the age and condition of the patient, the nature of the surgical procedure, the duration of cardiopulmonary bypass (CPB), and the need for postoperative ventilation. It is usually desirable to return the patient to an arousable, sedated state with spontaneous ventilation at the end of the procedure in the presence of normal homeostasis and absence of complications.
- The physiologic effects of CPB on neonates, infants, and children are significantly different from the effects on adults. During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (18° C), hemodilution (threefold to fivefold greater dilution of circulating blood volume), low perfusion pressures (20 to 30 mm Hg), and wide variation in pump flow rates (ranging from 200 mL/kg/minute to total circulatory arrest).
- After repair of complex congenital heart defects, separating patients from CPB may be difficult. The causes may be an inadequate surgical result with a residual defect requiring repair, pulmonary artery hypertension, or right or left ventricular dysfunction.
- The use of modified ultrafiltration (MUF) reverses the deleterious effects of hemodilution and the inflammatory response associated with CPB in children. Perioperative blood loss and blood use are significantly reduced when MUF is used. MUF also improves left ventricular function and systolic blood pressure and increases oxygen delivery. Pulmonary compliance and brain function after CPB are also improved.

†Deceased.

KEY POINTS—cont'd

- Neonates, infants, and children undergoing cardiac surgery with CPB have a more frequent rate of postoperative bleeding than that seen in older patients. This is due to several factors: (1) A disproportionate exposure to the nonendothelialized extracorporeal circuit produces an inflammatory-like response. This inflammatory response to CPB is inversely related to patient age—the younger the patient, the more pronounced is the response. (2) The type of surgery performed in neonates and infants usually involves more extensive reconstruction and suture lines, creating more opportunities for surgical bleeding than in adult cardiac patients. (3) Operations are frequently performed using deep hypothermia or circulatory arrest, which may further impair hemostasis. (4) The immature coagulation system in neonates also may contribute to impaired hemostasis. (5) Patients with cyanotic heart disease demonstrate an increased bleeding tendency before and after CPB.
- The guiding principle in the management of the postoperative patient is an understanding of both normal and abnormal convalescence after anesthesia and cardiac surgery. The immediate postoperative period, even that of normal convalescence, is one of continuous physiologic change because of the pharmacologic effects of residual anesthetic agents and the ongoing physiologic changes secondary to abrupt alteration in hemodynamic loading conditions, surgical trauma, and extracorporeal circulation.
- The care of adults with CHD is a new and expanding field of medicine that requires the skilled management of an experienced multidisciplinary team.
- Additional anesthetic considerations exist in patients with CHD who undergo transplantation, closed heart operations without CPB, cardiac interventional procedures, and noncardiac surgery.

Cardiac surgery is an established and effective treatment for children with congenital heart defects. Early successes in surgical treatment led to a new therapeutic era in the management of congenital heart disease (CHD) and fostered the development of the subspecialties pediatric cardiology and cardiac surgery and their collaboration. Through this cooperative effort, tremendous progress in medical diagnosis and surgical treatment has been achieved. In turn, these accomplishments gave rise to the development of pediatric cardiac anesthesiologists, individuals who understand the pathophysiology of congenital heart malformations, the diagnostic and surgical procedures used to treat heart disease, and the principles of pediatric and cardiac anesthesia and intensive care medicine. Pediatric cardiac anesthesia continues to evolve as an exciting and technically demanding subspecialty in which anesthetic management is based on physiologic principles.

Cardiovascular surgery and anesthesia in CHD are often performed under unusual physiologic conditions. Rarely in clinical medicine are patients exposed to such biologic extremes as during surgery for CHD. Commonly, patients are cooled to 18° C, are acutely hemodiluted by more than 50% of their extracellular fluid volume, and undergo periods of total circulatory arrest lasting up to 1 hour. Management of patients under these physiologic extremes is a vital function of the pediatric cardiovascular anesthesiologist. As with other areas of medicine, the application and management of technology preceded a comprehensive understanding of its physiologic effects.

Clearly, the perioperative management of these complex cases requires a group of physicians (surgeon, anesthesiologist, cardiologist, critical care specialist), nurses, and perfusionists to work as a team. This team orientation is essential to achieving an optimal outcome. Although the quality of the surgical repair, the effects of cardiopulmonary bypass (CPB), and postoperative care are the major determinants of outcome, meticulous anesthetic management is also imperative. Ideally, despite the complexity of the cases and the marked physiologic changes attributed to CPB and the surgical procedures, anesthetic care should never contribute substantially to morbidity or mortality.[1] The challenge is to understand the principles underlying the management of patients with CHD and apply them to clinical anesthesia. We assume that the reader already understands the fundamentals of adult cardiac (see Chapter 67) and general pediatric anesthesia (see Chapter 93).

UNIQUE FEATURES OF PEDIATRIC CARDIAC ANESTHESIA

Pediatric cardiovascular management is unique, with important differences from adult cardiac surgery (Box 94-1). These differences are attributable to normal organ system maturation in the neonate and young infant, differing pathophysiologic conditions in CHD, the diversity of surgical repairs, and the use of specialized CPB techniques such as deep hypothermia and total circulatory arrest.

BOX 94-1 ***Unique Characteristics of Pediatric Cardiac Anesthesia***

PATIENT

Normal organ system development and maturational changes of infancy
- *Cardiovascular:* Blood flow patterns of circulation at birth, myocardial compliance, systemic and pulmonary vasculature, and β-adrenergic receptors
- *Pulmonary:* Respiratory quotient, closing capacity, chest compliance
- *Central nervous system:* Brain growth, cerebral blood flow, autonomic regulation
- *Renal:* Glomerular filtration rate, creatinine clearance
- *Hepatic:* Liver blood flow, microsomal enzyme activity

Disease and growth interrelationship
Effects of systemic disease alter somatic and organ growth
Compensatory ability of developing organs to recover from injury
Immunologic immaturity of the infant
Obligatory miniaturization (i.e., small patient size and body surface area)

CONGENITAL HEART DISEASE

Diverse anatomic defects and physiologic changes
Altered ventricular remodeling owing to myocardial hypertrophy and ischemia
Chronic sequelae of congenital cardiac disease

SURGICAL PROCEDURES

Diversity of operations
Frequent intracardiac and right ventricular procedures
Use of deep hypothermia and circulatory arrest during repair
Trend toward repair in early infancy
Evolution of surgical techniques to avoid residua and sequelae
Trend toward wider application of certain operations

PHYSIOLOGIC CONSIDERATIONS AND MATURATIONAL FEATURES OF THE PEDIATRIC PATIENT

The cardiovascular system changes markedly at birth because of a dramatic alteration in blood flow patterns (Fig. 94-1). During fetal life, blood flow returning to the right atrium (RA) bypasses the unventilated fluid-filled lungs. Blood is then preferentially shunted across the patent foramen ovale into the left atrium (LA) or passes from the right ventricle (RV) across the patent ductus arteriosus (PDA) to the systemic circulation. At birth, physiologic closure of the PDA and of the foramen ovale brings about the normal adult circulatory pattern. The presence of certain congenital heart defects or pulmonary disease can disrupt this normal adaptive process, creating a transitional circulation in which right-to-left shunting persists across the foramen ovale or the PDA. Under such circumstances, the continued presence of a transitional circulation can lead to severe hypoxemia, acidosis, and hemodynamic instability, which are poorly tolerated in the neonate. In contrast, when initially treating some forms of CHD, the prolongation of this transitional circulation is actually beneficial, promoting systemic blood flow or pulmonary blood flow (PBF) and postnatal viability. An example of the latter is pulmonary atresia, in which PBF is supplied via the PDA. In the absence of collateral vessels, closure of the PDA eliminates the principal source of PBF, resulting in hypoxemia and death. Ductal patency can be maintained with the administration of prostaglandin E1. Importantly, the transitional circulation can be manipulated by pharmacologic ventilatory strategies, thereby promoting hemodynamic stability in the pediatric patient. Another unique feature of the normal neonatal and infant cardiovascular system is the reduced myocardial reserve in contrast to that in the healthy adult. The newborn left ventricular function is restricted by a reduced number of α-adrenergic receptors, high resting levels of circulating catecholamines, limited recruitable stroke work, an immature calcium transport system, and decreased ventricular compliance.[2] This limits contractile reserve and results in a left ventricle (LV) with a high level of resting tone. Although the resting performance of the neonatal myocardium may be greater than in adults and older children, sensitivity to β-blockade is greater and only modest increases occur in cardiac performance after administration of the β-agonist drugs dobutamine and isoproterenol.[3]

On the ultrastructural level, a variety of cellular synthetic functions are occurring in immature myofibrils that dominate the newborn heart. Large nuclei, mitochondria, and surface membranes predominate within the myofibrils. In neonates, a 50% reduction in the number of myofibrils is seen and the myofibrils are arranged in a nonlinear, disordered array. As a direct result, the contractile mass of the heart is effectively reduced, resulting in a ventricle with low compliance. Preload augmentation is effective at low filling pressures (1 to 7 mm Hg). However, when left-sided filling pressures exceed 7 to 10 mm Hg, further increases in left ventricular stroke volume are minimal.[2] As a consequence, neonates are more dependent on heart rate and, to a lesser extent, on preload, to maintain cardiac output at filling pressures of 7 to 10 mm Hg or greater.[4]

In addition to a reduced contractile mass, the calcium transport system in the neonatal myocardium is underdeveloped. The transverse tubular system is absent, and the sarcoplasmic reticulum, which has to store and release calcium, is small and inefficient. The neonatal heart therefore depends more on extracellular calcium levels than the adult myocardium.[5-8] Because intracellular calcium concentrations play a central role in myocardial contractility, normal or even elevated plasma levels of ionized calcium may be necessary to augment or maintain an effective stroke volume. This is in contrast to adult cardiac patients in whom calcium use during cardiac surgery has fallen into some disfavor, owing to direct concerns over myocardial ischemia and reperfusion injury.

Another unique feature relates to the pulmonary circulation. The pulmonary circulation undergoes significant changes during the first months of life. These changes are largely characterized by regression of the hypertrophied medial smooth muscular layer in the pulmonary arteries that exists in utero, resulting in a concomitant drop in pulmonary vascular resistance (PVR). In the immediate newborn period, the large decrease in PVR is due to lung expansion and the vasodilatory effects of a higher PaO_2 than existed in utero. Further decline in PVR throughout the next 2 months of life is attributable to regression

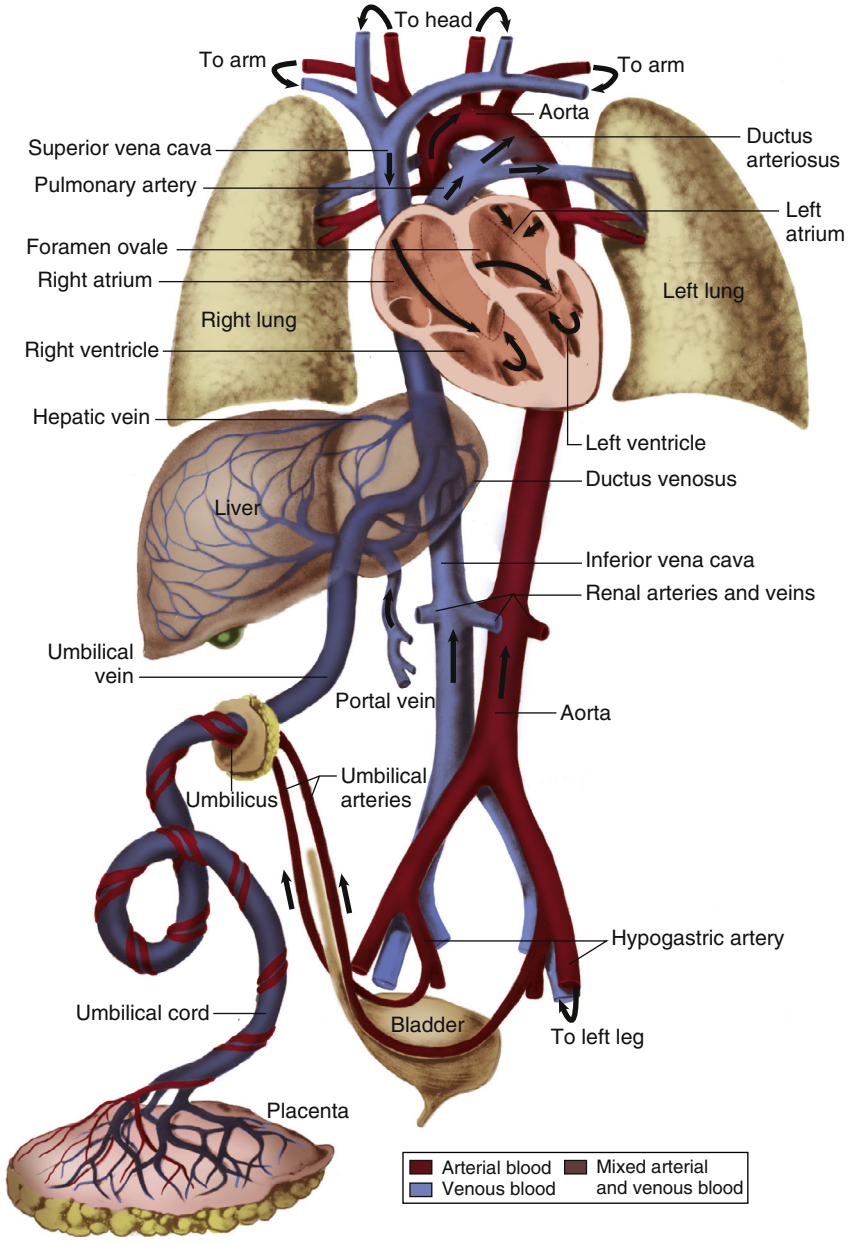

Figure 94-1. Course of the fetal circulation in late gestation. Note the selective blood flow patterns across the foramen ovale and the ductus arteriosus.

of the smooth muscle layer in the pulmonary arterioles. A corresponding decrease in pulmonary artery pressure occurs as PVR declines. Acute physiologic stress in the newborn period, such as hypoxemia or acidosis, can increase pulmonary artery pressure and thus PVR. If the resulting right ventricular hypertension causes reduced right ventricular compliance, right-to-left shunting can occur at the foramen ovale. Once PVR exceeds systemic vascular resistance (SVR), right-to-left shunting develops at the PDA. Either phenomenon will worsen the hypoxemia and eventually limit tissue oxygen (O_2) delivery to the point of lactic acidosis. In contrast, left-to-right shunts, such as with a ventricular septal defect (VSD), produce intimal changes in the pulmonary vasculature and delay regression of medial muscle hypertrophy. This results in persistent elevation of PVR.

Size differences between adult and pediatric cardiac patients require different anesthetic techniques and miniaturization. Anatomically, pediatric patients have small upper and lower airways, small veins and arteries, and a decreased body surface area in contrast to those in adult patients. Several anesthetic implications exist related to patient size. Some centers think placement of arterial catheters by cutdown in neonates and infants represents the most expedient approach, particularly when optimal sites are limited. Pulmonary artery catheters are used infrequently, both because of the technical difficulties in positioning the tip in the pulmonary artery and because of the fundamental fact that pulmonary flow bears no obligatory relationship to systemic output in children with either intracardiac or extracardiac communications. Transthoracic catheters for pressure monitoring and delivery of

vasoactive substances are commonly placed from the surgical field instead of percutaneous approach via the neck. Adequacy of the repair and function can be assessed by transesophageal echocardiography with Doppler color flow imaging with miniaturized probes.[9,10] CPB serves as another example of the influence of patient size on management. The ratio of pump priming volume to patient blood volume is considerably higher in small children than in adults, resulting in a greater degree of hemodilution. Several studies demonstrated a heightened inflammatory response to CPB in children in contrast to in adults.[11] This effect is related to the disproportionate exposure to the nonendothelialized surfaces of the pump circuit per body surface area. Greater damage to the formed blood elements and plasma proteins is incurred, resulting in activation of mediators of inflammation.

In pediatric patients with CHD, the cardiovascular system often represents the sole cause of the medical problem. This is in contrast with the multiplicity of diagnoses and organ system involvement frequently found in adults with acquired cardiovascular disease. Moreover, a special disease and growth interrelationship, unique to growing infants and children, permits developing organs to compensate for and modify existing disease processes. Reparative and recuperative processes in children are greater as a result of this compensatory ability of developing organ systems. Adult cardiac patients unfortunately do not exhibit the same recuperative ability. Although children adapt well to cardiovascular pathologic processes, negative aspects to long-standing heart disease also exist. CHD has detrimental effects on somatic growth and on the growth and development of the brain, myocardium, and lung.

Other unique considerations are issues surrounding the premature infant (see Chapter 95). Premature infants are classified as infants with low birth weight (31 to 34 weeks, 1 to 1.5 kg), infants with very low birth weight (26 to 30 weeks, 600 g to 1 kg), and infants with extremely low birth weight (<26 weeks, 400 to 600 g). This population of infants manifests unique anesthetic challenges. Cardiorespiratory failure is common and multifactorial. The small airways are prone to obstruction, which results in increased airway resistance and work of breathing with easy fatigability. Diseases of the upper airway such as subglottic stenosis, tracheomalacia, and tracheal stenosis are poorly tolerated, and the use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure is often necessary to stent open the airway. Lung compliance is reduced because of a deficiency of surfactant, resulting in intrapulmonary shunt and ventilation-perfusion mismatch. Mechanical ventilation prevents alveolar collapse, maintains patency of the airway, and maintains lung volume, preventing hypoxia. Premature lungs are susceptible to barotrauma and oxidant injury. Ventilation should use measures to reduce peak inspiratory pressures and barotrauma, and the inspired O_2 concentration should be reduced to avoid generation of free radicals. Premature infants are also prone to perioperative periods of apneas. Such apneas might be central in origin or obstructive, both of which can be aggravated by anesthetic agents. Apnea can be precipitated by abrupt changes in oxygenation, pulmonary mechanics, brain hemorrhage, and hypothermia. Sustained apnea can result in desaturation and usually begins after emergence from anesthesia and persists for up to 48 hours. Continuous apnea and saturation monitoring with correction of anemia (hematocrit >30) and intravenous administration of caffeine are therapeutic options. The incidence of postoperative apnea is related to postconceptional and gestational age, the presence of anemia, and the type of surgical procedure. The premature heart is a poorly contractile organ, sensitive to changes in intracellular calcium, with poor diastolic function. Cardiac output depends on heart rate, with marginal reserve. The premature infant also has a relatively low absolute blood volume and tolerates blood loss poorly. Autoregulation is not well developed, and blood loss compromises cerebral and coronary flow before other manifestations of hypovolemia. It is also imperative to avoid fluid overload in these patients. Patency of the ductus arteriosus results in pulmonary overcirculation with heart failure and a large left-to-right shunt. If uncorrected, this would result in pulmonary hypertension secondary to the development of pulmonary vascular occlusive disease. Thermoregulation by nonshivering thermogenesis is also poor owing to inadequate stores of brown fat in prematurity. It is critical to maintain normothermia by increasing the operating room temperature, using incubators for transport, warming and humidifying respiratory gases, and warming all intravenous fluids. Glycemic control is difficult, with a tendency to hypoglycemia and hyperglycemia. Euglycemia should be confirmed and maintained. Typically, these infants receive higher concentrations of parenteral glucose solutions, which need to be continued in the perioperative period. Premature infants are also prone to retinopathy of prematurity with high inspired O_2 concentrations and intraventricular hemorrhage. Every attempt should be made to avoid hemodynamic perturbances and fluctuation in O_2 saturations. In general, immaturity of organ systems results in both increased drug effect and duration of action, warranting careful titration of drugs.

Premature infants have a twofold increase in cardiovascular malformations compared with infants born at term.[12] One in six infants with CHD, not including those with PDA or ASD, is born prematurely. Some malformations such as tetralogy of Fallot (TOF), pulmonary stenosis, pulmonary atresia with VSD, complete atrioventricular (AV) septal defect, large VSDs in isolation or associated with coarctation, and aortic stenosis are more prevalent in this population.[13] A significant increase in the likelihood of being small for gestational age is seen among infants with TOF, complete AV septal defect, hypoplastic left heart, pulmonary stenosis, or large VSD.[14]

Cardiac catheterization, intervention, and complete surgical repair in the newborn of very low birth weight (<1.5 kg) can be successfully undertaken with low risk, although longer term follow-up remains necessary to determine growth and development patterns. However, because of the complexity of premature organ systems and superimposed cardiorespiratory pathophysiology, morbidity and mortality are increased.[15-17] Surgical adaptations have been described that enable the use of CPB in low-birth-weight infants. However, low birth weight remains a significant risk for mortality in neonates with complex single ventricle disease undergoing surgical palliation.[18,19] Interventional

catheterization is associated with higher risk for complications, especially related to problems with vascular access, arrhythmias, and respiratory compromise.[15] Premature infants are electively tracheally intubated and ventilation controlled for both catheterization and surgical procedures. Adequate intravenous access and invasive monitoring can be challenging but are necessary in most cases. Maintenance of euglycemia and normothermia and attention to fluid and electrolyte balance are important. O_2 delivery should be optimal by maintaining age-appropriate blood pressures, adequate intravascular volume, and hematocrit. Any acidosis must be sought and aggressively corrected. Generally, such infants should recover in a specialized pediatric cardiac intensive care unit (ICU).

CONGENITAL HEART DISEASE

The marked array of anatomic and physiologic conditions seen with CHD distinguishes these processes from acquired adult cardiac disease. The spectrum of intracardiac shunts, valve pathology (stenoses, regurgitation, or atresia), and disrupted great artery connections and the absence of one or more chambers of the heart preclude a uniform anesthetic approach to patients with CHD. Moreover, myocardial changes result from the hemodynamic impact and increased cardiac work incurred by these defects. Functionally, these myocardial changes place the ventricles at great risk for the development of intraoperative ischemia and failure. Therefore, an understanding of the isolated defect, associated myocardial changes, and hemodynamic consequences is fundamental to planning an appropriate anesthetic regimen. Distilling CHD into a finite number of physiologic categories enables the anesthesiologist to construct a strategy that employs the qualitatively predictable impact of drugs, ventilatory management, and fluid administration to optimize cardiovascular performance. Although an isolated heart malformation may be identified, the entire cardiopulmonary system is usually affected.

Physiologic Approach to Congenital Heart Disease

Although the structural variations seen in CHD constitute an encyclopedic list of malformations, anesthetic management is more logically designed to achieve physiologic goals. A general physiologic classification is listed in Table 94-1. Fortunately, although structurally complex, these defects can be understood within a more limited physiologic spectrum. Identification and classification on the basis of physiology provide an organized framework for the intraoperative anesthetic management and postoperative care of children with complex congenital cardiac defects. In general, congenital heart lesions fit into one of four categories: shunts, mixing lesions, flow obstruction, and regurgitant valves (see Table 94-1). Each category imposes at least one of three pathophysiologic states: ventricular volume overload, ventricular pressure overload, or hypoxemia. Ultimately, these pathophysiologic conditions can result in myocardial failure or pulmonary vascular disease. Medical and surgical perioperative management strategies should be focused on minimizing the pathophysiologic consequences of these lesions.

TABLE 94-1 CLASSIFICATION OF CONGENITAL HEART DEFECTS

Physiologic Classification	Pulmonary Blood Flow	Comments
Left-to-right shunts		
VSD	↑	Volume-overloaded ventricle
ASD		Development of CHF
PDA		
AV canal		
Right-to-left shunts		
Tetralogy of Fallot (TOF)	↓	Pressure-overloaded ventricle
Pulmonary atresia/VSD		Cyanotic
Eisenmenger complex		Hypoxemia
Mixing lesions		
Transposition/VSD	Generally↓ but variable $\dot{Q}p/\dot{Q}s$	Variable pressure versus volume loaded
Tricuspid atresia		Usually cyanotic
Anomalous venous return		
Univentricular heart		
Obstructive lesions		
Interrupted aortic arch		Ventricular dysfunction
Critical aortic stenosis		Pressure-overloaded ventricle
Critical pulmonic stenosis		Ductal dependence
Hypoplastic left heart syndrome		
Coarctation of the aorta		
Mitral stenosis		
Regurgitant lesions		
Ebstein anomaly		Volume-overloaded ventricle
Other secondary causes		Development of CHF

ASD, Atrial septal defect; *AV,* atrioventricular; *CHF,* congestive heart failure; *PDA,* patent ductus arteriosus; $\dot{Q}p$, pulmonary blood flow; $\dot{Q}s$, systemic blood flow; *VSD,* ventricular septal defect.

Shunt Lesion. Shunts are intracardiac connections between chambers or extracardiac connections between a systemic and pulmonary artery—examples are an atrial septal defect (ASD), a VSD, and a PDA. The direction of blood flow through the shunt depends on the relative resistances on either side of the shunt and on the size of the shunt orifice. With a nonrestrictive VSD or PDA that does not impede blood flowing freely in each direction, the main determinant of blood flow is the resistance of the pulmonary and systemic vascular beds. The direction and magnitude of shunt at the atrial level are governed by the relative differences in ventricular compliance and respective AV valve function. The effect that a shunt lesion has on the cardiovascular system depends on its size and direction, either right-to-left or left-to-right. Left-to-right shunts occur when

the PVR is lower than the SVR and blood flow is preferentially directed toward the lungs, resulting in increased PBF.

In patients with large left-to-right shunts and low PVR, a substantial increase in PBF can occur. This results in three pathophysiologic problems: (1) congestion of the pulmonary circulation; (2) intravascular volume overload with resulting increased cardiac work for the LV, which is required to increase stroke volume and heart rate to ensure adequate systemic perfusion; and (3) excessive PBF, resulting in progressive elevation in PVR. Volume overload causes ventricular dilation that places the heart at a mechanical and physiologic disadvantage, resulting in reduced diastolic compliance. These diastolic changes lead to engorgement of the respective venous beds, which produces the signs and symptoms of clinical congestive heart failure (CHF) early in the natural history of volume-overload condition. The demand for increased cardiac output placed on the LV is limited in the infant by virtue of its immature structure, so that large left-to-right shunts may outstrip the capacity of the left side of the heart to maintain adequate systemic perfusion, and CHF will result. Surgical closure of a hemodynamically significant VSD usually provides immediate benefit by dramatically lowering left ventricular volume output demands.

Occasionally, the sudden increase in wall stress imposed on a dilated ventricle that must now pump solely against SVR can produce worsening ventricular failure during the early postoperative period after eliminating the low-resistance "pop off" into the pulmonary circulation. If the left-to-right shunt is not repaired, prolonged exposure to increased PBF results in progressive elevations in PVR. Fixed changes in pulmonary arterioles may occur, leading to pulmonary vascular obstructive disease. Table 94-1 lists common left-to-right shunt lesions.

Right-to-left shunts occur when pulmonary vascular or right ventricular outflow tract resistance exceeds SVR, thereby reducing PBF. The systemic circulation receives an admixture of deoxygenated blood via the shunt and manifests clinically as cyanosis and hypoxemia. Pure right-to-left shunting resulting from increased PVR is seen in the Eisenmenger complex and persistent pulmonary hypertension of the newborn with atrial and ductal level shunting. More commonly, PVR is low, and a more complex lesion with obstruction of pulmonary outflow, proximal to the pulmonary vasculature, produces right-to-left shunting. Defects such as TOF represent classic right-to-left shunts. The shunting occurs through the VSD because of pulmonary outflow obstruction. Systemic perfusion is generally normal with right-to-left shunting lesions unless hypoxemia becomes severe enough to impair O_2 delivery to tissue. Thus, two pathophysiologic problems exist: (1) reduced PBF resulting in systemic hypoxemia and cyanosis and (2) an increased impedance to right ventricular ejection, which may ultimately lead to ventricular dysfunction and failure of the RV. However, the physiologic mechanisms designed to compensate for pressure overload rarely create abnormalities in systolic or diastolic function early in the natural history of the disease process. In contradistinction to lesions that produce excessive ventricular volume, ventricular dysfunction and failure typically take years to develop in the context of isolated pressure overload.

TABLE 94-2 DUCTAL-DEPENDENT LESIONS

PDA Provides Systemic Flow	PDA Provides Pulmonary Flow
Coarctation of the aorta	Pulmonary atresia
Interrupted aortic arch	Critical pulmonary stenosis
Hypoplastic left heart syndrome	Severe subpulmonic stenosis with VSD
Critical aortic stenosis	Tricuspid atresia with pulmonic stenosis

PDA, Patent ductus arteriosus; *VSD,* ventricular septal defect.

Mixing Lesions. Mixing lesions constitute the largest group of cyanotic congenital heart defects (see Table 94-1). In these defects, the mixing between the pulmonary and the systemic circulation is so large that the systemic and pulmonary artery O_2 saturations approach each other. The pulmonary-to-systemic flow ratio ($\dot{Q}p/\dot{Q}s$) is independent of shunt size and totally dependent on vascular resistance or outflow obstruction. The pulmonary and systemic circulations tend to be in parallel with one another rather than in series (see Table 94-1). In patients with no outflow obstruction, flow to the systemic or pulmonary circulation depends on the relative vascular resistances of both circuits, such as with univentricular hearts or double-outlet RV. If SVR exceeds PVR, as in the typical circumstance, the tendency is toward excessive PBF, and the predominant pathophysiologic process is left-to-right shunting. These patients have increased PBF, ventricular volume overload, and a gradual elevation of PVR over time. If PVR exceeds SVR, as may occur episodically in ductal-dependent lesions such as hypoplastic left heart syndrome, systemic blood flow predominates and PBF dramatically decreases, causing progressive hypoxemia (Table 94-2).

In patients with a mixing lesion and left ventricular outflow obstruction, PBF may be sufficiently excessive to impair systemic perfusion. In patients with mixing lesions and a right ventricular outflow obstruction such as a single ventricle with subpulmonic stenosis, systemic-to-pulmonary flow can vary from balanced flow to significantly decreased PBF in which the severity of hypoxemia depends on the degree of obstruction. Typical mixing lesions include truncus arteriosus, univentricular heart, total anomalous pulmonary venous return, pulmonary atresia with large VSD, and single atrium.

Obstructive Lesions. Obstructive lesions range from mild to severe. Severe lesions manifest in the newborn period with a pressure-overloaded, diminutive, or profoundly dysfunctional ventricle proximal to the obstruction. These lesions include critical aortic stenosis, critical pulmonic stenosis, coarctation of the aorta, and interrupted aortic arch. Although aortic and pulmonary atresia represent the most extreme variants of outflow tract obstruction, they are associated with such extreme hypoplasia of the ventricle (hypoplastic left heart syndrome and pulmonary atresia with intact ventricular septum, respectively) that the ventricle's function does not contribute to the circulatory physiology. As with other critical obstructive lesions, these extreme variants have ductal-dependent circulations, but beyond that similarity they are perhaps better understood as univentricular hearts for which the

management characteristics of a mixing lesion dominate in importance. In critical neonatal left-sided obstructive defects, systemic perfusion depends on blood flow (desaturated) from the RV via the PDA and the coronary perfusion is supplied by retrograde flow from the descending aorta (see Table 93-3). In right-sided lesions, PBF is supplied from the aorta via the PDA and right ventricular function is impaired.

Pathophysiologic problems in critical neonatal left-sided heart obstructive lesions include (1) profound left ventricular failure, (2) impaired coronary perfusion with an increased incidence of ventricular ectopy, (3) systemic hypotension, (4) PDA-dependent systemic circulation, and (5) systemic hypoxemia. The pathophysiologic problems in critical neonatal right-sided heart obstructive lesions include (1) right ventricular dysfunction, (2) decreased PBF, (3) systemic hypoxemia, and (4) PDA-dependent PBF. Apart from the most extreme variants that become evident in the neonatal period, infants and children with outflow obstruction (e.g., mild-to-moderate aortic or pulmonary stenosis, coarctation of the aorta) manifest the effective compensatory mechanisms for pressure overload, often remaining clinically asymptomatic for many years.

Regurgitant Valves. Regurgitant valves are uncommon as primary congenital defects. Ebstein malformation of the tricuspid valve is the only pure regurgitant defect manifesting in the newborn period. However, regurgitant lesions are frequently associated with an abnormality of valve structure, such as incomplete or partial AV canal defect, truncus arteriosus, and TOF with an absent pulmonary valve. The pathophysiology of regurgitant lesions includes (1) volume-overloaded circulation and therefore (2) progression toward ventricular dilation and failure.

In summary, when considering the incidence of all the congenital heart defects, three uncomplicated left-to-right shunts (VSD, ASD, PDA) and two obstructive lesions (pulmonic stenosis, coarctation) constitute 60% of all congenital cardiac defects. Mixing lesions, complicated obstructive defects, and right-to-left shunting lesions account for the vast majority of the remaining 40%. The latter group of defects, which are more difficult to manage, are more labor intensive and have a significantly higher morbidity and mortality rate. This observation is directly attributed to the complexity of the cardiovascular abnormalities seen in this group, in which an absence of a chamber or a major ventricular-arterial connection is present.

Chronic Consequences of Congenital Heart Disease. The chronic effects of CHD are a consequence of the imposed hemodynamic stress of the defect or the residua and sequelae after cardiac surgery. These effects continue to alter normal growth and development of the cardiovascular system and other organ systems throughout life. Complete surgical cures are rarely achieved, and some repairs are palliative rather than corrective; therefore, abnormalities before and after repair produce long-term effects in patients with CHD.[20] Although the overall outlook for these patients is good in most instances, every defect has associated myocardial changes and every repair leaves certain obligatory abnormalities. Many of the abnormalities are trivial and have no major import. Others affect major organ system processes, such as ventricular function, central nervous system (CNS) growth, the conduction system of the heart, or PBF. Under these circumstances, the long-term quality of life is affected. Whether anesthetizing these patients for their primary or subsequent cardiac repair or for noncardiac surgery, these chronic changes should be ascertained and reflected in the anesthetic plan.

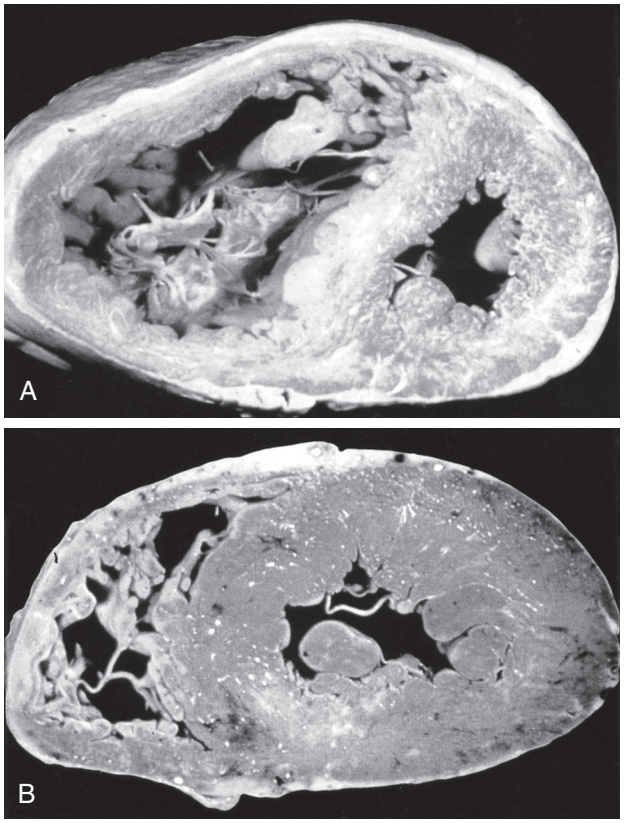

Figure 94-2. Comparison of ventricular hypertrophy patterns demonstrating altered ventricular remodeling in two different congenital heart defects. **A,** Note the right ventricular hypertrophy and the diminutive left ventricle in tetralogy of Fallot. **B,** Note the severe left ventricular hypertrophy and septal bulging into the right ventricle in aortic stenosis.

The myocardium is continually remodeled by specific hemodynamic stresses in utero and throughout life. Right ventricular growth and development are influenced by the low-resistance afterload of the pulmonary circulation. The LV is coupled to the high-resistance systemic circulation, which accelerates its rate of growth and development. This situation gives rise to the adult condition in which left ventricular dominance of myocardial muscle mass occurs. This entire developmental process is referred to as dynamic ventricular modeling. Abnormal hemodynamic loading conditions associated with CHD interrupt the normal ventricular modeling process (Fig. 94-2).[21] Abnormal ventricular remodeling typically begins in utero and stimulates an increase in ventricular mass. Increased ventricular mass is due to both hyperplasia and hypertrophy of myocytes in response to altered wall stress on the developing ventricle. The resultant biomechanical

deformation of the ventricle alters its geometry, affecting normal systolic and diastolic function.

Abnormalities of ventricular performance at rest and with exercise can be detected in patients with chronic hemodynamic overload and complex cyanotic lesions. These abnormalities in ventricular function are the consequences of chronic ventricular overload, repeated episodes of myocardial ischemia, and residua or sequelae of surgical treatment (ventriculotomy, altered coronary artery supply, inadequate myocardial protection). The physiologic adaptive responses to chronic hypoxemia and ventricular pressure or volume overload are the primary stimuli producing the long-term ventricular dysfunction. Although chronic volume overload of the LV as seen with left-to-right shunts or a chronic pressure-loaded LV from left-sided obstructive lesions results in CHF, the compensatory mechanisms for pressure overload create less physiologic disturbance, particularly in diastolic function. Consequently, CHF occurs later in the natural history of isolated obstructive lesions that do not require treatment in the neonatal period. Similarly, chronic right ventricular volume overload as seen in pulmonic insufficiency after TOF repair is more likely to be associated with chronic ventricular dysfunction and failure than a pressure-loaded RV that manifests with residual pulmonic stenosis. In fact, the most potent combination for inducing ventricular dysfunction and failure occurs when a pressure overload is superimposed on a dilated, volume-overloaded ventricle (e.g., postoperative TOF with pulmonary insufficiency and branch pulmonary artery stenosis). The mechanism for the dysfunction and failure is multifactorial.

Initial manifestations of CHF reflect alterations in ventricular compliance that result from a variety of biophysical responses to abnormal loading conditions. The ventricular dilation and compensatory hypertrophy that accompany excessive intravascular volume provide effective compensation to preserve normal systolic wall stress, but alterations in diastolic wall stress become evident (Fig. 94-3). Ultimately, chronic or severe pressures cause similar changes as the resultant myocardial hypertrophy outgrows vascular supply and results in ischemia and fibroblast proliferation. Permanent changes in myocardial structure and function are the end result.

In patients with cyanotic conditions, the long-term compensation for chronic hypoxemia is a major redistribution of organ perfusion with selected blood flow to the heart, brain, and kidney and decreased flow to the splanchnic circulation, skin, muscle, and bone. Chronic hypoxemia is associated with increased work of breathing in an attempt to increase O_2 uptake and delivery. The most dramatic complications are decreased rate of somatic growth, increased metabolic rate, and an increase in hemoglobin concentrations.

Congenital syndromes may have associated CHD that will influence long-term outcome (Table 94-3).

	Normal	Pressure overload	Volume overload
LVp	117 ± 7 / 10 ± 1	220* ± 6 / 23* ± 3	139 ± 7 / 24* ± 2
h	.8 ± .1	1.5* ± .1	1.1* ± .1
r	2.4 ± .1	2.8 ± .2	3.3* ± .1
h/r	.34 ± .02	.58* ± .05	.34 ± .02
σ_s	151 ± 14	161 ± 24	175 ± 7
σ_p	17 ± 2	23 ± 3	41* ± 3

Figure 94-3. Changes in ventricular physiology that accompany abnormal pressure and volume loading in human adolescents and adults. Schematic diagram represents the changes in cross-sectional ventricular geometry that accompany abnormal pressure and volume loads. Data are measured and derived from catheterization and echocardiography of 30 adolescent and adult human subjects. Pressure overload triggers significant increases in wall thickness and wall thickness-to-radius ratio (*h/r*), but these compensatory mechanisms preserve σ within normal limits. Whereas volume overload causes dilation and enough hypertrophy to preserve normal σS, diastolic function deteriorates significantly. σ_d, End-diastolic wall stress; *LVp,* left ventricular pressure; *r,* radius of the left ventricular chamber; σ_s, peak systolic wall stress. *$P = .01$. *(From Grossman W, Jones D, McLaurin LP: Wall stress and patterns of hypertrophy in the human left ventricle,* J Clin Invest *56:56, 1975.)*

Surgical Procedures and Special Techniques. The ultimate objectives for congenital heart surgery are (1) physiologic separation of the circulation, (2) relief of outflow obstruction, (3) preservation or restoration of ventricular mass and function, (4) normalization of life expectancy, and (5) maintenance of quality of life. The available surgical procedures to accomplish these objectives are diverse and complex (Table 94-4). In contrast to cardiac operations in adult patients, pediatric congenital heart repairs involve more intracardiac surgery, with a greater preponderance performed via the RA and RV. In general, operations performed for congenital heart defects can be divided into palliative and corrective procedures. The type and timing of repair depend on the age of the patient, the specific anatomic defect, and the experience of the surgeon and the team (see Table 94-4).

Palliation in infancy is usually performed when anatomic parts are missing, as in pulmonary atresia (absent RV and pulmonary artery), tricuspid atresia (absent RV and tricuspid valve), hypoplastic left heart syndrome (aortic atresia and hypoplastic LV), univentricular heart (absent RV or LV), and mitral atresia (absent LV). These palliative procedures can be further subdivided into those that increase PBF, those that decrease PBF, and those that increase mixing (see Table 94-4). Palliative procedures that increase PBF include shunts (Blalock-Taussig, central, and Glenn), outflow patch, and enlargement of the VSD. Those that decrease PBF include pulmonary artery banding and ligation of a PDA. Those that improve intracardiac mixing include atrial septostomy (balloon, blade, and Blalock-Hanlon).

The improvements in surgical technique, coupled with advancements in anesthetic and technologic support, make repair in early infancy not only feasible but in many cases preferable.[22] Currently, repair in infancy can be offered for a number of congenital heart defects,

TABLE 94-3 SYNDROMES ASSOCIATED WITH CONGENITAL HEART DISEASE

Syndrome	Lesion	Cardiac Lesion	Comments
Syndromes With Airway Issues and CHD			
CHARGE syndrome (association)		VSD, ASD, PDA, TOF	Micrognathia, possible difficult airway
Edwards syndrome	Trisomy 18	VSD, ASD, PDA	Micrognathia, small mouth, difficult intubation
Di George sequence	Microdeletion 22q11.2	Aortic arch and conotruncal lesions	Short trachea—tendency to endobronchial intubation
Goldenhar syndrome		VSD, PDA, TOF, CoA	Maxillary and mandibular hypoplasia, C-spine anomalies—difficult intubation
Hurler syndrome	MPS 1, storage disorder	Multivalvular disease, CAD, cardiomyopathy	Macroglossia, short neck—extremely difficult intubation
Noonan syndrome		PS, ASD, cardiomyopathy	Short webbed neck, macrognathia—difficult intubation
Turner syndrome	Monosomy X	LVOT O, AS, HLHS, CoA	Micrognathia, webbed neck—difficult intubation
VATER association		VSD, TOF, ASD, PDA	Potential for difficult intubation
Syndromes With Risk for Arrhythmias			
Long QT syndrome (LQTS)		Torsade de pointes, SCD	
Brugada syndrome		VT/VF/SCD	
Arrhythmogenic right ventricular dysplasia (ARVD)		VT/SCD	
Catecholaminergic polymorphic ventricular tachycardia		Polymorphic VT/SCD	
Wolff-Parkinson-White syndrome		SVT	
Maternal lupus		CCHB in the newborn	
Chromosomal Disorders Associated With CHD			
Down syndrome	Trisomy 21	VSD, ASD, CAVC	
Edwards syndrome	Trisomy 18	VSD, ASD, PDA	
Patau syndrome	Trisomy 13	VSD, PDA, ASD	
Turner's syndrome	Monosomy X	LVOT O, AS, HLHS, CoA	
3p–syndrome	Deletion 3p	CAVC	
Cri du chat syndrome	Deletion 4p	Variable	
8p–syndrome	Deletion 8p	CAVC	
9p–syndrome	Deletion 9p	VSD, PDA, PS	
Williams syndrome	Microdeletion 7q11	SVAS, SVPS, branch PS	
Smith-Magenis syndrome	Microdeletion 17p11.2	ASD, VSD, PS, AV valve malformations	
Miller-Dieker syndrome	Microdeletion 17p13.3	TOF, VSD, PS	
CHARGE association		VSD, ASD, PDA, TOF	Coloboma, heart, choanal atresia, retardation, genital and ear anomalies

AS, Atrial stenosis; *ASD,* atrial septal defect; *AV,* atrioventricula; *CAVA,* vena cava; *CAD,* coronary artery disease; *CHARGE,* coloboma of the eye, heart defects, atresia of the nasal choanae, restriction of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness; *CCHB,* congenital complete heart block; *CHD,* congenital heart disease; *CoA,* coarctation of the aorta; *HLHS,* hypoplastic left heart syndrome; *LVOT O,* left ventricular outlet obstruction; *MPS 1,* mucopolysaccaridosis type 1; *PDA,* patent ductus arteriosus; *PS,* pulmonary stenosis; *SCD,* sudden cardiac death; *SVAS,* supraventricular aortic stenosis; *SVPS,* supravalvular pulmonic stenosis; *SVT,* supraventricular stenosis; *TOF,* tetralogy of Fallot; *VATER,* vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia; *VSD,* ventricular septal defect; *VT/VF,* ventricular tachycardia/ventricular fibrillation.

as shown in Table 94-4. The timing of surgical intervention reflects medical necessity, physiologic and technical feasibility, and optimal outcome. Cardiac defects that require a PDA to sustain sufficient systemic blood flow or PBF (e.g., pulmonary atresia, hypoplastic left heart syndrome, interrupted aortic arch, critical aortic stenosis, and critical pulmonic stenosis) require an intervention in the neonatal period. A variety of defects are optimally repaired in early infancy. Lesions such as transposition of the great arteries (TGA) may exhibit better left ventricular function if the arterial switch operation is performed in the first few weeks of life when the PVR has recently been high enough to increase left ventricular systolic pressure, whereas other repairs may manifest less volatile postoperative physiology if deferred a few weeks or months until PVR has consistently fallen (e.g., TOF, AV canal defect). Each defect may have mitigating factors for which deferred definitive repair will enable optimal surgical result (e.g., TOF with aberrant coronary branching pattern or multiple VSDs; TGA with VSD and severe left ventricular outflow tract obstruction).

Although some lesions merit repair whenever they are diagnosed (e.g., total anomalous pulmonary venous return, coarctation of the aorta), others exhibit such a wide spectrum of physiologic disturbance that the timing of an intervention must be made individually (e.g., VSD, aortic stenosis, pulmonic stenosis). A few cardiac malformations produce pathophysiologic changes that are sufficiently mild that repair is typically deferred to later infancy or childhood (e.g., isolated ASD). Palliative

TABLE 94-4 CONGENITAL CARDIAC DEFECTS AND THEIR REPAIR

Anatomic Defects	Palliation	Complete Repair
Tetralogy of Fallot (TOF)		VSD closure and RVOT patch
With PA atresia	Shunt	
With anomalous right coronary artery	Rastelli	
HLHS	Norwood I/transplant	
Transposition of the great arteries		Arterial switch
Unfavorable coronary anatomy	Atrial switch (Senning)	
Tricuspid atresia	Shunt followed by Fontan	
Pulmonary atresia with VSD	Shunt followed by Fontan	
With intact septum	Shunt followed by Fontan	
Critical aortic stenosis		Aortic valvotomy
Interrupted aortic arch		End-to-end anastomosis/reverse subclavian flap/tube graft
Total anomalous pulmonary		Anastomosis of pulmonary veins to left atrium venous return and ASD closure
Single ventricle/normal PAs	Band followed by Fontan	
With small PAs	Shunt followed by Fontan	
Truncus arteriosus		RV-PA conduit and VSD closure
Atrioventricular canal		Repair valve clefts/patch closure of ASD/attach valves to patch

ASD, Atrial septal defect; *HLHS,* hypoplastic left heart syndrome; *PA,* pulmonary artery; *RV,* right ventricle; *RVOT,* right ventricular outflow tract; *VSD,* ventricular septal defect.

surgery is entertained when a physiologic derangement requires intervention but circumstances preclude definitive repair.

Pediatric cardiovascular surgery repairs defects in infancy rather than palliates.[24] This trend reflects improved technical capabilities coupled with a desire to limit the morbidity and mortality associated with long-term medical management and the sequelae of multiple palliative operations. Early correction should decrease the incidence of the chronic complications of CHD, such as the problems associated with ventricular overload, cyanosis, and pulmonary vascular obstructive disease.[23] Early repair also may have the selective advantage of enhancing organ system protection during repair because of poorly understood factors promoting resistance to injury and enhanced recovery potential (i.e., enhanced plasticity). With the continued improvement in surgical techniques and the early treatment of CHD, specific organ systems such as the brain, heart, and lungs will be spared the detrimental effects of chronic derangements of hemodynamics and O_2 delivery.

Procedures for the treatment of CHD continue to evolve to decrease long-term morbidity and enhance survival. For example, the long-term problems with right ventricular dysfunction and failure associated with the Mustard procedure for repair of TGA encouraged many surgical groups to develop the neonatal arterial switch operation. The latter procedure probably provides an anatomic correction with better long-term results. A second example of the continuing evolution of technique is surgery for TOF. Long-standing pulmonary insufficiency after right ventricular outflow repair for TOF is associated with right ventricular dysfunction and failure. Preservation of the pulmonary valve at initial repair using a combined transatrial and transpulmonary approach during correction and the early insertion of a pulmonary homograft in the setting of pulmonary insufficiency are techniques being used in an attempt to avoid the long-term problems of right ventricular dysfunction and failure.[24] Similarly, nonsurgical procedures in the cardiac catheterization laboratory continue to develop to treat patients who may be poor surgical candidates. Patients presenting with right ventricular dysfunction or failure secondary to valveless right ventrical–to–pulmonary artery (RV-PA) conduits used in the palliation of TOF show improved outcomes from a transcatheter pulmonary valve.[25] The benefits include avoidance of a repeat sternotomy with an enlarged RV and CPB.

Surgery for hypoplastic left heart syndrome, once considered a fatal disease, has achieved significant long-term survival after a series of staged reconstructive procedures.[26,27] The use of RV-PA conduits as an alternative to traditional systemic-to-pulmonary shunts has been shown to confer some advantage in survival after stage 1 palliation owing to elimination of diastolic runoff into the pulmonary circulation with concurrent unloading of the systemic RV. Myocardial perfusion improves with higher diastolic pressures, lower aortic saturations, and decreased myocardial work. The long-term impact of a right ventriculotomy in a univentricular heart is unknown.[28-30] In 2008, the Pediatric Heart Network, an organization sponsored by the National Institutes of Health, completed enrollment in a randomized control trail comparing the effects of modified Blaylock Taussig shunt (mBTS) to RV-PA conduits as part of the stage 1 Norwood procedure.[31] Recent results revealed infants treated with an RV-PA shunt had improved survival over those with mBTS, although the long-term outcomes were not different.[31,32] The use of a low-resistance strategy provides a stable postoperative course with use of vasodilators such as phenoxybenzamine on CPB and optimal reduction of PVR with inhaled nitric oxide (NO) and 100% O_2 after CPB.[33,34]

Several factors considered to be associated with an increased risk for single ventricle palliation include anatomic variants such as aortic atresia, mitral atresia, ascending aorta less than 2.0 to 2.5 mm, restrictive atrial septum, obstructed pulmonary venous return, the presence of other congenital anomalies, prematurity, birth

weight less than 2.5 kg, older age at time of surgery (>14 days), surgical inexperience, and prolonged CPB and arrest times. Perioperative factors can adversely affect outcome and include preoperative metabolic acidosis, preoperative inotrope support, morphologic RV in the systemic circuit, right ventricular dysfunction, presence of severe tricuspid regurgitation, pulmonary valve regurgitation (beyond mild), and low mixed venous oxygen saturation ($S\bar{v}O_2$) (<30%) after a Norwood procedure.[35-41] Neurologic outcome after surgical repair is an ongoing concern. Preoperative cerebral blood flow (CBF) was shown to be diminished in patients with a variety of congenital heart defects, and low CBF values were associated with periventricular leukomalacia.[42] Some centers routinely advocate regional low-flow cerebral perfusion and measurement of regional cerebral O_2 saturation index and CBF velocity using transcranial Doppler imaging during arch reconstruction in this population. Reductions in the regional cerebral O_2 saturation index or CBF greater than 20% of baseline are treated aggressively in an attempt to increase cerebral O_2 delivery by increasing the mean perfusion pressure, red blood cell (RBC) transfusion, and maintenance of high normal levels of $Paco_2$ to achieve cerebral vasodilation.

Surgical management has evolved in a broader application of certain surgical procedures initially designed for a specific defect. For example, modifications of the Fontan operation, which was originally devised for patients with tricuspid atresia, are now being used to repair a variety of univentricular hearts, including hypoplastic left heart syndrome.[43,44] Initially, the wider application of the Fontan operation to include complex defects once considered inoperable was associated with a rise in morbidity and mortality. However, this trend has been reversed in recent years by several groups who have demonstrated improved outcome with the staging of the operation (superior cavopulmonary anastomosis, subsequent completion of the Fontan operation), the creation of a fenestration between the RA and LA at the time of the Fontan operation, and the use of modified ultrafiltration (MUF) at least in the early years.[45] The communication allows for right-to-left shunting, thereby preserving cardiac output at lower systemic venous pressure in the early postoperative period. When necessary, once the patient has convalesced from the acute postoperative changes, the fenestration can be closed at the bedside with a snare placed at the time of the operation or in the catheterization laboratory with a clamshell device. In a substantial proportion of cases, these fenestrations close spontaneously without further intervention. However, as these patients grow older, they present with the unique pathophysiologic challenges of refractory arrhythmias, the failing single ventricle, protein-losing enteropathy, and plastic bronchitis. Most of these adults are cared for in a combined pediatric and adult cardiac program and require intensive multidisciplinary care to optimize cardiorespiratory status. Ingenuity and innovation such as demonstrated with the difficult Fontan procedure have permitted continued improvements in survival for all patients with CHD. As incisions in the myocardium become smaller and sutures more precisely placed, and as improvements in surgical techniques continue to evolve, the complications of ventricular dysfunction, arrhythmias, and residual obstruction should decline, contributing to improved patient quality of life.

One final difference unique to congenital heart surgery that has a major impact on anesthetic management relates to the type of cardiopulmonary support. Because of the complexity of repair in small patients, surgery often requires significant alterations in the bypass techniques, such as the use of deep hypothermic CPB at temperatures of 18° C and total circulatory arrest. Many operations are undertaken in this setting of extreme biologic conditions of temperature and perfusion. Current methods of CPB management in neonates, infants, and children involve extensive alterations in temperature, hemodilution, systemic perfusion pressure, and flow. Despite widespread use of these techniques during CPB, their physiologic effects on major organ system function are just beginning to be understood. These effects are discussed in subsequent sections.

In summary, unique features in caring for children with CHD who are undergoing pediatric cardiac surgery must be considered. These features include the patient's growth and development, the developing cardiovascular system of the young, the pathophysiology of CHD, the surgical procedures, and the CPB techniques. A basic understanding of these differences coupled with the fundamental knowledge of adult and pediatric cardiac anesthesia principles underlies the approach to successful perioperative management of these patients.

ANESTHETIC MANAGEMENT

PREOPERATIVE MANAGEMENT

Anesthetic Evaluation

Caring for children with CHD presents the anesthesiologist with a wide spectrum of anatomic and physiologic abnormalities (see also Chapter 96). Patients range from young, healthy, asymptomatic children who are having closure of a small ASD to the neonate with hypoplastic left heart syndrome requiring aggressive perioperative hemodynamic and ventilatory support. Intertwined with the medical diversity of these patients are the psychological factors affecting both the patient and the parents. Preparation of the patient and the family is time-consuming, but omitting or compromising this aspect of patient care is a major deterrent to a successful outcome and patient and parental satisfaction. This team-oriented approach also serves as a safeguard to prevent errors and omissions in the exacting perioperative care necessitated by the complexity of cardiac surgery for CHD. The preoperative visit offers the family the opportunity to meet the surgeon and anesthesiologist.

Parents should be questioned about the general health and activity of their child. Fundamentally, a child's general health and activity will reflect cardiorespiratory reserve. Deficiencies may point toward cardiovascular or other systems that may influence anesthetic or surgical risk. Whether the child has an impaired exercise tolerance is important. Is the child gaining weight appropriately or exhibiting signs of failure to thrive on the basis of cardiac cachexia? Does the child exhibit signs of CHF

TABLE 94-5 **COMMON PERIOPERATIVE MEDICATIONS AND CONSIDERATIONS**

Cardiac Drug Class	Interactions	Considerations
Angiotensin-converting enzyme inhibitors	Hypotension with induction of general anesthesia	Consider withholding morning dose, or reducing dosage, in hypotensive patients; avoid fixed dose induction regimens with drugs having a profound vagomimetic effect
β-Blockers	Acute withdrawal can precipitate tachycardia and arrhythmias; can potentiate hypotension with volatile anesthesia; can decrease response to inotropic agents	Continue in the perioperative period
Calcium channel blockers	May augment the negative inotropic and chronotropic effects of volatile anesthesia	Continue in the perioperative period
Diuretics	Hypovolemia/hypokalemia; may augment effect of neuromuscular blocking agents	Discontinue preoperatively
Antiarrhythmics	Can be proarrhythmic with inotropes, electrolyte disturbances; high catecholaminergic states; can interact with other antiarrhythmics and precipitate bradycardia	Avoid electrolyte imbalance Avoid drugs that are proarrhythmic Monitor carefully
α_2-Agonists	Reduces perioperative shivering, ischemia, anesthetic and analgesic requirements	Continue into the perioperative period with appropriate monitoring

(diaphoresis, tachypnea, poor feeding, recurrent respiratory infections)? Is there progressive cyanosis or new onset of cyanotic spells? Any intercurrent illness such as a recent upper respiratory tract infection or pneumonia must be ascertained. Lower respiratory tract infections may require a delay in proposed surgery, based on the negative impact that airway reactivity and elevations in PVR may have on surgical outcome. Recurrent pneumonia is frequently associated with pulmonary overcirculation and altered lung compliance in patients with increased PBF.

A good history must delineate previous surgical and cardiologic interventions. These may have an impact on both surgical and anesthetic plans for the current procedure. Patients who have had their subclavian artery sacrificed for a subclavian flap angioplasty to correct coarctation or a Blalock-Taussig shunt will not accurately display systemic arterial pressure or perhaps even pulse oximetry readings when the monitoring is applied to the left arm. Likewise, children who have femoral venous occlusion after catheterization are not candidates for femoral venous access, particularly for femoral CPB should sternotomy prove impossible. It is equally important to ascertain current medications, previous anesthetic problems, and family history of anesthetic difficulties.

In the modern era of echocardiography and cardiac catheterization, physical examination rarely contributes additional anatomic information about the underlying cardiac lesion. However, it is extremely useful in assessing the overall clinical condition of the child. For example, an ill-appearing, cachectic child in respiratory distress has limited cardiorespiratory reserve and the use of excessive premedication or a prolonged inhaled induction of anesthesia could result in significant hemodynamic instability.

Concurrent Medications and Drug Interactions

Drug interactions are common both among the cotherapeutic cardiovascular agents and between cardiovascular drugs and anesthetic drugs (see also Chapter 93). An understanding of the mechanisms and of the interactions is useful to the pediatric cardiovascular anesthesiologist. Some common cardiovascular medications and anesthesia considerations are shown in Table 94-5.

Pediatric oncology patients presenting for cardiac or noncardiac procedures may manifest higher cardiovascular risk because of cardiotoxic chemotherapy.[46] Common cardiotoxic agents include the antimetabolite 5-fluorouracil, the anthracycline antibiotics doxorubicin and daunorubicin, and the alkylating agent cyclophosphamide. The acute form of toxicity is characterized by acute ST segment/T wave changes on the electrocardiogram (ECG), serious dysrhythmias, and CHF associated with pericardial effusion. Chronic cardiotoxic heart failure is cumulative, dose related, and unresponsive to digoxin therapy. Serious cardiomyopathy can occur and is related to dose, irradiation, and use of an anthracycline. The mortality rate can exceed 50%. These patients should undergo thorough preoperative evaluation, including a full blood cell count, assessment of renal and hepatic function and coagulation parameters, and an echocardiogram. An isoflurane/nitrous oxide (N_2O)-based anesthetic might confer better hemodynamic stability than opioid-based anesthesia in such patients.[47]

Anesthetics can cause torsade de pointes, a malignant arrhythmia. Risk factors for torsade de pointes include female gender, electrolyte imbalances such as hypokalemia and hypomagnesemia, genetic ion channel polymorphisms of congenital long QT syndrome (LQTS), subclinical LQTS, baseline QT prolongation, and use of QT-prolonging drugs especially in high concentrations or as rapid intravenous infusions. Conditions with reduced repolarization reserve such as CHF or digoxin toxicity can precipitate torsade de pointes. Drugs that may cause torsade de pointes in patients with congenital LQTS are shown in Table 94-6. The website http://www.qtdrugs.org provides an updated list of drugs that prolong the QT interval.

Laboratory evaluation should include analysis of hemoglobin, hematocrit, pulse oximetry, and, in selected patients (e.g., those on diuretics or with renal impairment), serum electrolytes. An increased hematocrit in a normovolemic child gives an indication of the magnitude and chronicity of hypoxemia. A hematocrit

TABLE 94-6 DRUGS THAT MAY CAUSE TORSADE DE POINTES IN PATIENTS WITH CONGENITAL LONG QT SYNDROME

Drug Category	Drug Name
Antiarrhythmics	Amiodarone
	Procainamide
	Disopyramide
	Ibutilide
	Quinidine
	Sotalol
Antipsychotics	Chlorpromazine
	Haloperidol
	Thioridazine
	Mesoridazine
Antimicrobials	Erythromycin
	Clarithromycin
Miscellaneous	Cisapride
	Arsenic
	Methadone
	Droperidol
	Domperidone
	Dolasetron
	Ondansetron
	Glycopyrrolate

more than 60% may predispose to capillary sludging and secondary end organ damage, including stroke. Despite these risks, liberalized guidelines for nothing by mouth that permit children to consume clear liquids up to 2 hours before anesthetic induction have virtually eliminated the need to admit these patients to the hospital early for preoperative intravenous hydration.[48,49]

Echocardiography with Doppler color flow imaging (echo-Doppler) is an invaluable tool that provides a noninvasive means of assessing intracardiac anatomy, blood flow patterns, and estimates of physiologic data.[50] For many cardiac defects, more invasive studies are generally not required if a good echocardiographic assessment is made. Echo-Doppler imaging is especially helpful for defining intracardiac abnormalities. Extracardiac abnormalities, such as pulmonary artery or vein stenosis, are more difficult to define by echo-Doppler and often require cardiac catheterization. The ability to interpret anatomy and physiology accurately requires a skilled echocardiographer, reaffirming the need for a well-integrated interactive team. Although the complexities posed by extreme anatomic variation and changing loading conditions render intraoperative echo-Doppler challenging even for experienced echocardiographers, the pediatric cardiac anesthesiologist should develop some familiarity with its capabilities and limitations so as to participate in critical intraoperative management decisions.

Magnetic resonance imaging (MRI) of the heart and major vessels has become a very useful noninvasive imaging tool in children with heart disease (see also Chapter 90). Typically, MRI is used for segmental description of cardiac anomalies; evaluation of thoracic aortic anomalies; noninvasive detection and quantification of shunts, stenoses, and regurgitations; evaluation of conotruncal malformations and complex anomalies; identification of pulmonary and systemic venous anomalies; and postoperative studies and evaluation of CHD in adult patients.[51] MRI is particularly useful in quantifying ventricular function, regional wall motion, valvular competence, and velocity flow mapping. It is especially useful for imaging the aortic arch, pulmonary arteries, and the mediastinal vessels in children with complex CHD. Lesions for which MRI provides accurate and useful information include coarctation of the aorta, anomalies of the pulmonary arteries, anomalous pulmonary venous connections and persistent left superior vena cava, and intracardiac baffles, conduits, and shunts. MRI is also useful in older patients with poor acoustic windows and patients with chest wall deformities.[51] It can be used as an alternative to cardiac catheterization in select patients. More recent developments have enabled the use of MRI to provide noninvasive assessment of coronary anomalies, myocardial perfusion defects, and the detection of conditions associated with myocardial scarring (e.g., arrhythmogenic RV dysplasia). These scans are prolonged and require absolute patient immobility, with control of ventilator parameters to obtain optimal images. Adenosine stress cardiac MRI is used to delineate areas of inducible ischemia. However, physiologic data such as O_2 saturations cannot be obtained with MRI. Anesthetic considerations remain the same as for all cardiac lesions, with the additional concerns for MRI safety and restricted access to an anesthetized patient with suboptimal monitors.

Cardiac catheterization remains the gold standard for assessing anatomy and physiologic function in CHD. Although many anatomic questions can now be reliably answered noninvasively, cases that present complex anatomic questions or those for which physiologic data are required, catheterization remains a vital tool. Important catheterization data for the anesthesiologist include the following:

1. Child's response to sedative medications
2. Pressure and O_2 saturation in all chambers and great vessels
3. Location and magnitude of intracardiac and extracardiac shunt ($\dot{Q}p/\dot{Q}s$)
4. PVR and SVR
5. Chamber size and function
6. Valvular anatomy and function
7. Distortion of systemic or pulmonary arteries related to prior surgery
8. Coronary artery anatomy
9. Anatomy, location, and function of previously created shunts
10. Acquired or congenital anatomic variants that might have an impact on planned vascular access or surgery

Careful review of the cardiac catheterization data and an understanding of their potential impact on the operative and anesthetic plan are essential. Not all the medical problems can be evaluated and corrected preoperatively; the surgeon, cardiologist, and anesthesiologist must discuss the potential management problems and any need for further evaluation or intervention before arrival in the operating room. Appropriate communication and cooperation between the two physicians will optimize patient care and facilitate perioperative clinical management. Typically, institutions have a regularly scheduled

combined cardiology and cardiac surgery meeting to discuss candidates for surgery, during which all essential information is displayed and discussed. Such a meeting provides an invaluable opportunity for learning about specific patients proposed for surgery and a continuing educational forum that promotes an interdisciplinary exchange directed at contemporary concepts in CHD and its treatment, both medical and surgical.

Premedication

See Chapter 93.

INTRAOPERATIVE MANAGEMENT

Operating Room Preparation

Advance, careful preparation of the operating room is essential (see also Chapter 92). The anesthesia machine must have the capacity to provide air, O_2, carbon dioxide (CO_2), NO, and N_2O to help balance pulmonary and systemic blood flow. Intravenous tubing must be free from air bubbles to prevent paradoxical air embolism. Resuscitative drugs, labeled and ready for administration, should include succinylcholine, calcium gluconate or calcium chloride, sodium bicarbonate, atropine, phenylephrine, lidocaine, and epinephrine. An inotropic infusion, usually dopamine, should be premixed and ready for administration in high-risk cases, but additional infusions are prepared if their need is strongly suspected. For all pediatric cases, certain anesthetic drugs should be available (etomidate, propofol, ketamine). In pediatric cardiac anesthesia, many patients have limited reserve and high endogenous catecholamine levels released in an adaptive response to their underlying cardiac disease. The resuscitative drugs should therefore be prepared and immediately available before anesthetic induction.

For congenital heart surgery, the ability to alter body temperature rapidly for cooling and rewarming is essential. During deep hypothermic CPB, patients are cooled to 18° C. Surface cooling with a heating and cooling water mattress and an efficient room and ambient temperature control system are important in the operative management of these patients (also see Chapter 54).

Physiologic Monitoring

The specific monitoring used should depend on the child's condition and the magnitude of the planned surgical procedure. The perioperative monitoring techniques available are listed in Box 94-2. Noninvasive monitoring equipment is placed before induction of anesthesia. In the crying pediatric patient, the anesthesiologist may elect to defer application of monitoring devices until immediately after the induction of anesthesia. Standard monitoring includes an electrocardiographic system, pulse oximetry, capnography, precordial stethoscope, and an appropriate-sized blood pressure cuff (either oscillometric or Doppler). Additional monitoring includes an indwelling arterial catheter, temperature probes, and an esophageal stethoscope. Foley catheters are generally employed when surgical intervention entails CPB or might produce renal ischemia or when the anesthetic management includes a regional technique associated with urinary retention.

BOX 94-2 *Monitoring of Organ Systems*

Cardiopulmonary System

Esophageal stethoscope
Electrocardiogram
  Standard seven-lead system, ST-T wave analysis, esophageal electrocardiographic lead
Pulse oximetry
Automated oscillatory blood pressure
Capnograph
Ventilator parameters
Indwelling arterial catheter
Central venous pressure catheter
Pulmonary artery catheter
Transthoracic pressure catheter
  Left or right atrium, pulmonary artery
Echocardiography with Doppler color flow imaging
  Epicardial or transesophageal

Central Nervous System

Peripheral nerve stimulator
Processed electroencephalography
Specialized
  Cerebral blood flow: Xenon clearance methodology
  Cerebral metabolism: Near-infrared spectroscopy, oxygen consumption measurements
  Transcranial Doppler
  Jugular venous bulb saturations

Temperature

Nasopharyngeal, rectal, esophageal, tympanic

Renal Function

Foley catheter

Some centers routinely employ central venous pressure (CVP) monitoring for major cardiovascular surgery. Alternatively, we typically use directly placed transthoracic atrial lines to obtain that information for separation from CPB and the postoperative period. In that setting, the benefits of the information or access provided by percutaneous CVP catheters in the prebypass period must be weighed against the risks they pose.

Continuous monitoring of arterial pressure is possible only through an indwelling intraarterial catheter. In young children, cannulation of the radial artery with a 22- or 24-gauge catheter is preferred. In older children and adolescents, a 20-gauge catheter may be substituted. Careful inspection, palpation, and four-extremity noninvasive blood pressure determinations help ensure that previous or currently planned operative procedures (e.g., a previous radial artery cutdown, subclavian flap for coarctation repair, or Blalock-Taussig shunt) do not interfere with the selected site of arterial pressure monitoring. Other sites available for cannulation include the ulnar, femoral, axillary, and umbilical (in neonates) arteries. Cannulation of the posterior tibial or dorsalis pedis arteries is not usually sufficient for complex operative procedures. Peripheral arterial catheters, principally of the distal lower extremities, function poorly after CPB and do not reflect central aortic pressure when distal extremity temperature remains low.[52]

Myocardial and cerebral preservation is maintained principally through hypothermia; therefore, the accurate

and continuous monitoring of body temperature is crucial. Rectal and nasopharyngeal temperatures are monitored because they reflect core temperature and brain temperature, respectively. Monitoring of esophageal temperature is a good reflection of cardiac and thoracic temperature. Tympanic probes, although a useful reflection of cerebral temperature, can cause tympanic membrane rupture.

Pulse oximetry and capnography provide instantaneous feedback concerning adequacy of ventilation and oxygenation. They are useful guides in ventilatory and hemodynamic adjustments to optimize $\dot{Q}p/\dot{Q}s$ before and after surgically created shunts and pulmonary artery bands. Peripheral vasoconstriction in patients undergoing deep hypothermia and circulatory arrest renders digital O_2 saturation probes less reliable. In the newborn, the use of a tongue sensor has been advocated to provide a more central measure of O_2 saturation, with less temperature-related variability.[53]

The use of transthoracic (in the RA, LA, pulmonary artery) or transvenous pulmonary artery catheters is determined on an individual basis based on the disease process, physiologic state, and surgical intervention. For example, in children undergoing a Fontan procedure for tricuspid atresia or a univentricular heart, catheters in the Fontan pathway and the pulmonary venous atrium are especially useful. After a Fontan operation, PBF must occur without benefit of a ventricular pumping chamber. Subtle changes in preload, PVR, and pulmonary venous pressure will influence PBF and thus systemic cardiac output. Data derived from systemic venous pressure and left atrial pressure (LAP) help identify the relative importance of intravascular volume (CVP), PVR (CVP-LAP gradient), or ventricular compliance (LAP), each of which requires a different therapeutic approach.

As a general guideline, a transvenous pulmonary artery catheter may be placed using the internal jugular approach in children weighing more than 7 kg. A 5.0-Fr catheter is used for children weighing between 7 and 25 kg, and a 7.0-Fr one is used for children weighing more than 25 kg. For infants weighing less than 7 kg, percutaneous placement of a pulmonary artery catheter can be performed from the femoral vein. Occasionally, the latter technique will require fluoroscopy. The use of intraoperative transthoracic monitoring lines and echo-Doppler imaging limits the need for transvenous pulmonary artery catheters in most cases.

Special Monitoring

Intraoperative Echocardiography. Of the newer techniques available for monitoring patients during pediatric cardiovascular surgery, the most promising is echo-Doppler imaging (see also Chapter 46). Several reports have described the usefulness of intraoperative echo-Doppler imaging during congenital heart surgery.[54-56] Two-dimensional echocardiography combined with pulsed-wave Doppler ultrasonography and color flow mapping is able to provide detailed morphologic as well as physiologic information in the majority of operative cases. Using echo-Doppler in the operating room, anatomic and physiologic data can be obtained before CPB, thus refining the operative plans. Prebypass echo-Doppler precisely defines anesthetic and surgical management.[9,54] Because of the unrestricted epicardial and transesophageal echocardiography (TEE) approaches in anesthetized patients, new findings are frequently discovered and management plans changed accordingly (Fig. 94-4).

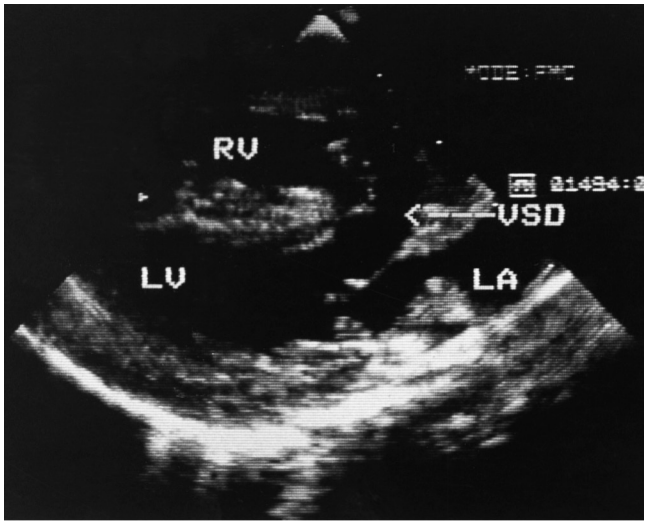

Figure 94-4. Intraoperative pre–cardiopulmonary bypass epicardial echocardiogram in the long-axis view. Note the insertion of the papillary muscle of the tricuspid valve on the interventricular septum. On the basis of this view, the surgeon decided that ventricular septal defect (VSD) closure was possible in a child thought preoperatively to be a candidate for only palliation. *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle. (See also Chapter 46.)

Postbypass echo-Doppler evaluation is able to immediately assess the quality of the surgical repair and assess cardiac function by examining ventricular wall motion and systolic thickening.[9,54] This technique can show residual structural defects after bypass, which can be immediately repaired in the same operative setting and avoids leaving the operating room with significant residual structural defects that will require reoperation at a later time (Fig. 94-5). By identifying patients with new right ventricular and left ventricular contraction abnormalities after bypass, as determined by a change in wall motion or systolic thickening, echo-Doppler provides guidance for immediate pharmacologic interventions. Importantly, postbypass ventricular dysfunction and residual structural defects identified by echo-Doppler imaging are associated with an increased incidence of reoperation and higher morbidity and mortality rate.[57] Thus, this monitoring tool is helpful in assessing surgical outcome and identifying operative risk factors, which will hopefully improve outcomes.

Two techniques for intraoperative echo-Doppler imaging have been described: epicardial and transesophageal echocardiography. Using TEE, the probe is placed after induction of anesthesia and intubation and is then available for monitoring of the patient (see also Chapter 46). The advantage of this technique is its utility as a continuous monitor of cardiac structure and function, without interrupting surgery.[9,58] Because of its ideal imaging location, TEE has been especially helpful in evaluating pulmonary venous return and the integrity of the left AV valve after mitral valvuloplasty, complete AV valve repair, and correction of complex CHD. Early limitation in views

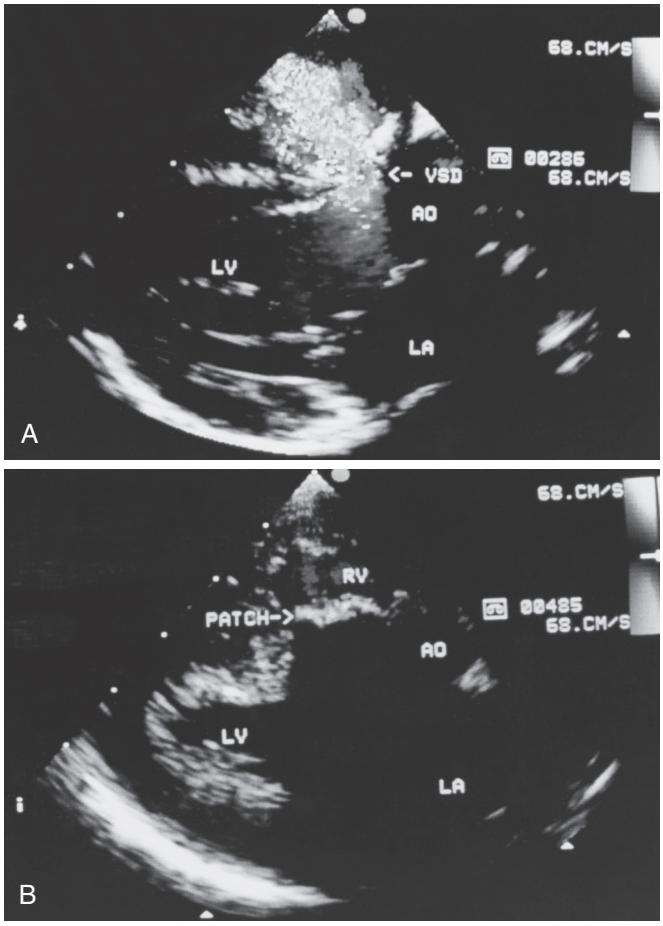

Figure 94-5. A, Echocardiogram with a Doppler flow map in the long-axis view illustrating a residual ventricular septal defect (*VSD*) resulting from patch dehiscence after initial repair. Turbulent flow through the VSD appears as a mosaic of white particles (*arrow*). This finding necessitated immediate reinstitution of cardiopulmonary bypass and repeat repair. **B,** Repeat Doppler flow map in the long-axis view illustrates patch closure (*arrow*) of the VSD after repeat repair. Note the absence of turbulent flow with the loss of the mosaic of white particles. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

has been virtually eliminated as a result of clinical experience and improved biplane images. Pediatric biplane TEE probes have now extended the patient weight limits to neonates between 2.5 and 3 kg.[59] Potential hazards of TEE that merit particular vigilance include descending aorta and airway compression because of probe size or during probe flexion. If TEE is indicated before repair, the probe is removed during the procedure because of concerns about esophageal damage during hypothermia and low or no flow states.

A second technique for intraoperative echocardiographic analysis in children is the epicardial approach.[54,59] This approach requires passing a clean, short-focused 5.0- or 7.0-MHz transducer over the anesthesia screen into a sterile sheath, where it then can be placed on the epicardial surface of the heart. This technique best facilitates the probe manipulations necessary for thorough interrogation of the major structures and dynamic function of the heart. The advantage of this approach is that all views can be obtained in patients of any size. Among the disadvantages are the need for sufficient operator skill and experience to perform the manipulations, the need to interrupt surgery to manipulate the probe, and the possible deleterious impact of direct myocardial mechanical manipulation.[57] With the current TEE capabilities, epicardial imaging is rarely employed.

Specialized Central Nervous System Monitoring. The primary goal of brain monitoring is to improve our understanding of cerebral function and dysfunction during cardiac surgery so that effective brain protection strategies can be developed. Because many of the determinants of normal brain perfusion become externally controlled by the cardiac team during CPB, such as flow rate (cardiac output), perfusion pressure, temperature, hematocrit, and $Paco_2$, a knowledge of the effect of these factors on the brain in neonates, infants, and children is essential. Furthermore, the examination of the brain under unusual biologic circumstances, such as after deep hypothermic circulatory arrest (DHCA) or during continuous-flow CPB at deep hypothermia (18° C), permits a unique opportunity to describe cerebrovascular physiology and pathophysiology. Numerous intraoperative techniques have been used for monitoring the brain to prevent secondary brain injury from hypoxia, ischemia, emboli, and electrophysiologic derangements (see Chapter 49). These have primarily included the following three modalities in isolation or combination: (1) near-infrared spectroscopy (NIRS) to provide a measure of venous-weighted, tissue oxyhemoglobin saturation; (2) transcranial Doppler imaging to measure arterial flow and resistance; and (3) electroencephalography (EEG) to assess perfusion-related changes in cortical activity.[60] Additionally, the measurement of CBF and metabolism with specialized clinical research tools has been very important in furthering our understanding of brain function during and after surgery. Multimodal neurologic monitoring is also used to guide the conduct of CPB, DHCA, and regional low-flow cerebral perfusion techniques in neonatal arch reconstruction.[61-63]

Electroencephalographic monitoring allows detection of ischemia or recognition of an adequate decrease in cerebral metabolic activity during hypothermia before DHCA. EEG is helpful in monitoring physiologic functions of the CNS during deep hypothermic bypass and total circulatory arrest. For example, during deep hypothermia and before total circulatory arrest, the processed EEG can identify residual cerebral electrical activity. Isoelectric silence can then be induced by further cooling and any further brain activity detected by EEG. Because this residual electrical activity during arrest is associated with ongoing cerebral metabolism, an isoelectric state may prevent ischemic injury to the brain during circulatory arrest. EEG also may be useful in detecting the level and depth of anesthesia. Postoperative electroencephalographic analysis has demonstrated subclinical seizure activity in a number of high-risk patients, potentially linking these abnormalities to poorer neuropsychologic outcome. The value of intraoperative electroencephalographic monitoring after CPB and the significance of the findings remains to be determined.

Transcranial Doppler imaging has been used primarily for research purposes in infants and allows detection

of venous or arterial flow abnormalities and the detection of microemboli.[64] This technology uses the Doppler principle to detect shifts in the frequency of reflected signals from blood in the middle cerebral artery to calculate blood flow velocity.[65] Because the diameter of this large cerebral artery is relatively constant, flow velocity should approximate that of CBF. Transcranial Doppler imaging has several advantages: (1) it is noninvasive, (2) it does not require radiation exposure, and (3) it is a continuous monitor. An additional advantage of this technique is the capability of assessing rapid alterations in blood flow velocity caused by temperature or perfusion changes, as commonly occur during cardiac surgery. The limitations of transcranial Doppler monitoring include (1) reproducibility, especially at low flow rates, when minute movement of the patient's head can dramatically alter signal intensity and alter baseline measurements, and (2) the lack of validating studies during hypothermic CPB, when temperature, reduced flow rates, and the laminar flow characteristics of nonpulsatile perfusion may limit the accuracy of CBF velocity measurements. CBF velocity measurements by TCD have reasonable correlation with more standard measures of CBF during normothermia, and some studies have examined its validity during hypothermic CPB.[66]

Transcranial Doppler imaging has been used to investigate the effect of CPB and DHCA on cerebral hemodynamics in children, as well as to assess the incidence of cerebral emboli. Recent studies examining the brain using TCD have enabled several investigative groups to provide important information regarding questions of normal and abnormal brain perfusion during cardiac surgery in children. Questions regarding cerebral perfusion pressure, autoregulation, effect of $Paco_2$, and temperature have been addressed using transcranial Doppler imaging in children and are discussed subsequently.[66-68] This technique also has provided qualitative information regarding the presence of gaseous emboli in the middle cerebral artery during cardiac surgery.[69] Quantification of this important mechanism of cerebral injury during cardiac surgery would be instructive. Future investigations using transcranial Doppler should address this mechanism of injury, as well.

Centers with excellent outcomes may report "never" or "always" using NIRS during the perioperative care of neonates with CHD. Given that cerebral NIRS values have been shown to correlate with jugular venous bulb saturations, the interest in using NIRS as a way to noninvasively assess O_2 delivery to the brain is sensible.[70] Austin and associates reported the value of monitoring cerebral NIRS intraoperatively. They noted that cerebral oxyhemoglobin desaturation accounted for a majority of neurophysiologic abnormalities during multimodality neuromonitoring using NIRS, transcranial Doppler, and EEG.[71] Over two thirds of the patients in their study had detectable neuromonitoring events, and a similar percentage of these events required intervention by the perfusionist, surgeon, or anesthesiologist. Surgical interventions, such as cannula repositioning, were performed in one fourth of the events, and the perfusionist intervened in over half of the events. The incidence of postoperative neurologic sequelae was also higher in those patients who had untreated events. During some specific surgical techniques, such as regional cerebral perfusion, NIRS monitoring may be of benefit in guiding intraoperative care.[72,73] However, improved neurodevelopmental outcomes postoperatively has not been demonstrated.

CBF studies using xenon clearance technology have improved the understanding of cerebrovascular dynamics in young children during CPB and especially during deep hypothermia and after periods of circulatory arrest.[74-77] In general, this investigational tool has described the effects of CPB, temperature, and various perfusion techniques on CBF and, indirectly, on brain metabolism (Fig. 94-6). Studies using this methodology have shown that some of the mechanisms of CBF autoregulation, such as pressure-flow regulation, are lost with deep hypothermia and that cerebral reperfusion is impaired after a period of total circulatory arrest.

Induction and Maintenance of Anesthesia

The principles of intraoperative management of cardiothoracic surgical procedures are based on an understanding of the pathophysiology of each disease process and a working knowledge of the effects of the various anesthetic and other pharmacologic interventions on a particular patient's condition (see also Chapter 92). Selecting a technique for induction of anesthesia depends on the degree of cardiac dysfunction, the cardiac defect, the degree of sedation provided by the premedication, and the presence or absence of an indwelling catheter. In children with good cardiac reserve, induction techniques can be quite varied in well-monitored patients. The titration of anesthetics for induction of anesthesia is more important than the specific anesthetic technique in patients

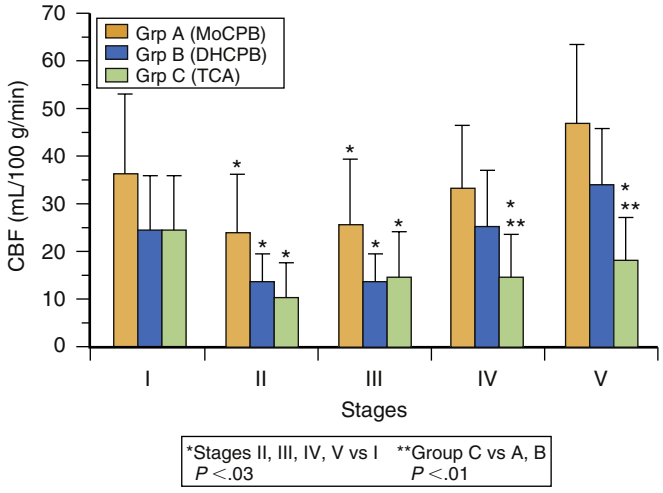

Figure 94-6. Bar chart of the changes in cerebral blood flow (*CBF*) before, during, and after cardiopulmonary bypass (*CPB*) in 67 infants and children (mean ± SD). Group A underwent repair with moderate hypothermic bypass (*MoCPB*) at 28° to 32° C; group B, with deep hypothermic bypass at 18° to 22° C; and group C, with total circulatory arrest (*TCA*) at 18° C. Note the impaired cerebral reperfusion after total circulatory arrest (group C). Stage I, prebypass; stages II and III, during hypothermic bypass; stage IV, rewarmed on bypass; stage V, after bypass. *(From Greeley WJ, Brusino FG, Ungerleider RM, et al: The effects of cardiopulmonary bypass on cerebral blood flow in neonates, infants, and children,* Circulation *80:I209, 1989.)*

with reasonable cardiac reserve. A wide spectrum of anesthetic induction techniques have been used safely and successfully, such as sevoflurane, isoflurane, and N_2O; intravenous and intramuscular ketamine; and intravenous propofol, fentanyl, and midazolam.[78] For neonates undergoing open-heart surgery, opioid-relaxant inductions are most prevalent, whereas older children with sufficient cardiac reserve typically receive inhaled inductions with either sevoflurane or halothane. Ketamine is often used in anesthetic induction in patients with cyanotic conditions because it increases SVR and cardiac output, thereby diminishing the magnitude of right-to-left shunting. Administration of ketamine can be intravenous or intramuscular. An intramuscular injection may result in pain, agitation, and subsequent arterial desaturation.

Inhaled inductions are generally well received and tolerated by most children. An inhaled induction of anesthesia with sevoflurane can easily and safely be performed even in cyanotic patients, such as those with TOF (Fig. 94-7). In these patients, who are at risk for right-to-left shunting and systemic desaturation, oxygenation is well maintained with a good airway and ventilation despite halothane-induced reduction in systemic arterial pressure.[79] Skilled airway management and efficiency of ventilation are equally essential components of anesthetic induction. Yet the complexities of shunts and vascular resistance changes, as well as airway and ventilation effects on the cardiovascular system, are of primary importance during the induction of anesthesia.

After anesthetic induction, intravenous access is established or augmented as appropriate. A nondepolarizing muscle relaxant is usually administered and an intravenous opioid or inhaled anesthetic or both chosen for maintenance anesthesia. The child is preoxygenated with 100% FiO_2, and a lubricated nasal endotracheal tube is carefully positioned. A nasal tube is usually selected because in most patients who require an intraoperative TEE, postoperative mechanical ventilation, or both, a nasotracheal tube provides greater stability and patient comfort than with the oral route. Some degree of alveolar preoxygenation is recommended, even in the infant whose systemic perfusion might be jeopardized by lowering PVR with resulting increase in PBF. This maneuver delays desaturation during intubation. If the child arrives in the operating room with an endotracheal tube in place, it is our practice to change it. Inspissated secretions in a tube with a small internal diameter can cause significant obstruction to gas flow. During periods of bypass when humidified ventilation is discontinued, significant endotracheal tube obstruction can occur. This can be minimized by placing a new endotracheal tube at the beginning of the procedure.

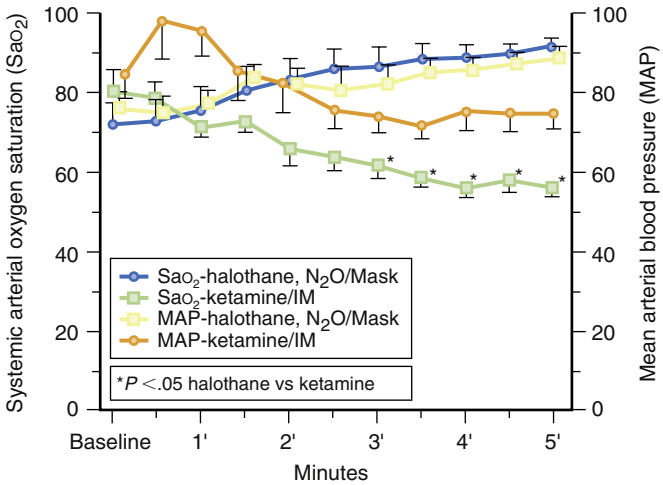

Figure 94-7. Comparative changes in arterial oxygen saturation (Sao_2) and mean arterial pressure (*MAP*) during mask halothane nitrous oxide ($n = 7$) and intramuscular ketamine ($n = 7$) inductions in children with tetralogy of Fallot (TOF) at risk for right-to-left shunting. Note the maintenance of Sao_2 in the halothane group despite the significant drop in MAP. *(From Greeley WJ, Bushman GA, Davis DP, et al: Comparative effects of halothane and ketamine on systemic arterial oxygen saturation in children with cyanotic heart disease,* Anesthesiology *65:666, 1986.)*

Because of the diverse array of congenital heart defects and surgical procedures, an individualized anesthetic management plan is essential. The maintenance of anesthesia in these patients depends on the age and condition of the patient, the nature of the surgical procedure, the duration of the CPB, and the need for postoperative ventilation. An assessment of the hemodynamic objectives designed to lessen the pathophysiologic loading conditions should be developed for each patient, taking advantage of the known qualitative effects of specific anesthetic drugs and ventilatory strategies. These individualized plans must also be integrated with the overall perioperative goals to configure the optimal anesthetic. In patients with complex defects requiring preoperative inotropic and mechanical ventilatory support, a carefully controlled hemodynamic induction and maintenance anesthetic with a potent opioid is generally chosen. In patients with a simple ASD or VSD, a potent inhaled anesthetic is preferred. This allows for early postoperative tracheal extubation and a less prolonged period of intensive care monitoring. More important than the specific anesthetic techniques and drugs is the skilled execution of the anesthetic plan, taking into account patient response to drugs, the changes associated with surgical manipulation, and early recognition of intraoperative complications.

The reported changes in arterial blood pressure and heart rate from the inhaled anesthetic in normal children are observed in pediatric cardiac surgical patients as well (see Chapter 92). Although both halothane and isoflurane decrease blood pressure in neonates, infants, and children, the vasodilatory properties of isoflurane may improve overall myocardial contractility in contrast to the effects of halothane.[80] Despite improved cardiac reserve with isoflurane, the incidence of laryngospasm, coughing, and desaturation during induction of anesthesia limits its use as an induction agent in children with congenital heart defects.[81] The use of potent inhaled anesthetics as primary anesthetics should be reserved for the child with adequate cardiovascular reserve who is a candidate for early postoperative extubation. In these patients, the myocardial depression and hypotension associated with the use of inhaled anesthetics are well tolerated. Examples include closure of an ASD or VSD, excision of a discrete subaortic membrane, pulmonic or

aortic stenosis, TOF, shunts, ligation of a PDA, and repair of coarctation of the aorta.

Desflurane has cardiorespiratory properties similar to those of isoflurane (also see Chapters 47 and 28).[82] Its main advantage is low blood gas and tissue solubility. This allows for rapid equilibration between the inspired and alveolar concentrations and rapid decrease of alveolar concentrations during elimination.[83] This provides greater precision in drug dosing during the operative period and may make desflurane a more titratable adjunctive drug for pediatric cardiac anesthesia. The three main disadvantages of desflurane are potency, pungency, and negative inotropic effect.[84,85] Studies in normal infants and children suggest that 1 minimum alveolar concentration (MAC) of desflurane requires concentrations of 8% to 10%.[86,87] Desflurane is also quite pungent, and, although its uptake is rapid, early experience with this drug for inhalation induction in children has reported a fairly high incidence of airway reactivity and laryngospasm.[87-89] Although its negative inotropic effect is significantly less potent than that of halothane, desflurane should not be used as the sole anesthetic in patients with significant cardiac dysfunction.[89]

Sevoflurane offers a more tolerable aroma without the magnitude of myocardial depression that accompanies halothane.[90] In addition, its blood gas solubility is nearly as low as that of desflurane. Hemodynamically, sevoflurane tends to produce some tachycardia, particularly in older children, and preserve systemic arterial pressure.[91] Reductions in heart rate and systemic arterial pressure are more modest in infants anesthetized with sevoflurane than in control subjects anesthetized with halothane, and the former exhibit echocardiographic evidence of normal contractility and cardiac index. This effect is particularly seen in children with trisomy 21.[92,93] Controversies continue to surround the potential toxic by-products of sevoflurane anesthesia, related to both patient metabolism and the production of compound A in the anesthesia breathing circuit. Although the importance of compound A in adult practice remains unclear, evidence suggests that production of this toxin is significantly diminished in children.[94]

Children with complex CHD and limited cardiac reserve demand an anesthetic technique that provides hemodynamic stability. Inhalation anesthetics are less well tolerated as a primary anesthetic in patients who have limited cardiac reserve, especially after CPB. Fentanyl is an excellent induction and maintenance anesthetic for this group of patients. Low-to-moderate doses of this opioid can be supplemented with inhalation anesthetics. Adding low concentrations of inhalation anesthetics to smaller doses of opioids shortens or eliminates the need for postoperative mechanical ventilation while maintaining the advantage of intraoperative hemodynamic stability. Postoperative mechanical ventilation will be required when a high-dose opioid technique is used. The hemodynamic effects of fentanyl at a dose of 25 µg/kg with pancuronium given to infants in the postoperative period after operative repair of a congenital heart defect include no change in LAP, pulmonary artery pressure, PVR, and cardiac index and a small decrease in SVR and mean arterial pressure.[95] Because of its cardiovascular effects, pancuronium was an ideal neuromuscular blocking drug for pediatric heart surgery. Unfortunately, pancuronium is no longer available for clinical use. Therefore, either vecuronium or rocuronium must be used (also see Chapter 34). Larger doses of fentanyl at 50 to 75 µg/kg with rocuronium or vecuronium doses of fentanyl at 50 to 75 µg/kg with pancuronium result in a slightly larger decrease in arterial blood pressure and heart rate in infants undergoing repair for complex congenital heart defects.[96] Despite the wide safety margin exhibited by this opioid, a selected population of infants and children with marginally compensated hemodynamic function sustained by endogenous catecholamines may manifest more extreme cardiovascular changes with these doses. Fentanyl also has been shown to block stimulus-induced pulmonary vasoconstriction and contributes to the stability of the pulmonary circulation in neonates after congenital diaphragmatic hernia repair.[97] Thus, the use of fentanyl may be extrapolated to the operating room, where stabilizing pulmonary vascular responsiveness in newborns and young infants with reactive pulmonary vascular beds is crucial to weaning from CPB and stabilizing shunt flow. Fentanyl in the 5 to 10 µg/kg dose range should provide some analgesia, but still sufficient ventilation to allow for postoperative extubation with stable hemodynamics during the procedure.

Historically, sufentanil and pancuronium have provided the same cardiovascular stability as with fentanyl and pancuronium in pediatric cardiovascular patients. As previously indicated, the lack of availability of pancuronium requires its replacement by vecuronium or rocuronium. Children receiving sufentanil for induction of anesthesia as a single dose of 5 to 20 µg/kg have a stable preintubation period.[98,99] Intubation and other stimuli such as sternotomy do not produce clinically significant alterations in hemodynamics, although changes are more than with equipotent doses of fentanyl. The use of fentanyl as an infusion (0.1 µg/kg/minute) produces fewer alterations in heart rate and blood pressure. This is particularly important in infants, in whom significant hemodynamic changes are poorly tolerated. For neonates with critical CHD, sufentanil anesthetic and postoperative infusion reduce morbidity after cardiac surgery when compared with a halothane anesthetic and routine morphine postoperatively.[100] The blunting of the stress response observed in this study probably accounted for the differences in morbidity; no comparison group representing a more typical dose of a phenylpiperidine opioid (e.g., fentanyl, 0 to 75 µg/kg) was included to permit conclusions as to whether such large opioid doses are optimal.

In contrast to other opioids (see also Chapter 31), remifentanil, an ultra–short-acting opioid, offers the unique advantage of metabolism by nonspecific and tissue esterases, thereby limiting the potential for accumulation related to protracted elimination.[101] Remifentanil may provide advantages in the selected group of patients for whom the blunting of endogenous responses is desirable intraoperatively but potentially deleterious at the end of the procedure. A randomized controlled trial comparing equipotent doses of alfentanil and remifentanil for outpatient pediatric surgery revealed delayed emergence, requiring naloxone only in the alfentanil group.[104] In both adults and children, remifentanil is associated with qualitative hemodynamic changes similar to those with other opioids, a variable tendency to bradycardia, and a small decrease in arterial blood pressure.[102-105]

TABLE 94-7 SUFENTANIL PHARMACOKINETICS IN PEDIATRIC CARDIOVASCULAR PATIENTS*

Age Group	$t_{½}\ \alpha$ (min)	$t_{½}\ \beta$ (min)	Clearance (mL/kg/min)	Vdss (L/kg)
1-30 days	23 ± 17	737 ± 346	6.7 ± 6.1	4.2 ± 1.0
1-24 mo	16 ± 5	214 ± 41	18.1 ± 2.7	3.1 ± 1.0

$t_{½}\ \alpha$, Slow distribution half-life; $t_{½}\ \beta$, elimination half-life; *Vdss,* volume of distribution at steady state.
*All values are mean ± standard deviations (see reference 38).

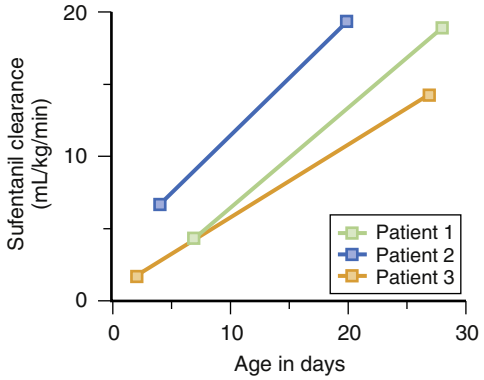

Figure 94-8. Sequential sufentanil clearance during the first month of life in three neonates with congenital heart disease. Clearance of sufentanil increases above adult rates within the neonatal period. *(Data from Greeley WJ, de Bruijn NP: Changes in sufentanil pharmacokinetics within the neonatal period,* Anesth Analg *67:86, 1988.)*

Because of the widespread use of the opioids for pediatric cardiac surgery and the availability of invasive monitoring, the pharmacokinetics and pharmacodynamics of these drugs have been well studied.[98,104] In general, the clinical pharmacology of fentanyl and sufentanil share the same age-related pharmacokinetic and pharmacodynamic features. For example, sufentanil has increased clearance in patients 1 month to 12 years of age, comparable adult clearance in adolescents (12 to 16 years of age), and decreased clearance during the neonatal period (newborn to 1 month of age) (Table 94-7).[88,92] Furthermore, sequential sufentanil anesthetics in neonates with CHD show marked increases in clearance and elimination between the first week and the third or fourth week of life (Fig. 94-8).[94] The latter observation is most likely attributable to maturational changes in hepatic microsomal activity and improved hepatic blood flow from closure of the ductus venosus. The variability in clearance and elimination, coupled with limited cardiovascular reserve in the neonate during the first month of life, makes opioid dosing difficult in this age group. Careful titration of fentanyl 5 to 10 µg/kg of or sufentanil 1 to 2 µg/kg of or a continuous infusion technique provides the most reliable method of achieving hemodynamic stability and an accurate dose response. CPB, different institutional anesthetic practices, and individual patient differences influence pharmacokinetic and pharmacodynamic disposition of the opioids in ways that are not predictable. Even certain disease states such as TOF or pathophysiologic conditions such as increased intraabdominal pressure alter pharmacokinetic processes.[95,96]

Dexmedetomidine is an α_2-agonist approved by the U.S. Food and Drug Administration for sedation in adults. It has been used in pediatric anesthesia as part of a balanced technique preoperatively and intraoperatively for sedation and anxiolysis and postoperatively for prevention of emergence delirium and sedation.[106] Potts and colleagues[107] summarized the pharmacokinetic data of dexmedetomidine in children and found it to possess a larger volume of distribution, delayed elimination, and decreased clearance with significant interpatient variability in younger patients in contrast to adults. The pharmocodynamic effects of dexmedetomidine may be significant and should be kept in mind by the anesthesiologist when used in pediatrics. Hypotension and bradycardia are two of the most commonly reported effects of dexmedetomidine in children, although hypertension may be common as well.[108] Dexmedetomidine is known to demonstrate significant cardiac conduction effects, primarily bradycardia via depression of the sinus and AV node.[109] It is recommended that dexmedetomidine be used with caution in children at risk for bradycardia or sinus or AV node dysfunction. Dexmedetomidine also has been used as an adjunctivant for pain control in adults, although data supporting its use in children are lacking.[110] At our institution, dexmedetomidine is used primarily for postprocedural sedation. Dexmedetomidine 0.5 to 1 µg/kg may be given as a loading dose slowly over 10 minutes. Infusions are often started at 0.3 to 1 µg/kg/hr if prolonged sedation is desired postoperatively.

CARDIOPULMONARY BYPASS

DIFFERENCES BETWEEN ADULT AND PEDIATRIC CARDIOPULMONARY BYPASS

The physiologic effects of CPB on neonates, infants, and children are significantly different from the effects on adults (Table 94-8) (see also Chapter 66). During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (18° C), hemodilution (threefold to fivefold greater dilution of circulating blood volume), low perfusion pressures (20 to 30 mm Hg), wide variation in pump flow rates (ranging from 200 mL/kg/minute to total circulatory arrest), and differing blood pH management techniques (α-stat, pH-stat, or both sequentially). These parameters significantly differ from those of normal physiology and affect preservation of normal organ function during and after CPB. In addition to these prominent changes, subtle variations in glucose supplementation, cannula placement, presence

TABLE 94-8 DIFFERENCES BETWEEN ADULT AND PEDIATRIC CARDIOPULMONARY BYPASS

Parameter	Adult	Pediatric
Hypothermic temperature	Rarely below 25-30° C	Commonly 15-20° C
Use of total circulatory arrest	Rare	Common
Pump prime		
Dilution effects on blood volume	25%-33%	150%-300%
Additional additives in pediatric primes		Blood, albumin
Perfusion pressures	50-80 mm Hg	20-50 mm Hg
Influence of α-stat versus pH-stat management strategy	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured $Paco_2$ differences	30-45 mm Hg	20-80 mm Hg
Glucose regulation		
Hypoglycemia	Rare—requires significant hepatic injury	Common—reduced hepatic glycogen stores
Hyperglycemia	Frequent—generally easily controlled with insulin	Less common—rebound hypoglycemia may occur

BOX 94-3 ***Central Nervous System Injury and Potential Modifiable Intraoperative Factors***

Air or particulate embolus
Rate and depth of core cooling (if used)
Deep hypothermic circulatory arrest (if used)
Reperfusion injury and inflammation
Rate of core rewarming/hyperthermia
Hyperglycemia
Hyperoxia
pH management during cardiopulmonary bypass
Hematocrit management during cardiopulmonary bypass

of aortopulmonary collaterals, and patient age may be important factors affecting organ function during CPB.

Adult patients are infrequently exposed to these biologic extremes. In adult cardiac patients, temperature is rarely lowered below 25° C, hemodilution is more moderate, perfusion pressure is generally maintained at 50 to 80 mm Hg, flow rates are maintained at 50 to 65 mL/kg/minute, and pH management strategy is less influential because of moderate hypothermic temperatures and rare use of circulatory arrest. Variables such as glucose supplementation rarely pose a problem in adult patients owing to large hepatic glycogen stores. Venous and arterial cannulas are larger and less deforming of the atria and aorta, and their placement is more predictable. Although superficially similar, the conduct of CPB in children is considerably different from that in adults. Marked physiologic differences in the response to CPB in children can occur. Additionally, several modifiable intraoperative factors can influence neuropsychologic morbidity (Box 94-3).

Volume of Priming Solutions

The priming solutions used in pediatric CPB take on great importance because of the disproportionately large priming volume–to–blood volume ratio in children. In adults, the priming volume is equivalent to 25% to 33% of the patient's blood volume, whereas in neonates and infants the priming volume may exceed the patient's blood volume by 200%. With contemporary low-volume bypass circuits (e.g., small volume oxygenators, smaller tubing), priming volume is not more than one blood volume in a small neonate. Care must be taken, therefore, to achieve a physiologically balanced priming solution and limit the volume as much as possible. Most pediatric priming solutions, however, have quite variable levels of electrolytes, calcium, glucose, and lactate. Electrolytes, glucose, and lactate levels may be quite high if the solution includes large amounts of banked blood or quite low if a minimal amount of banked blood is added. Calcium levels are generally very low in pediatric priming solutions; this may contribute to the rapid slowing of the heart with the initiation of bypass.

The main constituents of the priming solution include crystalloid, banked blood (to maintain a temperature-appropriate hematocrit), and colloid. Other supplements that may be added to the prime are mannitol, a buffer (sodium bicarbonate or trishydroxymethylaminomethane [THAM]), and steroids. Many institutions add colloid or fresh frozen plasma to the pump prime in neonates and small infants or use whole blood in the priming solution. Low concentrations of plasma proteins have been shown experimentally to impair lymphatic flow and alter pulmonary function by increasing capillary leak.[111] Although adding albumin to the pump prime has not been shown to alter outcome in adults during CPB, one study suggested that maintaining normal colloid osmotic pressure may improve survival in infants undergoing CPB.[112,113]

The addition of fresh frozen plasma or whole blood (see also Chapters 61 and 62) is an attempt to restore the level of procoagulants, which are severely diluted with CPB in infants. For neonates and infants, blood must be added to the priming solution. Most institutions use packed RBCs, but some use whole blood. The use of whole blood supplements both RBCs and the coagulation factors with a single donor exposure. In fact, low-volume bypass circuits may enable perfusionists and anesthesiologists to share a single unit of whole blood, thereby limiting the donor exposure to one throughout the entire perioperative course.

The addition of any blood products will cause a much higher glucose load in the priming solution. Hyperglycemia may increase the risk for neurologic injury if brain ischemia occurs. Mannitol is added to promote an osmotic diuresis and scavenge O_2 free radicals from the circulation. Steroids are added to stabilize membranes to produce the theoretic advantage of reducing ion shifts during periods of ischemia. Steroids, however, may raise glucose levels, and this may be detrimental if there is a

period of cerebral ischemia. Steroids remain one of the more controversial additives in priming solutions.

Temperature

Hypothermic CPB is used to preserve organ function during cardiac surgery (see also Chapter 93). Three distinct methods of CPB are used: moderate hypothermia (25° to 32° C), deep hypothermia (18° C), and DHCA. The choice of method of bypass is based on the required surgical conditions, patient size, type of operation, and potential physiologic impact on the patient.

Moderate hypothermic CPB is the principal method of bypass employed for older children and adolescents. In these patients, venous cannulas are less obtrusive and the heart can easily accommodate superior and inferior vena cava cannulation. Bicaval cannulation reduces right atrial blood return and improves the surgeon's ability to visualize intracardiac anatomy. Moderate hypothermia may also be chosen for less demanding cardiac repairs in infants, such as an ASD or an uncomplicated VSD. Most surgeons are willing to cannulate the inferior and superior venae cavae in neonates and infants. In these patients, however, this approach is technically more difficult and likely to induce brief periods of hemodynamic instability. Additionally, the pliability of the venae cavae and the rigidity of the cannulas may result in caval obstruction, impaired venous drainage, and elevated venous pressure in the mesenteric and cerebral circulation.

Deep hypothermic CPB is generally reserved for neonates and infants requiring complex cardiac repair. However, certain older children with complex cardiac disease or severe aortic arch disease benefit from deep hypothermic temperatures. For the most part, deep hypothermia is selected to allow the surgeon to operate under conditions of low-flow CPB or total circulatory arrest. Low pump flows (50 mL/kg/minute) improve the operating conditions for the surgeon by providing a nearly bloodless field. DHCA allows the surgeon to remove the atrial or aortic cannula. If this technique is used, surgical repair is more precise because of the bloodless and cannula-free operative field. Arresting the circulation, even at deep hypothermic temperatures, introduces the concern of how well deep hypothermia preserves organ function, with the brain being at greatest risk.

Hemodilution

Hemodilution has been used during CPB to decrease homologous blood use and has been thought to improve microcirculatory flow by reducing blood viscosity. Although hemoconcentrated blood has an improved O_2-carrying capacity, its viscosity reduces efficient flow through the microcirculation. With hypothermic temperatures, blood viscosity increases significantly and flow decreases. Hypothermia, coupled with the nonpulsatile flow of CPB, impairs blood flow through the microcirculation. Blood sludging, small vessel occlusion, and multiple areas of tissue hypoperfusion may result. Therefore, hemodilution is an important consideration during hypothermic CPB. The appropriate level of hemodilution for a given hypothermic temperature, however, is not well defined. However, hemodilution also reduces perfusion pressure; increases CBF, thereby potentially increasing the microembolic load to the brain; and reduces the O_2-carrying capacity of blood.[114] Using an animal model, one group of investigators found that extreme hemodilution to a hematocrit less than 10% resulted in inadequate O_2 delivery, but with higher hematocrit levels of 30%, there was improved cerebral recovery after DHCA.[115] Jonas and colleagues[116] confirmed these findings in a randomized trial using two hemodilution protocols (20% versus 30% hematocrit) in infants younger than 9 months of age. Developmental outcomes were assessed at follow-up at 1 year of age with the Bayley Scales of Infant Development. In the short term, the group with lower hematocrit values had lower nadirs of cardiac index, higher serum lactate levels 1 hour after CPB, and a greater increase in total body water on the first postoperative day. At 1 year of age, mental development index scores were similar but psychomotor development index scores were significantly lower in the group with lower hematocrit values. Also, infants in the this group had psychomotor development scores that were 2 standard deviations below the mean. Because RBCs serve as the major reservoir of O_2 during circulatory arrest, especially during rewarming, hematocrit values closer to 30% are generally preferred for deep hypothermia when this technique is contemplated. Currently, most centers maintain hematocrit levels approximately 25% to 30% during CPB, enhancing O_2 delivery to vital organs such as the brain. Cerebral O_2 delivery is an especially important consideration because cerebral autoregulation is impaired at deep hypothermic temperatures and after DHCA.

To achieve a hematocrit level of 25% to 30% in neonates and infants, banked blood should be added to the priming solution. The mixed hematocrit level on CPB (the hematocrit level of the total priming volume plus the patient's blood volume) can be calculated by the following formula:

$$\mathrm{Hct_{CBP}} = \mathrm{BV_{pt}} \times \mathrm{HCT_{pt}}/\mathrm{BV_{pt}} + \mathrm{TPV}$$

where Hct_{CPB} is the mixed hematocrit (TPV + BVpt), BV_{pt} is the patient's blood volume (weight in kilograms × estimated blood volume in milliliters per kilogram), *TPV* is the total priming volume, and Hct_{pt} is the starting hematocrit level of the patient. This calculation allows an estimate of the hematocrit level of the patient using an asanguineous priming solution and is therefore useful for older children and adolescents. In neonates and infants, the perfusionist must add blood to the pump prime to achieve a desired hematocrit level during hypothermic CPB. The following formula estimates the amount of packed RBCs in milliliters that must be added to the prime volume to achieve this hematocrit level:

$$\text{Added RBCs (mL)} = (\mathrm{BV_{pt}} + \mathrm{TPV})\,(\mathrm{Hct_{desired}}) - (\mathrm{BV_{pt}})\,(\mathrm{Hct_{pt}})$$

where BV_{pt} is the patient's blood volume, *TPV* is the total priming volume, $\mathrm{Hct_{desired}}$ is the desired hematocrit level on CPB, and Hct_{pt} is the starting hematocrit level of the patient.

The optimal hematocrit level after weaning from CPB is not clear. Likewise, the adult transfusion trigger is not clear (see also Chapter 61). Decisions concerning post-CPB hematocrit levels are made based on the patient's postrepair function and anatomy. Patients with residual hypoxemia or those with moderate-to-severe myocardial

dysfunction benefit from the improved O_2-carrying capacity of hematocrit levels of 40% or higher. Patients with a physiologic correction and excellent myocardial function may tolerate hematocrit levels of 25% to 30%.[117] In children with mild-to-moderate myocardial dysfunction, accepting hematocrit values between these levels seems prudent. Therefore, in patients with physiologic correction, moderately good ventricular function, and hemodynamic stability, the risks associated with blood and blood product transfusion should be strongly considered during the immediate postbypass period.

BLOOD GAS MANAGEMENT

The theoretic benefit of α-stat versus pH-stat blood gas management during hypothermic CPB has been a topic of great debate (see also Chapters 60 and 94). Although the pH-stat strategy may not be optimal for adults in whom the principal risk for brain injury is microembolism, this risk is thought to be lower in infants because of the lack of atherosclerotic disease. With pH-stat management, the addition of CO_2 to the inspired gas mixture during cooling on CPB increases CBF and may improve cerebral tissue oxygenation and outcomes.

The controversial issue of pH management during CPB has been addressed in a large study from Boston Children's Hospital. In this study, infants younger than 9 months of age were randomized to α-stat versus pH-stat during deep hypothermic CPB with excellent long-term follow-up.[118,119] Neurodevelopmental outcomes were evaluated in infants undergoing biventricular repair for a variety of cardiac defects when younger than 9 months of age. The short-term benefits identified with the pH-stat strategy included a trend toward less postoperative morbidity and shorter recovery time to first electroencephalographic activity. In patients with TGA, there was a shorter duration of intubation and ICU stay in patients.[118] However, the use of either the α-stat or pH-stat strategies was not consistently related to either improved or impaired neurodevelopmental outcomes at 2- and 4-year follow-up.[119]

INITIATION OF CARDIOPULMONARY BYPASS

Arterial and venous cannula in the heart before initiating CPB may result in significant problems in the peribypass period. A malpositioned venous cannula has the potential for vena cava obstruction. The problems of venous obstruction are magnified during CPB in the neonate because arterial pressures are normally low (20 to 40 mm Hg), and large, relatively stiff cannulas easily distort these very pliable venous vessels.[111,113] A cannula in the inferior vena cava may obstruct venous return from the splanchnic bed, resulting in ascites from increased hydrostatic pressure or directly reduced perfusion pressure across the mesenteric, renal, and hepatic vascular beds. Significant renal, hepatic, and gastrointestinal dysfunction may ensue and should be anticipated in the young infant with unexplained ascites. Similar cannulation problems may result in superior vena cava obstruction. This condition may be more ominous during bypass. Under these circumstances, three problems may ensue: (1) cerebral edema, (2) a reduction in regional or global CBF, and (3) reduced proportion of pump flow reaching the cerebral circulation, causing inefficient brain cooling.

In the operating room, superior vena cava pressures via an internal jugular catheter should be monitored by examining the patient's head for signs of suffusion after initiating bypass. Discussions with the perfusionist regarding adequacy of venous return and large cooling gradients between the upper and lower body should alert the anesthesiologist and the surgeon to potential venous cannula problems. Patients with anomalies of the large systemic veins (persistent left superior vena cava or azygous continuation of an interrupted inferior vena cava) are at particular risk for problems with venous cannulation and drainage.

Problems with aortic cannula placement can occur. The aortic cannula may slip beyond the takeoff of the innominate artery, with blood therefore selectively flowing to the right side of the cerebral circulation. Also, the position of the tip of the cannula may promote preferential flow down the aorta or induce a Venturi effect to steal flow from the cerebral circulation. This problem has been confirmed during CBF monitoring by the appearance of large discrepancies in flow between the right and left hemispheres after initiating CPB. The presence of large aortic-to-pulmonary collaterals, such as a large PDA, also may divert blood to the pulmonary circulation from the systemic circulation, thereby reducing CBF and the efficiency of brain cooling during CPB. The surgeon should gain control of the ductus either before or immediately after instituting CPB to eliminate this problem and, if possible, large aortopulmonary collaterals should be embolized in the cardiac catheterization laboratory before the operative procedure. Neonates with significant aortic arch abnormalities (e.g., aortic atresia, interrupted aortic arch) may require radical modifications of cannulation techniques, such as placing the arterial cannula in the main pulmonary artery and temporarily occluding the branch pulmonary arteries to perfuse the body via the PDA or even dual arterial cannulation of both the ascending aorta and main pulmonary artery. Such adaptations require careful vigilance to ensure effective, thorough perfusion and cooling of vital organs.

Once the aortic and venous cannulas are positioned and connected to the arterial and venous limb of the extracorporeal circuit, bypass is initiated. The arterial pump is slowly started, and, once forward flow is ensured, venous blood is drained into the oxygenator. Pump flow rate is gradually increased until full circulatory support is achieved. If venous return is diminished, arterial line pressure is high, or mean arterial pressure is excessive, pump flow rates must be reduced. High line pressure and inadequate venous return are usually caused by malposition or kinking of the arterial and venous cannulas, respectively. The rate at which venous blood is drained from the patient is determined by the height difference between the patient and the oxygenator inlet and the diameter of the venous cannula and line tubing. Venous drainage can be increased by using vacuum-assisted drainage under certain circumstances.

In neonates and infants, deep hypothermia is commonly used. For this reason, the pump prime is kept cold

(18° to 22° C). When the cold perfusate contacts the myocardium during the institution of CPB, heart rate slows immediately and contraction is impaired. The contribution of total blood flow pumped by the infant's heart rapidly diminishes. Therefore, to sustain adequate systemic perfusion at or near normothermic temperatures, the arterial pump must reach full flows quickly.

CPB is initiated in neonates and infants by beginning the arterial pump flow first. Once aortic flow is ensured, the venous line is unclamped and blood is siphoned out of the RA into the inlet of the oxygenator. Flowing before unclamping the venous line prevents the potential problem of exsanguination if aortic dissection or misplacement of the aortic cannula occurs. Neonates and infants have a low blood volume–to–priming volume ratio, and intravascular volume falls precipitously if the venous drainage precedes aortic inflow. Once the aortic cannula position is verified, pump flow rates are rapidly increased to maintain effective systemic perfusion. Because coronary artery disease is rarely a consideration, the myocardium should cool evenly unless distortion caused by the cannulas compromises the coronary arteries. When a cold prime is used, caution must be exercised in using the pump to infuse volume before initiating CPB. Infusion of cold perfusate may result in bradycardia and impaired cardiac contractility before the surgeon is prepared to initiate CPB.

Once CPB is begun, appropriate circuit connections, myocardial perfusion, and optimal cardiac decompression should be confirmed. Ineffective venous drainage can rapidly result in ventricular distention. This is especially true in infants and neonates, in whom ventricular compliance is low and the heart is relatively intolerant of excessive preload augmentation. If ventricular distention occurs, pump flow must be reduced and the venous cannula repositioned. Alternatively, the heart may be decompressed by placing a cardiotomy suction catheter or small vent in the appropriate chamber.

PUMP FLOW RATES

Recommendations for optimal pump flow rates for children have historically been based both on the patient's body mass and on evidence of efficient organ perfusion as determined by arterial blood gases, acid-base balance, and whole-body O_2 consumption during CPB.[120] At hypothermic temperatures, metabolism is reduced, and CPB flow rates can therefore be reduced and still meet or exceed the tissue's metabolic needs (see the discussion of low-flow CPB in the following section).

SPECIAL TECHNIQUES

Deep Hypothermic Circulatory Arrest

A certain subset of neonates, infants, and children with CHD require extensive repair of complex congenital heart defects using DHCA. This technique facilitates precise surgical repair under optimal conditions, free of blood or cannulas in the operative field and providing maximal organ protection and often resulting in shortened total CPB time. The scientific rationale for the use of deep hypothermic temperatures rests primarily on a temperature-mediated reduction of metabolism. Whole-body and cerebral O_2 consumption during induced hypothermia decreases the metabolic rate for O_2 by a factor of 2 to 2.5 for every 10° C reduction in temperature.[121] These results are consistent with in-vitro models, which relate temperature reduction to a decrease in the rate constant of chemical reactions, as originally described by Arrhenius using the equation k = Ae – RT. The reduction in O_2 supply during deep hypothermic low-flow CPB is associated with preferential increases in vital organ perfusion (e.g., to the brain) and increased extraction of O_2.[122] Therefore, to some extent, deep hypothermic low-flow CPB exerts a protective effect by reducing the metabolic rate for O_2, promoting preferential organ perfusion, and increasing tissue O_2 extraction.

The duration of the safe period of DHCA has not clearly been delineated.[123] Although all organ systems are at risk for the development of ischemic and reperfusion injury, as manifested by lactate and pyruvate production during DHCA, the brain appears to be the most sensitive to and the least tolerant of these effects. Brainstem and cortical evoked potentials as well as processed electroencephagraphs are altered after DHCA.[123-125] The abnormalities in the evoked potentials appear to be related to the duration of DHCA and are attributed to altered metabolism. During reperfusion after the arrest period, CBF and metabolism remain depressed in neonates and small infants (Fig. 94-9; also see Fig. 94-6).[76] Importantly, during the use of these extremes of temperature, it appears that autoregulation is lost and cerebral perfusion becomes highly dependent on the conduct of extracorporeal perfusion and presumably postbypass hemodynamic performance.

The potentially deleterious effects of prolonged DHCA in infants and neonates are well described. In general, it is agreed that very prolonged periods of uninterrupted DHCA may have adverse neurologic outcomes. However, considerable disagreement exists if a "safe" period of

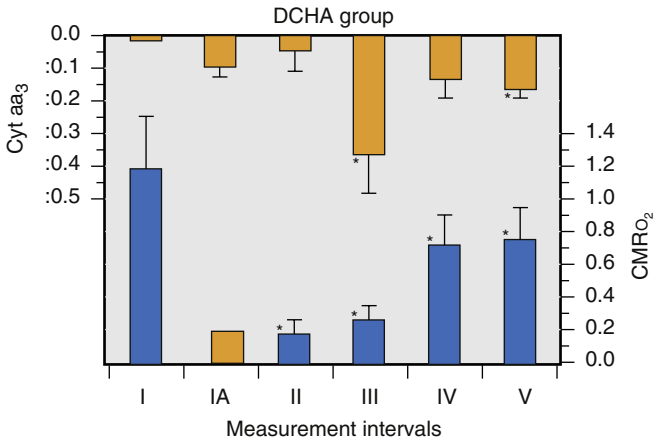

Figure 94-9. Bar graph of variations in cytochrome oxidase (*cyt aa*$_3$) near-infrared spectroscopic signals and cerebral metabolic rate for oxygen (*CMRo*$_2$) in subjects with deep hypothermic circulatory arrest (DHCA). Each point of cyt aa$_3$ represents mean ± SE in six subjects; CMRo$_2$ values are mean ± SD. Negative values in cyt aa$_3$ represent relative decreases in quantity of oxidized enzyme. *CMRo$_2$ and cyt aa$_3$ are significantly different from control, P ± .05.

DHCA exists and whether patient-specific, procedure-specific, or postoperative management strategies may attenuate or promote CNS damage from DHCA. Cases have been reported of detrimental effects of DHCA on a variety of outcomes regarding the CNS and others on either an inconsistent effect or no effect.[118,126,127] Three issues have become clear over time: (1) The effects of short durations of DHCA are inconsistently related to adverse outcomes, (2) the effect of DHCA is not a linear phenomenon, and (3) the effects are most likely modified by other patient-related, preoperative, and postoperative factors.[127-129] A recent large-scale study of 549 subjects undergoing the Norwood stage 1 procedure with DHCA found duration of greater than 45 minutes to be a risk factor for 30-day mortality.[130]

Regional Cerebral Perfusion

Some surgeons have developed innovative and challenging strategies to provide continuous cerebral perfusion during complex reconstruction of the aortic arch or intracardiac repair to avoid or minimize the use of DHCA. However, avoiding DHCA, the duration of CPB is necessarily lengthened, and longer durations of CPB have been shown to adversely affect both short- and long-term outcomes.[58,59] The relative risks and benefits of longer CPB versus less (or no) DHCA remain a subject of continued controversy. In efforts to study this newer strategy, two recent studies have evaluated the technique of regional cerebral perfusion. In one nonrandomized study from Boston, Wypij and colleagues[131] followed 29 infants who underwent a stage I palliation, 9 of whom received regional cerebral perfusion at 30 to 40 mL/kg/minute.[131] The authors reported no difference in mental or psychomotor developmental indices at 1 year of age between the regional cerebral perfusion group and those who received DHCA as a primary strategy. A group from the University of Michigan published a larger, randomized trial of DHCA with or without regional cerebral perfusion at 20 mL/kg/minute in patients with a functional single ventricle, with long-term studies that are in the planning stages.[132] A total of 77 patients were enrolled with similar survival to hospital discharge (88%) and at 1-year follow-up (75%). No significant difference was seen in either the psychomotor development index or the mental development index scores between the two groups at any time points, although the scores tended to be lower in the regional cerebral perfusion group.

Glucose Regulation

The detrimental effects of hyperglycemia during complete, incomplete, and focal cerebral ischemia are well demonstrated (see also Chapter 39).[133,134] The role of glucose in potentiating cerebral injury appears to rest on two factors: adenosine triphosphate (ATP) usage and lactic acidosis.[135,136] The anaerobic metabolism of glucose requires phosphorylation and the expenditure of two molecules of ATP before ATP production can occur. This initial ATP expenditure may result in a rapid depletion of ATP and may explain why hyperglycemia worsens neurologic injury. Lactic acidosis is also important in glucose-augmented cerebral injury. Its important role, however, may be as a glycolytic enzyme inhibitor. Lactate slows anaerobic ATP production by inhibiting glycolysis immediately after ATP is consumed in the phosphorylation of glucose.[137]

Although the detrimental effects of hyperglycemia during ischemia are clear, very little evidence supports a relationship between a worsening neurologic outcome and hyperglycemia during CPB or DHCA in children. Although a retrospective review of 34 children undergoing DHCA suggested a worse neurologic outcome in the hyperglycemic children, the results were reported as a nonsignificant statistical trend.[138] A review of acquired neurologic lesions in patients undergoing the Norwood stage I procedure for hypoplastic left heart syndrome suggested hyperglycemia as a significant associated finding in patients with extensive cerebral necrosis or intraventricular hemorrhage. A host of other potentially damaging factors (e.g., periods of hypoxia, low diastolic and systolic pressure, thrombocytopenia) were statistically associated with the observed neuropathology.[139] Whether glucose directly contributes to neurologic injury or merely serves as a marker for a high-risk population that ultimately suffers neurologic insult as a result of other factors is not clear.

Hypoglycemia is a frequent concern in neonates during the perioperative period (see also Chapter 94). Reduced hepatic gluconeogenesis coupled with decreased glycogen stores places the newborn at increased risk for hypoglycemic events. In newborns with CHD, reduced systemic perfusion (e.g., critical coarctation, hypoplastic left heart syndrome, critical aortic stenosis) may result in worsening hepatic biosynthesis, further impairing glucose production. These patients may be fully dependent on exogenous glucose; therefore, it is not uncommon for them to require 20% to 30% dextrose infusions to maintain euglycemia in the prebypass period. Older children are not immune to hypoglycemic events and are therefore susceptible to hypoglycemia-induced neurologic injury. Patients with low cardiac output states (cardiomyopathies, pretransplant patients, critically ill postoperative patients) requiring reoperation and when on substantial inotropic support are at risk for reduced glycogen stores and intraoperative hypoglycemia.[140]

The impact of hypoglycemia during CPB is further complicated by the consequences of hypothermia, CO_2 management, and other factors that may modify normal cerebrovascular responses during bypass. In a dog model, insulin-induced hypoglycemia to 30 mg/dL did not alter the electroencephalographic findings. However, after 10 minutes of hypocapnic hypoglycemia, the electroencephalogram became flat.[141] When regional blood flow was examined in these animals, cortical and hippocampal blood flow remained normal whereas other regions of the brain had reduced flow. The loss of electroencephalographic activity from hypoglycemia alone does not normally occur above glucose levels of 8 mg/dL.[142]

During deep hypothermic CPB and DHCA, CBF and metabolism are altered. The additive effect of hypoglycemia, even if mild, may cause alterations in cerebral autoregulation and culminate in increased cortical injury.[139] The common practice of using hyperventilation to reduce PVR in neonates and infants during weaning from CPB and in the early postbypass period can further exacerbate hypoglycemic injury. Glucose monitoring and rigid

maintenance of euglycemia are an important part of CPB management in the patient with CHD.

Renal Effects

After CPB, the combined effects of hypothermia, nonpulsatile perfusion, and reduced mean arterial pressure cause release of angiotensin, renin, catecholamines, and antidiuretic hormones.[143-145] These circulating hormones promote renal vasoconstriction and reduce renal blood flow. However, despite the negative impact of CPB on renal function, low-flow, low-pressure, nonpulsatile perfusion has not been linked with postoperative renal dysfunction (Table 94-9).[144] The factors that best correlate with postoperative renal dysfunction are preoperative renal dysfunction and profound reductions in post-CPB cardiac output. Preoperative factors include primary renal disease, low cardiac output, and dye-related renal injury after cardiac catheterization.[145]

The incidence of acute renal insufficiency after pediatric cardiac surgery is approximately 8%. Multiple causative factors are involved, and the final common result is oliguria and an increased serum creatinine. Diuretics have been the mainstay of promoting urine flow after pediatric CPB. Furosemide in a dose of 1 to 2 mg/kg or ethacrynic acid 1 mg/kg every 4 to 6 hours, or both, induces diuresis and may reverse renal cortical ischemia associated with CPB. After DHCA, a 24-hour period of oliguria or anuria can occur that resolves over the next 12- to 24-hour period. The use of diuretics is effective only after spontaneous urine output has been initiated in these patients.

Glomerular filtration rate, creatinine clearance, and medullary concentrating ability are substantially reduced in neonates and young infants. Therefore, the use of CPB in these patients results in greater fluid retention than is typically seen in older children and adult patients. The net result may be increased total body water, increased organ weight (e.g., lungs, heart), and greater difficulty with postoperative weaning from ventilatory support. The use of ultrafiltration during rewarming or after CPB is effective in reducing total body water, limiting the damaging effects of CPB, and decreasing the postoperative ventilation period.[146,147]

TABLE 94-9 SEQUELAE OF PEDIATRIC CARDIOPULMONARY BYPASS

End-Organ Injury	Cause and Signs
Renal injury	Organ immaturity, preexisting renal disease Post–cardiopulmonary bypass low cardiac output, use of DHCA Renal dysfunction characterized by reduced GFR and ATN
Pulmonary injury	Endothelial injury, increased capillary leak, complement activation, and leukocyte degranulation Pulmonary dysfunction characterized by reduced compliance, reduced FRC, and increased A-a gradient
Cerebral injury after DHCA	Loss of autoregulation, suppressed metabolism and cerebral blood flow, cellular acidosis, and cerebral vasoparesis CNS dysfunction characterized by seizures, reduced developmental quotients, choreoathetosis, learning disabilities, behavioral abnormalities

A-a, alveolar-arterial; *ATN,* acute tubular necrosis; *CNS,* central nervous system; *DHCA,* deep hypothermic circulatory arrest; *FRC,* functional residual capacity; *GFR,* glomerular filtration rate.

Pulmonary Effects

Cardioplegia protects the heart, but no parallel protection is afforded the lung during bypass. Pulmonary dysfunction is common after CPB, and its pathogenesis is poorly understood (see Table 94-9). In the broadest terms, lung injury is mediated in one of two ways: first, by an inflammatory response resulting from leukocyte and complement activation and, second, by a mechanical effect culminating in surfactant loss, atelectasis with resultant ventilation-perfusion mismatch, loss of lung volumes, and altered mechanics of breathing.

Pulmonary function after CPB is characterized by reduced static and dynamic compliance, reduced functional residual capacity, surfactant deficiency, and an increased A-a gradient.[148,149] Atelectasis and increased capillary leak due to hemodilution and hypothermic CPB are the most likely causes. Hemodilution reduces circulating plasma proteins, reducing intravascular oncotic pressure, and favors water extravasation into the extravascular space. Hypothermic CPB causes complement activation and leukocyte degranulation.[150] Leukocytes and complement are important in causing capillary-alveolar membrane injury and microvascular dysfunction through platelet plugging and release of mediators, which increase PVR. The technique of MUF is highly effective in reducing lung water and pulmonary morbidity during the postoperative period.

STRESS RESPONSE AND CARDIOPULMONARY BYPASS

The release of a large number of metabolic and hormonal substances, including catecholamines, cortisol, growth hormone, prostaglandins, complement, glucose, insulin, endorphins, and other substances, characterizes the stress response during hypothermic CPB.[11,151] The likely causes of the elaboration of these substances include contact of blood with the nonendothelialized surface of the pump tubing and oxygenator, nonpulsatile flow, low perfusion pressure, hemodilution, hypothermia, and light anesthesia depth. Other factors that may contribute to elevations of stress hormones include delayed renal and hepatic clearance during hypothermic CPB, myocardial injury, and exclusion of the pulmonary circulation from bypass. The lung is responsible for metabolizing and clearing many of these stress hormones. The stress response generally peaks during rewarming from CPB. Strong evidence indicates that the stress response can be blunted by increasing the depth of anesthesia.[11,151]

When do elevated circulating stress hormones, a normal neonatal adaptive response, become detrimental? These substances can mediate undesirable effects such as myocardial damage (catecholamines), systemic and pulmonary hypertension (catecholamines, prostaglandins), pulmonary endothelial damage (complement, prostaglandins), and pulmonary vascular reactivity (thromboxane).

The benefits of controlling the stress response with fentanyl in premature infants undergoing PDA ligation and with sufentanil in neonates with complex CHD have been demonstrated.[100,152] Although blunting the stress response seems warranted, additional evidence suggests that the newborn stress response, especially the endogenous release of catecholamines, may be an adaptive metabolic response necessary for survival at birth.[153] Thus, the complete elimination of an adaptive stress response may not be desirable. To what extent acutely ill neonates with CHD depend on the stress response for maintaining hemodynamic stability is currently unknown.

A depth of anesthesia adequate to attenuate the stress response should be used, but to attempt to block the response altogether may not be necessary. Acceptable anesthesia during CPB may be best accomplished by the continuous administration of an inhaled anesthetic via a vaporizer connected to the pump oxygenator, careful titration of incremental doses of opioids, or the precise administration of an opioid or opioid and benzodiazepine by a continuous infusion technique. Primary opioid anesthetic techniques result in reduced stress hormone release and decreased postoperative metabolic acidosis and lactate production compared with primary halothane anesthesia and may therefore be a preferred technique in complex CHD.[100] If an adequate depth of anesthesia is accomplished by the administration of excessively large doses of opioids (e.g., fentanyl or sufentanil), postoperative mechanical ventilation will be necessary. By contrast, residual levels of inhaled anesthetics (e.g., halothane or isoflurane) can produce transient myocardial depression at the termination of CPB, complicating separation from CPB. Because of the improved surgical techniques coupled with the reduced morbidity of CPB, the use of high doses of an opioid anesthetic is infrequent in our current practice.

DISCONTINUATION OF CARDIOPULMONARY BYPASS

In separating the patient from CPB, blood volume is assessed by direct visualization of the heart and monitoring right atrial or left atrial filling pressures (see also Chapter 66). When filling pressures are adequate, the patient is fully warmed, acid-base status is normalized, heart rate is adequate, and sinus rhythm has been achieved, the venous drainage is stopped and the patient can be weaned from bypass. The arterial cannula is left in place so that a slow infusion of residual pump blood can be used to optimize filling pressures. Myocardial function is assessed by direct cardiac visualization and a transthoracic left or right atrial catheter, by a percutaneous internal jugular catheter, or by the use of intraoperative echocardiography. Pulse oximetry also can be used to assess the adequacy of cardiac output.[154] Low systemic arterial saturation or the inability of the oximeter probe to register a pulse may be a sign of very low output and high systemic resistance.[155]

After the repair of complex congenital heart defects, the anesthesiologist and surgeon may have difficulty separating patients from CPB. Under these circumstances, a diagnosis must be made and includes (1) an inadequate surgical result with a residual defect requiring repair, (2) pulmonary artery hypertension, and (3) right or left ventricular dysfunction.

Two general approaches are customarily used, either independently or in conjunction. An intraoperative "cardiac catheterization" can be performed to assess isolated pressure measurements from the various great vessels and chambers of the heart (i.e., catheter pullback measurements or direct needle puncture to evaluate residual pressure gradients across repaired valves, sites of stenosis and conduits, and O_2 saturation data to examine for residual shunts).[156] Alternatively, echo-Doppler imaging may be used to provide an intraoperative image of structural or functional abnormalities to assist in the evaluation of the postoperative cardiac repair.[9,157] If structural abnormalities are found, the patient can be placed back on CPB and residual defects can be repaired before the patient leaves the operating room. Leaving the operating room with a significant residual structural defect adversely affects survival and increases patient morbidity (see Fig. 94-5).[9,157] Echo-Doppler imaging can rapidly identify right and left ventricular dysfunction and suggest the presence of pulmonary artery hypertension. In addition, echo-Doppler imaging can identify regional wall motion abnormalities caused by ischemia or intramyocardial air that will direct specific pharmacologic therapy and provide a means of assessing the results of these interventions (Fig. 94-10).[158]

ULTRAFILTRATION

Institution of CPB in neonates, infants, and young children results in a profound proinflammatory response and significant hemodilution. This may lead to post-CPB morbidity and mortality resulting from poor organ function. The organ systems most affected by this are the heart, lungs, and brain. Although contact between the patient's blood and the foreign surface of the bypass circuit is a potent stimulus to trigger the inflammatory cascade, other factors including ischemia, profound hypothermia, rewarming, and surgical trauma are also important in its genesis. These inflammatory mediators include complement anaphylatoxins, vasoactive amines, and cytokines (e.g., tumor necrosis factor-α [TNF-α]) that lead to an increase in vascular permeability.[73] Hemodilution occurs at the onset of CPB despite the use of physiologically balanced priming solutions that include blood, crystalloid, albumin, and buffer and smaller volume circuits. Hemodilution may, however, be advantageous in patients in whom the surgery is performed under hypothermic conditions ranging from mild hypothermia to DHCA. Initiation of CPB will change the viscoelastic properties of blood, and these changes have been shown to continue into the post-CPB period.[159] Although the mode of perfusion, cardiotomy suction, arterial roller pump type, and shear forces of the CPB circuit are important, it is the temperature and hematocrit of the blood that play the most important role in changing viscoelasticity. It has been shown that low temperature with a high hematocrit leads to a higher viscosity.[160] This elevated viscosity may lead to altered organ perfusion, particularly in the brain. Because of these alterations in blood viscosity, hemodilution is

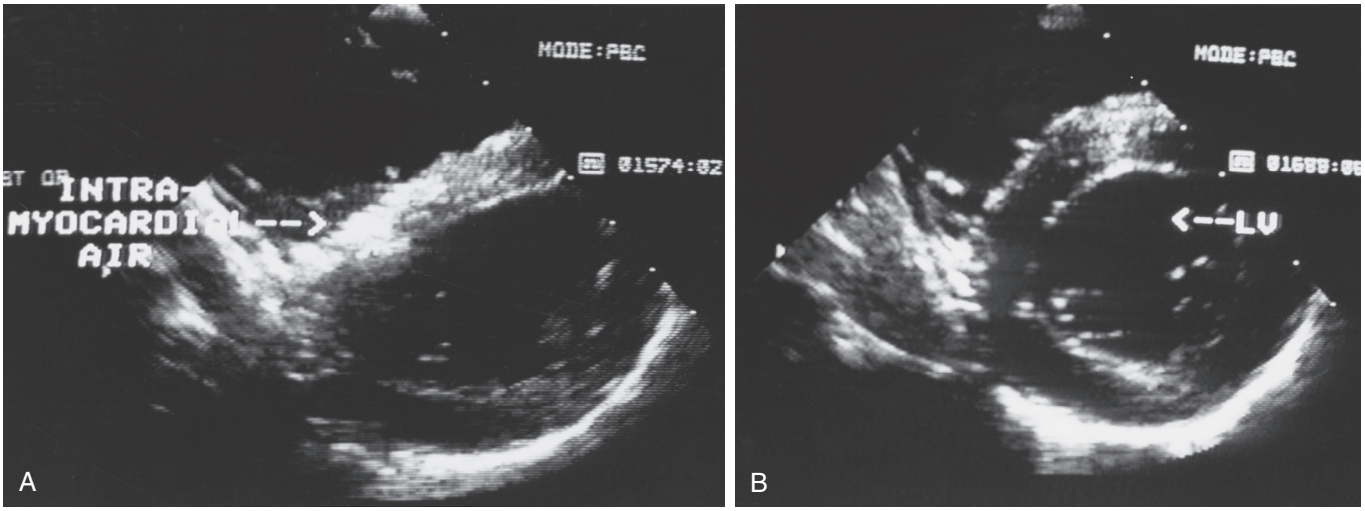

Figure 94-10. A, Two-dimensional echocardiogram in the short-axis view across the ventricles demonstrating the presence of intramyocardial air (*arrow*) in the ventricular septum and right ventricular wall. The intramyocardial air appears as a dense, "snowy" echogenic area. Note the associated wall motion abnormality appearing as flattening of the ventricular septum. **B,** The patient was treated with phenylephrine, increasing systemic and coronary perfusion pressure, resulting in clearance of the air, normalization of the echogenic density, and restoration of normal left ventricular (*LV*) wall motion and configuration.

tolerated in the cooling phases of CPB. Although advantageous early, this hemodilution combined with the inflammatory response will lead to transudation of fluid into the extravascular space, which in turn leads to the potential for organ dysfunction as eluded to earlier. Prevention of organ dysfunction and improved oxygenation by the removal of excess fluid and inflammatory mediators are the rationale, therefore, in the use of ultrafiltration. The end result is removal of plasma water and low-molecular-weight solutes across a semipermeable membrane.

Essentially, five forms of ultrafiltration are used in modern perfusion practice, three of which are while the patient is on CPB. Prime ultrafiltration is used when packed RBCs are added to the prime solution and is performed in the prebypass phase. Its aim is to replace crystalloid prime with blood prime, adjust pH, alter electrolyte concentration to safer levels, and remove inflammatory mediators potentially present in the donor blood.[161] Conventional ultrafiltration (CUF) involves the removal of fluid at any time while the patient is being supported by CPB. A common use for this method is removal of the volume of clear fluid equal to the volume of cardioplegia used. Conventional ultrafiltration can be performed during all phases of CPB. It involves the placement of an ultrafilter within the circuit and connected either to the venous line or the venous reservoir. The removal of an excess of ultrafiltrate will result in low reservoir volumes. In zero balance ultrafiltration, once fluid has been removed it is replaced with crystalloid to avoid inadequate reservoir volume, and thus there is no net removal of volume. The third method of on-bypass ultrafiltration is dilutional ultrafiltration, which is employed when the concentration of a given electrolyte (e.g., potassium) is deemed elevated. The method involves removal of ultrafiltrate with its replacement by half with normal saline, thus diluting the concentration of the given electrolyte to safer levels. From the description of on-bypass ultrafiltration it can be appreciated that although these methods have different names, their end point is similar—that is, attempted removal of excess clear fluid resulting in hemoconcentration, removal of inflammatory mediators, and manipulation of electrolyte concentrations to safe levels.

First described by Naik and associates[146] in 1991, MUF involves filtration of blood once the patient has been weaned from bypass. This can be achieved either by a venovenous technique in which blood is removed and returned to the atrium once concentrated or by an arteriovenous technique in which blood is removed via the aortic cannula and returned via the venous line.[146,162,163] In more detail, in this technique blood is removed in a retrograde fashion by the aortic cannula and passes through the ultrafilter along with remaining circuit volume from the venous reservoir and oxygenator. Flow through the ultrafilter is maintained by a roller pump at flows of between 10 and 30 mL/kg, with the slower rates resulting in a more gradual change in the intravascular fluid compartment and thus potentially better tolerated. A constant atrial pressure is maintained throughout the procedure by adding crystalloid into the venous reservoir as needed. Suction is applied to the filtrate port to achieve a maximal transmembrane pressure, thus allowing for ultrafiltration rates of between 100 and 150 mL/minute.[60] End points for the process of MUF are time (15 to 20 minutes) and reaching of a target hematocrit (usually 40%) once the circuit volume has been replaced by crystalloid or should the patient's hemodynamics not tolerate the procedure.

Cardiac surgeries in the very young may be complex with potentially protracted CPB and cross-clamp times. Therefore, myocardial performance is depressed after weaning from CPB. Although ultrafiltration is used during CPB in an attempt to remove excess body water, it appears from studies that it is the use of MUF

that significantly improves myocardial performance (Fig. 94-11).[60,164,165] Using echocardiographic measurements in a study of infants undergoing corrective surgery under nonhypothermic arrested conditions, Davies and associates[166] found improvements in both systolic and diastolic function in the children studied. They found that the preload recruitable stroke work, which is load independent, improved after MUF and was thus a good indicator of improved systolic function. The same study showed that after MUF a decrease in the myocardial wall thickness and cross-sectional area occurred that was not present in the control group of patients who received no ultrafiltration. These reductions result in an increase in end-diastolic length and a fall in end-diastolic pressure, both of which are indicators of improved diastolic function. Although presumably it was the decrease in myocardial edema that was the cause for these improvements, increased hematocrit also was observed. Because these positive effects were not seen past 24 hours, the absolute benefit of MUF is not clear.[166]

Pulmonary dysfunction is one of the most common negative effects of CPB.[167] Therefore the use of ultrafiltration and MUF is to improve oxygenation and decrease the effects of inflammatory mediators on the alveolar capillary membrane and pulmonary vascular reactivity. Studies have demonstrated that in patients in whom ultrafiltration and MUF were used, improvements in pulmonary compliance, decreased airway resistance, pulmonary arterial reactivity, and improved oxygenation were demonstrated.[167-171] It is therefore obvious why these methods have found such wide acceptance in pediatric cardiac surgery, particularly in patients in whom normal compliance with low PVR is vital (i.e., those with single-ventricle physiology). Although these studies commonly find improvement in pulmonary function immediately after weaning from CPB and the completion of MUF, disagreement exists as to whether these effects result in improved function much beyond 6 hours, with some showing little if any benefit at 24 hours. A conclusion, however, from these studies is that combination of on-bypass ultrafiltration coupled with MUF has the best results in the early postbypass period.

Studies into the long-term effects of CPB and indeed DHCA on the brain of children are ongoing. As has been mentioned previously, the initiation of CPB will affect the major organs. In a study performed on a piglet model of DHCA, the use of MUF after CPB improved hematocrit, cerebral O_2 delivery, and cerebral O_2 consumption, thus representing a potential reduction in cerebral injury. Further studies have made similar conclusions. These studies demonstrated that four variables are of importance in improving cerebral oxygenation: P_{CO_2}, mean arterial pressure, hematocrit, and MUF flow rate.[172,173] Increasing all except MUF flow rate improved O_2 delivery. Increasing the flow rate appeared to cause a steal-like phenomenon in which apparent diastolic runoff occurred into the MUF circuit from the aortic cannula. Thus, although the process of MUF is important for recovery of normal cerebral function, care must be used not to negate the benefits by decreasing the time on MUF by increasing the flow rates (Fig. 94-12).

Common to the improvement in cardiac and pulmonary function are the associated decrease in inflammatory mediators seen after ultrafiltration. Studies have shown that the ultrafiltrate contains a wide variety of low-molecular-weight inflammatory mediators, including C3a, C5a, interleukin (IL)-6, IL-8, TNF, myocardial depressant factor, and endothelin.[168,169,174] It is the removal of endothelin-1 after MUF that results in the improvement of pulmonary vascular reactivity, which is of great importance, particularly in

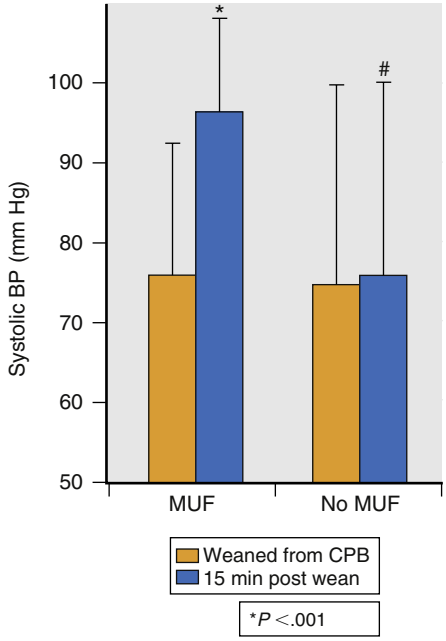

Figure 94-11. Systolic blood pressure (*BP*) after separating from cardiopulmonary bypass (*CPB*) and 15 minutes after separating with and without modified ultrafiltration (*MUF*). Note the significant improvement in systolic BP with the use of MUF. *(From Ungerleider RM: Effects of cardiopulmonary bypass and use of modified ultrafiltration,* Ann Thorac Surg *65:S35, 1998; reprinted with permission from the Society of Thoracic Surgeons.)*

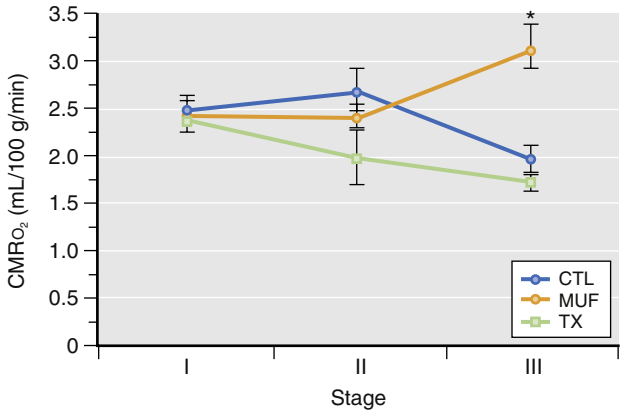

Figure 94-12. Cerebral metabolic rate for oxygen measurements ($CMRo_2$) before and after deep hypothermic circulatory arrest. Note the significant increase in $CMRo_2$ in the MUF animals compared with the control and transfusion groups at stage 3. *CTL,* Control; *MUF,* modified ultrafiltration; *TX,* transfusion. *(From Skaryak LA, Kirshbom PM, DiBernardo LR, et al: Modified ultrafiltration improves cerebral metabolic recovery after circulatory arrest,* J Thorac Cardiovasc Surg *109:744, 1995.)*

infants younger than 4 to 6 months of age, when pulmonary vascular reactivity is high, and in patients who are having staged cavopulmonary reconstructions. TNF, a potent inflammatory mediator implicated in the development of capillary leak syndrome seen after CPB, has been shown to be removed best by MUF. Despite these positive effects of MUF, the literature does not give a clear advantage of one form of ultrafiltration over the other, and it may be the combination of these methods that once again shows the best potential results.

Another important post-CPB issue is ongoing blood loss. Little doubt exists that the use of MUF will result in an elevation of the patient's hematocrit secondary to the removal of the excess body water, as already discussed. This further results in decreased blood use and the observation that there is less postoperative bleeding.[175] Indeed, in older children attempts can thus be made to avoid the use of donor blood altogether.

Disadvantages to these techniques are noted. The addition of an ultrafilter to the CPB circuit adds a level of complexity to the circuitry and thus another potential area in which circuit-related complications may occur. Antagonists of MUF note also the following potential problems: the potential for air entrainment into the arterial cannula, additional time in which the patient is anticoagulated, potential for hypovolemia as volume is drawn off from the patient, hypothermia because the filtered volume does not pass through the heater/oxygenator, and the potential for the increase in the plasma concentration of drugs (e.g., fentanyl).[176] Another interesting complication potentially associated with ultrafiltration was the reduction in thyroid hormone. This acute hypothyroidism may lead to depressed function, manifesting as decreased contractility, heart rate, cardiac output, and elevated SVR, all of which will clearly affect the immediate post-CPB period.[177] As with other techniques in medicine the benefit versus risk must be seriously considered, but from the presented evidence the use of ultrafiltration both on and off CPB is extremely beneficial and these methods are thus commonly used in modern pediatric cardiac surgery with good result and little complication.[163,165,178,179]

In the preceding paragraphs the discussion concluded that no clear advantage has been determined of one method of ultrafiltration over the other. Unfortunately, comparing a wide range of patients having different surgeries under different conditions is difficult, and thus it appears that from the articles referenced the best strategy would include both the use of on-CPB ultrafiltration and the use of MUF once the patient has been separated from bypass to achieve the goals of decreasing total-body water; removal of inflammatory mediators; improved hematocrit, and thus O_2-carrying capacity; and preservation of vital organ function.

SPECIFIC PROBLEMS ENCOUNTERED IN DISCONTINUING CARDIOPULMONARY BYPASS

See also Chapter 66.

Left Ventricular Dysfunction

The contractile state of the LV may be reduced after pediatric cardiac surgery. This is due to surgically induced ischemia during the repair, the preoperative condition of the myocardium, the effects of DHCA on myocardial compliance, and new, altered loading conditions on the LV caused by the repair.[180,181] Left ventricular dysfunction can be treated by optimizing preload, increasing heart rate, increasing coronary perfusion pressure, correcting ionized calcium levels, and adding inotropic support. The neonate's heart rate–dependent cardiac output, reduced myocardial compliance, and diminished response to calcium and catecholamines are factors influencing the need for inotropic support. Inotropic support is usually begun with dopamine 3 to 10 μg/kg/minute. Several studies suggest that the effect of dopamine in children is age dependent. After cardiac surgery in young children, dopamine increases cardiac output, which correlates more with elevations in heart rate than augmentation of stroke volume, whereas, in young adults, dopamine clearly increases stroke volume. Nonetheless, infants and neonates respond favorably to dopamine infusions with increased systemic blood pressure and cardiac output and improved systemic perfusion.

Calcium supplementation is important in augmenting cardiac contractility. Although calcium supplementation has fallen into some disfavor because of concerns over reperfusion injury, it remains an important therapy after pediatric cardiac surgery. Fluctuations in ionized calcium levels occur commonly in the immediate post-CPB period in children. This is most often due to the relatively large transfusions of citrate-rich and albumin-rich blood products, such as whole blood, fresh frozen plasma, platelets, and cryoprecipitate necessary for hemostasis, all of which bind calcium.[182] Routine calcium supplementation during the early post-CPB period is especially helpful in patients with diminished left ventricular function. In patients with a slow sinus or junctional rate, calcium must be administered cautiously because marked slowing of AV conduction may occur.

Epinephrine 0.02 to 0.2 μg/kg/minute is useful in patients with significant left ventricular dysfunction who remain hypotensive with high left atrial filling pressures or echo-Doppler imaging evidence of reduced contractility or regional ischemia.[183]

Milrinone, a potent phosphodiesterase-3 inhibitor, is also an effective inotrope-vasodilator in infants and children. Studies in neonates after open-heart surgery reveal significant reductions in SVR and PVR and increases in cardiac index, primarily as a result of larger stroke volume.[184] Infants and children demonstrate a larger volume of distribution and clearance of milrinone than that in adults; thus, the initial dose necessary to achieve therapeutic levels may be as large as 100 μg/kg.[185] In neonates, the initial dose of milrinone on CPB is 100 μg/kg, followed by a continuous infusion to be started within 90 minutes of the initial dose at a rate of 0.2 μg/kg/minute to maintain a therapeutic level. In older infants and children, the rate of continuous infusion is larger, usually 0.5 to 1 μg/kg/minute.

Dobutamine is an effective, albeit weaker, inotropic agent in children. Although it is reported to have fewer chronotropic effects than dopamine in neonates, significant tachyarrhythmias may occur. This may be related to structural similarities between dobutamine

and isoproterenol.[183] In children after cardiac surgery, dobutamine increases cardiac output primarily through increased heart rate. The efficacy of dobutamine seems to be reduced in immature animals. This is consistent with reduction in α-receptors and a higher level of circulating catecholamines in newborns.

Right Ventricular Dysfunction

Primary right ventricular dysfunction is a common finding after CPB in neonates, infants, and children. For example, after repair of TOF, preexisting right ventricular hypertrophy, a right ventriculotomy, and the placement of a transannular patch across the right ventricular outflow tract, resulting in acute pulmonary regurgitation and right ventricular volume overload, are common causes of postoperative right ventricular dysfunction.[20] The treatment of right ventricular dysfunction consists of measures directed at lowering PVR and preserving coronary perfusion without distending the RV. Metabolic acidosis should be addressed and inotropic agents selected for their vasodilating properties (e.g., dopamine, amrinone, or milrinone). In cases of extreme ventricular dysfunction, low-dose epinephrine (0.01 to 0.03 μg/kg/minute) may provide inotropy without vasoconstriction.[181] Mechanical ventilation should be adjusted to assist right ventricular function and minimize PVR.

In contrast with the LV, the low intracavitary pressure of the normal RV receives two thirds of its coronary filling during ventricular systole. In patients with right ventricular dysfunction, maintaining a normal or slightly elevated systolic arterial pressure maximizes coronary perfusion to the RV and augments contractility. If the need for inotropic support persists after the early post-CPB period, a critical evaluation for other structural and functional abnormalities should be aggressively pursued. Preload should be maintained at a normal to slightly elevated level. Because right ventricular contractility is reduced, it is important to maximize preload to the highest portion of the Starling curve. Overdistention of the RV, however, is not well tolerated, owing to diminished ventricular compliance and diastolic dysfunction. Excessive volume loading may result in significant diastolic dysfunction, tricuspid regurgitation, and worsening forward flow. Generally, CVP much above 12 to 14 mm Hg is poorly tolerated in neonates and infants with right ventricular dysfunction.[186] If right ventricular dysfunction is severe, the sternum should be left open.[187] This eliminates the impedance imposed by the chest wall and mechanical ventilation, allowing the RV to maximize its end-diastolic volume. An additional strategy in neonates, infants, and children with significant post-CPB right ventricular dysfunction is to allow right-to-left shunting at the atrial level. Typical patients who would benefit from this strategy include neonates undergoing repairs for TOF and truncus arteriosus. Allowing an atrial communication to remain open, with blood shunting in a right-to-left direction, preserves cardiac output and O_2 delivery to the systemic circulation. Although these patients have somewhat diminished systemic O_2 saturation, as their effective cardiac output and tissue O_2 delivery are enhanced, systemic perfusion pressure improves and coronary perfusion of the RV is maintained. As right ventricular function improves, right atrial pressure falls, right-to-left shunting decreases, and systemic arterial saturation rises.

If right ventricular dysfunction persists to the extent that systemic cardiac output is compromised, consideration should be given to extracorporeal life support (extracorporeal membrane oxygenation [ECMO]). When ECMO is used for circulatory support, venoarterial cannulation is preferred. Venous and arterial access may be achieved through a large central artery and vein, usually the carotid artery and internal jugular vein, or by direct chest cannulation. Recovery from severe ventricular dysfunction is predicated on the concept that the myocardium has sustained a transient injury (i.e., "stunned myocardium") and is capable of recovery with time.[188,189] ECMO is used to decrease ventricular wall tension, increase coronary perfusion pressure, and maintain systemic perfusion with oxygenated blood. ECMO also may be used for left ventricular failure, although success with this condition is less common than that seen with right ventricular dysfunction or pulmonary artery hypertension. Patients placed on ECMO because they fail to separate from CPB demonstrate significantly greater mortality than do those for whom ECMO was instituted later in the postoperative course.[190] The children who consistently have the lowest survival rate are those who require ECMO after a Fontan operation.[191] The role of ECMO in patients with myocardial injury or pulmonary hypertension is to provide adequate systemic O_2 transport and systemic perfusion while allowing the ventricles to rest and recover. ECMO may even provide an effective means of resuscitation for postoperative cardiac patients, particularly if instituted promptly.[192] In larger infants and children with predominantly right ventricular dysfunction and satisfactory pulmonary function, a selective right ventricular assist device may be preferable to ECMO.[193]

Pulmonary Artery Hypertension

Primary pulmonary hypertension is a devastating disease. The progressive and sustained elevation in PVR eventually leads to right-sided heart failure and death.[194,195] Pulmonary arterial hypertension (PAH) is defined by the presence of mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg during exercise.[196] In two recent studies, presence of PAH was shown to be a significant predictor of major perioperative cardiovascular complications, including pulmonary hypertensive crises, cardiac arrest, and death in patients undergoing cardiac catheterization or noncardiac surgery under anesthesia.[197,198] Suprasystemic pulmonary artery pressure was predictive of major complications. Complications, however, were not associated with age, cause, type of anesthetic, or airway management. Preanesthesia evaluation should evaluate disease severity. A history significant for chest pain, syncope, and dizziness, with signs of dyspnea at rest, low cardiac output state, metabolic acidosis, hypoxemia, and signs of right-sided heart failure warrants caution. Acute increases in PVR resulting in pulmonary hypertensive crises cause an increase in right ventricular afterload, right ventricular dysfunction, and hemodynamic decompensation. Suprasystemic pulmonary artery pressure results in inadequate PBF, inadequate left ventricular preload, low cardiac output, and biventricular

failure. The associated hypotension results in coronary ischemia, which worsens this cycle. Perioperative factors thought to precipitate a pulmonary hypertensive crisis include hypoxia, hypercarbia, acidosis, hypothermia, pain, and airway manipulations in patients with pulmonary hypertension. Such patients present for hemodynamic catheterization, drug study, and noncardiac and cardiac surgical procedures. Although each anesthetic has to be tailored to the patient's pathophysiologic condition and surgical procedure, certain common principles remain. Pulmonary vasodilator therapy and inotropes must be continued in the perioperative period. Investigations include a comprehensive echocardiogram with occasional chest computed tomography (CT) angiography to exclude pulmonary thromboembolic disease. In our center, premedication is avoided and intravenous induction is performed with carefully titrated doses of ketamine. Procedures with potential for blood loss, hemodynamic instability, and changes in ventilatory status mandate invasive arterial monitoring. Care should be taken to avoid systemic hypotension while achieving general anesthesia. Ventilation and oxygenation are controlled, and acidosis is treated aggressively. Hypotension in the presence of euvolemia may need to be treated with inotropes and, if necessary, α_1-agonists.[199,200]

Therapy for elevated pulmonary artery pressures is directed at lowering PVR and unloading the RV. Reduction of PVR is accomplished by altering ventilation pattern, inspired O_2 concentration, and blood pH. Specifically, manipulating the pulmonary vascular bed in newborns and infants is a matter of regulating $Paco_2$, pH, PaO_2, PAO_2, and ventilatory mechanics.[201,202] $Paco_2$ is a potent mediator of PVR, especially in the newborn and young infant. Reducing $Paco_2$ to 20 mm Hg and increasing pH to 7.6 produces a consistent and reproducible reduction in PVR in infants with pulmonary artery hypertension. Manipulating serum bicarbonate levels to achieve a pH of 7.5 to 7.6 while maintaining a $Paco_2$ of 40 mm Hg has equal salutary effects on PVR.[203] Both the PaO_2 and the PaO_2 decrease PVR as well. In the circumstance of intracardiac shunts, changes in FiO_2 have little effect on PaO_2. Thus, by inference, a reduction in PVR induced by increasing the inspired O_2 concentration is probably a direct pulmonary vasodilatory effect of PaO_2 rather than PaO_2.

Ventilatory mechanics also play a major role in reducing PVR. Neonates and infants have a closing volume above functional residual capacity. Thus, at the end of a normal breath, some airway closure occurs. This process results in areas of lung that are perfused and yet underventilated. As these lung segments become increasingly hypoxemic, secondary hypoxic vasoconstriction occurs. The net effect is an increase in PVR. Therefore, careful inflation of the lungs to maintain functional residual capacity will selectively reduce PVR. In practice, this is accomplished with relatively large tidal volumes and low respiratory rates, which produce an exaggerated chest excursion. Generally, tidal volumes of 15 to 25 mL/kg are required. Respiratory rates of 15 to 25 breaths/minute are used for neonates and infants. A reduced ventilatory rate with large tidal volumes reduces mean airway pressure and provides a longer expiratory phase of ventilation.

Because PBF occurs predominantly during the expiratory phase of the respiratory cycle, the ventilatory pattern should be adjusted to allow an adequate distribution of gas throughout the lung during inspiration and a more prolonged expiratory phase to promote blood flow through the lungs. End-expiratory pressure must be applied cautiously during the post-CPB period. Low PEEP (3 to 5 mm Hg) prevents narrowing of the capillary and precapillary blood vessels, thereby reducing PVR. Higher PEEP or excessive mean airway pressure results in alveolar overdistention and compression of the capillary network in the alveolar wall and interstitium. This condition elevates PVR and reduces PBF.[149]

The final and perhaps the least well-recognized use of the mechanical ventilator is to assist in unloading the RV. During inspiration, intrathoracic pressure increases and creates an increased pressure gradient from the lung to the LA, promoting cardiac output. This ventilatory assist is commonly seen in patients with PAH or right ventricular dysfunction. An augmentation of the arterial pressure trace during inspiration is seen. The use of the ventilator to augment systemic blood flow is very similar to the thoracic pump concept used to explain blood flow during CPR.[204] The inspiratory assist must be balanced by the potential negative effects of increased mean airway pressure on PVR and right ventricular afterload. To maximize these cardiopulmonary interactions, high tidal volume with low respiratory rates should be employed.

Attempts to manipulate PVR through pharmacologic interventions have been generally unsatisfactory. Drugs that have shown the greatest promise in decreasing PVR both clinically and experimentally have been the phosphodiesterase inhibitors. Amrinone and milrinone are the only drugs of this class currently available in the United States. Both reduce PVR and SVR and increase RV contractility.[205] Isoproterenol has mild pulmonary artery–vasodilating properties in the normal pulmonary circulation.[206] It reduces PVR in adults after cardiac transplantation, but very few data support PVR reduction in infants and young children after cardiac surgery. In immature animals, the myocardium is less responsive to isoproterenol and causes tachycardia and increased myocardial O_2 consumption. These latter effects may reduce coronary perfusion and result in relative myocardial ischemia. Both prostaglandin E1 and prostacyclin have a pulmonary vasodilating effect; however, both drugs produce systemic hypotension, which severely limits their use.[207,208]

Because of the lack of specificity of vasodilator drugs on the pulmonary bed, newer pharmacologic methods of controlling pulmonary artery hypertension and elevated PVR are being sought. Two new concepts include ultra–short-acting intravenous vasodilators and inhaled vasodilating agents such as NO. Ultra–short-acting intravenous vasodilators are nonspecific potent vasodilators, with a half-life measured in seconds. Infusion of these drugs into the right side of the circulation produces a potent short-lived relaxation of the pulmonary artery smooth muscle.[209] Once the drug reaches the systemic circulation it is no longer functional. Adenosine and ATP-like compounds have these properties and may have clinical applicability in pulmonary artery hypertension in the future.[210]

Beginning in the past decade, several potent therapies for pulmonary hypertension have evolved.[201,202] A continuous intravenous infusion of prostacyclin improves pulmonary vascular hemodynamics, exercise tolerance, and survival in pulmonary hypertension.[211] Sildenafil is a selective phosphodiesterase type 5 inhibitor. Phosphodiesterase type 5 breaks down cyclic guanosine monophosphate. Sildenafil produces acute and relatively selective pulmonary vasodilatation and acts synergistically with nitric oxide.[212-214] Bosentan is a dual endothelin receptor blocker. Preliminary reports indicate that bosentan improves symptoms, exercise tolerance, and hemodynamics in patients with pulmonary hypertension. The drug is well tolerated and free of side effects apart from a dose-dependent increase in liver enzymes.[215] Lung transplantation is the only available surgical therapy for primary pulmonary hypertension; however, the 5-year survival remains less than 50%, and bronchiolitis obliterans remains the single most common cause of death.[216,217] Before listing for transplantation, all patients undergo a hemodynamic cardiac catheterization and drug study in which reversibility of pulmonary hypertension with increased inspired O_2 concentrations and NO is determined.[218] Inhaled iloprost, although used in adult centers, has not become routine in pediatric practice.

CPB with associated endothelial injury predisposes to the development of postoperative pulmonary hypertension in patients with CHD. Anatomic factors that impose either obstruction to PBF or residual left-to-right shunting need to be surgically addressed. Elevated LAP resulting from mitral valve disease or left ventricular dysfunction, pulmonary venous obstruction, branch pulmonary artery stenosis, or surgically induced loss of the pulmonary vascular cross-sectional area all raise right ventricular pressure and impose a burden on the right side of the heart.

NO, an endothelium-derived vasodilator that is administered as an inhaled gas, represents the most promising development in the therapy for elevated PVR in patients with CHD (see Chapter 104). Although nonselective, it is rapidly inactivated by hemoglobin and, when inhaled, produces no systemic vasodilation.[219] NO reduces pulmonary artery pressure in adult patients with mitral valve stenosis and in selected pediatric cardiac patients with PAH.[220-222] The congenital cardiac patient population in whom NO appears to be effective is patients with acute PVR elevation after open-heart surgery, as well as preoperative pulmonary hypertension accompanying specific anatomic conditions (e.g., total anomalous pulmonary venous return, congenital mitral stenosis).[220,222] Because it acts directly on vascular smooth muscle, NO remains effective despite the post-CPB endothelial injury frequently encountered in children.[223] Some centers routinely employ NO in low dose (1 to 5 ppm) after a Fontan operation when the CVP-LAP gradient exceeds 10 mm Hg.[224] Finally, NO can provide diagnostic information that helps distinguish reactive pulmonary vasoconstriction from fixed anatomic obstructive disease either in the postoperative surgical patient or in the patient undergoing pretransplant evaluation.[225,226] In the latter, the distinction between pulmonary vasoconstriction and advanced pulmonary vascular occlusive disease will influence the prediction as to whether a child with pulmonary hypertension in association with either CHD or cardiomyopathy will survive a heart transplant or requires replacement of both heart and lungs.

Management strategies for postoperative pulmonary hypertension and treatment of pulmonary hypertensive crises include sedation, moderate hyperventilation (maintaining P_{CO_2} between 30 and 35 mm Hg), moderate alkalosis (pH >7.5), increased inspired O_2, optimization of PEEP (to maximize functional residual capacity), pulmonary vasodilators (e.g., NO), and the creation or maintenance of an intracardiac right-to-left shunt in an attempt to maintain cardiac output.[227,228] NO is also useful in the manipulation of PVR after Fontan-type procedures.[229] Care should be exercised in weaning NO in patients, because abrupt withdrawal can precipitate rebound pulmonary hypertension and pulmonary hypertensive crises.[229,230]

ANTICOAGULATION, HEMOSTASIS, AND BLOOD CONSERVATION

Modern pediatric cardiac anesthesia must include the principles and practice of effective anticoagulation, hemostasis, and blood conservation (see also Chapters 61 through 63). Bleeding after CPB remains a significant problem in pediatric cardiac surgery.[231] Continuing blood loss after CPB requiring blood component replacement is associated with hemodynamic compromise as well as morbidity from multiple donor exposures. In pediatric patients, restoration of hemostasis has proved difficult; diagnosis of the problem and treatment are marginally effective.

Neonates, infants, and children undergoing cardiac surgery with CPB have a higher rate of postoperative bleeding than that seen in older patients.[231] This is due to several factors. First, exposure to the nonendothelialized extracorporeal circuit is disproportionate, which produces an inflammatory-type response. This inflammatory response to CPB is inversely related to patient age—the younger the patient, the more pronounced is the response.[11] Because complement and platelet activation are linked to the activation of other protein systems in the blood (i.e., fibrinolytic), it is probable that this hemostatic activation, which results in impaired hemostasis and increased bleeding tendency, plays a major role during pediatric cardiac surgery. Second, the type of operation performed in neonates and infants usually involves more extensive reconstruction and suture lines, creating more opportunities for surgical bleeding than in adult cardiac patients. Operations are also frequently performed using DHCA, which may further impair hemostasis.[232] Third, the immature coagulation system in neonates also may contribute to impaired hemostasis.[233] Although procoagulant and factor levels may be reduced in young patients with CHD resulting from immature or impaired hepatosynthesis,[234] functional bleeding tendencies are usually not present before surgery. Finally, patients with cyanotic heart disease demonstrate an increased bleeding tendency before and after CPB.

CPB is a significant thrombogenic stimulus requiring anticoagulation with heparin before its initiation. Heparin is usually administered empirically based on patient

weight, and its effect is followed by activated clotting time monitoring. Because the heparin effect is primarily due to coupling with antithrombin III and because of the age-related differences and quantitative differences in procoagulants and inhibitors, variability of heparin dosing and its effect has been a concern. High heparin sensitivity is observed in the first week of life and then decreases progressively until about 3 years of age, when values approach those observed in adults.[235] These findings are consistent with evidence in infants of variable quantities of both procoagulants and inhibitors, especially prothrombin and antithrombin III.[236] Heparin administration also must include a consideration of the quantity and composition of the priming volume for CPB, especially if fresh frozen plasma is added. The authors recommend a heparin dose of 200 units/kg plus an additional dose of 1 to 3 units/mL of priming solution and maintaining the activated clotting time above 480 seconds.

Heparin is neutralized with protamine dosed according to the quantity of heparin administered or based on body weight. Protamine excess may actually contribute to postoperative bleeding.[237] It appears that the protamine dose requirement is high for neonates and decreases with increasing age of the patient. The relatively increased protamine requirement for young compared with older children and adults is indicative of higher circulating heparin levels after CPB.[238] Delayed hepatic clearance of heparin resulting from organ immaturity and the predominant use of hypothermic circulatory arrest in the young will decrease metabolism and excretion of heparin. We typically administer protamine 4 mg/kg in neonates, whereas 2 mg/kg usually restores the activated clotting time to baseline values in adolescents and adults. Interpatient variability mandates some form of individual assessment to guide drug dose to prevent excess protamine.[237]

Neonates and young infants with CHD will have low circulating levels of procoagulants and inhibitors. The thrombogenic and dilutional effects of CPB further contribute to hemostatic abnormalities after CPB. Formed blood elements such as leukocytes and platelets may be activated, and procoagulants may be diluted by CPB. Furthermore, DHCA causes increased clotting and fibrinolytic activity. The lower the temperature, the higher the degree of hemostatic activation. Therefore, the causes of bleeding after CPB are many.[238] Injudicious use of blood products to correct individual coagulation abnormalities separately can further exacerbate dilution of existing procoagulants, as well as carrying the risks for multiple donor exposure. Because the transfusion of blood products is associated with numerous complications, transfusion is to be assiduously avoided, unless specifically indicated by an impairment in tissue oxygenation or documented coagulopathies with clinically significant bleeding. All efforts at blood conservation during cardiac surgery should be routinely employed by all members of the operative team, intraoperatively as well as postoperatively.

Bleeding after CPB is not an unusual occurrence (see also Chapter 66). The surgeon should first attempt to identify any obvious source of surgical bleeding at the sites of repair. Next, adequate protamine reversal of heparin is assessed by measuring an activated clotting time. In general, standard coagulation tests show a prolongation of the partial thromboplastin time, prothrombin time, hypofibrinogenemia, dilution of other procoagulants, and prolonged bleeding time in many pediatric patients, with and without bleeding (Fig. 94-13). The most common reason for persistent bleeding is platelet dysfunction.[239,240] Under such circumstances, administration of platelets is warranted in the presence of bleeding. Routine administration of blood products to correct laboratory coagulation abnormalities in the absence of bleeding is never clinically indicated. After platelets have been given and if bleeding is still present, reassessment and repeat platelet infusion or the administration of cryoprecipitate or fresh frozen plasma may be beneficial. Under most circumstances, meticulous surgical technique, appropriate administration of protamine, adequate patient temperature, and platelet infusion will correct excessive bleeding. In neonates, excessive bleeding and the escalating dilutional effects of selective component therapy on the remaining procoagulants make the treatment of bleeding difficult. The use of fresh whole blood may be warranted under these circumstances. The administration of fresh whole blood (<48 hours old) after CPB can meet all the hematologic requirements with minimum donor exposure. The efficacy of whole blood in restoring hemostasis and reducing blood loss after CPB has been demonstrated in patients younger than 2 years of age undergoing complex surgical repairs.[231]

It is our practice to arrive at an optimum hematocrit for the patient after discussion with the surgeon based on the individual patient's lesion and complexities. This is achieved with the minimal amount of product that can be used to achieve the hematocrit level both on bypass

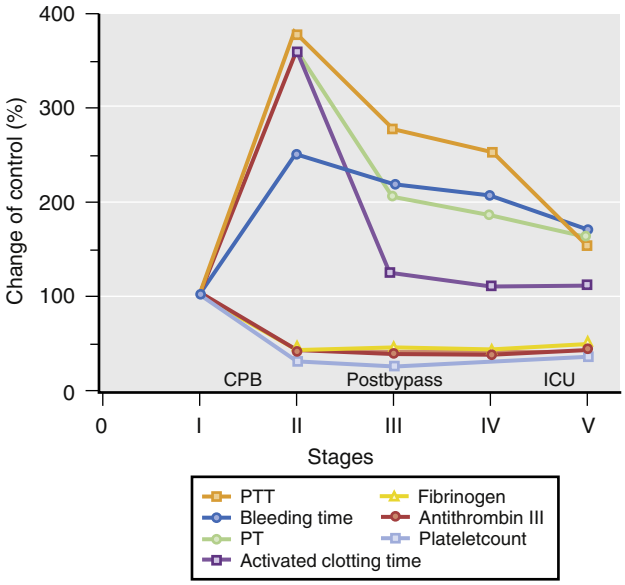

Figure 94-13. Plot of blood coagulation profile changes before, during, and after cardiopulmonary bypass (*CPB*) in 25 children. Clotting times and coagulant factors are shown as percent change from control. Stage I, baseline, before CPB; stage II, post-CPB, before protamine reversal of heparin; stage III, after protamine; stage IV, just before leaving the operating room; stage V, after 3 hours in the intensive care unit (*ICU*). *PT,* Prothrombin time; *PTT,* partial thromboplastin time.

and after bypass, minimize bleeding and coagulopathy, minimize donor exposure, and mitigate against transfusion-related acute lung injury (see also Chapter 61).

Many attempts have been made to reduce bleeding after CPB by pharmacologic interventions. Desmopressin acetate and the antifibrinolytics aminocaproic acid and tranexamic acid have been tried with variable success in significantly reducing postoperative blood loss after cardiac surgery.[241-243] The proteinase inhibitor aprotinin showed promise in its ability to reduce postsurgical cardiac blood loss, but it was removed from the United States market because of concerns of life-threatening anaphylactic reactions.[232,244-248] Antifibrinolytics exert their effects by reversibly binding to lysine analogue sites on plasminogen, a molecule primarily responsible for the breakdown of fibrin. By inhibiting plasminogen, and therefore plasmin, the procoagulant effects of fibrin remain. In a recent large-scale observational study of 22,258 patients, aprotinin was found to have effects similar to those of both aminocaproic acid and tranexamic acid in terms of reducing bleeding requiring surgical intervention and mortality.[249] Given the risk for analyphylatic reactions with aprotinin and similar benefits in surgical bleeding with the antifibrinolytics, many institutions report favorable use of aminocaproic acid and tranexamic acid. We have chosen to use aminocaproic acid as an antifibrinolytic in neonates undergoing complex procedures, and for repeat operations before sternotomy and repeat dosing at the start of CPB.

The techniques of blood conservation must be continued during the postoperative period. Isolated coagulation abnormalities are often present in the postoperative patient with uncomplicated cardiac issues (see Fig. 94-13). Usually, these coagulation abnormalities self-correct during the first postoperative day and are not associated with excessive bleeding. Therefore, routine correction of these abnormalities with infusion of blood products is not warranted. Administration of blood products should not occur in the absence of clinical evidence of bleeding and the identification of a specific defect requiring targeted component therapy. Routine use of blood products for volume replacement is also to be avoided; lactated Ringer or saline solution can be satisfactorily administered at a reduced cost without the hazards associated with transfusion.

POSTOPERATIVE MANAGEMENT

Immediate postoperative care of the pediatric patient who has undergone cardiothoracic surgery is an important period in the overall sequence of anesthetic and surgical management. Although the primary influence on outcome is determined by the conduct of the operation, postoperative care is an important factor. As a member of the operative team, it is necessary that the anesthesiologist understand and become involved during the immediate postoperative period. Detailed principles of postoperative management of pediatric cardiac surgical patients are beyond the scope of this chapter. However, a few general guiding principles and approaches are given to provide fundamental knowledge for the anesthesiologist.

The postoperative period can be characterized by a series of physiologic and pharmacologic changes as the body convalesces from the abnormal biologic conditions of CPB and cardiac surgery. During this period, the effects of the cardiac operation, any underlying disorders, the effects of hypothermic CPB, and special techniques such as DHCA may create special problems. In the immediate postoperative setting, abnormal convalescence and specialized problems must be recognized and managed appropriately. Fortunately, most patients are able to balance the cost imposed by the physiologic trespass created by the surgical repair and the effects of CPB against the benefit of reduced pathophysiologic loading conditions, resulting in low morbidity and mortality.

Therefore, the guiding principle in the management of the postoperative patient is an understanding of both normal and abnormal convalescence after anesthesia and cardiac surgery. The immediate postoperative period, even that of normal convalescence, is one of continuous physiologic change because of the pharmacologic effects of residual anesthetic agents and the ongoing physiologic changes secondary to abrupt alteration in hemodynamic loading conditions, surgical trauma, and extracorporeal circulation. Anesthesia and surgery affect not only the patient's conscious state but also cardiovascular, respiratory, renal, and hepatic function; fluid and electrolyte balance; and immunologic defense mechanisms. Despite these changes, postoperative care should be predictable and standardized for most patients undergoing cardiac procedures.

In general, the four temporal phases of postoperative management in the cardiac patient are (1) transport to the ICU, (2) stabilization in the ICU, (3) weaning from inotropic and ventilatory support, and (4) mobilization of fluids. Patients proceed through these phases at variable rates based on such factors as the underlying disease process, preoperative medical condition, sequelae of the surgical procedure, duration of CPB, and presence or absence of intraoperative complications. One of the most important functions of the ICU team is to identify postoperative complications in the patient who convalesces abnormally and to provide interventional therapy. Because physiologic change after cardiac surgery is dramatic but self-limiting during normal convalescence, recognition of abnormal processes can be difficult. Under such circumstances a uniform, multidisciplinary approach with experienced clinicians and nurses facilitates the identification of any abnormalities in convalescence. These abnormalities often are indications for closer observation, more invasive monitoring, pharmacologic intervention, and increased cardiopulmonary technical support. Complications include hypovolemia, residual structural heart defect, right and left ventricular failure, hyperdynamic circulation, pulmonary artery hypertension, cardiac tamponade, arrhythmias, cardiac arrest, pulmonary insufficiency, oliguria, seizures, and brain dysfunction. It is critical to detect these departures from the normal convalescent course and to treat them aggressively.

One important area in which the anesthesiologist can aid the recovery of the cardiac patient is pain control (see also Chapter 97). Pain and sedation are among the most common problems requiring ICU intervention.

Many factors influence the onset, incidence, and severity of postoperative pain. The attenuation of the stress response in the immediate postoperative period using infusions of potent opioids in the critically ill infant reduces morbidity.[100] Attenuation of postoperative pain can be attempted with a preoperative medication and an intraoperative anesthetic management technique that includes the use of potent opioids. Patients who receive no opioids preoperatively or during the operative procedure will require analgesics in the immediate postoperative period once the inhalation anesthetic is eliminated. Most cases of postoperative pain can be managed by the administration of small intravenous doses of opioids, usually morphine. This is important in a patient being weaned from the ventilator during the early postoperative period. Patients who are intubated and ventilated overnight should receive adequate sedation and pain control until ventilatory weaning is begun. This is usually accomplished by a continuous infusion of a benzodiazepine and an opioid. Continuous infusion of sedatives and analgesics results in a more consistent and reliable control of postoperative pain. When separated from mechanical ventilation, the patient is concurrently weaned from the sedatives and analgesics. Under these circumstances, careful titration of opioids often results in prompt pain relief. In patients with reactive pulmonary artery hypertension, opioids have been shown to prevent hypertensive crisis.[97]

Regional anesthesia may be used for postoperative pain control in infants and children after thoracotomy (see also Chapter 92). This method avoids opioid-induced respiratory depression from intravenous doses of these drugs. The administration of opioids in the epidural space is a very effective approach to pain management. This technique is used in children for postoperative pain control when given in the epidural space via the caudal route as a "single shot" or by a small caudal catheter. Morphine or hydromorphone provides effective analgesia with a duration of 6 to 12 hours, with no significant respiratory depression. Caudal morphine diluted in 0.05 to 0.075 mg/kg delivered in a total volume of 1.25 mL/kg of sterile saline has been used with good success in our practice. The use of regional anesthesia for postoperative pain appears to be best suited for the child extubated in the early postoperative period. Relative contraindications of this technique include hemodynamic instability and patients with abnormal clotting profiles with continued active bleeding. Using this regional technique, better arterial oxygenation, a more rapid ventilator weaning, and decreased postoperative respiratory complications may be expected. However, urinary retention occurs frequently in patients without a bladder catheter. Generally, no treatment is required.

Children requiring large thoracotomies or a bilateral thoracosternotomy (i.e., "clamshell") incision merit consideration for thoracic epidural analgesia. This technique significantly reduces the respiratory depression and pulmonary mechanics abnormalities that accompany the quantity of systemic opioids that would be necessary to provide adequate analgesia for these excruciatingly painful incisions. If the procedure requires systemic heparinization, we will typically defer placement of these catheters until the heparin effect is neutralized. For the patient undergoing coarctation repair via a left thoracotomy, we place the caudal or epidural catheter after demonstration of motor function in the lower extremities. For patients undergoing heart, lung, or both transplantations, a thoracic epidural catheter is placed at a time in the postoperative period when the patient can be weaned from intravenous medications that will adversely affect the patient's ability to breathe in close proximity to the planned extubation. It is common for these patients to need a functioning thoracic epidural catheter for several days.

POSTOPERATIVE NEUROPSYCHOLOGIC MORBIDITY

Neurologic morbidity has been identified to be increasingly problematic in neonates and infants with CHD as surgical mortality rates have improved (see also Chapter 99). Although early postoperative CNS sequelae such as stroke and seizures occur in a small percentage of neonates with CHD, the importance of more subtle neurologic abnormalities at long-term follow-up is being increasingly recognized.[217,226,250]

These findings may include fine and gross motor impairments, speech and language delays, disturbances in visual-motor and visual-spatial abilities, attention-deficit disorders, learning disorders, and impaired executive functioning. The presence of congenital brain disease in patients with CHD represents a challenge in improving long-term neurologic outcomes. Many neonates with CHD have congenital structural brain abnormalities, chromosomal abnormalities, or both, as well as physiologic abnormalities that may impair brain development. Brain abnormalities on head ultrasonography have been noted in one fifth of full-term infants undergoing heart surgery, with half of the abnormalities being present preoperatively.[250]

Postoperatively, secondary neurologic injury may be related to post-CPB alterations in cerebral autoregulation and additional hypoxic-ischemic insult, seizures, or other issues associated with prolonged ICU stay. In addition to prenatal and modifiable perioperative factors, genetic and environmental factors are known to be important. Unfortunately, modifiable perioperative factors may explain less of the variability in long-term outcomes than do patient-specific factors.

New, postoperative neurologic injury may be detected clinically in over 10% of infants,[7] and in over 50% using more sensitive brain imaging techniques such as MRI.[251,252] Given that new neurologic injury can occur at various time points during the neonate's hospitalization, perioperative attention to reducing known risk factors is critical. Mechanisms of CNS injury in infants undergoing cardiac surgery include hypoxia-ischemia, emboli, reactive O_2 species, and inflammatory microvasculopathy. Preoperatively, the primary focus is on preventing hypoxic-ischemic injury and thromboembolic insults. Modifiable intraoperative factors associated with CNS injury include, but are not limited to, pH management, hematocrit during CPB, regional cerebral perfusion, and the use of DHCA. The adverse effects of CPB may be greater in infants than larger children or adults given their immaturity in organ function and tissues and the size of

the CPB circuit relative to their body size.[253] However, a significant amount of research has been conducted in the area of intraoperative prevention of neurologic injury. With ongoing changes in technology and new therapies, the conduct of CPB and other support techniques have been actively under investigation.

The developmental consequences of exposure to general anesthetics is not well understood and is difficult to elaborate on in the absence of prospective randomized controlled trials, because of multiple factors that affect neurologic outcome in this population. Current literature suggests that multiple exposures, cumulative doses of exposure, and exposure in infancy might increase the risk for neurodevelopmental delay.[254-256] Thus, pediatric cardiac anesthesia is associated with all three risk factors, so attempting to minimize time of exposure, bundling of necessary procedures, and delaying nonessential procedures to an age associated with less neurologic risk might be appropriate. Careful choice of anesthetic agents that do not act on different neuroreceptors at key time points in development might be critical. Our current practice has evolved to using fentanyl 5 to 10 µg/kg body weight, which allows earlier extubation and may minimize anesthesia-related neurologic risk. Current multicenter trials funded by the National Institutes of Health are exploring this concept and the use of a pure α_2 agonist (dexmedetomidine) for neuroprotection during this vulnerable period.

MECHANICAL ASSIST DEVICES

Survival in children with congenital cardiac as well as pulmonary defects has improved over recent decades as a result of improved preoperative management, surgical techniques, anesthesia management, drug therapies, and postoperative management. Despite these advances, patients may still require therapies for both acute and chronic heart failure that are refractory to medical therapy. Mechanical support in the form of ECMO or ventricular assist devices (VADs) may then need to be instituted. Examples of conditions that may require support include failure to wean from CPB, acute cardiac arrest, malignant arrhythmia, and worsening myocardial function secondary to the underlying congenital defect or related to acquired cardiomyopathy. Fortunately, however, the numbers are small, with less than 2% of post-CPB patients requiring this intervention.[257] Mechanical support can thus be used as a treatment option to allow for recovery of ventricular function, as a bridge to transplant, or to support the heart in those with marginal functional reserve requiring invasive diagnostics or treatments (e.g., Williams syndrome with severe supravalvular pulmonary or aortic stenosis). As with any therapy, contraindications must be excluded before embarking on the use of a mechanical assist device. These contraindications may include extreme prematurity, severe and irreversible multiorgan failure, incurable malignancy, and preexisting neurologic devastation.[257] Anesthetic management in the use of ECMO is supportive, with management limited to assistance in the resuscitative efforts and hemorrhage associated with the cardiac surgery that was ongoing at the time of conversion to ECMO. Once the patient is on full ECMO support, ventilation is continued but at a slower rate of ventilation on the order of 10 breaths/minute, with a peak pressure of 20 cm H_2O, PEEP set at 5 to 10 cm H_2O, and FiO_2 decreased to about 40%. These settings aid in the prevention of atelectasis with management of CO_2 and O_2 related to flow across the circuit membrane. This is very different from the patient into whom a VAD is placed. Here the anesthesiologist continues to manage the patient as for routine CPB weaning. Obviously differences exist in this scenario. If a systemic VAD is placed, careful attention must be given to the ventricle pumping blood into the pulmonary bed because failure of this ventricle will have disastrous consequences. Thus, management tailored to unload this pulmonary ventricle is vitally important and will include inodilators in the form of phosphodiesterase inhibitors, inotropic support, and possibly even inhaled NO to decrease PVR and promote forward flow. In association with the perfusionist, intravascular volume loading is assessed and maintained for effective functioning of the VAD and thus adequate offloading of the assisted ventricle. Careful attention to pulmonary function is also vital. Adequate pulmonary toilet, recruitment maneuvers, and appropriate ventilatory parameters must be used. As will be alluded to later, bleeding is a potential in the implantation of the VAD and thus a clear strategy must be planned for in the form of antifibrinolytics, adequate volumes of blood and blood products, and even possibly the use of activated clotting factors (e.g., factor VII).[258]

As can be seen in Table 94-10 differences can be appreciated between assist devices. The potential for bleeding exists at the time of insertion of both of these modalities; however, it would seem from clinical experience that because of the extensive dissection and need for sizeable ventriculotomy, implantation of a VAD (and especially bi-VAD) is more problematic. The requirements of anticoagulation to keep the activated clotting time in the range of 180 to 200 for ECMO also may lead to ongoing and significant bleeding, especially if placed into a patient who requires support in the immediate perioperative phase. The use of an ECMO circuit with a membrane oxygenator requires ongoing intravenous anticoagulation with maintenance of the activated clotting time in the aforementioned range. Apart from the immediate postoperative phase, patients with VAD systems can be transitioned to oral agents. A two-part therapy is recommended. Antiplatelet therapy includes aspirin or clopidogrel. The

second part of the therapy will entail the use of anticoagulation with either warfarin (Coumadin) or subcutaneous low-molecular-weight heparin.[257]

As previously mentioned, these modalities are used as a potential bridge to transplant and, thus, exposure to donor antigens is of great importance. A study by Stiller and associates[259] comparing the volume of blood products used demonstrated that the volume was less in those treated with a VAD in a period up to 8 days after insertion. Importantly, the authors pointed out that this difference remained even when support was started at a time remote from surgery.[259]

Three potential disadvantages exist in the use of the VAD system. The lack of pulmonary support when using the VAD limits its use to patients whose lung function is adequate. From Table 94-10 it can be seen that when biventricular support is needed the patient will require two separate VAD devices, necessitating the placement of four cannulas, which may be technically difficult in a very young child. The third disadvantage is that VAD placement cannot be performed in a code situation or at the bedside as with ECMO.

Important advantages of the VAD system are the ability of patients to ambulate while on support and that VAD support can be maintained for months in contrast to the weeks only of ECMO support. Another important advantage over ECMO is that these patients will not require further venting of the LA. In patients on ECMO this is achieved by the placement of a left atrial vent at the time of sternotomy or a balloon atrial septectomy, which may require transfer to the catheterization laboratory with the possible complications associated with transport of a patient on an ECMO circuit.

Despite successful resuscitation and placement onto mechanical assist devices, morbidity and mortality remain high, with ECMO appearing to have worse outcomes. The mortality rate for ECMO in the 1990s was on the order of 47%, with survival in series published in the early 2000s not showing much improvement.[260-263] In contrast, the survival in those into whom a VAD is placed appears to be superior within the quoted series up to 80% of patients surviving to transplantation or being successfully weaned from support.[262,264] In the study by Blume and co-workers,[261] however, it was noted that associated CHD, and patients who are younger and smaller, have a higher mortality than those with fulminant myocarditis and cardiomyopathy.[261] Alongside survival data, the next most important marker is neurologic outcome, and it appears that this is better in the VAD group.[265,266] Risk factors for poor neurologic outcome were once again of low weight and duration of DHCA, both of which place patients on ECMO at a survival disadvantage because patients on ECMO will be smaller and some of those who undergo DHCA for repair of congenital anomalies will require emergent ECMO support to wean from CPB or in the immediate postoperative phase.[267]

Survival predictors are important in our management of these patients. One common variable that can predict survival is the return of ventricular function between 3 and 5 days after the initiation of support, and should the support be required for longer periods, morbidity and mortality increase.[263,267] Both of these modalities have been used successfully as a bridge to transplantation, with patients with a VAD having a greater than 80% survival to transplantation and patients on ECMO showing a less than 60% survival. Yet ECMO is used often in the infant population and in those with complex CHD, both of which are factors known to increase mortality among VAD patients.[267] The important causes of morbidity and mortality in patients on both of these modalities include cerebrovascular events secondary to either hemorrhagic or embolic phenomena, circuit-related issues (e.g., circuit thrombosis), renal failure requiring hemofiltration, sepsis, ongoing hemorrhage, and multiple-organ failure.

Although these modalities are often compared to each other, they both have unique places in the care of children with cardiac disability. ECMO has a great advantage in that it can be employed rapidly in a code situation for a patient of any age or size. In the past, size has been the limiting factor for implantation of VAD systems into pediatric patients. The Berlin Heart VAD (Berlin Heart AG, Berlin, Germany) is available for use even in neonates. The system has been employed in Europe for over 10 years and has pump sizes from 10 to 80 mL. At this time the device is available only for emergency compassionate use in the United States. From this, however, it can be appreciated that these two modalities can certainly complement each other, with ECMO being used acutely; once the patient is physiologically stable, but still requiring support, a VAD can be used should long-term support be warranted.

A newer mechanical assist device for use in children is the temporary Total Artificial Heart (TAH) system. The TAH system is indicated for use as a bridge to transplant for patients in imminent risk for death from biventricular failure. The implantation and use of this device is unique in that it requires the complete removal of the native myocardium, such that recovery without transplantation is not possible. Once the myocardium is removed, inflow and outflow pumping chambers are sown into the right and left heart vessels. Sizing requirements include patient body surface area of 1.7 m^2 or greater, echocardiographic left ventricular end-diastolic diameter of 70 mm or greater, a CT scan with an anterior-to-posterior dimension at the 10th thoracic vertebrae of 10 cm or greater, and a chest radiograph with a cardiothoracic ratio of 0.5 or greater. Smaller TAH devices may be available soon, which would allow implantation in smaller patients. This device has been used successfully as a bridge to transplant in a patient with failing Fontan physiology who later went on to receive a heart transplant.

ANESTHESIA FOR HEART AND LUNG TRANSPLANTATION

Although perioperative management for thoracic organ transplantation is considered elsewhere in this text, the application of these procedures to children requires some specific modification (see also Chapter 75). Differences include the characteristics of the candidates, preparation of these children, anesthetic management, surgical considerations, post-CPB management, and outcome. Even though some of the earliest heart transplant procedures were performed for congenital heart malformations, this indication became rare by the early 1980s. In 1984, over

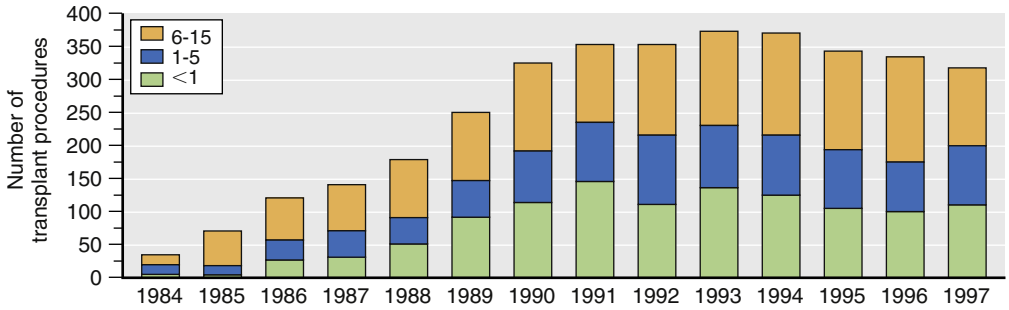

Figure 94-14. Demographic data for pediatric heart transplantation by age. Stacked bar graph illustrates the total number and age distribution for heart transplantation in patients younger than 16 years of age. Note the rapid rise in transplant procedures performed during the late 1980s, with particular growth in the population of children 5 years of age and younger. Having peaked in the mid-1990s, the total number of transplant procedures (both adult and pediatric) has declined slightly, but the relative age proportions within the pediatric population remain relatively constant. *(Data from the Registry of the International Society for Heart and Lung Transplantation, Addison, Tex.)*

60% of the few pediatric heart transplant procedures were performed in patients with cardiomyopathy, usually adolescents. In the next decade, a dramatic rise in the number of infants and young children with congenital heart malformations treated with heart transplantation resulted in a marked shift in the demographics (Fig. 94-14).[268] By 1995, over 70% of the children receiving heart transplants were younger than 5 years of age, with half of those younger than 1 year. The overwhelming majority of these infants received transplants for congenital heart malformations for which reconstructive options either had failed or were not believed to exist (Fig. 94-15).[268] The implications of this shift reach into every element of perioperative management.

Children considered for heart transplantation are more likely to have pulmonary hypertension than adults. Most adult transplant programs will not offer heart transplant therapy to patients with PVR over 6 Wood units/m^2.[269] The exclusion threshold in infants and children remains controversial. Some programs accept patients with PVR as high as 12 Wood units/m^2, particularly if the pulmonary vasculature responds to vasodilators such as O_2, NO, calcium channel blockers, or prostacyclin.[270] Neonates are generally assumed to have elevated PVR, but outcome data from some programs suggest that the importance of this factor for postoperative outcome is substantially less in the first year of life, perhaps because the infant donor hearts, having recently undergone transitional circulation, are better prepared to cope with the right ventricular pressure load that elevated PVR imposes.[271]

The anesthetic plan for pediatric heart transplantation must accommodate a wide spectrum of pathophysiology. Recipients with congenital heart malformations benefit from the analysis of loading conditions and optimizing hemodynamics discussed previously. Although a few of these patients undergo heart transplantation because the natural history of reconstructive heart surgery poses greater risk despite reasonable ventricular function, most candidates exhibit some manifestations of impaired ventricular performance. Accordingly, they require careful titration of anesthetic agents with minimal myocardial depressant characteristics to avoid cardiovascular collapse. In this fragile population, even modest doses of opioids can be associated with marked deterioration in

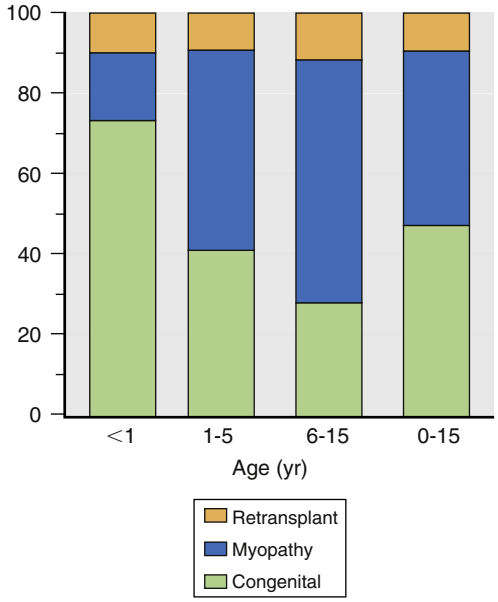

Figure 94-15. Indication for heart transplantation in children. Over the past 2 decades, the major indications for pediatric heart transplantation were nearly equally divided between congenital malformation and cardiomyopathy. In later years, pediatric recipients with congenital malformations assumed a slight plurality as a result of shifting age demographics. As illustrated, younger children are more likely to undergo heart transplantation because of congenital malformation. *(Data from the Registry of the International Society for Heart and Lung Transplantation, Addison, Tex.)*

systemic hemodynamics, presumably by reducing endogenous catecholamine release. As with most congenital heart patients, skilled management of the airway and ventilation represents crucial elements in a satisfactory induction, particularly in the presence of elevated PVR. No matter how elegant the anesthetic plan in conception and implementation, a certain proportion of these children will decompensate on induction, necessitating resuscitative therapy.

Although orthotopic heart transplantation poses some technical challenges in neonates and young infants, the replacement of an anatomically normal heart is less complex than several reconstructive heart procedures

commonly performed in patients at this age. However, the need to adapt this procedure to incorporate repair of major concurrent cardiovascular malformations requires the consummate skill and creativity that remain the province of a few exemplary heart surgeons in congenital disease.[272,273]

Having withstood extended ischemic periods, heart grafts are extraordinarily intolerant of superimposed residual hemodynamic loads that may accompany imperfect vascular reconstruction. The extensive vascular repair and, particularly in older children with long-standing hypoxemia, the propensity to coagulopathy together elevate hemorrhage to a major cause of morbidity and even mortality in pediatric heart transplantation. Nevertheless, once successfully implanted, these grafts will respond to physiologic factors that stimulate growth and adaptation in the developing infant and child.[274]

Management considerations during separation from CPB and the early postoperative period are primarily focused on three pathophysiologic conditions: myocardial preservation, denervation, and PVR. Even expeditious transplant procedures usually force the heart to endure ischemic periods that exceed those encountered during reconstructive surgery. Although some researchers believe the infant heart is more tolerant of extended ischemia, these hearts will demonstrate a period of reperfusion injury, and virtually all require pharmacologic and, in some cases, mechanical support.[271] In addition, endogenous adaptive responses and exogenous pharmacologic agents that act by myocardial sympathetic activation are ineffective in the denervated graft. Because the majority of children presenting for heart transplantation exhibit some element of elevated PVR, even with isolated end-stage cardiomyopathy, the RV of a newly implanted heart is particularly vulnerable to failure.

Ventilatory and pharmacologic interventions are usually configured to exert a favorable impact on PVR and provide inotropic and chronotropic support. Once the lungs are fully expanded, we ventilate to $Paco_2$ values in the low 30 mm Hg range using an FiO_2 of 1. Virtually all recipients receive low-dose dopamine 3 to 5 µg/kg/minute and isoproterenol 0.02 to 0.05 µg/kg/minute to promote inotropy, chronotropy, and lower PVR. In the event that these do not provide sufficient inotropy in the presence of more significant postischemic dysfunction, additional agents are added (e.g., milrinone, epinephrine). Most transplant centers have a specific regimen for immunosuppression to be initiated in the perioperative period. As with adults, pediatric transplant programs typically employ triple-drug immunosuppression with a calcineurin inhibitor (e.g., cyclosporine, tacrolimus), antimetabolite (e.g., azathioprine), and steroid. After an interval without rejection, some pediatric programs will taper and discontinue one or even two of these agents, particularly in neonates, in whom some element of tolerance is thought to develop.[275,276]

National statistics indicate that the outcome from pediatric heart transplantation is slightly less favorable than comparable results in adults.[268] The principal risk factors are age younger than 1 year and congenital heart defects. Because these factors are closely related (i.e., the vast majority of infants younger than 1 year of age undergo transplantation for a congenital heart defect), it is difficult to determine the independent effect of age. Concurrent repair of structural cardiovascular anomalies substantially increases perioperative risk for hemorrhage, residual hemodynamic loading conditions, and right-sided heart failure from elevated PVR. When these two factors are taken together, infants younger than 1 year of age have an operative mortality rate of 24%, more than twice that of older children.[268] Beyond the early postoperative period, mortality rates are quite comparable for all age groups. Nevertheless, the sequelae of rejection and the consequences of the requisite immunosuppression result in significant ongoing morbidity and mortality. Because even the best transplant recipients have achieved only a 28% 14-year survival rate, these procedures must be considered palliative for children.[268]

Lung and heart-lung transplantation have achieved respectable operative survival rates in children.[277,278] They remain the only viable surgical therapy for infants and children with severe pulmonary vascular disease and selected progressive pulmonary diseases. These remain uncommon procedures in pediatrics. Lung transplantation carries the additional morbidity of obliterative bronchiolitis, a debilitating small airway disease that results in gradual deterioration in flow-related pulmonary functions over time. Despite an operative mortality rate that is currently less than 20%, the 3-year survival rate is only 50% to 60%.[268,277]

Patients with transplanted hearts also present for surveillance cardiac catheterizations, biopsies, and other procedures.[257,279-281] The anesthesia plan in these patients should take into account the physiologic and pharmacologic problems of allograft denervation, the side effects of immunosuppression, the risk for infection, and the potential for rejection.[279-281] Cardiac allograft vasculopathy is the leading cause of morbidity and mortality after transplantation, leading to progressive graft dysfunction with heart failure, an increased risk for dysrhythmia, and the possibility of arrhythmogenic sudden death. Conventional revascularization procedures are ineffective because cardiac allograft vasculopathy is caused by intimal proliferation; thus, retransplantation is the only therapeutic option. Hyperlipidemia after heart transplantation is a common occurrence in both adults and children and is aggravated by chronic steroid therapy and other immunosuppressive agents. Statins are used with good results in controlling hyperlipidemia after transplantation and are likely to manifest inherent immunosuppressive effects. Risk factors for posttransplant renal dysfunction are the use of calcineurin inhibitors, mechanical circulatory support, prolonged inotropic support, and preexisting renal dysfunction. Newer, more potent immunosuppressive agents (e.g., tacrolimus) have led to steroid-sparing regimens late after transplantation, eliminating the detrimental effects of long-term steroid administration. Agents such as sirolimus may now be used in combination with lower levels of calcineurin inhibitors, thus minimizing long-term nephrotoxicity. Posttransplant lymphoproliferative disorders represent a pathologic spectrum of abnormal lymphoid proliferation ranging from localized early lesions to polymorphic disease or, in some cases, monomorphic lymphomatous disease. From a clinical

perspective, the most common sites of disease and presenting symptoms included the gastrointestinal tract and pulmonary systems. Patients with polymorphic disease are treated primarily by a reduction or temporary cessation of immunosuppression, along with adjunctive surgical therapy for tissue diagnosis or obstructive lesions. Most centers reserve traditional chemotherapeutic regimens for patients with nonresponsive polymorphic disease and monomorphic disease. As a result of cardiac denervation, autonomic regulatory mechanisms are not available to prevent the wide swings in a patient's hemodynamic state and the stress response is slower than usual. Cardiac parameters are significantly altered, and patients may experience a decrease in systemic blood pressure and cardiac filling pressures. Compensatory mechanisms are delayed, and reductions in cardiac output lead to decreased coronary and cerebral perfusion, especially on the background of hypertension. Drugs with direct myocardial and vascular effects are the mainstay of therapy. Most immunosuppressive agents affect hepatic and renal functions and interact with anesthetic drugs.

ANESTHESIA FOR CLOSED-HEART OPERATIONS

Early corrective repair in infancy has significantly reduced the number of noncorrective, palliative closed-heart operations. Corrective closed-heart procedures include PDA ligation and repair of coarctation of the aorta. Noncorrective closed-heart operations include pulmonary artery banding and extracardiac shunts such as the Blalock-Taussig shunt. These procedures are performed without CPB. Therefore, venous access and intraarterial monitoring are important in evaluating and supporting these patients. A pulse oximeter remains an invaluable monitor during intraoperative management.

Ligation of a PDA is typically performed through a left thoracotomy, although video-assisted thoracoscopic techniques are increasingly common.[282,283] Physiologic management is that of a left-to-right shunt producing volume overload. Patients with a large PDA and low PVR generally present with excessive PBF and CHF. Neonates and premature infants also run the risk for having substantial diastolic runoff to the pulmonary artery, potentially impairing coronary perfusion. Thus, patients range from an asymptomatic healthy young child to the sick ventilator-dependent premature infant on inotropic support. The health of the former patient allows a wide variety of anesthetic techniques culminating in extubation in the operating room. The latter patient requires a carefully controlled anesthetic and fluid management plan. Generally, a trial of medical management with indomethacin and fluid restriction is attempted in the premature infant before surgical correction. Transport of the premature infant to the operating room can be especially difficult and potentially hazardous, requiring great vigilance to avoid extubation, excessive patient cooling, and venous access disruption. For these reasons, many centers are now performing ligation in the neonatal ICU.

A subset of premature infants with PDAs is located at institutions without cardiac surgical teams. Ligation of the PDA in these patients requires either transfer of these high-risk neonates to a center that has a team who routinely perform the procedure or the availability of a team capable of performing the procedure who is willing to travel to perform the procedure in the neonate's home neonatal ICU (NICU). Gould and associates[284] reviewed the experience with onsite and off-site ligations of a team composed of a pediatric cardiac attending anesthesiologist, a certified registered nurse anesthetist, an attending pediatric cardiothoracic surgeon and fellow, and cardiac operating room nurses. There were no anesthetic-related complications in their group. No differences were found in the incidence of perioperative complications in the procedures in the two sites. This study showed PDA ligations can be performed safely in the NICUs of hospitals lacking onsite pediatric cardiac surgical units, without incurring the risk inherent in transport of critically ill infants. In addition, patient care is continued by the neonatology team most familiar with the child's medical and social history and the patient's family is minimally inconvenienced.

Complications of PDA ligation include inadvertent ligation of the left pulmonary artery or descending aorta, recurrent laryngeal nerve damage, and excessive bleeding as a result of inadvertent PDA disruption. After ductal ligation in premature infants, worsening pulmonary compliance can precipitate a need for increased ventilatory support; and manifestations of an acute increase in left ventricular afterload should be anticipated, especially if left ventricular dysfunction has developed preoperatively. PDA ligation has been performed in infants and children using thoracoscopic surgical techniques. This approach has the advantage of limited incisions at thoracoscopic sites, promoting less postoperative pain and discharge from the hospital the same day of surgery.

Coarctation of the aorta is a narrowing of the descending aorta near the insertion of the ductus arteriosus. Obstruction to aortic flow results and may range from severe obstruction with compromised distal systemic perfusion to mild upper extremity hypertension as the only manifestation. Associated anomalies of both the mitral and aortic valves can occur. In the neonate with severe coarctation, systemic perfusion depends on right-to-left shunting across the PDA. In these circumstances, left ventricular dysfunction is very common and prostaglandin E1 is necessary to preserve sufficient systemic perfusion. Generally, a peripheral intravenous line and an indwelling arterial catheter, in the right upper extremity, are recommended for intraoperative and postoperative management. In patients with left ventricular dysfunction, a central venous catheter may be desirable for pressure monitoring and inotropic support.

The surgical approach is through a left thoracotomy, whereby the aorta is cross-clamped and the coarctation repaired with an end-to-end anastomosis, patch aortoplasty, or subclavian patch. During cross-clamping, we usually allow significant proximal hypertension (20% to 25% increase over baseline), based on evidence that vasodilator therapy may jeopardize distal perfusion and promote spinal cord ischemia. Intravascular crystalloid administration of 10 to 20 mL/kg is given just before removal of the clamp. The anesthetic concentration is

decreased, and additional blood volume support is given until the blood pressure rises. Postrepair rebound hypertension as a result of heightened baroreceptor reactivity is common and often requires medical therapy. After cross-clamping, aortic wall stress resulting from systemic hypertension is most effectively lowered by institution of β-blockade with esmolol or α/β-blockade with labetalol.[285] Recent work indicates that patients younger than 6 years of age should receive an initial dose of esmolol 250 to 500 µg/kg, followed by an infusion of 250 to 750 µg/kg/minute, depending on the blood pressure. Despite an esmolol infusion, 25% to 50% of patients have a blood pressure that is above the targeted range, requiring a second drug. Sodium nitroprusside, which increases the calculated aortic wall stress in the absence of β-blockade, is usually chosen as the second drug. Other agents that may have a greater likelihood of achieving the targeted pressure include nitroglycerin and nicardipine. Propranolol is useful in older patients but can cause severe bradycardia in infants and young children. Although it actually increases calculated aortic wall stress in the absence of β-blockade by accelerating dP/dT (contractile force), the addition of sodium nitroprusside may be necessary to control refractory hypertension. Captopril or an alternative antihypertensive regimen is begun in the convalescent stage of recovery in patients with persistent hypertension.

The management of infants undergoing placement of extracardiac shunts without CPB centers on goals similar to those of other shunt lesions—balancing pulmonary and systemic blood flow by altering Pa_{CO_2}, PaO_2, and ventilatory dynamics. Central shunts are usually performed through a median sternotomy, whereas Blalock-Taussig shunts may be performed through a thoracotomy or sternotomy. In patients in whom PBF is critically low, partial cross-clamping of the pulmonary artery required for the distal anastomosis causes further reduction of PBF and desaturation, necessitating meticulous monitoring of pulse oximetry. Careful application of the cross-clamp to avoid pulmonary artery distortion will help maintain PBF. Under circumstances in which severe desaturation and bradycardia occur with cross-clamping, CPB will be required for the procedure.

Intraoperative complications include bleeding and severe systemic O_2 desaturation during chest closure, usually indicating a change in the relationship of the intrathoracic contents that results in distortion of the pulmonary arteries or kink in the shunt. Pulmonary edema may develop in the early postoperative period in response to the acute volume overload that accompanies the creation of a large surgical shunt. Measures directed at increasing PVR, such as lowering inspired O_2 to room air, allowing the Pa_{CO_2} to rise, and adding PEEP are helpful maneuvers to decrease PBF until the pulmonary circulation can adjust. Decongestive therapy such as diuretics and digoxin may alleviate the manifestations of CHF. Under such circumstances, early extubation is inadvisable.

Pulmonary artery banding is used to restrict PBF in infants whose defects are deemed uncorrectable for either anatomic or physiologic reasons. These patients are generally in CHF with reduced systemic perfusion and excessive PBF. The surgeon places a restrictive band around the main pulmonary artery to reduce PBF. Band placement is very imprecise and requires careful assistance from the anesthesia team to accomplish successfully. Many approaches have been suggested. We place the patient on 21% inspired O_2 concentration and maintain the Pa_{CO_2} at 40 mm Hg, to simulate the postoperative state. Depending on the malformation, a pulmonary artery band is tightened to achieve hemodynamic (e.g., distal pulmonary artery pressure 50% to 25% systemic pressure) or physiologic (e.g., $\dot{Q}p:\dot{Q}s$ approaching 1) goals. Should the attainment of these objectives produce unacceptable hypoxemia, the band is loosened.

ANESTHESIA FOR INTERVENTIONAL OR DIAGNOSTIC CARDIAC PROCEDURES

Advances in interventional and diagnostic cardiac catheterization techniques are significantly changing the operative and nonoperative approach to the patient with a congenital heart defect (see also Chapter 90). Common interventions in the cardiac catheterization laboratory are shown in Table 94-11. Nonoperative interventional techniques are being used instead of procedures requiring surgery and CPB for safe closure of secundum ASDs, VSDs, and PDAs. Stenotic aortic and pulmonic valves, recurrent aortic coarctations, and branch pulmonary artery stenoses can be dilated in the catheterization laboratory, avoiding surgical intervention.[286,287] These techniques shorten the hospital stay and are particularly beneficial to patients with recurrent coarctation and muscular or apical VSDs, who are at a higher risk for operative intervention. Many patients with complex cardiac defects are poor operative risks. Innovative interventional procedures improve vascular anatomy, reduce pressure loads on ventricles, and decrease the operative risk for these patients. For example, in TOF with hypoplastic pulmonary arteries, balloon angioplasty and vascular stenting procedures create favorable pulmonary artery anatomy and reduce pulmonary artery pressure and right ventricular end-diastolic pressure. Complications are more common during interventional catheterization and include arterial thrombosis, arrhythmias (especially heart block), hemodynamic instability, embolization of devices or coils, bleeding, and perforation of the major vessels or heart.[288] Complications are more common in infants younger than 6 months of age and with smaller infants. Constant vigilance, correction of electrolyte imbalance, maintenance of acid-base status, and appropriate heparinization will mitigate some of the morbidity. Appropriate and early transfusion with deployment of rapid-response ECMO in the resuscitation of an infant in cardiac arrest improves outcome. High-risk patients undergoing diagnostic evaluation of pulmonary artery hypertension in anticipation of heart-lung transplantation also require anesthetic management. Despite the attendant high risks for the procedure in patients with suprasystemic right ventricular pressure, these patients are best managed with general anesthesia and controlled ventilation.

Anesthetic management of interventional or diagnostic procedures in the catheterization laboratory

TABLE 94-11 COMMON INTERVENTIONS IN THE CARDIAC CATHETERIZATION LABORATORY

Simple Interventions	
Device Closures	***Coil Embolization***
Atrial septal defect (ASD)	Decompressing veins
Ventricular septal defect (VSD)	Aortopulmonary (AP) collaterals
Patent ductus arteriosus (PDA)	Surgical shunts
Patent foramen ovale (PFO)	Coronary/atrioventricular fistulas
Balloon valvuloplasty	Balloon angioplasty
Aortic stenosis (AS)	Branch pulmonary artery stenosis
Pulmonary stenosis (PS)	Coarctation of the aorta
Complex Interventions	
Hypoplastic Left Heart Syndrome (HLHS)	
After Norwood	
Pulmonary artery stenosis	Angioplasty
Shunt thrombosis	Dilation/thrombectomy
Restrictive ASD	Balloon septostomy
Aortic arch obstruction	Angioplasty
AP collaterals	Coil embolization
Post Glenn/Fontan	
Decompressing veins	Coil embolization
Baffle leaks	Device/coil embolization
Systemic vein stenosis/thrombosis	Angioplasty/ thrombectomy
Right ventricular failure	Creation of fenestration
Exercise intolerance	Closure of fenestration
AP collaterals	Coil embolization
Obstructive Fontan pathway	PA angioplasty, balloon septostomy)
Transposition of Great Arteries	Balloon atrial septostomy
Tetralogy of Fallot (TOF)	
Shunt thrombosis	Thrombectomy
Pulmonary artery stenosis	Angioplasty
AP collaterals	Coil occlusion
Miscellaneous Interventions	
Severe pulmonary hypertension	Atrial septostomy
ECMO left heart decompression	Atrial septostomy
Stenosis of pulmonary veins	Balloon angioplasty stent
Stenosis/thrombosis of systemic veins	Balloon angioplasty/ thrombectomy

ECMO, Extracorporeal membrane oxygenation.

must include the same level of preparation that applies in caring for these patients in the operating room. These patients have the same complex cardiac physiology and, in some cases, greater physiologic complexity and less cardiovascular reserve. Interventional catheterization procedures can impose acute pressure load on the heart during balloon inflation. Large catheters placed across mitral or tricuspid valves create acute valvular regurgitation or, in the case of a small valve orifice, transient valvular stenosis. When catheters are placed across shunts, severe reductions in PBF and marked hypoxemia may occur. The anesthetic plan must consider the specific cardiology objectives of the procedure and the impact of anesthetic management in facilitating or hindering the interventional procedure. In general, the three distinct periods involved in an interventional catheterization are the data acquisition period, the interventional period, and the postprocedural evaluation period.

During the data acquisition period, the cardiologist performs a hemodynamic catheterization to evaluate the need for and extent of the planned intervention. Catheterization data are obtained under normal physiologic conditions—that is, room air, physiologic $Paco_2$, and spontaneous ventilation are preferred. Increased FiO_2 or changes in $Paco_2$ may obscure physiologic data. Although some patients may require O_2 administration if the PBF is such that the administration of room air may lead to life-threatening hypoxia, a discussion with the interventional cardiologist is essential in the care of these children. During the procedural period, the patient is usually intubated and mechanically ventilated. A secured airway allows the anesthesiologist to concentrate on hemodynamic issues. Positive-pressure ventilation also reduces the risk for air embolism. During spontaneous ventilation, a large reduction in intrathoracic pressure can entrain air into vascular sheaths and result in moderate-to-large pulmonary or systemic air emboli. Precise device placement is also facilitated with muscle relaxants that eliminate patient movements and controlled ventilation, thereby reducing the respiratory shifting of cardiac structures. Substantial blood loss and changes in ventricular function occur commonly during the intervention. Blood volume replacement and inotropic support may be necessary during or immediately after the interventional procedure.

In the postprocedural period, the success and physiologic impact of the intervention are evaluated. Blood pressure, mixed venous O_2 saturation, ventricular end-diastolic pressure, and cardiac output, when available, are used to assess the impact of the intervention. Persistent severe hemodynamic derangement indicates the need for ICU monitoring and respiratory or cardiovascular support. Because of the hemodynamic variability of many of these patients, as well as changing anesthetic requirements, continuous intravenous infusion with ketamine/midazolam or propofol is appropriate. Potent inhaled anesthetics are generally not used as the primary anesthetic and are reserved for adjunctive anesthesia.

A brief description of some of the interventional procedures and the associated anesthetic implications follows. The success of these interventions will undoubtedly result in widespread availability and use over the next few years.

TRANSCATHETER TECHNIQUE FOR ATRIAL SEPTAL DEFECT CLOSURES

In the transcatheter technique for ASD closures, a collapsed double-umbrella clamshell device is loaded into a large introducer sheath placed through the femoral vein, advanced to the RA, and placed across the ASD into the left atrial chamber. Each side of the device consists of a Dacron mesh patch suspended in six spring-loaded arms that open like an automatic umbrella. Using biplane fluoroscopy and TEE, the catheter is positioned in the LA away from the mitral valve.[289] The sheath is pulled back to open the six distal arms and its

Dacron mesh cover into the LA. The sheath and device are then pulled back so the distal arms contact the left atrial septum. Fluoroscopy and TEE are used to confirm that the arms are on the left atrial side and do not interfere with mitral valve motion. Once adequately seated, the sheath is pulled farther back to expose the proximal side of the device and the proximal arms, which spring open to engage the right side of the atrial septum. When proper positioning is certain, the device is released.[289] In a review of data for 122 children undergoing transcatheter ASD closures, a 9% incidence of procedural complications resulted in hemodynamic complications requiring treatment.[290]

Device closure of secundum ASD is the preferred therapeutic approach. Data continue to support closure of defects of small-to-moderate size (<8 to 20 mm) in appropriate-size patients with appropriate septal length and device diameter.[291-293] The procedure is well tolerated with minimal long-term complications. Complications such as cardiac erosions and heart block can occur in patients who receive a large device for patient size, especially those who have a deficient anterosuperior rim.[294,295] Thrombus is a rare problem that can usually be treated medically, and its incidence appears to be device-dependent.[296] Despite nearly a decade of experience, these devices remain under investigational protocol and are therefore available only at a limited number of study centers.

TRANSCATHETER VENTRICULAR SEPTAL DEFECT CLOSURES

Most VSDs that are electively closed in the catheterization laboratory are mid-muscular or apical VSDs that are either difficult to close in the operating room or would require a left ventriculotomy. Left ventriculotomies are associated with a high incidence of left ventricular dysfunction and have been relegated to a position as the least desirable surgical option. The preferred therapeutic approach for VSD is surgical closure. Transcatheter closure of muscular VSDs can be performed safely. However, a significant incidence of complications occurs, including heart block, blood loss, and hemodynamic instability.[297,298] Device closure of membranous VSD is in early stages of investigation, and the incidence of complications remains to be determined.[299,300] The transcatheter approach requires a blade atrial septostomy and a retrograde catheter placed through the femoral artery and advanced to the LA. This catheter is pulled across the atrial septum into the RA and is used to guide a superior vena cava catheter (placed through the internal jugular vein) across the ASD into the LA, across the mitral valve, and into the LV. The VSD defect is approached from the left ventricular side. The large sheath containing the double-umbrella clamshell device prevents closure of the mitral valve, resulting in acute mitral regurgitation or, in cases in which the VSD is large or the mitral annulus small, acute severe mitral stenosis. In this latter case, systemic output is decreased and a period of severe hypotension is unavoidable. Judicious use of vasoconstrictors to maintain coronary perfusion may be required during the catheter placement, followed by volume and inotropic resuscitation after the VSD device is deployed. This highly specialized application of the clamshell device is confined to only a few pediatric centers in the United States.

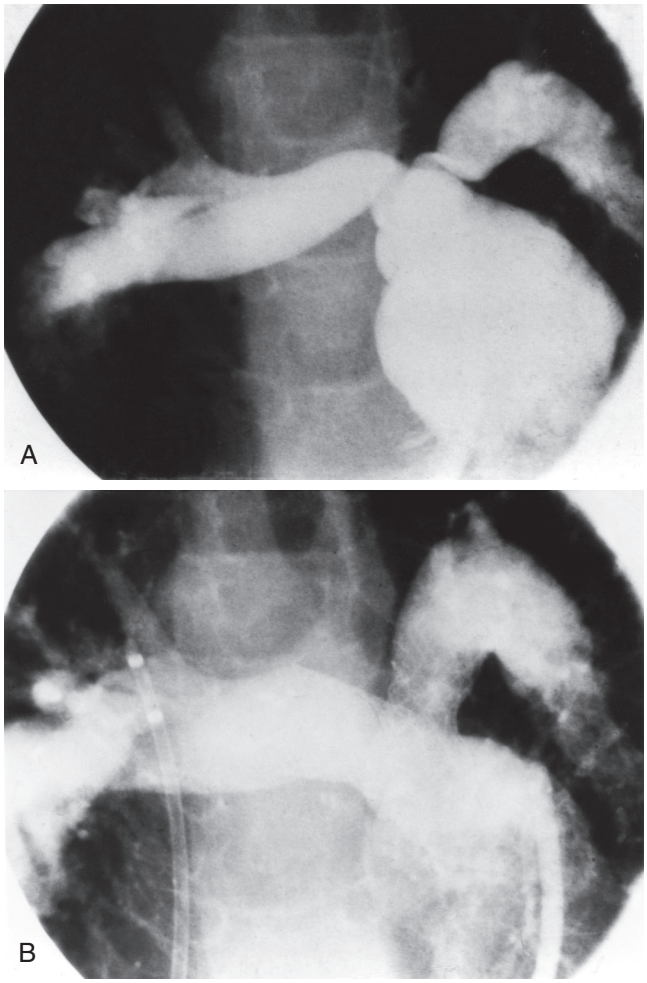

Figure 94-16. A, Severe bilateral branch pulmonary artery stenoses at the distal end of a conduit in a patient with pulmonary trunk atresia and ventricular septal defect. Stents were placed in the right and left pulmonary arteries. **B,** Follow-up angiogram in the same projection and magnification showed marked improvement of both right and left stenoses.

ANGIOPLASTY OF BRANCH PULMONARY ARTERY STENOSIS

One of the most important areas of interventional catheterization has been the dilation and stenting of hypoplastic or stenotic branch pulmonary arteries. In patients with TOF with hypoplastic pulmonary arteries, pulmonary atresia, or single ventricle with surgically induced peripheral stenoses, the use of balloon angioplasty and stenting procedures creates favorable pulmonary artery anatomy and reduces the risk for subsequent surgical repairs (Fig. 94-16). Peripheral pulmonary artery stenosis is not a surgically amenable lesion and is particularly suited to catheterization and angioplasty. Balloon angioplasty is accomplished by tearing the vascular intima and media, allowing the vessel to remodel and heal with a larger diameter. The balloon is placed across the stenotic lesion so that the middle of the balloon is at the stenosis. The balloon is inflated until

the waist of the balloon is eliminated. Ideally, the most stenotic lesions are dilated first to minimize the impact on PBF and cardiac output. When the balloon is inflated, PBF is reduced, right ventricular afterload is increased, and cardiac output falls. In patients with an associated VSD or ASD, right-to-left shunting and desaturation occur with balloon inflation. In patients without a shunt, acute increase in right ventricular afterload can cause systemic hypotension and right ventricular failure. The large vascular sheaths required for these procedures can introduce tricuspid regurgitation, which is poorly tolerated in patients with severe RV hypertension. Occasionally, balloon catheters must be placed across aortopulmonary shunts, significantly reducing PBF.

The procedure is successful in approximately 60% of patients. In an early series, complications included hypotension (40%), pulmonary artery rupture (3%), unilateral reperfusion pulmonary edema (4%), aneurysmal dilation of the dilated pulmonary vessel (8%), death (1.5%), and transient postprocedural right ventricular dysfunction.[301] Improved techniques and patient selection have favorably influenced the results with superior balloon catheters and stents while significantly reducing serious complications. Anesthetic support minimizes hemodynamic compromise by anticipating changes in blood flow patterns, treating transient hypotension, and providing airway support to minimize the risks associated with pulmonary artery disruption and acute unilateral pulmonary edema.[301]

A unique group of patients are those with William syndrome with supravalvular aortic and pulmonary stenosis. Such patients can have multiple areas of severe branch pulmonary artery stenosis, with resultant systemic or suprasystemic right ventricular pressures and right ventricular dysfunction. Patients can also have coronary stenosis and develop subendocardial ischemia from hemodynamic disturbances in the setting of biventricular hypertrophy. The presence of supravalvular aortic stenosis, biventricular outflow tract obstruction, and coronary stenosis is associated with increased perioperative risk. Typically, such patients undergo general anesthesia with positive-pressure ventilation and recover in the cardiac ICU for angioplasty of branch pulmonary artery stenosis.[302] Care must be exercised in maintaining SVR, myocardial oxygenation, and contractility. Tachycardia and subendocardial ischemia should be avoided in the presence of ventricular hypertrophy.

BALLOON VALVULOTOMIES

Balloon valvulotomies conducted in well-compensated infants and children often can be accomplished without anesthetic support. Exceptions include neonates with critical aortic or pulmonary stenosis and patients with significant ventricular dysfunction who exhibit unstable hemodynamics. Balloon valvuloplasty is indicated in valvular pulmonary or aortic stenosis with valvular gradients more than 50 mm Hg. Balloon dilation is effective in most patients, except those with dysplastic valves (e.g., Noonan syndrome); postdilation pulmonary incompetence is anticipated and does not pose a problem in the immediate and intermediate period. Long-term prophylaxis for subacute bacterial endocarditis is needed. Only 8% of patients require repeat interventions. Typically, patients recover in the ICU and may require transfusion depending on hemodynamic stability. Valvular aortic stenosis is associated with poor surgical outcome in the neonatal period. All therapies are palliative, with a high incidence of repeat interventions, and balloon valvuloplasty is often the initial treatment. Residual obstruction or regurgitation is common after balloon dilatation and can require repeat intervention. A real risk exists for damage to the aortic valve and subaortic septum, with the consequence of acute aortic insufficiency and coronary ischemia. Hypotension and bradycardia commonly occur during valvuloplasty, and many centers have a policy of ECMO standby for these high-risk interventions in the catheterization laboratory. Ready availability of a surgical and perfusion team is crucial to a good outcome. Neonates with critical aortic stenosis often require stabilization with inotropes and prostaglandins to maintain systemic perfusion before the procedure. Balloon dilation of recurrent coarctation is often the therapy of choice in older children with recoarctation after surgery. Such patients are often hypertensive. The procedure can be performed with the patient under deep sedation or general anesthesia. In infants after Norwood palliation for hypoplastic left heart syndrome, coarctation can occur in the distal arch anastomotic site. Catheters placed antegrade via the right side of the heart into the neoaorta can induce hemodynamically significant tricuspid and neoaortic regurgitation, resulting in hemodynamic instability. Careful monitoring and aggressive hemodynamic intervention result in a good outcome.

COIL EMBOLIZATION

Transcatheter methods can be adapted to occlude undesired vascular structures. Intravascular coils have been used to close PDAs, aortopulmonary collaterals, surgical systemic and pulmonary artery shunts, venous collaterals in single ventricle lesions, coronary fistulas, and some arteriovenous malformations (e.g., vein of Galen malformation). In selected instances, to minimize the risk that coils may escape to threaten vital organ perfusion, cardiologists request the use of general anesthesia with a muscle relaxant.

Depending on the lesion, patients might manifest severe cyanosis, low-output or high-output cardiac failure, or coronary ischemia. Extra care should be exercised in patients with coronary fistulas to maintain myocardial O_2 supply and reduce demand. Materials used for embolization can include surgical gel (Gelfoam), alcohol, and coils. Some of these substances can induce severe allergic reactions with hemodynamic collapse. Antibiotic prophylaxis is mandatory to prevent bacterial endocarditis. Angiography is used to demonstrate successful occlusion of the vascular structure and ascertain appropriate placement.

VALVE PROSTHESES

Transcatheter bioprosthetic valve replacement of the pulmonary and aortic valves is being performed. The pulmonary valve is a bovine jugular venous valve mounted on a balloon-expandable Cheatham platinum stent. The technique is limited by the maximum size of 22 mm of the bovine jugular venous valve. Percutaneous placement

of bioprosthetic valve in the pulmonary position is a reality, and further refinement and miniaturization will lead to its application in aneurysmal right ventricular outflow tract. Current candidates for the implantation of transcatheter pulmonary valve include age of 5 years or older, weight of 30 kg or more, and a conduit diameter of 16 to 22 mm. Candidates have moderate-to-severe pulmonary regurgitation, often with RV dilation or dysfunction and mean right ventricular outflow tract gradients greater than 35 mm Hg. Transcatheter aortic valve replacement continues to be used in the management of adult patients with complex status and aortic stenosis who are not considered surgical candidates because of surgical risk. The use of these devices in pediatrics has been limited. Some authors have described the use of transcatheter pulmonary valves in the high-pressure circuit with good short term performance. Complications of the transcatheter valve placements include wire perforation of vessels, conduit rupture or coronary artery compression.

EMERGENT PROCEDURES

Emergent interventions such as balloon atrial septostomy to ensure adequate mixing in patients with transposition physiology and in patients who have restrictive ASD with single ventricle physiology are lifesaving and enable planning surgery at a suitable time. The procedure can be performed at the bedside with echocardiography or in the catheterization laboratory with fluoroscopic confirmation of balloon position. Access is by the femoral or umbilical vein, and the balloon catheter is advanced through the foramen ovale into the LA. The balloon is inflated with contrast and pulled back via the septum until a satisfactory ASD is created. If the procedure is successful, the left and right atrial pressures should equalize and adequate mixing should occur. Oxygenation and pulmonary venous drainage should improve. Complications include atrial perforation, laceration of the mitral or tricuspid valves and pulmonary veins, and low cardiac output state. Balloon atrial septostomy is also performed emergently in patients receiving ECMO therapy for left-sided heart decompression.

ENDOMYOCARDIAL BIOPSY

Typically, endomyocardial biopsies are performed as part of posttransplant surveillance catheterizations at regular intervals to ascertain absence of rejection in patients after orthotopic heart transplantation. Right-sided heart catheterization is usually performed by access of the right internal jugular vein, through which the long sheath and biotome are introduced. Usually five to eight samples are taken. Endomyocardial biopsies are also used to confirm a diagnosis of myocarditis or cardiomyopathy; sedation or general anesthesia is required for smaller children, although older children can undergo this procedure with local anesthesia alone. Children who undergo catheterization during a period of acute rejection are at high risk for malignant arrhythmias during endomyocardial biopsy and might require resuscitation. A clinical history suggestive of an episode of rejection includes fever, gastrointestinal disturbances, and arrhythmias. Complications include perforation, tricuspid valve damage, and the development of coronary-to–right ventricular fistulas.

CARDIAC CATHETERIZATION OF PATIENTS SUPPORTED BY EXTRACORPOREAL MEMBRANE OXYGENATION

Booth and associates[303] reported on the Boston experience of cardiac catheterization in pediatric patients supported on ECMO. Indications included assessment of surgical repair, left-sided heart decompression, myocarditis or cardiomyopathy, hemodynamic assessment, catheter interventions, and ablation of arrhythmias. The most common interventions were left-sided heart decompression in patients with left atrial hypertension, balloon angioplasty of the pulmonary arteries, and endomyocardial biopsy. The anesthesiologist coordinates safe transport of the patient on mechanical support with the perfusion and nursing team. The logistics of the transport, availability of surgeon, and blood need to be addressed before the transfer. Anesthesia is provided using isoflurane or sedatives on the ECMO circuit, and paralysis must be achieved before transport. Rest ventilation of the lungs is continued. The anesthesiologist's role is in managing a safe transport and attending to emergency mechanical, cardiorespiratory, and hematologic issues.

At present, hybrid techniques find a niche in lesions in which cardiac surgery is problematic, such as apical muscular or anterior muscular VSDs or in high-risk patients with more complex lesions in which immediate surgery is contraindicated or is associated with significant morbidity and mortality. Close collaboration is required so that a surgical approach is modified to facilitate the subsequent interventional approach. The hybrid approach has been used in the management of hypoplastic left heart syndrome. Stage 1 palliation is performed by creation of an atrial septal communication and stent placement in the ductus arteriosus during catheterization to maintain ductal patency with surgically applied external right and left pulmonary artery bands or transcatheter placed internal bands.[304,305] A modified Norwood procedure with a bidirectional Glenn anastomosis is performed with CPB during stage 2 palliation.[306] Stage 3 (Fontan operation) is performed entirely by transcatheter techniques.[307] In the current surgical climate, it seems difficult to promote ductal stenting as a method of choice but in patients with contraindications to immediate surgery this provides an attractive bridge.[308]

ADULT CONGENITAL HEART DISEASE

EPIDEMIOLOGY AND CLASSIFICATION

The care of adults with CHD is a new and exciting frontier in medicine. Adult congenital heart disease (ACHD) represents a large spectrum of clinical entities ranging from mild to severe and palliated to corrected, with no or multiple adult comorbidities. In addition, some patients with ACHD may have had palliative repairs no longer primarily employed for specific diseases today, such as the Mustard or Senning procedure for dextro-transposition

of the great arteries (d-TGA). Another unique problem is therapeutic noncompliance in patients with ACHD. The incidence of CHD is estimated to be 3 to 6 cases per 1000 live births. Approximately 85% of these patients can be expected to reach adulthood.[309] The prevalence of CHD is rising in both children and adults, with adults representing the largest group

At the Bethesda conference in 2001, patients with ACHD were categorized into groups of simple, moderate, or great complexity based on medical diagnosis.[309] Anesthesiologists should be aware of the Bethesda task conference recommendations for ACHD in terms of distribution of care for these patients. It is recommended that patients with CHD of great complexity be regularly seen at tertiary care centers that specialize in ACHD

CONSIDERATIONS IN THE CARE OF PATIENTS WITH ADULT CONGENITAL HEART DISEASE

Adults with CHD may present with unique anatomy or physiologic sequelae not otherwise encountered in pediatric patients with CHD. In addition, these patients may not have complete awareness or access to information on medical treatments completed when they were a child, significantly complicating their care. As the number of patients with ACHD increases, so do the chances an anesthesiologist will need to care for one of these patients in an emergent situation. In general, practitioners would want to gather as much information as available in regard to the details of the patient's medical history, surgical repairs, and current functional status. General considerations include presence of arrhythmias, hypoxemia, pulmonary hypertension, ventricular dysfunction, shunts, thrombosis, and need for antibiotic prophylaxis. Arrhythmias are one of the most common sequelae in adults with CHD. Common arrhythmias occur as the result of atrial dilation and include atrial fibrillation or flutter, which may or may not be hemodynamically significant. A right bundle branch block pattern of the QRS segment of the ECG is common after repair of TOF. In the absence of lung disease, hypoxemia results from a decrease of PBF. Limited PBF may be the result of obstruction or residual right-to-left shunting. Strategies to avoid further hypoxemia include adequate hydration, ventilation, and pulmonary perfusion while decreasing PVR or O_2 consumption. It is always prudent to determine patient baseline SpO_2 as a reference for the anesthetic. In addition, O_2-carrying capacity may be maximized by the administration of packed blood cells. Many patients with ACHD with chronic hypoxemia may require hematocrit values greater than 45% to allow for adequate O_2 delivery. Along with cyanosis, the presence of polycythemia in these patients increases their thrombovascular risk. The presence of pulmonary hypertension should always be considered when caring for patients with ACHD. Chronic volume overload to the pulmonary vascular bed creates hypertrophy of the arterioles with resultant pulmonary hypertension. Common defects where pulmonary hypertension may be found in childhood include shunt lesions, which, if untreated, result in pulmonary vasoocclusive disease. When hypoxemia is present with these conditions, a high level of suspicion for pulmonary hypertension and possibly Eisenmenger syndrome is necessary. The anesthesiologist should always have a high level of suspicion for the presence of ventricular dysfunction in patients with ACHD. Many CHD defects place a volume or pressure load on the heart that over time may lead to dilated or hypertrophied performance. The care titration of induction and maintenance agents that maintain ventricular performance is warranted in providing anesthesia care. Shunts of varying size and location may be created in the care of hypoxic patients with CHD in an effort to increase PBF. In many cases, patients rely on the patency of these shunts to supply the lungs with blood and their occlusion could be catastrophic. Likewise, thrombosis of various shunt or cardiac chambers may occur related to altered patterns of blood flow. Therefore, specific anticoagulation strategies may be required to ensure blood flow. The American Heart Association has provided updated guidelines regarding recommendations for prophylaxis against infective endocarditis, and specific guidelines may be found in this chapter.

SPECIFIC LESIONS WITH UNIQUE CONSIDERATIONS FOR ADULT CONGENITAL HEART DISEASE

Tetralogy of Fallot

TOF consists of four defects of varying physiologic significance: malignant type VSD, varying degrees of right ventricular outflow tract obstruction, right ventricular hypertrophy, and an overriding aorta. The typical clinical significance of this pattern of cardiac anomalies is that of hypoxia as a result of decreased PBF. In the early stages of treatment of TOF the systemic–pulmonary artery shunt (Blalock-Taussig shunt) was used to allow the child to grow, followed by a definitive repair later in life. Many patients up until the 1970s may have had classic Blalock-Taussig shunt or central shunts performed. The use of the Blalock-Taussig shunt in a modified version still occurs today for some patients with TOF in whom the anatomy is considered high risk for an early complete repair. Typically, most clinicians prefer a complete repair electively within the first year of life in an effort to avoid secondary damage from the altered physiology. On occasion, the degree of pulmonary stenosis may protect the lung from overcirculation of blood from the VSD while allowing adequate PBF for growth, and these patient may not have undergone any type of repair. Adults with TOF may be found to possess any of these potential surgical repairs. When caring for adult patients with TOF it is prudent to attempt to determine the type of repair completed and functional status of such repairs. The anesthesiologist should be alert to degrees of cyanosis present in these adult patients, suggesting the adequacy of PBF. Arrhythmias of right ventricular origin or right bundle branch block patterns on the ECG may be likely if a previous ventriculotomy was performed. Careful attention should be paid to signs of right ventricular failure, including

elevated jugular venous pressures and hepatomegaly. Another common complication after repair of TOF is pulmonary regurgitation, which may lead to right heart failure over time if left untreated.

Fontan Circulations

In the early1970s, Fontan and Kreutzer preformed a procedure in a patient with tricuspid atresia in an attempt to separate the PBF from the systemic circulation.[310] Known now as the Fontan procedure, this principle is applied to many types of functionally single-ventricle patients. The procedure essentially diverts deoxygenated venous blood return directly and passively to the lungs, allowing the single ventricle to pump blood to the systemic circulation. When used in hypoplastic left heart syndrome, the Fontan procedure is the final staged procedure in a series of three, whereby the pulmonary circulation is separated from systemic circulation. These staged procedures typically occur early within the first 4 to 5 years of life. Occasionally, adults have been found who, through loss of follow-up, did not undergo a complete separation of circulations, with varying effects primarily exhibited by cyanosis and ventricular dysfunction. Even with the completion of the total cavopulmonary anastomosis, many patients experience a decreased survival beyond 15 years after surgery. Common causes of death include thromboembolism, heart failure, protein-losing enteropathy, and arrhythmias.[311] When caring for adults with Fontan physiology, the anesthesiologist should be mindful of conditions that may further impair oxygenation and myocardial function. Conditions that impair passive PBF may be poorly tolerated, such as dehydration, acidosis, hypoxia, and the use of myocardial depressants. In addition, the initial Fontan procedures were completed by a direct baffle of the atrium to the pulmonary artery, later found to be an inferior type of repair because of complication from atrial dilation and the resultant arrhythmias. Typical satisfactory Fontan repairs should produce O_2 saturation levels of at least 95%. Some patients with ACHD who have undergone a Fontan procedure may require chronic anticoagulation for previously demonstrated or presumed high risk for thromboembolism, and the management of this anticoagulation must be considered for any surgical procedure.

Transposition of the Great Arteries

TGA occurs when the aorta arises from the anatomic RV and the pulmonary artery arises from the anatomic LV. In classic d-TGA the two circulations are in parallel and require mixing to be compatible with life. In the 1980s, surgical management of TGA consisted of atrial-level switch procedures—the Mustard or Senning procedure—in which venous return to the heart was redirected at the atrial level though a baffle system. Therefore, highly oxygenated pulmonary venous return was redirected to the RV, which pumped to the aorta and systemic circulation. Systemic deoxygenated blood was directed to the LV, which pumped the blood through the pulmonary artery to the lungs for oxygenation. Long-term complications of this strategy include atrial dilation from baffle obstruction or leak with resultant arrhythmias, sinus node dysfunction, or sudden death. Particularly problematic complications included the systemic right ventricular dysfunction, AV valve regurgitation, subpulmonary stenosis, and pulmonary hypertension. Today, the arterial switch operation is preferred, in which the aorta with the coronary arteries are attached to the LV and the pulmonary artery is attached to the right ventricle. Complications from the arterial switch operation include regurgitation of the neoaortic valve, myocardial ischemia from coronary ostial stenosis, right or left ventricular outflow tract obstruction, residual intracardiac shunting, and left ventricular dysfunction.

PEDIATRIC CARDIAC ELECTROPHYSIOLOGY

DIAGNOSTIC EVALUATION

Cardiac Event Monitoring

Most patients with cardiac arrhythmias present with infrequent or episodic symptoms. These symptoms may include chest pain, palpitations, syncope, and presyncope. Transtelephonic electrocardiographic event monitors may yield documentation of the arrhythmia because they are portable and patient activated.[312]

Insertable Cardiac Recorders

Insertable loop recorders implanted subcutaneously allow continuous rhythm monitoring that is stored either when manually activated by a patient or parent or automatically when high or low rate parameters are met.[313] These insertable loop recorders have value in correlating arrhythmias with symptoms when noninvasive means do not make a diagnosis. Typically, loop recorders are inserted under general anesthesia as an outpatient procedure and cause minimal pain.

RADIOFREQUENCY ABLATION OF ACCESSORY PATHWAYS

Radiofrequency ablation is a nonsurgical approach designed to eliminate atrial or ventricular reentrant tachyarrhythmias. The technique requires pathway mapping and precision ablation of the aberrant pathway, using a radiofrequency ablation catheter. Catheter ablation is offered to patients with refractory arrhythmias that are bothersome and the focus or pathway is amenable to ablation. In pediatrics, the electrophysiology catheters are introduced by femoral venous catheterization and the tips are positioned in the right atrial appendage, the bundle of His area, right ventricular apex, and the coronary sinus. Occasionally, right internal jugular venous access is used for placement of the coronary sinus catheter. Rapid atrial pacing and, occasionally, an isoproterenol infusion are required during the mapping procedure to induce the arrhythmia. An ablation catheter is used to map the substrate, and, subsequently, the pathway is ablated. During the ablation, unexpected patient movement may result in catheter dislodgment and damage to normal conducting tissue; therefore, general anesthesia is usually required in younger children. Anesthetic agents and techniques

should be chosen to maintain circulating catecholamines and avoid suppression of arrhythmogenesis, for identification of the aberrant pathway. Our current preference is a propofol continuous intravenous anesthetic, although low-dose volatile anesthetics are equally satisfactory. Rapid atrial pacing and, occasionally, an isoproterenol infusion are required during the mapping procedure.

Severe postprocedural cardiomyopathy has been described but is very unusual. An underlying cardiomyopathy from frequent episodes of supraventricular tachycardia and myocardial O_2 imbalance caused by prolonged periods of rapid atrial pacing and isoproterenol infusions are the presumed causative factors. An arterial line is helpful during these lengthy procedures for continuous monitoring of blood pressure and blood gases. Complications of the procedure include radiation exposure, tamponade, pericarditis, groin hematoma, arterial thrombosis, AV block, systemic embolization, coronary artery dissection, trauma to the mitral and tricuspid valves, and endocarditis.

Intraatrial Reentrant Tachycardia

Intraatrial reentrant tachycardia (IART) is associated with significant morbidity and mortality for many patients with repaired CHD, particularly after extensive atrial surgery, such as Fontan and atrial switch operations. Therapeutic options for IART include antiarrhythmic medications, catheter ablation, surgery, and pacing. The arrhythmia occurs along with long-standing myocardial dysfunction and residual lesions. Careful choice of anesthetic, monitoring, and early management of low cardiac output, especially in patients with single-ventricle physiology, are important. Prolonged periods of arrhythmia induction during mapping can result in a low cardiac output state, necessitating inotropic therapy. Such patients may need to undergo recovery in the cardiac ICU. Despite reports of high acute success rates with catheter ablation, arrhythmia recurrence continues to be problematic in this population.[314] Acute success was reported in 93% of patients and was defined as no inducible, sustained IART. Recurrence occurred in 34% of patients, 88% within 1 year. Patients with Fontan physiology had the highest recurrence rate. Inadequate lesion size and depth with conventional radiofrequency ablation catheters are the principal reasons for recurrence. Intraoperative cryoablation within the RA for patients with IART or LA for atrial fibrillation using preoperative and intraoperative mapping can be used successfully. A new generation of antitachycardia pacemaker (AT500, Medtronic, Minneapolis, Minn.) has been used for treating IART. This device was able to successfully terminate 54% of treatable tachycardias by use of antitachycardia pacing, with no incidence of ventricular proarrhythmia.[315] In patients who are either unsuitable candidates for catheter ablation or in whom ablation has been unsuccessful, surgical ablation may be successfully combined with repair of CHD. This is particularly true of patients with complex physiology (e.g., Fontan revision with a maze procedure).[316-318]

Arrhythmias and Sudden Cardiac Death

Certain cardiomyopathies and channelopathies are associated with an increased risk for sudden cardiac death resulting from lethal arrhythmias. The patient usually has a history of syncope, near-syncope, or aborted sudden death. Such patients present for insertion of automated internal cardioverter-defibrillators (AICDs) for either primary or secondary prevention.

IMPLANTATION OF PACEMAKERS AND DEFIBRILLATORS

Pacemakers are indicated for complete heart block or sinus node dysfunction with symptomatic bradycardia and hemodynamic decompensation (see also Chapter 48). Children usually require general anesthesia with endotracheal intubation. It should be noted that the anesthetic can be associated with worsening bradycardia. Transthoracic pacing pads are applied before induction of anesthesia, and an isoproterenol (Isuprel) infusion might be required for chronotropic effect. External transthoracic, esophageal, or emergent transvenous pacing might be necessary until placement of a permanent pacing device is achieved. In small children the pacemaker generator is typically placed in the upper abdomen, and in older children and teenagers it is placed in the subclavicular region. Epicardial leads are used in small children because of inadequate size of the veins and in those in whom transvenous access to the heart is impossible (e.g., the Fontan circulation). Epicardial pacemaker placement usually is performed by a cardiac surgeon, with electrophysiologists readily available to program the device. Adequate peripheral venous access is mandatory in the event of major hemorrhage, and blood should be readily available. A mode of monitoring mechanical capture of electrical pacing activity is also necessary and can include invasive arterial monitoring or pulse plethysmography. Transvenous pacing can be achieved in the operating room with surgical backup or in the cardiac catheterization laboratory by the cardiologists. In the latter situation it is important to address the need for surgical backup during case planning.

AICDs are placed for life-threatening ventricular arrhythmias, which include long QT syndrome, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia. Of note, the device is tested after placement, with induction of ventricular fibrillation. It is absolutely essential to have external modes of defibrillation available, as well as antiarrhythmics such as amiodarone, magnesium, and lidocaine, in the event of device failure. These devices are placed with the patient under general anesthesia with endotracheal intubation and controlled ventilation. Invasive arterial pressure monitoring is typically used. Adequate analgesia can be provided with local infiltration with local anesthetics and short-acting intravenous opioids. Patients are admitted overnight with telemetry monitoring. Appropriate antibiotic therapy is provided for a 24-hour period.

ADVANCES IN RESYNCHRONIZATION THERAPY

Bundle branch block or interventricular conduction delay often accompanies heart failure and some forms of CHD, either preoperatively or postoperatively, and may result in ventricular dysfunction caused by asynchronous

myocardial contraction. Biventricular pacing is an attempt to resynchronize ventricular contraction by pacing both ventricles, thereby improving overall ventricular function. In patients with left bundle branch block, cardiac resynchronization therapy counteracts the underlying electrical and mechanical dyssynchrony, leading to improved contractility, function, exercise tolerance, and quality of life. Multisite pacing has been attempted in pediatric patients.[319] Two atrial and three ventricular epicardial leads were placed at the time of surgery, with the ventricular leads placed as far from one another as possible. Atrial synchronous ventricular pacing was established postoperatively, and the AV interval was adjusted to yield the narrowest QRS complex while simultaneously pacing two ventricular sites. Multisite pacing resulted in significant narrowing of the QRS complex, improved cardiac index, and increased systolic blood pressure overall. Multisite pacing after surgery for CHD in children may facilitate weaning from inotropic agents, thereby limiting side effects such as increasing myocardial O_2 consumption. Cases of biventricular pacing with improved outcome in infants with dilated cardiomyopathy and complete AV block have been reported.[320,321] Long-term improvements need to be studied. Right bundle branch block is a common outcome after surgery for congenital heart lesions. Right ventricular pressure, volume loading, or both also may be present, with attendant right ventricular enlargement and dyskinesis. The QRS duration decreased in all patients during dual-chamber pacing. Cardiac index also increased during resynchronization with dual-chamber pacing. The pacing site yielding the narrowest QRS duration also improved the cardiac index the most.[322,323]

ANESTHESIA FOR NONCARDIAC SURGERY

INFECTIVE ENDOCARDITIS PROPHYLAXIS: AMERICAN HEART ASSOCIATION GUIDELINES

Guidelines for infective endocarditis prophylaxis were updated by the American College of Cardiology and the American Heart Association in 2008. A detailed discussion of the changes is beyond the scope of this chapter.

Procedures for which prophylaxis for infective endocarditis is recommended include the following[324]:

- Dental procedures involving manipulation of the gingival tissue or periapical region of the teeth or involving perforation of the oral mucosa
- Respiratory procedures involving incision of the respiratory mucosa
- Procedures involving infected skin, skin structure, or musculoskeletal tissue

Prophylaxis is no longer routinely recommended for gastrointestinal and genitourinary procedures. For elective procedures, coexisting enterococcal urinary tract infections should be treated before genitourinary or gastrointestinal procedures; for emergent procedures, in patients at highest risk for infective endocarditis, prophylaxis can be considered.

Conditions for which prophylaxis is recommended for dental procedures include the following (Table 94-12):

- Prosthetic cardiac valve
- Previous infective endocarditis
- Unrepaired congenital heart disease, including palliative shunts and conduits
- Completely repaired congenital heart disease with prosthetic material or device within the first 6 months after the procedure
- Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or device
- Cardiac transplant recipients who develop cardiac valvulopathy

These are guidelines only. The authors' practice at the current time is to consult the child's cardiologist and make a decision based on the child's condition, the operative procedure, the risk for bacteremia, and the cardiologist's opinion.

MAGNETIC RESONANCE IMAGING OF THE HEART

Apart from the usual considerations of providing general anesthesia in a remote location, when working in a magnetic field necessitating the use of magnet-safe equipment, the anesthesiologist needs to be prepared to

TABLE 94-12 INFECTIVE ENDOCARDITIS PROPHYLAXIS

		Single Dose 30-60 min Before Dental Procedure	
Situation	**Drug**	**Adults**	**Children**
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin or	2 g IM/IV	50 mg/kg IM/IV
	Cefazolin/ceftriaxone	1 g IM/IV	50 mg/kg IM/IV
Allergic to penicillins/oral	Cephalexin or	2 g	50 mg/kg IM/IV
	Clindamycin or	600 mg	20 mg/kg IM/IV
	Azithromycin/clarithromycin	500 mg	15 mg/kg
Allergic to penicillins/unable to take oral medication	Cefazolin/ceftriaxone or	1 g IM/IV	50 mg/kg IM/IV
	Clindamycin	600 mg	20 mg/kg

Vancomycin is an alternative for patients who are unable to tolerate a β-lactam or when the infective agent is considered to be methicillin-resistant *Staphylococcus aureus*.

provide resuscitative care in these patients. Patients with implanted devices and hardware need to be assessed to ensure magnet compatibility and safety. Generally, pacemakers, implanted defibrillators, and aneurysm clips are contraindications to MRI. Other coils, stents, and surgical clips produce interference and artifact with imaging but do not constitute a threat to patient safety. Usually an MRI screening form is part of the evaluation and needs to be discussed with the MRI technologist or radiologist. In a majority of patients, the scan can be performed as an outpatient procedure. Patients who are younger, uncooperative, or claustrophobic require sedation or general anesthesia. Total intravenous anesthesia can be provided with a propofol infusion and a natural airway, avoiding the need for scavenging and allowing rapid recovery.[325] Anesthesia has been provided with a range of inhalational agents, such as dexmedetomidine, ketamine, and midazolam.[326] In patients for whom breath holding is necessary and potential for airway compromise exists, general endotracheal anesthesia with positive-pressure ventilation may be required and is often necessary when coronary artery anatomy details are required. Irrespective of the technique chosen it is mandatory to maintain continuous monitoring of heart rate, pulse oximetry, capnography, noninvasive blood pressure, and temperature. Supplemental O_2 should be delivered until the patient is fully recovered from the anesthetic. In the event of hemodynamic compromise, the patient should be removed from the MRI scanner into a safe environment where resuscitation equipment can be safely used. With the development of compatible catheters and devices, MRI will be a useful tool in minimizing x-ray exposure, particularly in patients whose congenital heart disease necessitates numerous catheterization procedures. Razavi and associates[327] have described their experience of MRI used in combination with fluoroscopy to decrease radiation exposure and improve soft tissue visualization during cardiac catheterization of congenital heart disease patients.

OFFSITE ANESTHESIA IN CARDIAC SURGERY PATIENTS

Patients with cardiac disease are no different from any other group of patients who require procedures or investigations in areas outside the operating room. Therefore, anesthesiologists should always be prepared for any eventuality and follow guidelines such as those set out by the American Society of Anesthesiologists. This discussion will exclude procedures performed in the cardiac catheterization laboratory because this has already been addressed elsewhere (see also Chapter 68). The nature of congenital cardiac surgery will result in a number of patients' requiring emergent chest exploration for ongoing hemorrhage or as part of resuscitation to relieve tamponade or for ECMO placement, all of which may take place in the ICU setting. It is obvious that we cannot predict which patients will have problematic postoperative courses with absolute certainty, but the practitioners who have participated in the operative phase will gain an accurate sense of which patients may require possible further exploration or surgery. Accordingly, it is best to plan ahead, and it cannot be stressed enough that even if as a group of practitioners we are overprepared, this is the best option to have. This being said, it is imperative that the patient have enough blood and blood products (see also Chapter 61) available to perform surgery at any given time. Successful treatment of these patients depends on a team approach to their care, and thus surgeons, anesthesiologists, intensivists, perfusionists, and operating room nurses must be immediately available. When the decision is made to perform a procedure within the ICU, speed of preparation is of the essence. We are fortunate in our practice that we can obtain a set of premade drugs, electrolytes, and infusions within a 15-minute period. Invariably, if a patient is within a few hours' window from returning from the operating room, this same set of drugs will have accompanied the patient from the operating room to the ICU and can thus be accessed. Emergent preparation includes ensuring that blood is checked and that a warmer is set up ready for use, emergency drugs are present as mentioned, and the code cart (with internal paddles) is readily available. The blood that will be used for these procedures will include fresh whole blood (<48 hours old and remaining from the operating room) or packed RBCs, which in our practice is less than 7 days old, or for blood older than this we would prefer it to be washed to avoid the possibility of acute hyperkalemia with transfusion. An anesthesiologist's role here is thus one of facilitation of the entire procedure from sedation of the patient, positioning and preparation, readying the blood, and continuing ongoing volume resuscitation, resuscitative drug use, and airway management.

The premature infant with a PDA poses an interesting management problem to cardiac surgery teams because frequently these ill neonates are at hospitals remote from major centers where the team is normally assembled. As referenced in an article by Gould and associates,[284] our team has been performing these ductal ligations with great success at hospitals remote from ours. The philosophy is to take the cardiac team to the neonate instead of having these fragile infants transported to us. In this article, neonates operated on in our home hospital NICU were used as the controls, and it was found that the success and complication rates were comparable in the two groups. Thus, from an anesthetic perspective we travel with a full complement of airway equipment and drugs, as described earlier, with packed red cells being made available at the host hospital. The anesthetic regimen for this procedure comprises a high-dose opioid, muscle relaxant, antibiotic, and a continuation of any preoperative vasoactive infusions. We have found that this is a stable and well-tolerated anesthetic regimen.

The requirement for anesthesia services is ever-widening, and in patients with pediatric heart disease this is also the case. Thus the patients will require radiologic investigations, including CT, MRI, and nuclear medicine scans; interventional radiology procedures; and gastrointestinal procedures, to name a few. Before discussion of the patient and the anesthetic, it is important for the practitioners to have a thorough knowledge of the environment into which they are taking the patient with regard to magnetic fields, closest code cart, and the ability to get help quickly if needed. Without going into the specifics

of every potential clinical scenario, a few basic points are discussed.

As with any anesthetic procedure, a thorough preoperative evaluation is vital. Most patients with pediatric heart disease have long and complex histories, so this assessment should include a detailed description of their cardiac status, including prior surgeries, catheterization findings, and associated conditions (e.g., neurocognitive function, pulmonary status, renal function). Depending on the patient's underlying condition a recent echocardiogram will give very important clinical details related to overall function, valve pathology, presence or absence of intracardiac shunt, patency of surgical shunts, and presence of pericardial fluid. Although this may be ideal, often the echocardiographic examination may be remote from the anesthetic encounter and thus the clinical history and examination are important. The group of heart transplant patients, however, requires an echocardiogram within a short time of the planned procedure because it will give vital information that may indicate worsening function in an otherwise asymptomatic patient. The last point is the nothing-by-mouth period. Many patients in this group have physiology in which dehydration may be very deleterious (e.g., single-ventricle physiology, presence of surgical shunts, unrepaired TOF). In these patients it is important that the patient stay orally hydrated up to 2 hours before the planned procedure; if this is not possible, intravenous fluids must be used. The anesthetic course will depend on the duration of the planned procedure, the patient's physiology (i.e., spontaneous versus controlled ventilation), airway management (natural versus laryngeal mask airway versus endotracheal tube airway), anesthetic maintenance, travel to and from the procedural area, and maintenance of the patient's temperature. Before leaving the induction area the anesthetic team must be prepared for airway misadventures and even a code situation; thus, the team must travel with auxiliary airway equipment and resuscitative drugs. The very number of these different venues may make it difficult to have an anesthesia machine present in each; however, an anesthetic cart with additional airway equipment, intravenous materials, and resuscitative drugs should be present. The anesthetic that is delivered may vary among practitioners and institutions, but the common details of importance are a thorough knowledge of the patient and the ability to treat expeditiously should any difficulty ensue in a remote venue.

Chapter 95

Pediatric and Neonatal Intensive Care

TODD J. KILBAUGH • MAURICE ZWASS • PATRICK ROSS

Acknowledgment: The editors and publisher would like to thank Dr. George A. Gregory for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The role of family in the pediatric intensive care unit (PICU) has evolved over time, and the inclusion of family in the care of their child is now recognized as an important part of critical care.
- Congenital heart disease causes significant alterations in oxygenation, perfusion, and myocardial function after birth, and it can be categorized into hypoxic and normoxic lesions.
- The overall goal of therapy in shock is to treat the underlying cause, return adequate oxygen delivery to the tissues, and remove metabolic products that developed during anaerobic metabolism. It appears that the faster the body returns to adequate perfusion, the better the overall outcome.
- One of the recent changes in neonatal resuscitation in the 2011 Neonatal Resuscitation Program Guidelines is the recommendation of positive pressure ventilation (PPV) with room air, unless chest compressions or medications are needed during the resuscitation, then the recommendation is still for PPV with 100% oxygen.
- Pediatric cardiac arrest is not a rare event. At least 16,000 American children (8-20 per 100,000 children per year) suffer a cardiopulmonary arrest each year.
- The four distinct phases of cardiac arrest and cardiopulmonary resuscitation (CPR) interventions are: (1) pre-arrest, (2) no-flow (untreated cardiac arrest), (3) low-flow (CPR), and (4) post-resuscitation and arrest.
- Acute respiratory distress syndrome (ARDS) diagnostic criteria have been revised recently and are now the Berlin Definition, where ARDS is separated into three mutually exclusive categories based on the degree of hypoxia. Mild is PaO_2/FiO_2 = 201 to 300 with positive end-expiratory pressure (PEEP) > 5, moderate is PaO_2/FiO_2 = 100 to 200 with PEEP > 5, and severe is PaO_2/FiO_2 < 100 with PEEP > 10.
- Traumatic brain injury (TBI) is composed of two components—an initial primary injury owing to direct mechanical deformation of brain parenchyma and a subsequent secondary injury that can develop over hours to days. Secondary injury may be the result of multiple mechanisms including ischemia, excitotoxicity, metabolic failure and eventual apoptosis, cerebral swelling, axonal injury, and inflammation and regeneration.
- A vascular occlusive crisis in the lungs leads to acute chest syndrome (ACS). Acute chest syndrome is the leading cause of death and the second most common complication in sickle cell disease.
- Tumor lysis syndrome is a metabolic crisis precipitated by acute lysis of a large number of tumor cells. Serum uric acid, potassium, and phosphate concentrations are elevated. The elevated phosphate concentrations cause hypocalcemia.
- Accidents and trauma are the leading causes of death in children 1 to 14 years of age.

RELATIONSHIP BETWEEN THE INTENSIVE CARE UNIT AND THE OPERATING ROOM

The field of pediatric intensive care may have originated from anesthesia, but these areas have grown apart over time. Because of the extensive training required, few individuals are qualified to cover both disciplines. With more complex patients, care will occur in the operating room and the intensive care unit (ICU). There needs to be excellent communication between the ICU and operating room clinicians to ensure a seamless transition of care. Many institutions require attending-to-attending

handoff between the ICU and anesthesia for each case. This should occur in both the preanesthetic and postanesthetic setting. Information regarding current ICU therapy response can simplify a potentially difficult anesthetic. Similarly, understanding the operative and anesthetic course will guide the next several days of management in the ICU. A complete anesthesia sign-out includes pertinent past medical history, allergies, ease of airway management, venous and arterial access, blood and fluids given, the need for inotropic drugs, medications delivered including timing of antibiotics, complications, laboratory values, and the most recent analysis of arterial blood gases (ABGs). This information may be available in the anesthetic record; however, a short verbal summary by the anesthesiologist provides details that are more practical.

FAMILY PARTNERED CARE IN THE PEDIATRIC INTENSIVE CARE UNIT

The role of family in the pediatric intensive care unit (PICU) has evolved over time. The inclusion of family in the care of their child is now recognized as an important part of critical care. Many intensivists identify the family unit as their patients. In many pediatric hospitals, parents are invited to participate in multidisciplinary rounds with the nurses, respiratory therapists, and physicians working with their child. The literature indicates that including families in rounds does not require more time than traditional rounds, and it does not compromise teaching.[1] Privacy can be maintained even in an open-bed environment. Satisfaction with this model is reported from families and care providers in the unit. More ICUs likely will move to this model over time.

Parents of children admitted to an ICU can incur severe emotional distress, sometimes resulting in symptoms of posttraumatic stress disorder.[2] The ICU is a unique and often terrifying experience for families and children. The process of ICU care involves multiple caregivers, changing shifts, and endless physicians (e.g., residents, students, fellows, multi-specialists). For families in the ICU, there can be a loss of control, significant financial worries, and other factors that affect coping. Helping parents to cope with their child's critical illness and these stressors is a central part of intensive care. Parents may display behaviors that are out of context and may seem abnormal, such as excessive clinginess, intellectualizing the process, blaming others (including their spouses), minimizing, and seeking opinions everywhere (e.g., the Internet, the environmental care people). It is imperative to attempt to understand what impels these behaviors to provide optimal care. It is also important to help the parents be parents and educate them about their child's illness. This situation emphasizes that social workers, psychologists, and child and family therapists are all part of the critical care team.

With the move to family-centered care, the issue of parental presence during invasive procedures and especially cardiopulmonary resuscitation (CPR) needs to be addressed. Unfortunately, most studies are from the setting of an emergency department rather than an ICU. A review by Dingeman and associates[3] found that 10 of 15 studies conducted in emergency departments addressed the issue of parental presence during procedures or CPR. A study by Dudley and associates[4] indicates that family presence does not delay care in pediatric trauma resuscitations. Mangurten and colleagues[5] also showed that care was uninterrupted by family presence during CPR or invasive procedures and that there was overall parental satisfaction. The experience of families present during CPR in a PICU setting was also positive.[6] Actually, allowing parents to stay during procedures or resuscitation may be helpful for the parents coping with the trauma of a critically ill child. Caregiver attitudes toward parental presence will need to be addressed as the likelihood of this event increases over time. The decision to allow parental presence cannot be forced on everyone. There should be in place a means for declining on the part of the clinician as well as the parent. In addition, an attendant for family members during these events is necessary; this is similar to the issue of parental presence during induction of anesthesia in the operating room (also see Chapter 93). Arrangements need to be made in advance to instruct family so that clinical care is not interrupted. In our ICUs this role been filled by social workers or members of the medical team. Parental presence during invasive procedures may pose a different challenge as these events occur more frequently compared with CPR. In the same manner, someone other than the person performing the procedure should be looking after the family.

DISCLOSURE OF MEDICAL ERRORS

We believe that it is ethically correct to disclose medical errors to families; however, some clinicians may continue to resist because of concerns regarding litigation. In a survey of 1018 Illinois residents, 27% indicated that they would sue, but 38% stated that they would recommend the hospital if appropriate disclosure and remediation occurred.[7] The conclusion drawn by the author of the study was that "Patients who are confident in their providers' commitment to disclose medical errors are not more litigious and far more forgiving than patients who have no faith in their providers' commitment to disclose." Explanations of medical errors to the family should come from the senior member of the team. This is usually the current ICU attending, but it can be the medical director of the ICU based on the complexity of the incident and outcome. The discussion should include an explanation of what happened in nontechnical language, how it occurred, the repercussions and change of care planned for the child, and what will be done to prevent a similar error in the future. We find it helpful to have the ICU social worker present to help validate concerns and provide support. The attending physician remains present until all questions are answered or additional time is scheduled, if necessary. Most hospitals will track errors or negative outcomes through a quality-assurance program. Depending on the incident, a "root cause analysis" should be performed. Medical errors will occur, but these should be viewed as opportunities to improve practice quality and prevent future events.

In an ICU setting, there unfortunately will also be a need to cope with death and dying.[8] Palliative care plays

an important role when nothing medically can be done for the child (see Chapter 65). We also find their services exceedingly helpful for children with chronic medical conditions who are anticipated to die during a future admission. Using a team approach, we try to minimize pain and suffering for the child and family at the end of life. Caregivers and ICU team members must understand when to allow the families' choices and support them over what may be their own beliefs and practices—as long as the goal remains to prevent further pain and suffering.[9] The awareness of medical futility is increasing over time; however, with this concept, there is a significant interplay with financial, societal, ethical, personal, and religious opinions and feelings. It may be difficult to define futility, but when the pain and suffering of continuing life are more severe than the inevitability of death, care may become futile. Pain relief and caring support for the child and family are never futile.

ORGANIZATION OF THE PEDIATRIC INTENSIVE CARE UNIT

Medical and nursing directors, hospital administrators, and representatives from pediatric medicine, anesthesia, surgery, and the pediatric subspecialties should be responsible for policy and procedures pertaining to the PICU, and they should make recommendations regarding personnel staffing, equipment purchases, and structural and design changes within the unit.

The medical director oversees the quality of patient care, patient triage, implementation of policy and procedures, in-service education, and coordination of consultants. Ideally, physician coverage should be full-time at the resident, fellow, and attending staff level and should include in-house, full-time coverage at night.

The nursing director should have special skills in pediatric intensive care, education, and personnel management. The nursing staff must be trained in all aspects of pediatric critical care and resuscitation. Staffing should be flexible enough to provide one-on-one patient care when necessary. A multidisciplinary in-service program is essential for continuing education and orientation.

Other team members include respiratory therapists, physical therapists, nutritionists, social workers, laboratory technologists, pharmacists, and psychiatrists and psychologists for the patients and staff. All medical and support personnel should be encouraged to participate in rounds, educational endeavors, and team meetings whenever possible.

There must be adequate workspace around each bed and enough storage space to keep life-support equipment within reach. Space for reading, meeting, sleeping, and showering should be available for the staff members. Space should be provided for parents to remain with their children during the day and for parents to sleep overnight. Parents should be encouraged to participate as much as possible in the care of their child.

Each bed space should be standardized so that it can be used to provide any level of care. Private rooms are ideal, but if shared rooms are necessary, the distance between beds must be adequate to ensure privacy and minimize nosocomial infection. Isolation rooms should be available within the confines of the unit.

Devices for diversion and entertainment should be available for conscious children. Television and computer games are often better than heavy sedation.[10,11] Adequate nurses and nursing involvement at the bedside will prevent potentially life-threatening events. Because sick children require close personal observation, centrally monitored nursing stations have little place in the PICU.

CARDIOVASCULAR SYSTEM (SEE ALSO CHAPTERS 93 AND 94)

STRUCTURAL AND FUNCTIONAL DEVELOPMENT

The shape of the heart is complete by 6 weeks' gestation, but myofibrillar density and maturation increase through the first year of postnatal life. During this time, myocytes engage in rapid protein synthesis and rapid cell growth, which requires a high intracellular concentration of nuclei, mitochondria, and endoplasmic reticulum. The greater number of nonelastic and noncontractile elements makes the neonatal myocardium less compliant and it contracts less efficiently than the adult myocardium. In the fetus and newborn, the decreased ventricular compliance causes small changes in end-diastolic volume to induce large changes in end-diastolic pressure. In addition, augmentation of stroke volume by the Frank-Starling mechanism is less effective in young children. The newborn is more dependent on heart rate for maintenance of cardiac output.[12,13] Cardiac output increases only approximately 15% with intravenous fluid administration; increasing the heart rate, however, increases cardiac output.[14] This consideration is important when taking care of the critically ill infant.

DEVELOPMENT OF THE CIRCULATION

The adult and fetal circulation differs in many ways. The fetal circulation is distinguished by (1) the placenta as the organ of respiration, (2) high pulmonary vascular resistance (PVR), (3) low systemic vascular resistance (SVR), and (4) fetal ventricles that pump in parallel with right ventricular dominance. While the fetus lives in a low oxygen environment, the oxygen content of the blood of the fetus is similar to that of adults (20 mL of oxygen per 100 mL of blood) because of a higher concentration of hemoglobin that has high affinity for oxygen. The neonatal circulation has several shunts—the ductus arteriosus, ductus venosus, and foramen ovale—that direct more oxygenated blood to the brain and heart and bypass the lungs. Changes then occur that allow parallel circulation of the fetus to convert to the series circulation of the adult:

1. With the first breath, expansion of the lung, increased alveolar oxygen, an increase in pH, and neurohumoral mediators and nitric oxide (NO) relax the pulmonary vasoconstriction.[15]
2. When the placenta separates from the uterine wall, the placental blood vessels constrict, and SVR and left

ventricular afterload increase. The decrease in PVR plus increase in SVR raises left atrial pressure above right atrial pressure and functionally closes the "flap valve" of the foramen ovale. The foramen ovale may not close anatomically for months to years, if ever. It is patent in at least 15% of adults.[16,17]

3. The decrease in PVR causes flow through the ductus arteriosus to reverse. This exposes the ductus to oxygenated systemic arterial blood, which along with the rapid decrease in prostaglandin E_2 after birth, closes the ductus. Anatomic closure of the ductus requires several weeks.
4. The ductus venosus closes passively with removal of the placental circulation and readjustment of portal pressure relative to inferior vena cava pressure.
5. There is a further gradual decline in PVR secondary to structural remodeling of the muscular layer of the pulmonary blood vessels. During fetal life, the central pulmonary vascular bed has a relatively thick muscle layer. After birth, the muscle coat thins and extends to the periphery of the lung, a process that takes months to years to complete.

DEVELOPMENT OF AUTONOMIC CONTROL OF THE CIRCULATION

The functional integrity of autonomic circulatory control during fetal and perinatal development is still a matter of considerable speculation. The fetal heart has reduced catecholamine stores and increased sensitivity to exogenously administered norepinephrine.

Adrenergic innervation of the human myocardium is complete between 18 and 28 weeks' gestation. Human newborns have low cardiac stores of norepinephrine and decreased numbers of sympathetic nerves after birth. Adrenergic responses are apparently present, but diminished in newborn humans. In human neonates, the cholinergic system is completely developed at birth, and the heart is sensitive to vagal stimulation. Bradycardia is the probable response to an increase in autonomic tone. The baroreceptor reflex is present, but incompletely developed at term in humans. In preterm infants, postural changes elicit no change in heart rate, suggesting an incomplete or attenuated baroreceptor response.[16] The chemoreceptor response is well developed in utero. The fetal bradycardia that occurs in response to hypoxia is thought to be mediated through chemoreceptors and may be similar to the oxygen-conserving mechanisms of diving animals.[17]

MYOCARDIAL METABOLISM

Fetal myocardial metabolism differs from that of adults. Relative hypoxia is normal in utero, and infant hearts tolerate hypoxia better than adult hearts do. This difference may be due in part to high concentrations of glycogen in fetal myocardial tissue and to the ability to use anaerobic metabolism more effectively. Because of the high glycogen stores and the ability to use anaerobic metabolism efficiently, the fetal or newborn heart is relatively resistant to hypoxia and can be resuscitated more easily if oxygenation and perfusion are reestablished reasonably quickly.

Oxygen consumption increases precipitously after birth, presumably because neonates are required to maintain their own temperature. A full-term infant's oxygen consumption in a neutral thermal environment is approximately 6 mL/kg/min; it increases to 7 and 8 mL/kg/min at 10 days and 4 weeks, respectively.

COMMON CARDIOVASCULAR DISEASE STATES

CONGENITAL HEART DISEASE

Congenital heart disease causes significant alterations in oxygenation, perfusion, and myocardial function after birth (Box 95-1; also see Chapter 94). These abnormalities can be divided into hypoxic and normoxic lesions. The latter include obstructive lesions of the left side of the heart (mitral valve stenosis, aortic valve stenosis, aortic stenosis, anomalous pulmonary venous return, ventricular septal defect, or patent ductus arteriosus with a right-to-left shunt), whereas hypoxic lesions include tricuspid valve stenosis, pulmonary valve stenosis, pulmonary artery stenosis or aplasia, and the tetralogy of Fallot. Right-sided lesions cause hypoxia if the left-to-right shunting of blood is sufficient to cause congestive heart failure (CHF) and pulmonary edema.

Newborns with significant congenital heart disease commonly have either cyanosis or CHF (Box 95-1). The degree of dysfunction usually changes during the first few months of life as PVR decreases to adult levels. As PVR decreases, left-to-right shunting of blood usually increases, and the symptoms of CHF become more apparent. Many neonates with a significant ventricular septal defect, which may or may not be observed during the preoperative workup, have no left-to-right shunting for several weeks after birth; however, induction of alkalosis during surgery can increase shunting. In the newborn, the usual signs and symptoms of CHF include poor feeding, irritability, sweating, tachycardia, tachypnea, decreased peripheral pulses, poor cutaneous perfusion, and hepatomegaly. Many patients with pulmonary edema exhibit tachypnea without retractions. Cyanosis occurs with structural cardiac disease, but other causes such as respiratory disease, increased PVR (persistent pulmonary hypertension), and methemoglobinemia must also be considered.

BOX 95-1 ***Common Congenital Heart Malformations in the Newborn***

1. Cyanotic congenital heart lesions
   - Tetralogy of Fallot
   - Transposition of the great arteries
   - Hypoplastic left heart syndrome
   - Pulmonary atresia with an intact ventricular septum
   - Single ventricle
   - Total anomalous pulmonary venous return
   - Tricuspid atresia
2. Congenital heart lesions manifested as congestive heart failure
   - Ventricular septal defect
   - Patent ductus arteriosus
   - Critical aortic stenosis
   - Coarctation of the aorta

Congenital heart disease is diagnosed by physical examination, electrocardiogram, chest radiograph, and postnatal echocardiogram, and via fetal echocardiography. Cardiac catheterization is occasionally performed as interventional therapy or as a diagnostic tool. Magnetic resonance imaging (MRI) is used to define the anatomy of congenital heart lesions before cardiac surgery.

Initial treatment of congenital heart disease is aimed at relieving CHF, improving systemic perfusion, and improving or maintaining pulmonary blood flow. The ductus arteriosus must be maintained open in instances of hypoplastic left heart syndrome, aortic stenosis or atresia, interrupted aortic arch, and symptomatic neonatal coarctation of the aorta. In many cases, infusion of prostaglandin E_1 sustains life until surgical palliation can be performed.[18]

ACUTE CIRCULATORY FAILURE IN CHILDREN (SHOCK AND SEPSIS)

Shock

Shock is the inability to provide adequate oxygen to the tissues that require it. The condition of shock depends on the balance of supply and demand of oxygen. Typically, the body delivers excess oxygen to the tissues. Under periods of stress or illness, there can be a decrease in supply caused by diminished blood flow or as decreased oxygen in blood. There can also be increased demand or oxygen extraction from the tissues. The content of oxygen in the blood is dependent on the amount bound to hemoglobin and the amount dissolved in plasma: Oxygen content (Cao_2) (mL/dL) = (1.34g/dL) (Sao_2) (Hb) + (PaO_2) (0.003). The normal oxygen content is approximately 20 mL/dL. Delivery of oxygen to the tissues depends on oxygen content and cardiac output. Oxygen delivery ($\dot{D}O_2$) (mL/min) = oxygen content (Cao_2) × cardiac output (CO). Oxygen consumption ($\dot{V}O_2$) is the demand portion of the equation. Oxygen consumption ($\dot{V}O_2$) is independent of oxygen delivery ($\dot{D}O_2$) above a critical threshold and over a wide range. Below this critical threshold, $\dot{V}O_2$ is dependent on $\dot{D}O_2$. For infants and young children $\dot{V}O_2$ is estimated at 175 mL/min/m^2. Oxygen consumption is equal to oxygen delivery multiplied by oxygen extraction (O_2EX) by the body: $\dot{V}O_2 = \dot{D}O_2 \times O_2EX$. Oxygen extraction O_2EX is equal to $(CaO_2 - CvO_2)/Cao_2$. Cao_2 is the oxygen content of arterial blood and CvO_2 is the oxygen content of venous blood. The difference between oxygen content of arterial and venous blood is predictably 4 to 6 mL/100 mL blood. Initially, as oxygen delivery decreases, the oxygen consumption can remain constant via increased extraction. Below a critical threshold in oxygen delivery, oxygen consumption becomes dependent on delivery. When oxygen cannot meet the metabolic needs of the body, nonessential metabolism is decreased or eliminated. Such metabolism includes growth, neurotransmitter synthesis, thermoregulation, and so on. In this way, the remaining oxygen can continue to be substrate for mitochondria. There are organs in the body such as the kidney, skin, intestines, and skeletal muscle that receive a high supply of blood relative to their metabolic needs. These organs also have a high proportion of sympathetic nerve innervations that allow for redistribution of blood flow to organs with limited oxygen reserves, such as the brain and heart.

Classification of Shock

There are several schemas that clinicians use to classify shock. Furthermore, within these classification schemas, disease states can fall into more than one category. One classification schema separates shock into hypovolemic, cardiogenic, distributive or vasogenic, and extracardiac obstructive.

Hypovolemic shock can be due to hemorrhage from trauma or gastrointestinal (GI) losses from internal bleeding. Nonhemorrhagic hypovolemic shock can be due to external losses of fluid from vomiting, diarrhea, polyuria, and poor fluid intake. Fluid redistribution in cases of burns, trauma, and anaphylaxis can also be a cause.

Cardiogenic shock can be myopathic because of decreased heart function. It commonly follows myocardial infarction in adults. For children, myocarditis or cardiomyopathy are more common. Other causes of cardiogenic shock include mechanical failure, such as valvular regurgitation or obstruction. Significant arrhythmias can result in cardiogenic shock when contractions are so asynchronous that they decrease cardiac output.

Extracardiac obstructive shock results from a physical obstruction that prevents adequate forward circulatory flow. Causes include inadequate preload secondary to mediastinal masses, increased intrathoracic pressure from tension pneumothorax, constrictive pericarditis, and cardiac tamponade from pericardial effusions. Pulmonary hypertension, pulmonary embolus, and aortic dissection can cause obstruction to systolic contraction.

Distributive shock is caused by a decrease in systemic vascular resistance and the maldistribution of end-organ blood flow. Cardiac output can be increased in distributive shock; however, arterial blood pressure can remain low because of a very low systemic vascular resistance. Septic causes of distributive shock can be related to bacterial, fungal, viral, or rickettsial infections or toxins produced from these infections. Toxic shock syndrome is an example of toxin-mediated hypotension. Anaphylactic or anaphylactoid reactions are a type of distributive shock. Systemic inflammatory response syndrome (SIRS) may present with distributive shock. Spinal shock can result in distributive shock on a neurogenic basis. Adrenal insufficiency with low circulating hormones results in distributive shock decreased systemic vascular resistance.

Diagnosis of Shock

Maintaining a high index of suspicion is important to identify shock rapidly in pediatric patients. Volume losses may be readily apparent from the history of present illness. Fever, rash, and irritability can indicate infection; however, cardiogenic shock can appear with vague reports of decreased activity and level of alertness. In addition, if the patient's shock is currently compensated, changes in physical findings may be limited. A child in shock may initially exhibit tachycardia, cold extremities, and poor capillary refill. Furthermore, in distributive shock the child may be warm with just an isolated tachycardia. A brief pertinent physical examination should evaluate

level of alertness, peripheral perfusion, mucous membranes, pulse rate and quality, respiratory effort, urine output, and arterial blood pressure. In children, arterial blood pressure may be preserved until the degree of shock has progressed. Hypotension is a sign of late and decompensated shock in children. Metabolic acidosis may not be initially present.

Compensatory Mechanisms

The body applies compensatory mechanisms with the onset of shock to maintain adequate tissue perfusion for as long as possible. There is redistribution of fluid from the intracellular and interstitium to the vascular space. There is a decrease in glomerular filtration to limit renal fluid losses. Renal fluid losses are also limited by the release of aldosterone and vasopressin. There is an increase in sympathetic activity and release of epinephrine; this results in decrease venous capacitance and some preservation of arterial blood pressure. Heart rate is increased as the body tries to maintain cardiac output. There is an increase in cardiac contractility through circulating catecholamines and adrenal stimulation. Increase in sympathetic nerve stimulation shunts blood away from nonvital organs. At the tissue level, transfer of oxygen from hemoglobin is increased by increased red blood cell 2, 3-diphosphoglycerate (DPG), fever, and tissue acidosis.

Therapy and Outcomes

Aggressive therapy to treat pediatric septic shock has resulted in improved outcomes; therefore, therapy for septic shock appears to be a good model for the treatment of shock in general. The overall goal of therapy in shock is to treat the underlying cause, return adequate oxygen delivery to the tissues, and remove metabolic products that developed during anaerobic metabolism. The faster the body returns to adequate perfusion, the better the overall outcome. Many hospitals have developed sepsis pathways based on the data presented in Figure 95-1. These pathways act as guidelines for resuscitation and are readily available to all care providers.

In 1991, Carcillo and colleagues[19] described a population of 34 children with septic shock in an emergency department. Shock was diagnosed based on hypotension for age, with decreased perfusion, poor peripheral pulses, cool extremities, and tachycardia. Sepsis was defined as a positive blood or tissue culture result. Remarkably, all the patients had a pulmonary artery catheter placed within 6 hours of presentation. The overall mortality for the group was 47%; however, there was only one death (11% mortality) among the nine patients who received more than 40 mL/kg of fluids in the first hour. The authors point out this patient died with a second episode of sepsis 2 weeks later. In this study, the rapid intravenous fluid administration did not increase the incidence of cardiogenic pulmonary edema or acute respiratory distress syndrome (ARDS).

In 2001, Rivers and colleagues[20] published a study in adult patients with septic shock showing that early, aggressive, goal-directed therapy in the first 6 hours of care improved mortality. Two hundred sixty-three adults enrolled, and 133 received standard therapy based on clinician discretion. The 130 patients randomized to early goal-directed therapy followed protocols treating hypovolemia and supporting arterial blood pressure with vasoactive medications, if necessary. The baseline characteristics of the two groups were similar. The in-hospital mortality was 46.5% in the standard therapy group and 30.5% in the early goal-directed therapy group ($p < 0.01$). Although the study occurred in adults, the results demonstrated the need for early aggressive intervention.

Following the Rivers' publication, a task force was formed from members of the Society of Critical Care Medicine to address shock in children; their work was published in 2002.[21] Their guidelines were incorporated into the American Heart Association's (AHA) Pediatric Advanced Life Support (PALS) Provider Manual and widely disseminated with Spanish and Portuguese translations. The effectiveness of these interventions and a 2007 update was published by the same group in 2009.[22] They highlighted significant improvements in mortality in dengue shock syndrome, malaria, and septic shock treated by community physicians using early goal-directed therapy.[23-25]

The guidelines include rapid recognition of shock, early antibiotic administration, and early administration of intravenous crystalloid. The initial resuscitation should include 20 mL/kg of isotonic saline or colloid pushed as a bolus to over 60 mL/kg until there is an improvement in the patient's perfusion or rales or hepatomegaly develops. The goal is for the initial fluid resuscitation to occur in the first 15 minutes of therapy, and therapy should be initiated by placing an intraosseous device, even if peripheral intravenous cannulation attempts fail (Fig. 95-2). The guidelines target therapeutic end points of normal pulses with no difference between peripheral and central pulses; capillary refill ≤ 2 seconds; warm extremities, normalization of blood pressure for age, mental status, glucose concentration, ionized calcium concentration; and urine output > 1 mL/kg/hr. If central venous access is not readily obtained, consideration should be given for placement of an intraosseous line. Cold shock (cold mottled extremities with prolonged capillary refill) should be treated with dopamine up to 10 μg/kg/min and then epinephrine (0.05 to 0.3 μg/kg/min) if there is no improvement. Warm shock (brisk capillary refill) should be treated with norepinephrine. Arrangements should be made early to admit the child to an ICU. If shock is not reversed with the inotropic support, hydrocortisone should be considered for catecholamine-resistant shock. Recommendations for stabilization in the ICU following the first hour of therapy include monitoring central venous pressure, central venous saturation, and cardiac output. Persistent shock that is resistant to catecholamines should prompt the clinician to rule out pericardial tamponade, pneumothorax, or significantly elevated intraabdominal pressure that may be compromising circulation. In the absence of a correctible condition, extracorporeal membrane oxygenation (ECMO) should be considered.

There were several new recommendations in the 2007 guidelines that addressed changes in the literature between 2002 and 2007. It was identified that the availability of skilled practitioners to place central venous access could delay the initiation of inotropic support. Therefore, the 2007 guidelines recommended the

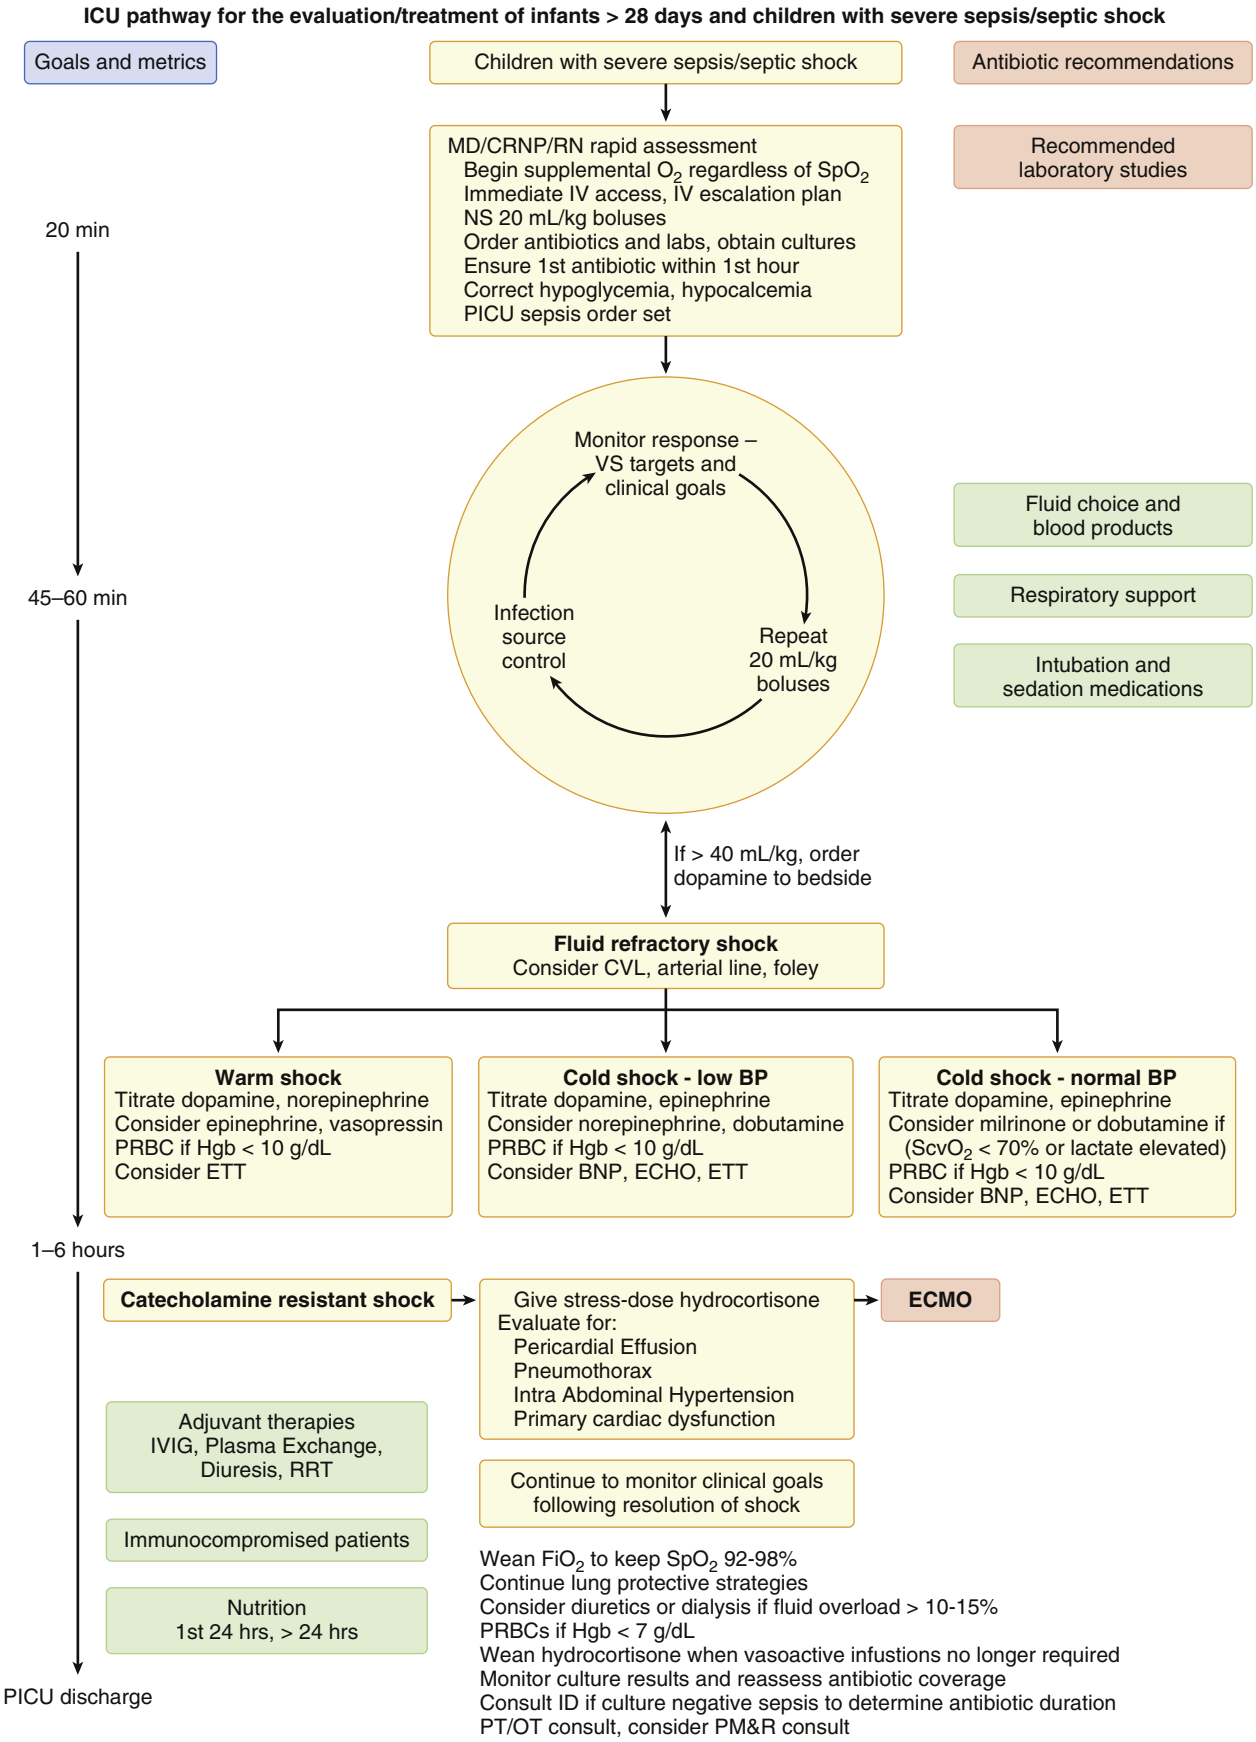

Figure 95-1. Sepsis resuscitation pathway.

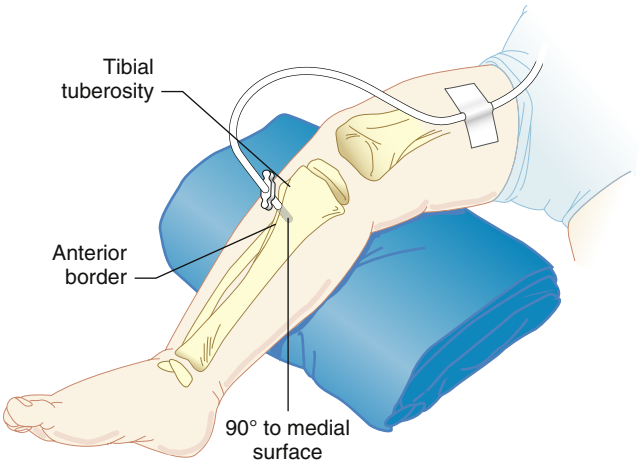

Figure 95-2. Intraosseous cannulation technique.

administration of dopamine or epinephrine via a peripheral intravenous line if there was a delay in obtaining central venous access. Ongoing monitoring of the access site should be performed. Norepinephrine should not be given in a peripheral intravenous injection because of the risk of extravasation. In the 2002-2007 interval, there were several pediatric and adult studies indicating adrenal suppression and increased severity of illness adjusted mortality with the use of etomidate.[26,27] The 2007 guidelines do not recommend the use of etomidate unless it is in the format of a randomized controlled trial. Ketamine with atropine was recommended for sedation for invasive procedures in infants and children. However, because of limited experience, ketamine cannot be recommended for the newborn population.

The 2007 guidelines[22] recommend titrating therapy to cardiac output and indicate that there are several methods by which cardiac output can be measured. The use of pulmonary arterial catheters in pediatrics has decreased, but other methods are available. A good review of monitoring techniques was published by Mtaweh and associates in 2013.[28] Cardiac output can be monitored by newer techniques analyzing the arterial pulse wave, transpulmonary thermodilution, carbon dioxide rebreathing, echocardiography, bio-impedance of the thorax, and ultrasound continuous-wave Doppler. These techniques are less invasive than pulmonary artery catheters; however, many still require validation studies in pediatric centers, and they might not be available at all centers.

One additional area to be addressed in the 2007 guidelines is in the area of fluid removal.[22] In a 2005 study by Goldstein and associates[29] with pediatric patients in multi-organ failure, including acute renal failure requiring continuous renal replacement therapy (CRRT), there was improved survival in the group that had a lower percentage of fluid overload at the initiation of CRRT.[29] While supporting the primary premise of fluid resuscitation, the 2007 guidelines offered new recommendation for fluid removal in patients with fluid overload and multiorgan failure.[21] They recommended the use of diuretics, peritoneal dialysis, or CRRT in patients who had received adequate fluids for resuscitation but were not able to maintain an even fluid balance through native urine output. Yet, peritoneal dialysis and CRRT for pediatric patients might not be available at all centers. However, the association between excessive intravascular fluid administration and mortality with acute renal failure is an ongoing issue in PICU care.

The concern for possible adrenal insufficiency during septic shock needs to be addressed by the clinician caring for the patient. There are certain instances in which limited function of the adrenal axis is anticipated. These instances include patients who have recently received a glucocorticosteroid, ketoconazole, or etomidate. Furthermore, patients with disease states such as purpura fulminans or those affecting the hypothalamus, pituitary or adrenal glands will be at increased risk. Patients with adrenal insufficiency need supplemental corticosteroids. However, for children with septic shock but without these factors, it is not clear whether the risk of relative adrenal insufficiency or treatment with systemic steroids alter outcome. Dr. Zimmerman[30] reviewed the adult and limited pediatric literature in 2007 for therapeutic steroid use in sepsis. He highlighted adult studies showing high-dose short courses of steroids are associated with decreased survival. Furthermore, data from the CORTICUS trial[31] indicated that low-dose steroids as a physiologic replacement during periods of vasopressor resistant shock resolve shock more quickly but there was no change in mortality. In turn, the 2007 guidelines were unchanged from 2002. Hydrocortisone treatment was only recommended for patients with absolute adrenal insufficiency or adrenal-pituitary axis failure and catecholamine-resistant shock. Absolute adrenal insufficiency was defined as peak cortisol concentration of less than 18 μg/dL obtained after corticotropin stimulation.

CARDIOVASCULAR PHARMACOLOGY

Pharmacologic support of the circulation includes positive inotropic and chronotropic agents, vasoconstrictors and vasodilators (afterload reduction), and antiarrhythmics (see Chapters 16 and 93). Most currently used drugs have not been tested adequately in children; therefore, dosage recommendations and anticipated effects must be extrapolated from adult doses and clinical experience.

Positive inotropic drugs are used to augment the cardiac output of patients with circulatory failure. Most inotropic agents also affect the heart rate and vasomotor tone. Tachycardia in a child is usually well tolerated and is frequently beneficial.[32] In a neonate whose ventricles are relatively noncompliant and whose stroke volume is less variable, tachycardia is an important means of augmenting cardiac output. Because drugs that increase the heart rate or contractility also increase myocardial oxygen consumption, adequate arterial oxygenation and sufficient metabolic substrates are required when these drugs are administered. The cardiovascular response to sympathomimetic amines is attenuated in the presence of severe acidosis and possibly sepsis; higher infusion rates of these drugs are required and need readjustment as the acidosis improves. In the following paragraphs, commonly used inotropic drugs are listed with brief comments regarding their use in pediatric intensive care (Table 95-1).

TABLE 95-1 VASOACTIVE AND INOTROPIC MEDICATIONS

Drug	Effect	Dose (μg/kg/min)	Inotropy	Chronotropy	Vasodilation	Vasoconstriction
Epinephrine (Adrenalin)	α, β	0.05-2.0	++	++		++
Isoproterenol (Isuprel)	β_1, β_2	0.05-2.0	++	++	+	
Dopamine (Inotropin)	δ	1-3			+Renal splanchnic	
	β > α	5-15	+	+		+ or –
	β, α	>15	+	+		+
Milrinone		Bolus: 50 μg/kg over 15-min period Infusion: 0.375-0.75	+		+	
Norepinephrine	α >> β	0.05-1.0	Slight+	+		++
Nitroprusside		0.5-10			++ Arterial > venous	
Nitroglycerin		1-20			++	

EPINEPHRINE

Epinephrine is useful for the treatment of shock in the presence of myocardial dysfunction. The typical starting dose in children is 0.05 to 0.2 μg/kg/min. Doses as large as 1 to 2 μg/kg/min have been given if there is profound vasodilation in the periphery and abdominal organs with the overall goal of shunting blood to the heart and brain.

Dopamine

Dopamine is the most commonly infused inotropic drug in pediatric patients. Dopamine is the metabolic precursor of both norepinephrine (NE) and epinephrine. Its effects are dose-dependent, with dopaminergic activity with small doses (although not well documented) in critically ill children; β-adrenergic activity with intermediate doses (5 to 10 μg/kg/min) exhibits chronotropic and inotropic effects; and some α-adrenergic activity at larger doses (10 to 20 μg/kg/min) exhibit peripheral vasoconstriction. Young children require larger doses of dopamine than adults do to produce the same effect. In one study of infants, an infusion of 15 μg/kg/min was required to increase cardiac output above control levels after cardiac surgery.[33] This may reflect the decreased releasable myocardial stores of norepinephrine in immature ventricles. Therefore, in the sick, preterm infant, there can be decreased dopamine clearance with a much greater vasopressor response than expected.

Vasopressin

Vasopressin is a pituitary peptide hormone with method of action on the kidney and vasculature. In the kidney, vasopressin controls water reabsorption in the renal tubules and in the vasculature causes vasoconstriction by stimulating smooth muscle V1 receptors. Its clinical applications include GI hemorrhage, central diabetes insipidus, and as a second- or third-line agent to treat hypotension.

Isoproterenol

Isoproterenol is a synthetic, potent, nonselective β-agonist with strong chronotropic effects with very low affinity to α-adrenergic receptors, and is usually well tolerated in children. However, high doses of isoproterenol can cause myocardial ischemia.[34] Isoproterenol also induces vasodilation that is responsive to acute volume administration. It is often used for increasing heart rate in complete heart block, in the immediate postoperative period after cardiac transplantation to improve cardiac output by increasing heart rate in the denervated donor heart, and as a potent pulmonary vasodilator during pulmonary hypertensive crisis via β_2-adrenergic receptor activity.

Dobutamine

Dobutamine provides positive inotropy and afterload reduction. It is active at β and α receptors. Its function is primarily as a inotropic agent but with less vasopressor activity compared with dopamine. It is only used as a continuous infusion of 5 to 20 μg/kg/min, and in some studies may increase myocardial oxygen. It causes tachycardia in children but not in adults.[35,36]

Norepinephrine

Norepinephrine, a drug with strong α- and β-agonist effects, has had a resurgence of use in infants and children.[37] Children with nearly normal cardiac function and marked peripheral vasodilation have good responses to this drug. It is especially useful in instances of warm septic shock, anaphylaxis, liver failure, and sympathetic blockade with regional anesthesia (see Chapter 92). It will increase SVR, but also limits mesenteric blood flow, including hepatic perfusion.

Milrinone

Milrinone is a selective phosphodiesterase III inhibitor that increases cyclic adenosine monophosphate by inhibiting breakdown. Milrinone has both inotropic and vasodilator effects, without acting on α and β receptors. The outcome of children is increased in those who have low cardiac output syndrome after cardiac surgery.[38] The initial dose of milrinone is 25 to 75 μg/kg administered over a period of 15 minutes; the maintenance infusion rate is 0.25 to 0.75 μg/kg/min. Initial doses are often avoided in the ICU setting because of resultant hypotension. Renal failure significantly increases the elimination half-life of

this drug.[39-41] Outside the cardiac ICU, milrinone is used for vasoconstricted septic shock and may have a role in the treatment of pulmonary hypertension.

Levosimendan

Levosimendan increases the sensitivity of the contractile apparatus to calcium increasing inotropy by binding to cardiac myocyte troponin C. This drug increases cardiac ejection fraction, while reducing catecholamine dose with minimal effects on arterial blood pressure and heart rate. In children, the most common indications have been for cardiac failure or after cardiac surgery, with an initial doses of 6 to 12 μg/kg followed by an infusion of 0.1 to 0.2 μg/kg/min.[41,42]

Nesiritide

Nesiritide is a recombinant form of the human B-type natriuretic peptide, the hormone released from the cardiac ventricles in response to excessive intravascular volumes and increasing mechanical wall stress. The action is on guanylyl cyclase with resulting venous and arterial vasodilation. In addition, B-type natriuretic peptide leads to myocardial relaxation (lusitropy) and natriuresis. In children, it decreases central venous pressure and increases urinary output.[43] The usual doses for children and adults are an initial 2 μg/kg bolus followed by a continuous infusion of 0.005 to 0.01 μg/kg/min.

Digitalis

Digitalis is useful for the long-term treatment of myocardial failure in children, but it may not be effective in neonates.[44] Because of its long half-life and unpredictability, digitalis should be administered cautiously to children who have changing levels of serum potassium, calcium, and pH values. In these cases, it is more appropriate to use rapid-acting, titratable, inotropic drugs.

Calcium

When serum ionized calcium levels are below normal, administration of calcium produces a positive inotropic effect. If the patient's ionized calcium levels are normal, less marked inotropic effects occur. Low ionized calcium levels most commonly occur in patients with DiGeorge's syndrome, when large volumes of citrate-containing blood products are rapid administered, and in neonates with relatively unstable calcium metabolism. Calcium also has effects on the cardiac conduction system. Rapid administration of calcium can cause severe bradycardia or asystole. This effect may be exaggerated in hypokalemic children or in those receiving digitalis. The vasomotor effects of calcium are controversial, but most reports show an increase in both SVR and PVR when the drug is administered.[45]

Bicarbonate Therapy

Severe acidosis decreases myocardial function and tissue perfusion. Correction of acidosis with 1 to 2 mEq/kg of sodium bicarbonate is indicated for a pH below 7.20 if ventilation is adequate (Pco_2 < 40 mm Hg if possible; see also Chapter 60). Treatment is necessary because the circulatory system is refractory to sympathomimetic amines when the pH is less than 7.00. After initial correction of pH, persistence or reappearance of metabolic acidosis suggests a continuing under-perfused state and the need for further therapy. Administration of sodium bicarbonate is only a stopgap measure to improve the response to drugs. Repeated infusions of sodium bicarbonate can cause hypernatremia and hyperosmolarity. Every 50 mEq of bicarbonate administered produces 1250 mL of CO_2 when the bicarbonate is fully reacted with acid. Consequently, adequate ventilation must be ensured to avoid worsening the acidosis. Tromethamine, also known as *Tris buffer* or by the trade name THAM, is an alternative to sodium bicarbonate, but larger volumes of THAM are required to produce the same amount of acid-base correction, which may be a problem in patients who have CHF. THAM does not increase $Paco_2$.

Vasodilators

Vasodilators are used to control systemic hypertension, increase cardiac output by decreasing afterload, control pulmonary hypertension, and control cardiac shunting. Vasodilators are an effective treatment of systemic hypertension and increase cardiac output in children with CHF. Treatment of pulmonary hypertension and intracardiac shunting with vasodilators has met with limited success because they decrease both PVR and SVR, which may increase extrapulmonary right-to-right shunting and further reduce pulmonary blood flow.

Nicardipine

Nicardipine is a dihydropyridine calcium channel-blocking drug used as an intravenous infusion; it has powerful, antihypertensive effects in children. The rapid onset of action is usually within 1 minute, adding to the profile appropriate for treating severe hypertension. Flynn and associates[46] report that nicardipine is an effective antihypertensive medication in children ranging in age from 2 to 18 years. At the authors' institution, nicardipine is the drug of choice for hypertensive crisis. Infusion ranges are 0.5 to 1.0 μg/kg/min up to 3.0 μg/kg/min.

Sodium Nitroprusside

Sodium nitroprusside relaxes arteriolar and venous smooth muscle, which decreases afterload and preload. The half-life of sodium nitroprusside is only minutes, making it safe to titrate the drug to a desired effect. Nitroprusside is commonly used to control severe systemic hypertension, to provide controlled hypotension to reduce blood loss, and to increase cardiac output in children with low cardiac output syndromes (myocarditis, post–cardiac surgery status).[47] Sodium nitroprusside can generally be used for days without problems, although cyanide and thiocyanate poisoning develops in some children, especially those with renal failure or reduced renal perfusion. Serum thiocyanate levels of 10 mg/dL are associated with weakness, hypoxia, nausea, muscle spasms, and disorientation. When these symptoms occur, nitroprusside administration should be discontinued immediately.

Hydralazine

Hydralazine administration can control systemic hypertension because it relaxes arterial smooth muscle more than it relaxes veins. Administration of the drug can cause headache, nausea, dizziness, sweating, and tremors. The most important acute side effect is tachycardia, which

may increase cardiac output. Labetalol, a β-antagonist, can counteract this effect.[48]

Tolazoline and Phentolamine

These competitive α-adrenergic blockers have had varied success in the treatment of pulmonary hypertension.[49] However, they are effective in treating the symptoms of pheochromocytoma preoperatively. Serious side effects of these drugs include tachycardia, ventricular arrhythmias, hypotension, and tissue edema.

Prostaglandin E_1

Prostaglandin E_1 acts directly on vascular smooth muscle and has greatly improved the care of neonates with heart disease. At infusion rates of 0.05 to 0.1 μg/kg/min, patency of the ductus arteriosus is maintained, and a closed ductus reopens in some neonates. The drug is indispensable in the care of patients with ductus-dependent cardiac lesions, such as interrupted aortic arch, critical aortic stenosis, or hypoplastic left heart syndrome, where systemic blood flow is supplied through the ductus arteriosus. It is equally important for the care of patients who have pulmonary atresia or critical pulmonic stenosis.[18] Apnea, fever, and hypotension are common side effects of this drug.

Nitric Oxide

Nitric oxide is an endothelium-derived relaxing factor that selectively vasodilates the pulmonary vasculature.[50] When administered by inhalation to patients with pulmonary hypertension, NO reduces PVR. It improves the survival of neonates who have reactive pulmonary hypertension.[51-53] This compound is inactivated by hemoglobin before it reaches the systemic circulation. On rare occasion, NO causes systemic vasodilation or clinically significant methemoglobinemia when administered at 5 to 80 ppm.[52]

Disorders of Cardiac Rhythm

Sinus tachycardia or an elevated heart rate for age is not considered an arrhythmia; however, patients with a significantly increased heart rate may be the most critically ill in the ICU. Causes of tachycardia include hypovolemia, fever, pain, anxiety, CHF, myocardial disease and dysfunction, and thyrotoxicosis. With all these possible causes, the goal is to treat the underlying disease state and not the tachycardia. For children without underlying heart disease, temporary increases in heart rate up to 180 to 200 beats/minute are well tolerated; this is also not uncommon. Children cannot increase their stroke volume; therefore, they increase their cardiac output by increasing their heart rate. Again, the goal is not to specifically control an increased heart rate but to treat the cause of the tachycardia. Sinus arrhythmia is a phasic acceleration and slowing of the heart rate that occurs with respiration. It indicates that the patient has a vagal tone greater than sympathetic tone and possibly a good cardiac reserve. A slow heart rate or sinus bradycardia is another relatively common heart rhythm seen in the ICU. It is an unremarkable finding in an older teenage patient who is relatively fit. Other potential causes can include increased intracranial pressure (ICP), hyperkalemia, hypothermia, profound hypoxia and hypothyroidism. These causes should also be investigated. A slow heart rate commonly occurs with the increased use of dexmedetomidine but can also occur with β-adrenergic blockers or digoxin use. Sinus node dysfunction can occur following repair of congenital heart disease in children. Temporary slowing may be treated with the transcutaneous pacemaker placed during surgery. In the absence of myocardial pacing, if there is complete heart block or a very slow ventricular escape rate a pacemaker may be needed shortly after cardiac surgery. Otherwise, some amount of time is given to see if this will resolve.

Normal cardiac conduction starts in the sinus node. The electrical activity propagates through the internodal pathways in the atrium, is delayed in the AV node, travels though the bundle of His, and is conducted to the ventricles through the left and right bundle branches. Supraventricular tachycardia (SVT) is an elevated heart rate occurring at the level of the atrium, the AV node, or both. SVT typically has a narrow QRS morphology. Sinus tachycardia is therefore not a type of SVT but an acceleration of the normal conduction pathways. SVT includes reentrant and non-reentrant tachycardias.

The reentrant tachycardias include AV node reentrant tachycardia (AVNRT), orthodromic reciprocating tachycardia, and atrial flutter. AVNRT is classically considered pediatric SVT. The reentrant tachycardias occur because of the presence of an accessory conduction pathway that allows for abnormal electrical conduction in the heart. The presence of the abnormal pathway may be apparent on a standard EKG, such as the case of Wolf-Parkinson-White syndrome (WPW). Alternatively, the abnormal pathway might not appear on an electrocardiogram, and it is described as a *concealed pathway*. Concealed pathways are non-WPW orthodromic reciprocating tachycardia. In AVNRT, the AV node itself is the area in which the reentrance occurs. In atrial flutter, there is a micro reentrant circuit within the atrial tissue itself. In children, the circuit is typically near the tricuspid valve. In atrial flutter, after the reentrant circuit in the atria, the conduction proceeds through the AV node where it is slowed. The reentrant circuit is small and the rates of atrial flutter can be high. As the conduction is slowed in the AV node these high rates usually are not conducted to the ventricle. However, if atrial flutter or fibrillation occurs in a patient with WPW, the accessory pathway can allow conduction of the electrical impulse at a rate much greater than through the AV node. Rapid conduction of electrical impulses down the accessory pathway can lead to ventricular tachycardia (VT) or ventricular fibrillation (VF) and can cause sudden death.

The non-reentrant causes of SVT occur due to abnormal automaticity of myocardial tissue. Causes of abnormal automaticity include atrial fibrillation and ectopic atrial tachycardia. In nonreentrant SVT the elevated atrial rate is slowed as conduction goes through the AV node. In children, atrial fibrillation is caused by disorganized circuits typically near the pulmonary veins. This rhythm is described as irregularly irregular. Ectopic atrial tachycardia is rapid atrial beats that are consecutive and occur without sinus morphology. There can be one focus of the rapid atrial beats. Alternatively, in multifocal or chaotic atrial tachycardia, there can be several different atrial origins. Brief periods of ectopic atrial tachycardia usually do not cause much sequela, but can lead to cardiomyopathy if prolonged.

Treatment of reentrant SVT is based on whether the patient's condition is clinically unstable or stable. The

abnormal reentrant circuit can be interrupted with synchronized cardioversion or other methods. If the patient's condition is unstable, reentrant SVT is treated with synchronized cardioversion with a dose of 0.5 to 1 joule/kg. If the patient's condition is stable, there is time to try other therapies. Therapies that increase vagal tone, such as ice to the eyes or a Valsalva maneuver, may interrupt the reentrant circuit. Adenosine will temporarily block conduction through the AV node. Adenosine can be used to interrupt episodes of reentrant SVT that have a reentrant circuit using the AV node. If the reentrant circuit does not include the AV node a, then adenosine might not stop the tachycardia, but it may be helpful with diagnosis. There will be a period of sinus pause after administration of adenosine. Adenosine is metabolized by erythrocytes so that it is a short-acting medication. Equipment to perform cardioversion should be immediately available when adenosine is given. The initial dose is 0.1 mg/kg (maximum 6 mg) and the dose should be given quickly with a sufficient flush. It is more effective when given centrally if available. If it is not effective at the dose of 0.1 mg/kg, the second dose can be increased to 0.2 mg/kg (maximum single dose 12 mg). Larger doses are not likely to be more effective. If SVT persists, other medications such as amiodarone, procainamide, or verapamil may be necessary. Amiodarone can block an accessory pathway as well as the AV node. If given too quickly, amiodarone will decrease arterial blood pressure. For both amiodarone and procainamide, continuous infusions may be necessary after the loading dose. Verapamil will block the AV node for a much longer period than adenosine will; however, verapamil can induce other life-threatening arrhythmias in younger patients (younger than 2 years). If a patient has SVT, a cardiology consultation should be obtained. Follow-up should be arranged if needed and an echocardiogram may be beneficial. Depending on the cause, there also may be a need for long-term follow-up.

Junctional ectopic tachycardia is caused by abnormal automaticity in an area around the atrioventricular junction. This pediatric arrhythmia is not common, but it can occur after repair of congenital heart disease. The most common lesion with which this occurs is tetralogy of Fallot (see Chapter 94).

Wide complex tachycardias arise from the ventricle until proven otherwise. SVT can cause a wide complex tachycardia if there is aberrancy of the conduction through the pathways in the ventricle. However, given the risk of delaying therapy all wide complex tachycardias should initially be treated as VT. If there is no pulse, initiate CPR, defibrillate and follow PALS guidelines. If the patient has a pulse and stable arterial blood pressure, there may be time to consider other therapies. These therapies are cardioversion or use of medications such as adenosine, amiodarone, or procainamide. VF is treated with CPR, defibrillation, and then medications following PALS guidelines. Ventricular rhythms should be examined quickly for the possibility of Torsades de Pointes, as giving magnesium will be especially helpful.

In the course of following the continuous rhythm strip of all children in the PICU, common abnormalities may be noted. A prolongation of the PR interval or first-degree heart block can occur in otherwise normal children. Typically, these children are asymptomatic. Second degree heart block occurs as Mobitz Type I and Mobitz Type II. Mobitz Type I is also known as *Wenckebach* and is a gradual prolongation of the PR interval until a QRS is not seen, and then the cycle restarts. The prolongation of conduction occurs due to delay of the electrical signal in the AV node and it can be a benign phenomenon. Mobitz Type II is less likely to be a benign phenomenon. The PR interval remains constant, but intermittently there is no QRS or ventricular beat. This phenomenon is evidence of disease of the His-Purkinje fibers and can progress to complete heart block. Mobitz Type II occurs much less frequently in children than in adults. Complete heart block or third-degree AV block is the complete dissociation of atrial and ventricular activity. In complete heart block, the atria contract at a rate more rapid than the ventricles do (see Chapter 47). Ventricular contraction occurs through ventricular escape. Congenital complete heart block can occur in infants born to mothers who have an autoimmune disorder, such as lupus erythematosus. When damage occurs to the conduction pathway during surgery for congenital heart disease, complete heart block can occur. As immediate treatment of complete heart block, the ventricular rate may be increased with intravenous isoproterenol. When this treatment is ineffective, transthoracic or transvenous pacing will be necessary until definitive therapy can be arranged.

Premature beats are also seen frequently in a PICU setting. Premature atrial contractions are usually benign and are caused by automaticity of atrial tissue other than the sinus node. Premature ventricular contractions (PVC) are usually benign with a few considerations. The presence of a central venous catheter touching the heart can cause increased PVCs, and the catheter should be pulled back if present. Electrolyte abnormalities; typically of potassium, magnesium, and calcium, can cause PVCs. The frequency of PVCs may improve as the electrolytes are corrected. Exogenous catecholamines may cause PVCs and the frequency of PVCs may improve if the catecholamines can be decreased. Endogenous catecholamines can cause PVCs and the frequency may be decreased if pain or anxiety is treated.

HYPERTENSION

Essential hypertension is uncommon in children. When it occurs, it is often associated with another disease process and is frequently difficult to control. The acute onset of severe systemic arterial hypertension is a medical emergency that has the potential of causing cardiovascular decompensation, encephalopathy, seizures, and intracranial hemorrhage. In older children, the neurologic manifestations of hypertension are more likely to precede cardiovascular decompensation. Neonates with severe hypertension are frequently initially found to have CHF. Treatment of hypertension is tailored to the disease process, the absolute degree of hypertension, and the presence of cardiovascular or neurologic symptoms.[54,55]

NEONATAL RESUSCITATION

Profound changes occur in the cardiovascular and respiratory systems at birth. Failure to make these changes successfully can result in death or central nervous system

(CNS) injury (see Chapter 108). Consequently, someone capable of performing neonatal resuscitation must be present at every delivery. Wasting time finding someone to resuscitate the neonate can be disastrous for the infant. This section discusses the causes and effects of cardiorespiratory insufficiency at birth and the techniques of resuscitation. When possible, the recommendations of the American Academy of Pediatrics have been followed. Guidelines for neonatal resuscitation have been issued by many organizations, including the AHA and the American Academy of Pediatrics.[56]

INITIAL ASSESSMENT OF THE FETUS AT BIRTH

Initial stabilization should begin with a rapid evaluation of the newborn to determine if the infant is term, breathing or crying, and has a normal tone[56] (see also Chapter 77; Table 95-2).

ONGOING ASSESSMENT

Ongoing assessment consists of three signs: heart rate (HR), respirations, and oxygenation. The preferred method for determination of HR is by auscultation. All these vital signs should be determined within the first 30 seconds.

CLEARING THE AIRWAY

Proper positioning by placing the infant in the sniffing position is recommended, and the practitioner must try to avoid either underextension or hyperextension both of which will obstruct the airway. Deep suctioning should be avoided even in healthy, vigorous newborns, because of the risk of vagal-mediated bradycardia.[57] This does not apply to newborns who might have airway obstruction or depressed infants with meconium (discussed later in this section.)

TABLE 95-2 EVALUATION OF THE NEWBORN

Clinical Condition	Intervention
Initial resuscitation	Clear infant airway Warm, dry, stimulate, position Evaluate HR, respirations, color
HR > 100 beats/min, breathing, no cyanosis	Observation
HR > 100 beats/min, but persistent respiratory distress or cyanosis	Clear airway SpO_2 monitoring Consider CPAP
Apnea, gasping, or HR < 100 beats/min	Bag-mask PPV SpO_2 monitoring
After initiation of resuscitation (PPV), HR > 100 beats/min, effective ventilation	Post-resuscitation care
HR < 60 beats/min	Consider intubation Chest compressions Coordinate PPV
HR = 60-100 beats/min	Continue with PPV SpO_2 monitoring

CPAP, Continuous positive airway pressure; *HR,* heart rate; *PPV,* positive pressure ventilation; *SpO_2,* saturation of peripheral oxygen.

TEMPERATURE CONTROL

During the initial resuscitation period, the goal body temperature for the newborn is normothermia. The initial step is to dry the infant and warm the infant to a goal axillary temperature of 36.5°C. Infants wrapped in polyethylene from the neck down will avoid evaporative heat loss. Controlled hypothermia should be attempted only in select tertiary centers within hours after birth of infants with hypoxic-ischemic encephalopathy.

OXYGEN

One of the recent changes in neonatal resuscitation in the 2011 Neonatal Resuscitation Program Guidelines is the recommendation of positive pressure ventilation (PPV) with room air, unless chest compressions or medications are needed during the resuscitation, then the recommendations are still for PPV with 100% oxygen. It is important to place a preductal (right hand) oximeter probe on the newborn if PPV is initiated. For the preterm infant, oxygen should be blended to goal saturation targets. In summary: (1) Use room air if the baby is cyanotic or needs PPV; (2) titrate oxygen if the baby is younger than 32 weeks (Table 95-3); (3) use 100% oxygen if chest compressions or medications are given, then titrate to targeted SpO_2; and (4) apply oximeter to right hand (preductal).

VENTILATION

Breathing usually begins by 30 seconds after birth and is sustained by 90 seconds of age. A few minutes after birth, the respiratory rate of normal neonates is between 40 and 60 breaths/minute. The absence of a pause between inspiration and expiration helps develop and maintain functional residual capacity (FRC). Apnea and bradypnea prolong exhalation, reduce FRC, and cause hypoxia. Causes of apnea and bradypnea include severe acidosis, asphyxia, maternal drugs, infections, and CNS damage. Tachypnea (>60 breaths/minute) occurs with hypoxemia, hypovolemia, metabolic and respiratory acidosis, CNS hemorrhage, pulmonary gas leaks, pulmonary disease (e.g., hyaline membrane disease, aspiration syndromes, infections), pulmonary edema, and maternal drugs (e.g., narcotics, alcohol, magnesium, barbiturates).

If needed, initial PPV breaths should be at 20 cm H_2O. Ventilation should be performed at 40 to 60 breaths/minute with reassessment of HR, color, and breath sounds. In the neonate, an increasing HR may be the best assessment

TABLE 95-3 PRETERM INFANT (<32 WEEKS): TITRATE OXYGEN USING OXYGEN BLENDER TO ACHIEVE TARGET SpO_2

Time after Birth (min)	Target SpO_2 (%)

of adequate ventilation. If gastric distention becomes a problem a gastric tube may be placed (8 Fr) to improve compliance. Both sides of the chest should rise equally and simultaneously with inspiration, but the amount of rise should not exceed that associated with the neonate's normal spontaneous breathing. The presence of breath sounds can be misleading because they are well transmitted within the neonate's small chest. A difference in breath sounds between the two sides of the chest should raise suspicion of pneumothorax, atelectasis, or a congenital anomaly of the lung. The presence of loud breath sounds over the stomach suggests a tracheoesophageal fistula. If ventilation is adequate, the neonate will become pink, initiate rhythmic breathing, and have a normal heart rate.

Because most asphyxiated neonates have no lung disease, their lungs can be ventilated effectively with peak airway pressures less than 25 cm H_2O, even for the first few breaths following intubation. Those with stiff lungs (e.g., erythroblastosis fetalis, congenital anomalies of the lung, pulmonary edema, severe meconium aspiration, diaphragmatic hernia) may require higher inspiratory pressure to ventilate their lungs, and they are more likely to have pulmonary gas leaks. To reduce this likelihood, the lungs should first be ventilated with an inspiratory pressure of 15 to 20 cm H_2O. If low-pressure (low-volume), high-rate ventilation does not improve the oxygenation, higher pressures and volumes may be required. Failure to ventilate the lungs adequately at birth can worsen hypoxemia and lead to CNS damage or even death. If PaO_2 exceeds 70 to 80 mm Hg or Sao_2 exceeds 94%, the inspired oxygen concentration should be reduced (if increased concentrations of oxygen are used) until Sao_2 and PaO_2 are normal for age. Oxygenation is maintained at the low range of normal in neonates 34 weeks' or less gestation to avoid retinopathy of prematurity.[58] The neonate's heart rate should be monitored continuously during endotracheal intubation, because the process of tracheal intubation may cause arrhythmias in hypoxic neonates. If the practitioner is having difficulty with bag-valve-mask ventilation or fails intubation, a laryngeal mask airway (LMA) should be considered.[59,60]

PNEUMOTHORAX

Pneumothorax occurs in 1% of all vaginal deliveries, in 10% of meconium-stained neonates, and in 2% to 3% of neonates who require mechanical ventilation in the delivery room. The hemithorax containing free air is usually hyperexpanded and moves poorly with ventilation. The point of maximum cardiac impulse is shifted toward the side without the pneumothorax. Heart tones may be muffled. If a small, high-intensity cold light is placed directly on the skin of the neonate's chest, the involved side of the chest will glow if a pneumothorax is present.[61] Pneumothoraces are relieved by needle or chest tube drainage.

ENDOTRACHEAL INTUBATION

The head should be placed in a neutral or "sniffing" position during bag-valve-mask ventilation and tracheal intubation. An appropriately sized endotracheal tube (ETT) is inserted and its tip is placed 1 to 2 cm below the vocal cords, depending on the size of the neonate. Usually, this means that the distance from the tip of the tube to the gums is 7, 8, 9, or 10 cm in 1-, 2-, 3-, and 4-kg infants, respectively. A small gas leak should be present between the ETT and trachea when the ventilation pressure is 15 to 25 cm H_2O. This leak usually entails the use of a 2.5-mm (internal diameter) tube for neonates weighing less than 1.5 kg, a 3.0-mm tube for those between 1.5 and 2.5 kg, and a 3.5-mm tube for those weighing more than 2.5 kg. Successful tracheal intubation is confirmed by observing the ETT pass through the vocal cords, by observing bilateral chest movement with each mechanical inspiration, and by observing condensation in the ETT during exhalation. Breath sounds should be much louder over the chest than over the abdomen, and the skin color, heart rate, and Sao_2 should improve with positive-pressure ventilation. Carbon dioxide should be present during exhalation. However, the small tidal volumes and low pulmonary blood flow of some infants at birth can make it difficult to use capnography effectively.

CARDIAC COMPRESSIONS

Place both thumbs on the sternum and allow the fingers to support the back (Fig. 95-3) Compress the sternum to approximately one-third the depth of the chest. Three compressions should be performed with a breath in place of the fourth compression for an effective compression rate of 90 compressions and 30 breaths/minute. HR should be evaluated every 45 to 60 seconds, and if after adequate ventilation and compressions for 60 seconds the HR is still less than 60 beats per minute, then medications should be considered.

MEDICATIONS

Medications are needed only for the infant who is critically depressed or has significant anomalies leading to cardiovascular depression. There should be a quick-reference drug list with dosing based on an estimated weight of the infant at birth designed for each delivery room for easy access for these rare occasions. Intravenous route of administration is preferred for administration of resuscitation medications; however, intraosseous and umbilical venous catheters can be placed rapidly by trained individuals and can be lifesaving.

Epinephrine

The primary medication used in the resuscitation of a newborn is epinephrine, and it should be given if the infant's HR is less than 60 beats/minute, 45 to 60 seconds after the initiation of PPV and chest compressions. The recommended dose is 0.1 to 0.3 mL/kg of 1:10,000 concentration; (0.01 to 0.03 mg/kg), followed by a 1 mL flush of saline. Intravenous administration is preferable, but if venous access is not obtained, then it is appropriate to give epinephrine via the ETT. If the ETT is used, the practitioner should give a higher dose of epinephrine: 0.5 to 1 mL/kg of 1:10,000 concentration (0.05 to 0.1 mg/kg). Epinephrine can be repeated every 5 minutes, as needed, while reevaluating HR every 45 to 60 seconds.

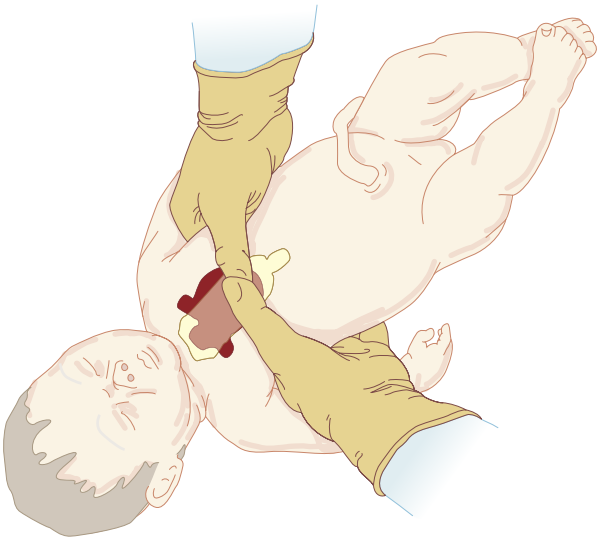

Figure 95-3. Neonatal chest compression. For simplification, ventilation is not shown. *(From Gregory GA: Resuscitation of the newborn,* Anesthesiology *43:225, 1975.)*

Naloxone

Naloxone (Narcan) is not recommended as an initial response to respiratory distress in neonatal resuscitation.[56,62] Neonates should be supported on PPV, including neonates whose mothers received narcotics less than 4 hours before delivery. However, if respiratory depression continues, naloxone can be considered. In addition, naloxone should be avoided in an infant whose mother has a history of narcotic dependence because of the risk of seizures from withdrawal.

DETECTION OF HYPOVOLEMIA

Hypovolemia is detected by measuring arterial blood pressure and by physical examination (i.e., skin color, perfusion, capillary refill time, pulse volume, and extremity temperature). Central venous pressure (CVP) measurements are useful in detecting hypovolemia and in determining the adequacy of fluid replacement. The venous pressure of normal neonates is 2 to 8 cm H_2O. If CVP is less than 2 cm H_2O, hypovolemia should be suspected.

TREATMENT OF HYPOVOLEMIA

Treatment of hypovolemia requires expansion of intravascular volume with blood and crystalloids. Albumin may also be used, but evidence of its effectiveness is limited. If it is suspected that the neonate will be hypovolemic at birth, Rh-negative type O packed red blood cells (PRBCs) should be available in the delivery room before the neonate is born.[63] Crystalloid and blood should be titrated in 10 mL/kg and given slowly over 10 minutes, if hemodynamics allow, to limit the risk of intraventricular hemorrhage. Occasionally, enormous volumes of blood and fluid are required to raise arterial blood pressure to normal. At times, more than 50% of the blood volume (85 mL/kg in term neonates and 100 mL/kg in preterm neonates) must be replaced, especially when the placenta is transected or abrupted during birth. In most cases, less than 10 to 20 mL/kg of volume restores mean arterial pressure to normal.

OTHER CAUSES OF HYPOTENSION

Hypoglycemia, hypocalcemia, and hypermagnesemia also cause hypotension in neonates. Hypotension induced by alcohol or magnesium intoxication usually responds to blood volume expansion or dopamine, or to both. Hypermagnesemic neonates generally respond to 100 to 200 mg/kg of calcium gluconate administered over a 5-minute period.[56]

MECONIUM

Meconium-stained amniotic fluid (MSAF) when aspirated into the lungs during delivery or in utero can cause serious lung injury and respiratory distress syndrome. Most cases of meconium aspiration occur in utero; therefore, endotracheal intubation to suction the airway to remove MSAF should occur only if the neonate is distressed (e.g., absent or depressed respirations, HR < 100 beats/minute, poor muscle tone).[56,64,65] A depressed MSAF-stained infant should be intubated as soon as possible after delivery. Suctioning is accomplished through an ETT. If there is a significant amount of MSAF or remains in extremis, the infant should be transferred directly to the neonatal intensive care unit.

COLOR

Essentially all neonates have a blue-tinged cast to their skin at birth. By 60 seconds of age, most of them are entirely pink, except for their hands and feet, which remain blue. If central cyanosis persists beyond 90 seconds of age, asphyxia, low cardiac output, pulmonary edema, methemoglobinemia, polycythemia, congenital heart disease, arrhythmias, and pulmonary disorders (e.g., respiratory distress, airway obstruction, hypoplastic lungs, diaphragmatic hernia) should be considered, especially if the infant remains cyanotic despite oxygen and controlled ventilation. Neonates who are pale at birth are often asphyxiated, hypovolemic, acidotic, or anemic, or they have congenital heart disease. A neonate whose skin is entirely pink within 2 minutes of birth may be intoxicated with alcohol or magnesium or may be alkalotic (pH > 7.50). Rubrous neonates are usually polycythemic.

RESUSCITATION EQUIPMENT

Resuscitation beds should allow positioning of the neonate's head below the level of the lungs to promote drainage of lung fluid and reduce the likelihood of aspirating gastric contents. A servo-controlled infrared heater should be used to maintain the neonate's temperature between 36°C and 37°C unless there is evidence of asphyxia. If asphyxia is noted, body temperature should be reduced to 34°C to 35°C for brain protection. A suction device should be available and should allow the suction pressure to be varied; pressures less than –100 mm Hg should not be used. Equipment required for tracheal intubation includes 0 and 00 straight laryngoscope blades; a

pencil-type laryngoscope handle; 2.5-, 3.0-, and 3.5-mm ETTs; and a suction catheter that fits easily through each size tube. The ventilation system must permit ventilatory rates of at least 150 breaths/minute and make it possible to maintain positive end-expiratory pressure (PEEP). One-way valves can stick in the closed position, especially when high gas flow and high respiratory rates are used. The modified Jackson-Rees or Ayres system works well when appropriately trained people use it. Overexpansion of the lungs with large tidal volumes injures the lungs and activates inflammatory processes that may cause chronic lung disease. Gentle inflation of the lung is less injurious to the lung. Airway inflation pressures should be measured continuously during assisted or controlled ventilation in the delivery room, and excessive pressures and tidal volumes should be avoided. As in any critical care situation, patient care should be guided by information. Consequently, blood gas and pH measurements are mandatory, and the results of these tests must be available within 10 minutes of drawing the blood sample. Umbilical arterial catheters are useful for measuring arterial blood pressure and withdrawing blood for blood gas analysis and pHa. They can also be used to infuse emergency fluids. Arterial oxygen saturation (Sa_{O_2}) can be measured immediately after birth by attaching a pulse oximeter to a hand or foot.[66] Pulse oximeters permit rapid detection of changes in oxygenation and rapid reduction of FiO_2. The normal Sa_{O_2} of neonates is usually 87% to 95%, which is associated with a PaO_2 of 55 to 70 mm Hg.

PEDIATRIC CARDIAC ARREST AND RESUSCITATION

Pediatric cardiac arrest is not a rare event. At least 16,000 American children (8 to 20 per 100,000 children per year) suffer a cardiopulmonary arrest each year.[67-71] More than half of these cardiac arrests probably occur in hospital.[67,72] With advances in resuscitation science and implementation techniques, survival from pediatric cardiac arrest has improved substantially over the past 25 years.[73]

Outcomes from pediatric cardiac arrest have improved significantly over the past 20 years. For example, survival to discharge from pediatric in-hospital cardiac arrest has increased from less than 10% in the 1980s[74,75] to more than 25% in the twenty-first century. Of the pediatric patients who survive to hospital discharge, nearly 75% will have favorable neurologic function defined by specific pediatric cerebral outcome measures and quality of life indicators.[73,76-78] Factors that influence outcome from pediatric cardiac arrest include: (1) the preexisting condition of the child; (2) the environment in which the arrest occurs; (3) the initial electrocardiographic rhythm detected; (4) the duration of no-flow time (the time during an arrest without spontaneous circulation or CPR); (5) the quality of the life-supporting therapies provided during the resuscitation; and (6) the quality of life-supporting therapies during post-resuscitation.

Not surprisingly, outcomes after pediatric out-of-hospital arrests are much worse than outcomes after in-hospital arrests,[68,69,79-87] possibly because there is a prolonged period of no flow in out-of-hospital arrests, where many of the pediatric cardiac arrests are not witnessed and only 30% of children are provided with bystander CPR. Because of these factors, less than 10% patients with pediatric out-of-hospital cardiac arrest survive to hospital discharge, and those who survive commonly have severe neurologic injury. These findings are especially troublesome given that bystander CPR more than doubles the patient survival rates in adults.[88] An exciting prospective, nationwide, population-based cohort study from Japan demonstrated that survival rates more than doubled for children who had out-of-hospital cardiac arrests and received bystander CPR either with conventional CPR (with rescue breathing) or chest compression only CPR compared to no bystander CPR.[89] The same study then further stratified outcomes for out-of-hospital cardiac arrest into "cardiac" and "noncardiac" causes for arrest and defined the relative value of rescue breathing during CPR by bystanders. Pediatric patients who have out-of-hospital cardiac arrests with noncardiac causes and receive bystander conventional CPR (including rescue breathing) had an association with higher frequency of favorable neurologic outcomes at 1 month after arrest compared with compression-only bystander CPR or no bystander CPR. For pediatric arrests defined as cardiac in nature, bystander CPR (conventional or compression-only) was associated with a higher rate of favorable neurologic outcomes 1 month after arrest compared with no bystander CPR. Interestingly, the two types of bystander CPR (conventional or compression only) seemed to be similarly effective for pediatric cardiac arrests with cardiac causes, consistent with animal and adult studies.[89]

Survival outcomes after in-hospital cardiac arrest are higher in the pediatric population compared with adults; 27% of children survive to hospital discharge compared with only 17% of adults.[73] For children and adults, outcomes are better after arrhythmogenic arrests (VF/VT). Importantly, pediatric in-hospital arrests are less commonly caused by arrhythmias (10% of pediatric arrests versus 25% of adult arrests), and approximately one third of children and adults with these arrhythmogenic arrests survive to hospital discharge. Interestingly, the superior pediatric survival rate following in-hospital cardiac arrest reflects a substantially higher survival rate among children with asystole or pulseless electrical activity compared with adults (24% versus 11%). Further investigation has shown that the superior survival rate seen in children is mostly attributable to a much better survival rate among infants and preschool-aged children compared with older children.[77] The higher survival rates in children may be due to improved coronary and cerebral blood flow during CPR because of increased chest compliance in these younger arrest victims, with improved aortic diastolic pressure and venous return, but this is speculative.[90,91] In addition, survival of pediatric patients from an in-hospital cardiac arrest is more likely in hospitals staffed with dedicated pediatric physicians.[92]

PHASES OF RESUSCITATION

The four distinct phases of cardiac arrest and CPR interventions are: (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation and

arrest. Interventions to improve outcome of pediatric cardiac arrest should optimize therapies targeted to the time and phase of CPR, as suggested in Table 95-4.

PREARREST

The prearrest phase refers to any relevant preexisting conditions of the child (e.g., neurologic, cardiac, respiratory, or metabolic problems) and precipitating events (e.g., respiratory failure or shock) uncoupling metabolic delivery and metabolic demand. Pediatric patients who suffer an in-hospital cardiac arrest often have changes in their physiologic status in the hours leading up to their arrest event.[93,94] Therefore, interventions during the prearrest phase focus on preventing the cardiac arrest, with special attention to early recognition and targeted treatment of respiratory failure and shock. Early recognition plays a key role in identifying a prearrest state in children, who, unlike adults, may be able to maintain an age appropriate blood pressure despite a worsening clinical picture until the last possible moment. Medical emergency teams (METs; also known as *rapid response teams*) are in-hospital emergency teams designed specifically for this purpose. Front-line providers, and even parents, are encouraged to initiate evaluation by METs based on physiologic protocol–driven parameters or even intuition. Patients are assessed by the METs, and those at high risk of clinical decompensation are transferred to a PICU if necessary, with the goal to prevent progression to full cardiac arrest or to decrease the response time to initiation of advanced life support; thereby, limiting the no-flow state. Implementation of METs decreases the frequency of cardiac arrests compared with retrospective control periods before MET initiation.[95-97] While early recognition protocols cannot identify all children at risk for cardiac arrest, transferring critically ill children to an ICU early in their disease process allows for better monitoring and more aggressive interventions, which can improve resuscitative care and clinical outcomes. The caveat is that pre-arrest states must be identified to initiate monitoring and interventions that can inhibit the progression to an arrest. While a significant amount of research dollars and resources are spent on the other phases of cardiac arrest, particular focus on the prearrest state can yield the greatest improvement in survival and neurologic outcomes.

TABLE 95-4 PHASES OF CARDIAC ARREST AND RESUSCITATION

Phase	Interventions
Pre-arrest phase (protect)	Optimize patient monitoring and rapid emergency response Recognize and treat respiratory failure or shock to prevent cardiac arrest
Arrest (no-flow) phase (preserve)	Minimize interval to BLS and ACLS Organize response with clear leadership Minimize interval to defibrillation, when indicated
Low-flow (CPR) phase (resuscitate)	Push hard, push fast Allow full chest recoil Minimized interruptions in compressions Avoid overventilation Titrate CPR to optimize myocardial blood flow (coronary perfusion pressures and exhaled CO_2) Consider adjuncts to improve vital organ perfusion during CPR Consider ECMO if standard CPR/ALS not promptly successful
Post-resuscitation phase: short-term	Optimize cardiac output and cerebral blood flow Treat arrhythmias, if indicated Avoid hyperglycemia, hyperthermia, hyperventilation Debrief to improve future responses to emergencies
Post-resuscitation phase: long-term rehabilitation (regenerate)	Early intervention with occupational and physical therapy Bioengineering and technology interface Possible future role for stem cell transplantation

ACLS, advanced cardiac life support; *ALS,* advanced life support; *BLS,* basic life support; *CPR,* cardiopulmonary resuscitation; *ECMO,* extracorporeal membrane oxygenation.

NO-FLOW AND LOW-FLOW

To improve outcomes from pediatric cardiac arrest, the no-flow phase of untreated cardiac arrest should be shortened. High-risk patients must be monitored to allow early recognition of the cardiac arrest and to prompt initiation of basic and advanced life support. Effective CPR optimizes coronary perfusion pressure (by elevating aortic diastolic pressure relative to right atrial pressure) and cardiac output to critical organs to support vital organ viability (by elevating mean aortic pressure) during the low-flow phase. Important tenets of basic life support are push hard, push fast, allow full chest recoil between compressions, and minimize interruptions of chest compression. The myocardium receives blood flow from the aortic root, mainly during diastole, via the coronary arteries. When the heart arrests and no blood flows through the aorta, coronary blood flow ceases. However, during chest compressions, aortic pressure rises at the same time as right atrial pressure and with the subsequent decompression phase of chest compressions, the right atrial pressure falls faster and lower than the aortic pressure, which generates a pressure gradient that perfuses the heart with oxygenated blood. Therefore, full elastic recoil (release) is critical to create a pressure difference between the aortic root and the right atrium. A cerebral perfusion pressure (CPP) less than 15 mm Hg during CPR is a poor prognostic factor for ROSC. Achieving optimal coronary perfusion pressure, exhaled carbon dioxide concentration, and cardiac output during the low-flow phase of CPR is consistently associated with an improved chance for return of spontaneous circulation (ROSC) and improved short- and long-term outcome in mature animal and human studies.[98-105] There is a critical need for research evaluating goal-directed CPR, both in immature animal models and pediatric patients. Other measures essential for truncating the no-flow phase during ventricular fibrillation and pulseless VT are rapid detection and prompt defibrillation. Clearly, CPR alone is inadequate for successful resuscitation from these arrhythmias. For cardiac

arrests resulting from asphyxia or ischemia, provision of adequate myocardial perfusion and myocardial oxygen delivery are the critical elements for return of spontaneous circulation.

POSTARREST AND RESUSCITATION

The postarrest and resuscitation phase includes coordinated, skilled management of the immediate postresuscitation stage, the next few hours to days, and long-term rehabilitation. The immediate postresuscitation stage is a high-risk period for ventricular arrhythmias and other reperfusion injuries. Goals of interventions implemented during the immediate postresuscitation stage and the next few days include adequate tissue oxygen delivery, treatment of postresuscitation myocardial dysfunction, and minimizing postresuscitation tissue injury (e.g., preventing postresuscitation hyperthermia and hypoglycemia and perhaps initiating postresuscitation therapeutic hypothermia, preventing hyperglycemia and avoiding hyperoxia). This postarrest and resuscitation phase may have the greatest potential for innovative advances in the understanding of cell injury (excitotoxicity, oxidative stress, metabolic stress) and cell death (apoptosis and necrosis), ultimately leading to novel molecular-targeted interventions. The rehabilitation stage concentrates on salvage of injured cells and support for reengineering of reflex and voluntary communications of these cell and organ systems to improve long-term functional outcome.

The specific phase of resuscitation dictates the focus of care. Interventions that improve outcome during one phase may be deleterious during another. For example, intense vasoconstriction during the low-flow phase of cardiac arrest improves coronary perfusion pressure and the probability of ROSC. The same intense vasoconstriction during the postresuscitation phase increases left ventricular afterload and can worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery allows for the crude manipulation of arterial blood pressure, oxygen delivery and consumption, body temperature, and other physiologic parameters in an attempt to optimize outcome. Future strategies likely will take advantage of the increasing knowledge of cellular injury, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology, including stem cells.

INTERVENTIONS DURING THE CARDIAC ARREST (NO-FLOW) AND CPR (LOW-FLOW)

AIRWAY AND BREATHING

During CPR, cardiac output and pulmonary blood flow are approximately 10% to 25% of that during normal sinus rhythm; therefore, a lower minute ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation. Animal and adult data indicate that overventilation (e.g., from exuberant rescue breathing) during CPR is common and can substantially compromise venous return and subsequently cardiac output.[106-108] These detrimental hemodynamic effects are compounded when one considers the effect of interruptions in CPR to provide airway management and rescue breathing and may contribute to worse survival outcomes.[109-112] Although overventilation is problematic, in light of the fact that most pediatric arrests are asphyxial in nature, immediate initiation of *adequate* ventilation is still important. The difference between arrhythmogenic and asphyxial arrests lies in the physiology. In animal models of sudden VF cardiac arrest, acceptable PaO_2 and $Paco_2$ persist for 4 to 8 minutes during chest compressions without rescue breathing.[113,114] This is in part because aortic oxygen and carbon dioxide concentrations at the onset of the arrest do not vary much from the pre-arrest state with no blood flow and minimal aortic oxygen consumption. The lungs act as a reservoir of oxygen during the low-flow state of CPR; therefore, adequate oxygenation and ventilation can continue without rescue breathing. Several retrospective studies of witnessed VF cardiac arrest in adults have also shown that outcomes are similar after bystander-initiated CPR with either chest compressions alone or chest compressions plus rescue breathing.[115] However, during asphyxial arrest peripheral and pulmonary blood flow continues during the prearrest state resulting in significant arterial and venous oxygen desaturation, elevated lactate levels, and depletion of the pulmonary oxygen reserve. Therefore, at the onset of cardiopulmonary resuscitation, there is substantial arterial hypoxemia and resulting acidemia. In this circumstance, rescue breathing with controlled ventilation can be a lifesaving maneuver. In contrast, the adverse hemodynamic effects from over-ventilation during CPR combined with possible interruptions in chest compressions to open the airway and deliver rescue breathing are a lethal combination in certain circumstances such as VT/VF arrests. In short, the resuscitation technique should be titrated to the physiology of the patient to optimize patient outcome.

CIRCULATION: OPTIMIZING BLOOD FLOW DURING LOW-FLOW CPR: PUSH HARD, PUSH FAST

When the heart arrests, no blood flows to the aorta and coronary blood flow ceases immediately.[115] At that point, provision of high-quality CPR ("push hard, push fast") is vital to reestablish coronary flow. The goal during CPR is to maximize the myocardial perfusion pressure (MPP). Related by the equation

$$MPP = AoDP - RAP$$

myocardial blood flow improves as the gradient between aortic diastolic blood pressure (AoDP) and right atrial pressure (RAP) increases. During downward compression phase, AoDP rises simultaneously with RAP with little change in the MPP; however, during the decompression phase of chest compressions, the RAP falls faster and lower than the AoDP, which generates a pressure gradient perfusing the heart with oxygenated blood during this artificial period of diastole. Several animal and human studies have demonstrated, in both VT/VF and asphyxial models, the importance of establishing MPP as a predictor for short-term survival outcome (i.e., ROSC).[104,116-119]

Because there is no flow without chest compressions, it is important to minimize interruptions in chest compressions. To allow good venous return in the decompression phase of external cardiac massage, it is also important to allow full chest recoil and to avoid overventilation (preventing adequate venous return because of increased intrathoracic pressure).

Based on the equation above, MPP can be improved by strategies that increase the pressure gradient between the aorta and the right atrium. As an example, the inspiratory impedance threshold device (ITD) is a small, disposable valve that can be connected directly to the tracheal tube or face-mask to augment negative intrathoracic pressure during the inspiratory phase of spontaneous breathing and the decompression phase of CPR by impeding airflow into the lungs. Application in animal and adult human trials of CPR has established the ability of the ITD to improve vital organ perfusion pressures and myocardial blood flow[120-125]; however, in the only randomized trial during adult CPR, mortality benefit was limited to the subgroup of patients with pulseless electrical activity.[125] Additional evidence that augmentation of negative intrathoracic pressure can improve perfusion pressures during CPR comes from the active compression-decompression device (ACD). The ACD is a handheld device that is fixed to the anterior chest of the victim by means of suction similar to a household plunger that can be used to apply active decompression forces during the release phase, thereby creating a vacuum within the thorax. By actively pulling during the decompression phase, blood is drawn back into the heart by the negative pressure.[126] Animal and adult studies have demonstrated that the combination of ACD with ITD act in concert to further improve perfusion pressures during CPR compared with ACD alone.[122] In the end, while novel interventions such as the ITD and ACD are promising adjuncts to improve blood flow during CPR, the basic tenants of *push hard, push fast, allow full chest wall release, minimize interruptions,* and *don't overventilate* are still the dominate factors to improve blood flow during CPR and chance of survival.

CHEST COMPRESSION DEPTH

The pediatric chest compression depth recommendation of at least one-third anterior-posterior chest depth (approximately 4 cm in infants and 5 cm in children) is based largely on expert clinical consensus, using data extrapolated from animal, adult, and limited pediatric data. In a small study of six infants, chest compressions targeted to half of anterior-posterior chest depth resulted in improved systolic blood pressures compared to those targeted at one-third anterior-posterior chest depth.[127] Although this series was small with only qualitatively estimated chest compression depths, it is the first study to collect actual data from children supporting the existing chest compression depth guidelines. On the contrary, two recent studies using computer-automated tomography (CT)[128,129] suggest that depth recommendations based on a relative (%) anterior-posterior chest compression depth are deeper than that recommended for adults, and that a depth of half of the anterior-posterior chest depth will result in direct compression to the point of fully emptying the heart and requisite shifting of heart because of inadequate anterior-posterior diameter reserve in most children. Future studies that collect data from actual children and that associate quantitatively measured chest compression depths with short- and long-term clinical outcomes (e.g., arterial blood pressure, end-tidal carbon dioxide, return of spontaneous circulation, survival) are needed.

COMPRESSION/VENTILATION RATIOS

The amount of ventilation provided during CPR should match, but not exceed, perfusion and should be titrated to the amount of circulation during the specific phase of resuscitation as well as the metabolic demand of the tissues. Therefore, during the low-flow state of CPR when the amount of cardiac output is 10% to 25% of normal, less ventilation is needed.[130] However, the best ratio of compressions to ventilations in pediatric patients is largely unknown and depends on many factors including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilation. A compression/ventilation ratio of 15:2 delivers the same minute ventilation and increases the number of delivered chest compressions by 48% compared with CPR at a compression/ventilation ratio of 5:1 in a simulated pediatric arrest model.[131,132] This is important because when chest compressions cease, the aortic pressure rapidly decreases and coronary perfusion pressure falls precipitously, thereby decreasing myocardial oxygen delivery.[115] Increasing the ratio of compressions to ventilations minimizes these interruptions, thus increasing coronary blood flow. The benefits of positive pressure ventilation (increased arterial content of oxygen and carbon dioxide elimination) must be balanced against the adverse consequence of decreased circulation. These findings are in part the reason the AHA recommends a pediatric compression/ventilation ratio of 15:2.

DUTY CYCLE

In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time (approximately 1:2 ratio of time in compression to time in relaxation).[133] As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250 to 300 msec (duty cycle of 40% to 50% at a compression rate of 120 per minute) correlates with improved cerebral perfusion pressures compared with shorter duty cycles of 30%.[134]

CIRCUMFERENTIAL VERSUS FOCAL STERNAL COMPRESSIONS

In adult and animal models of cardiac arrest, circumferential (vest) CPR has been demonstrated to improve CPR hemodynamics dramatically.[135] In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially (thoracic squeeze). In an infant animal model of CPR, this "two-thumb" method of compression with thoracic squeeze resulted in higher systolic and diastolic blood pressures and a higher pulse

pressure than traditional two-finger compression of the sternum.[136] Although not rigorously studied, our clinical experience indicates that it is difficult to attain adequate chest compression force and adequate aortic pressures with the two-finger technique; therefore, we fully support the AHA Guidelines for health care providers to perform CPR on infants with the two-thumb-encircling hands technique.[137]

OPEN-CHEST CARDIOPULMONARY RESUSCITATION

In animal models, high quality standard, closed-chest CPR generates myocardial blood flow that is more than 50% of normal, cerebral blood flow that is approximately 50% of normal, and cardiac output approximately 10% to 25% of normal.[115,117,138,139] By contrast, open-chest CPR can generate myocardial and cerebral blood flow that approaches normal. Although open-chest massage improves coronary perfusion pressure and increases the chance of successful defibrillation in animals and humans,[140-142] performing a thoracotomy to allow open-chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open-chest CPR and 12 with closed-chest CPR) demonstrated that open-chest CPR increased hospital cost without altering rates of ROSC or survival to discharge. However, survival in both groups was 0%, indicating that the population may have been too severely injured or too late in the process to benefit from this aggressive therapy.[143] Open-chest CPR is often provided to children after open-heart cardiac surgery and sternotomy. Earlier institution of open-chest CPR may warrant reconsideration in selected special resuscitation circumstances.

MEDICATIONS USED TO TREAT CARDIAC ARREST

Administration of epinephrine can likely improve initial resuscitation success after both asphyxial and VF cardiac arrests. However, whether epinephrine administration improves survival outcome from pediatric cardiac arrest is not documented. Many medications are used during pediatric resuscitation attempts including vasopressors (epinephrine and vasopressin), antiarrhythmics (amiodarone and lidocaine), and other drugs such as calcium chloride and sodium bicarbonate. A discussion of each follows.

VASOPRESSORS

Epinephrine

Epinephrine (adrenaline) is an endogenous catecholamine with potent α- and β-adrenergic stimulating properties. The α-adrenergic action (vasoconstriction) increases systemic and pulmonary vascular resistance. The resultant higher aortic diastolic blood pressure improves coronary perfusion pressure and myocardial blood flow even though it reduces global cardiac output during CPR; and as noted previously, adequacy of myocardial blood flow is a critical determinant of ROSC. Epinephrine also increases cerebral blood flow during good quality CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation.[144-146] However, epinephrine can decrease local cerebral microcirculatory blood flow at a time when global cerebral flow is increased.[147] The β-adrenergic effect increases myocardial contractility and heart rate, and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi; however, the β-adrenergic effects are not observed in the peripheral vascular beds secondary to the high dose used in cardiac arrest. Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation. High-dose epinephrine (0.05-0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than standard-dose epinephrine (0.01-0.02 mg/kg) in animal models of cardiac arrest and may increase the incidence of initial ROSC.[148,149] However, prospective and retrospective studies have indicated that the use of high-dose epinephrine in adults or children does not improve survival and may be associated with worse neurologic outcome.[150,151] A randomized, blinded, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine after failed initial standard-dose epinephrine in pediatric in-hospital cardiac arrest demonstrated a worse 24-hour survival in the high-dose epinephrine group (1 of 27 survivors versus 6 of 23 survivors; $p < 0.05$).[152] Based on these clinical studies, high-dose epinephrine cannot be recommended routinely for either initial or rescue therapy. Importantly, these studies indicate that high-dose epinephrine can worsen a patient's post-resuscitation hemodynamic condition and likelihood of survival.

Vasopressin

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction (V_1 receptor) and reabsorption of water in the renal tubule (V_2 receptor). Vasoconstrictive properties are most intense in the skeletal muscle and skin vascular beds. Unlike epinephrine, vasopressin is not a pulmonary vasoconstrictor. In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine. However, vasopressin can decrease splanchnic blood flow during and following CPR and can increase afterload in the post-resuscitation period placing further strain on the left ventricle.[138,153-156] Adult randomized controlled trials suggest that outcomes are similar after use of vasopressin or epinephrine during CPR.[157,158] During pediatric arrest, a case series of four children who received vasopressin during six prolonged cardiac arrest events suggested that the use of bolus vasopressin can result in ROSC when standard medications have failed.[159] However, a more recent retrospective study of 1293 consecutive pediatric arrests from the AHA National Registry of CPR (NRCPR) found that vasopressin use, while infrequent (administered in only 5% of events), was associated with a lower likelihood of ROSC. Therefore, it is unlikely that vasopressin will replace epinephrine as a first-line agent in pediatric cardiac arrest; however, the available data suggest that its use in conjunction with epinephrine may deserve further investigation, especially in prolonged arrest unresponsive to initial epinephrine resuscitation.

ANTIARRHYTHMIC MEDICATIONS

Calcium

Calcium is used frequently in cases of pediatric cardiac arrest, despite the lack of evidence for efficacy. In the absence of a documented clinical indication (i.e., hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia), administration of calcium does not improve outcomes from cardiac arrest.[160-168] To the contrary, three pediatric studies have suggested a potential for harm, as routine calcium administration was associated with decreased survival rates and worse neurologic outcomes.[160-168] Despite limited clinical data to support the use of calcium during CPR, it is reasonable to consider calcium administration during CPR for cardiac arrest patients at frequent risk of hypocalcemia (including renal failure, shock associated with massive transfusion—see also Chapter 61).

Buffer Solutions

There are no randomized controlled studies in children examining the use of sodium bicarbonate for management of pediatric cardiac arrest. Two randomized controlled studies have examined the value of sodium bicarbonate in the management of adult cardiac arrest[169] and in neonates with respiratory arrest in the delivery room.[170] Neither study was associated with improved survival. In fact, one multicenter retrospective in-hospital pediatric study found that sodium bicarbonate administered during cardiac arrest was associated with decreased survival, even after controlling for age, sex, and first documented cardiac rhythm.[167] Therefore, during pediatric cardiac arrest resuscitation, the use of sodium bicarbonate is not recommended. Clinical trials involving critically ill adults with severe metabolic acidosis do not demonstrate a beneficial effect of sodium bicarbonate on hemodynamics despite correction of acidosis.[171,172] Yet, severe acidosis can depress the action of catecholamines and worsen myocardial function.[173,174] Nevertheless, the use of sodium bicarbonate during CPR is not supported by clinical data. Pediatric patients with implanted cardiac pacemakers may have an increased threshold for myocardial electrical stimulation when acidotic[175]; therefore, administration of bicarbonate or another buffer is appropriate for management of severe documented acidosis in these children. Administration of sodium bicarbonate also is indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning. The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. Carbon dioxide must be cleared through adequate minute ventilation; thus, if ventilation is impaired during sodium bicarbonate administration, carbon dioxide buildup may negate the buffering effect of bicarbonate. Because carbon dioxide readily penetrates cell membranes, intracellular acidosis may paradoxically increase after sodium bicarbonate administration without adequate ventilation. Therefore, bicarbonate should not be used for management of respiratory acidosis. Unlike sodium bicarbonate, tromethamine (THAM) buffers excess protons without generating carbon dioxide; in fact, carbon dioxide is consumed following THAM administration. In a patient with impaired minute ventilation, tromethamine may be preferable when buffering is necessary to mitigate severe acidosis. Tromethamine undergoes renal elimination, and renal insufficiency may be a relative contraindication to its use. Carbicarb, an equimolar combination of sodium bicarbonate and sodium carbonate, is another buffering solution that generates less carbon dioxide than sodium bicarbonate. In a canine model of cardiac arrest comparing animals given normal saline, sodium bicarbonate, THAM, or Carbicarb, the animals given any buffer solution had a more frequent rate of ROSC than the animals given normal saline. In the animals given sodium bicarbonate or Carbicarb, the interval to ROSC was significantly shorter than in animals given normal saline. However, at the end of the 6-hour study period, all resuscitated animals were in a deep coma; therefore, no inferences regarding meaningful survival can be drawn.[176] It is premature to recommend either THAM or Carbicarb during CPR at this time.

POSTRESUSCITATION INTERVENTIONS

Temperature Management

Two seminal articles[177,178] have established that induced hypothermia (32°C-34°C) could improve outcome for comatose adults after resuscitation from VF cardiac arrest. In both randomized, controlled trials, the inclusion criteria were patients older than 18 years who were persistently comatose after successful resuscitation from nontraumatic VF.[179,180] However, in a recent randomized control trial of unconscious adult survivors of out-of-hospital cardiac arrest, a targeted temperature of 33°C did not confer a benefit as compared with the targeted temperature of 36°C.[181] Interpretation and extrapolation of these studies to children is difficult; however, fever within the first 48 hours following cardiac arrest, brain trauma, stroke, and ischemia is associated with poor neurologic outcome. Emerging neonatal trials of selective brain cooling and systemic cooling show promise in neonatal hypoxic-ischemic encephalopathy, suggesting that induced hypothermia can improve outcomes.[182,183] The efficacy of therapeutic hypothermia following pediatric cardiac arrest is being evaluated in a randomized controlled trial (clinicaltrials.gov identifier NCT00880087; THAPCA: Therapeutic Hypothermia After Pediatric Cardiac Arrest [www.thapca.org]). At a minimum, it is advisable to avoid hyperthermia in children after administering CPR. Using an approach of "therapeutic normothermia" with scheduled administration of antipyretic medications and the use of external cooling devices, while monitoring core temperature, may be necessary to prevent hyperthermia in this population. Notably, preventing hyperthermia is not easy. Many children become hyperthermic after arrest despite the intent to prevent hyperthermia.[178]

Glucose Control

Both hyperglycemia and hypoglycemia following cardiac arrest is associated with worse neurologic outcome.[184-187]

While it seems intuitive that hypoglycemia would be associated with worse neurologic outcome, it is not clear whether hyperglycemia per se is harmful or is simply a marker of the severity of the stress hormone response from prolonged ischemia. A recent randomized control trial suggests that tight glycemic control in critically ill children had no effect on major clinical outcomes, but was associated with a higher incidence of hypoglycemia.[188] In summary, there is insufficient evidence to formulate a strong recommendation on the management of hyperglycemia in children with ROSC following cardiac arrest. If hyperglycemia is treated after ROSC in pediatric patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia.

Blood Pressure Management

A patient with ROSC may have substantial variability in arterial blood pressure after cardiac arrest. Postarrest or resuscitation myocardial dysfunction is common and is often associated with hypotension (discussed later).[179,180,189-198] In addition, hypertension may occur, especially if the patient receives vasoactive infusions for postarrest myocardial dysfunction. Optimization of arterial blood pressure postarrest is critical to maintain adequate perfusion pressure to vital organs that may have already been injured from the "no flow" and "low blood flow" states during initial cardiac arrest and CPR. Cerebral blood flow in healthy patients is tightly controlled over a wide range of mean arterial blood pressure via cerebral neurovascular bundle (autoregulation); however, adults resuscitated from cardiac arrest have demonstrated impaired autoregulation of cerebral blood flow, and this might be the case in children.[199]

Autoregulation of the cerebral neurovascular bundle following cardiac arrest may limit the brain's ability to regulate excessive blood flow and microvascular perfusion pressure, thereby leading to reperfusion injury during systemic hypertension. However, in animal models, brief induced hypertension following resuscitation results in improved neurologic outcome compared with normotensive reperfusion.[200,201] Conversely, systemic hypotension can perpetuate neurologic metabolic crisis following ischemic injury by uncoupling bioenergetic demand and delivery. Therefore, a practical approach to blood pressure management following cardiac arrest is to attempt to minimize arterial blood pressure variability in this high-risk period following resuscitation.

POSTRESUSCITATION MYOCARDIAL DYSFUNCTION

Postarrest myocardial stunning and arterial hypotension occur commonly after successful resuscitation in both animals and humans.[179,180,189-198] Postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction. Postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and post–cardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediators and nitric oxide production.[192,195,196,198] Because cardiac function is essential to reperfusion following cardiac arrest, management of postarrest myocardial dysfunction may be important to improving survival. Administration of inotropic, vasopressors, and vasodilators must be carefully titrated during the postresuscitation phase to the cardiovascular physiology. Although the optimal management of post–cardiac arrest hypotension and myocardial dysfunction has not been established, aggressive hemodynamic support may improve outcomes. Dobutamine, milrinone, and levosimendan can effectively ameliorate post–cardiac arrest myocardial dysfunction.[189,190,202,203] In clinical observational studies, intravascular fluid resuscitation has been given to patients with hypotension and concomitant low central venous pressure. Various vasoactive infusions, including epinephrine, dobutamine, and dopamine, have been given to treat the myocardial dysfunction syndrome.[179,180,193-197] In the end, optimal use of these drugs involves close goal-directed titration, and the use of invasive hemodynamic monitoring may be appropriate. General critical care goals are simply adequate arterial blood pressures and oxygen delivery; however, the definition of *adequate* is elusive. Reasonable interventions for vasodilatory shock with low central venous pressure include intravenous fluid resuscitation and vasoactive infusions. Appropriate considerations for left ventricular myocardial dysfunction include euvolemia, inotropic infusions, and afterload reduction.

NEUROMONITORING

Continuous neuromonitoring and goal-directed intervention following cardiac arrest can improve neurologic outcomes (see also Chapter 49).[204] Continuous electroencephalogram (EEG) monitoring is an increasingly instituted modality for neuromonitoring of critically ill patients to diagnose nonconvulsive seizures and seizures in patient's receiving neuromuscular blocking drugs (see Chapter 34). Continuous EEG monitoring is noninvasive, performed at the bedside, and permits continuous assessment of cortical function. Interpretation of continuous EEG monitoring is usually performed by a neurologist from a remote location and not bedside critical care physicians. However, advances in quantitative EEG tools may allow bedside caregivers to identify important electrographic events, such as seizures or abrupt background changes, potentially to permit real-time analysis and intervention.[205] In a prospective study of continuous EEG monitoring in children, nonconvulsive seizures were detected in 39% (12 of 31) of children following cardiac arrest.[206] In a partially overlapping cohort of 19 children, nonconvulsive seizures were common in children undergoing therapeutic hypothermia after cardiac arrest.[206] Nonconvulsive seizures are a common occurrence following cardiac arrests in children. Although, not established in pediatric patients following cardiac arrest, nonconvulsive seizures are associated with worse outcomes among critically ill adults and neonates.[207-213] Continuous EEG monitoring should be considered for children after cardiac arrest, and patients with nonconvulsive seizures (especially status epilepticus with nonconvulsive seizure) should be treated with anticonvulsant medication. The frequency of the nonconvulsive

seizures and benefit from anticonvulsant therapy need to be clarified.

Oxidative injury may be the most intense in the early phases of post-resuscitation therapy following cardiac arrest.[214] The use of 100% oxygen (compared to room air) during and immediately following resuscitation in animal models can exacerbate oxidative injury to key mitochondrial enzymes (pyruvate dehydrogenase or manganese superoxide) or mitochondrial lipids (cardiolipin), leading to worse neurologic outcomes.[215-218] Using peripheral pulse oximetry to titrate oxygenation in the post-resuscitation phase can reduce post-resuscitation hyperoxia and significantly improve neuropathology and neurobehavioral outcomes.[219] A $PaO_2 \geq 300$ mm Hg was independently associated with in-hospital mortality compared with either hypoxia or normoxia in an observational study among critically ill adult patients admitted to the ICU within 24 hours of a cardiac arrest.[220] We believe that it is prudent to titrate oxygenation during and after pediatric cardiac arrest. Although the optimal SpO_2 is not known, the FiO_2 should be titrated to the lowest amount necessary to assure $SpO_2 > 94\%$. Perhaps the future of postarrest care will include more aggressive neurocritical care monitoring, such as near infrared spectroscopy, cerebral microdialysis, brain tissue oxygenation ($Pbto_2$), cerebral blood flow, and even bedside analysis of mitochondrial dysfunction.

QUALITY OF CARDIOPULMONARY RESUSCITATION

Despite evidence-based guidelines, extensive provider training, and provider credentialing in resuscitation medicine, the quality of CPR is typically poor (see also Chapter 108). CPR guidelines recommend target values for selected CPR parameters related to rate and depth of chest compressions and ventilations, avoidance of CPR-free intervals, and complete release of sternal pressure between compressions.[221] Slow compression rates, inadequate depth of compression, and substantial pauses are the norm. An approach to *push hard, push fast, minimize interruptions, allow full chest recoil,* and *don't overventilate* can markedly improve myocardial, cerebral, and systemic perfusion, and will likely improve outcomes.[111] Quality of postresuscitative management is also critically important to improve resuscitation survival outcomes.[193] Measuring the quality of CPR and avoiding overventilation during cardiac arrest resuscitation have recently been reemphasized by consensus of the International Liaison Committee on Resuscitation and the AHA.[222] Although the correct amount, timing, intensity, and duration of ventilation that is required during CPR is controversial, there is no controversy that measurement and titration of the amount of ventilation to the amount of blood perfusion are desirable. Thus, additional technology that is safe, accurate, and practical would improve detection and feedback of the quality of CPR.

Recent technology has been developed that monitors quality of CPR by force sensors and accelerometers and can provide verbal feedback to the CPR administrator regarding the frequency and depth of chest compressions and the volume of ventilations. Recent pediatric data illustrates that intensive training and real-time corrective feedback can help chest compression quality approach age-specific AHA CPR guideline targets.[223-225] Moreover, improvements in post-resuscitation care can improve resuscitation survival outcomes.[193]

EXTRACORPOREAL MEMBRANE OXYGENATION AND EXTRACORPOREAL CARDIOPULMONARY RESUSCITATION

Extracorporeal CPR (ECPR) improves short-term and long-term survival outcomes following in-hospital and out-of-hospital cardiac arrest refractory to conventional therapy in observational studies.[226-229] Such studies can be criticized for small numbers, selection bias, and the lack of randomization to control for confounding by indication.[230] A randomized controlled trial investigating the treatment effect of ECPR for in-hospital cardiac arrest is unlikely, because of the need for a large sample size, complexity of methodology, lack of blinding, and lack of equipoise among providers. Devoid of a randomized controlled trial, ECPR observational studies in children clearly suggest favorable early survival outcomes in children with primary cardiac disease when ECPR protocols were in place at the time of the arrest.[231] For pediatric patients without primary cardiac disease, the data are less clear. Impressively, these studies consistently show that more than one third of children provided with ECPR survive to hospital discharge despite median durations of CPR of approximately 50 minutes before ECMO implementation. Importantly, 64% of patients who survived to discharge after ECPR had favorable neurologic outcomes.[232] Current guidelines recommend that ECPR (or rescue ECMO) should be considered in pediatric patients with in-hospital cardiac arrest that is refractory to initial resuscitation efforts when the cause of the arrest is believed to be reversible or amenable to heart transplantation.[233] Timely, quality ECPR could be an important adjuvant to conventional CPR for pediatric patients. Future frontiers will define patient populations and optimize the clinical approach to extracorporeal support; however, clinicians providing CPR should consider ECPR early in the course of a resuscitation not responding to conventional CPR. Perhaps after failure to attain ROSC within 5 minutes, clinicians should ask themselves: (1) Does the patient have a potentially reversible process, (2) would ECMO be a "bridge" to a potentially good outcome, and (3) do we have the personnel and resources to provide EMCO promptly?

VENTRICULAR FIBRILLATION AND VENTRICULAR TACHYCARDIA IN CHILDREN

Pediatric VF or VT has been an underappreciated pediatric problem. Recent studies indicate that VF and VT (i.e., shockable rhythms) occur in 27% of in-hospital cardiac arrests at some time during the resuscitation.[234] In a population of PICU patients, as many as 41% of arrests were associated with VF or VT.[235] According to the NRCPR database, 10% of children with in-hospital cardiac arrest had an initial rhythm of VF/VT. In all, 27% of the children

had VF/VT at some time during the resuscitation.[234] The incidence of VF varies by setting and age.[236] In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, post-cardiac surgery, and prolonged QT syndromes, VF and pulseless VT are more likely. The treatment of choice for short-duration VF is prompt defibrillation. In general, the mortality rate increases by 7% to 10% per minute of delay to defibrillation. Because VF must be considered before defibrillation can be provided, early determination of the rhythm by electrocardiography is critical. An attitude that VF is rare in children can be a self-fulfilling prophecy with a uniformly fatal outcome. The recommended defibrillation dose is 2 J/kg. In the mid-1970s, starting doses of 60 to 200 J were recommended for all children. Because of concerns for myocardial damage, shock doses ranging from 0.5 to 1 J/kg were adequate for defibrillation in a variety of animal species. Gutgesell and associates[236a] evaluated the efficacy of their strategy to defibrillate with 2-J/kg monophasic shocks. Seventy-one transthoracic defibrillations in 27 children were evaluated. Shocks within 10 J of 2 J/kg resulted in successful defibrillation (i.e., termination of fibrillation) in 91% of defibrillation attempts. More recent data demonstrate that an initial shock dose of 2 J/kg terminates fibrillation in less than 60% of children, suggesting that a higher dose may be needed.[83,237-239] Interestingly, retrospective observational NRCPR data demonstrate that higher initial doses of 4 J/kg were associated with worse short-term survival (i.e., immediate survival of the cardiac arrest event with a spontaneous rhythm). Despite five decades of clinical experience with pediatric defibrillation, the optimal dose remains unknown.

ANTIARRHYTHMIC MEDICATIONS: LIDOCAINE AND AMIODARONE

Administration of antiarrhythmic medications should never delay administration of shocks to a patient with VF. However, after an unsuccessful attempt at electrical defibrillation, medications to increase the effectiveness of defibrillation should be considered. Epinephrine is the current first-line medication for both pediatric and adult patients in VF. If epinephrine and a subsequent repeated attempt to defibrillate are unsuccessful, lidocaine or amiodarone should be considered.

Lidocaine traditionally has been recommended for shock-resistant VF in adults and children. However, only amiodarone improved survival to hospital admission in the setting of out-of-hospital cardiac arrest with shock-resistant VF compared with placebo.[240] In another study of shock-resistant out-of-hospital VF, patients receiving amiodarone had a higher rate of survival to hospital admission than patients receiving lidocaine did.[241] Neither study included children. Because there is moderate experience with amiodarone use as an antiarrhythmic agent in children and because of the adult studies, it is rational to use amiodarone similarly in children with shock-resistant VF/VT. The recommended dose is 5 mg/kg by rapid intravenous bolus. There are no published comparisons of antiarrhythmic medications for pediatric refractory VF. Although extrapolation of adult data and electrophysiologic mechanistic information suggest that amiodarone may be preferable for pediatric shock-resistant VF, the optimal choice is not clear.

PEDIATRIC AUTOMATED EXTERNAL DEFIBRILLATORS

Automated external defibrillators (AEDs) have improved adult survival from VF.[242,243] AEDs are recommended for use in children 8 years or older with cardiac arrest.[137,244] The available data suggest that some AEDs can accurately diagnose VF in children of all ages, but many AEDs are limited because the defibrillation pads and energy dosage are geared for adults. Adapters having smaller defibrillation pads that dampen the amount of energy delivered have been developed as attachments to adult AEDs, allowing their use in children. However, it is important that the AED diagnostic algorithm is sensitive and specific for pediatric VF and VT. The diagnostic algorithms from several AED manufacturers have been tested for such sensitivity and specificity and therefore can be reasonably used in younger children.

WHEN SHOULD CPR BE DISCONTINUED?

Several factors determine the likelihood of survival after cardiac arrest including the mechanism of the arrest (e.g., traumatic, asphyxial, progression from circulatory shock), location (e.g., in-hospital or out-of-hospital), response (i.e., witnessed or unwitnessed, with or without bystander CPR), underlying pathophysiology (i.e., cardiomyopathy, congenital defect, drug toxicity, or metabolic derangement), and the potential reversibility of underlying diseases. These factors should all be considered before deciding to terminate resuscitative efforts. Continuation of CPR has been traditionally considered futile beyond 15 minutes of CPR or when more than 2 doses of epinephrine are needed.[245] Presumably in part because of improvements in CPR quality and post-resuscitation care, improved outcomes from in-hospital CPR efforts beyond 15 minutes or two doses of epinephrine are increasingly the norm.[73,76] The potential for excellent outcomes despite prolonged CPR has been highlighted by the ECPR data noted previously.[246-250] Conversely, the decision to discontinue CPR prematurely is final and cannot be rescinded. In the second decade of the twenty-first century, there is still no simple answer to the important clinical question: When should CPR be discontinued?

RESPIRATORY SYSTEM

STRUCTURAL AND FUNCTIONAL DEVELOPMENT: AGE-DEPENDENT VARIABLES

Airways and Alveoli

The lungs appear in the fourth to eighth weeks of gestation. At this time, the lung buds divide into the mainstem bronchi; by 6 weeks, all subsegmental bronchi are present; and by 16 weeks, the number of airway generations is similar to that of adults. When airway development is complete, the terminal airways remodel and multiply

to form a cluster of large saccules, or alveolar precursors, that can support gas exchange. True alveoli appear before and after birth, and the respiratory saccules are thin and septate during postnatal growth.

At birth, children have approximately 24 million alveoli; by 8 years of age, the number has increased to 300 million. After that, further lung growth is primarily the result of increased alveolar size. There is less elastic tissue in the neonatal lung than in the lungs of adults, and the elastin extends only to the alveolar duct. By 18 years of age, elastin extends to the alveolus and is at its maximum. It then slowly decreases over the next 5 decades. Lung compliance is integrally related to the amount of elastin; hence, compliance peaks in adolescence. It is lower in the very young and the very old. Airways close in the tidal volume range until approximately 5 years of age.

Pulmonary Circulation

The main axial arteries of the lungs are present at 14 weeks' gestation. By 20 weeks' gestation, the pattern of branching is similar to that of adults, and collateral supernumerary vessels are present. During fetal life, additional arteries develop to accompany the respiratory airways and saccules. Bronchial arteries appear between the ninth and twelfth weeks of gestation. The arterial wall develops a fine elastic lamina by 12 weeks' gestation, and muscle cells are present as early as 14 weeks' gestation. By 19 weeks, the elastic tissue extends to the seventh generation of arterial branching, and muscularization extends distally. In the fetus, muscularization of the arteries ends at a more proximal level than in children and adults. The muscularized arteries have thicker walls than arteries of similar size in adults. The pulmonary arteries are actively constricted until the latter part of gestation. In the fetal lamb, pulmonary blood flow is only 3.5% of the combined ventricular output at 0.4 to 0.7 of gestation and is just 7% near term. Immediately after birth, pulmonary blood flow increases to near adult levels. Development of the pulmonary venous system mirrors that of the arterial system. The pulmonary arteries continue to develop after birth; new artery formation follows airway branching up to about 19 months of age, and supernumerary arteries continue to grow until 8 years of age. As alveolar size increases, the acinar branching pattern becomes more extensive and complex. The arterial structure also changes as preexisting arteries increase in size; the thickness of the muscular arteries decreases to adult levels during the first year of life.

Biochemical Development

By 24 weeks' gestation, the alveolar cuboidal epithelium flattens, and type I pneumocytes become the lining and supporting cells for the alveoli. The larger type II cells, which manufacture and store surfactant, also develop at this time. Surfactant initially appears at 23 to 24 weeks' gestation in humans and increases in concentration during the last 10 weeks of gestational life.[58] Surfactant is released into the alveoli at about 36 weeks' gestation, thus making normal extrauterine life possible.

Respiratory Transition: Placenta to Lung

By approximately 24 weeks' gestation, the lungs are capable of extrauterine gas exchange. However, several important circulatory and mechanical changes must occur immediately after birth for pulmonary gas exchange to be adequate. Ventilation begins to match perfusion within the first hours of life. Initially, there is right-to-left intrapulmonary shunting through atelectatic areas of the lung, as well as left-to-right shunting through the ductus arteriosus and some right-to-left shunting through the foramen ovale. The resultant PaO_2 of 50 to 70 mm Hg indicates a right-to-left shunt that is threefold that of normal adults. Transition from fetal to neonatal respiration and circulation is dynamic. Postnatally, the pulmonary vascular bed remains constricted if it is exposed to acidosis, cold, or hypoxia. If pulmonary artery constriction occurs, right-to-left shunting of desaturated blood through the foramen ovale and ductus arteriosus increases and consequently reduces pulmonary blood flow. Maintenance of this active pulmonary vasoconstriction is called persistent pulmonary hypertension of the newborn or persistent fetal circulation.

Mechanics of Breathing

For ventilation of the lungs, the respiratory muscles must overcome the lung's static-elastic and dynamic-resistive forces. Changes in these opposing forces during postnatal development affect lung volume, the pattern of respiration, and the work of breathing.

Lung Compliance versus Age

Lung compliance changes with age because of the changing alveolar structure, amount of elastin, and amount of surfactant. At birth, compliance is low because alveolar precursors have thick walls and decreased amounts of elastin. A deficiency of surfactant (e.g., hyaline membrane disease) further decreases lung compliance. The improved lung compliance occurring over the first years of life is the result of continued development of alveoli and elastin.

Chest Wall

The chest wall of infants is highly compliant because their ribs are cartilaginous. Because of the boxlike configuration of an infant thorax, there is less elastic recoil than there is with the dorsoventrally flattened thoracic cage of adults. Adults have a high proportion of slow-twitch, high-oxidative, fatigue-resistant fibers in their diaphragm and intercostal muscles. Whereas adults have 65% of these fibers in the intercostal muscles and 60% in the diaphragmatic muscles, neonates have only 19% to 46% of these fibers in their intercostal muscles and 10% to 25% in the diaphragm.[60] Consequently, infants are more vulnerable to muscle fatigue and decreased stability of the chest wall. The net effect of the compliant chest wall and the poorly compliant lungs is alveolar collapse and lower resting lung volume (i.e., FRC). Despite this tendency for lung collapse, a child maintains a large dynamic FRC via rapid respiratory rates, laryngeal breaking, and stabilization of the chest wall with increased intercostal tone during exhalation.

Upper Airway

The upper airways of children and adults have several anatomic differences that affect their ability to maintain a patent airway. The more anterior and cephalad position

of the larynx in children makes the "sniffing position" ideal for mask ventilation and endotracheal intubation. Extreme neck extension can actually obstruct the airway. The narrowest part of the adult airway is the vocal cords. Up to the age of 5 years, the narrowest portion of a child's airway is at the cricoid cartilage because the posterior larynx is positioned more cephalad than the anterior larynx, which causes the cricoid ring to be an ellipse rather than a circle. By 5 years of age, the posterior larynx has descended to the adult level.[251] An ETT that passes easily through the vocal cords of a young child may cause ischemic damage to the distal airway. The cricoid narrowing and very pliant tracheal cartilage provide an adequate seal around an uncuffed ETT. Children younger than 5 years rarely require a cuffed ETT, although some practitioners use cuffed tubes regularly in these patients.[252]

Closing Capacity

The elastic properties of the lung closely correlate with closing capacity. Closing volume is the lung volume at which the terminal airways close and gas is trapped behind the closed airways. Large closing volumes increase dead space ventilation, which leads to atelectasis and right-to-left shunting of blood. Elastic tissues help keep the airways open, so the greater the elastic stroma in the small airways, the lower the lung volume required to close small, noncartilagineous airways. Closing volume is small in late adolescence and relatively large in older adults and the very young. Children overcome the complications of large closing volumes and secondary atelectasis by breathing rapidly, by constant activity, and by crying. Closing volume becomes a significant problem in infants who are inactive, sedated, or anesthetized.

Resistive Forces

Neonates have small airways with high resistance or low conductance (conductance = 1/resistance). The diameter of the small airways does not significantly increase until approximately 5 years of age; hence, young children have elevated airway resistance at baseline and are particularly vulnerable to diseases that cause further narrowing of the airways (i.e., smooth muscle constriction, airway edema or inflammation). The normal high airway resistance of neonates and young children helps maintain FRC.

Control of Breathing

The newborn's respiratory control is unique. Hypoxia initially increases ventilation for a short time. This increase is followed by a sustained decrease in ventilation. The response is more exaggerated in preterm neonates. In full-term infants, it disappears after several weeks. Periodic breathing is also more common in infants, particularly preterm infants, and is probably due to inadequate development of the medullary respiratory centers.

Oxygen Transport: Oxygen Loading and Unloading

Fetal hemoglobin has low levels of 2,3-diphosphoglycerate and an oxygen half-saturation pressure of hemoglobin (P_{50}) of 18 mm Hg, which is much lower than the 27 mm Hg in adults. This lower P_{50} allows the fetus to load more oxygen at low placental oxygen tension, but it makes unloading oxygen in tissues more difficult. Three to 6 months after birth, fetal hemoglobin has been replaced with adult hemoglobin. The increased oxygen content of fetal hemoglobin and the increased fetal hemoglobin concentration are advantageous to the fetus because it allows an oxygen content of 20 mL of oxygen per 100 mL of blood to be delivered to the brain and heart. This is the same oxygen content that adults have when breathing room air. The oxygen concentration of neonates at birth is 6 to 8 mL/kg/min. It decreases to 5 to 6 mL/kg/min over the first year of life. The decreased ventilation-perfusion ratio, the decreased P_{50} of fetal hemoglobin,[53] and the progressive anemia characteristic of infants can make it difficult to deliver adequate oxygen during the first few months of life. Infants compensate by having a cardiac output of approximately 250 mL/kg/min for the first 4 to 5 months of life.

RESPIRATORY FAILURE

Respiratory failure is the inability of the lungs to adequately oxygenate and remove CO_2 from pulmonary arterial blood. There are many causes of respiratory failure, including a low environmental oxygen concentration, parenchymal lung disease, and pulmonary vascular disease. A complete history of the severity and chronicity of the respiratory problem helps formulate a differential diagnosis and an approach to treatment. Specific data should include a history of prematurity, previous airway instrumentation, previous mechanical ventilation, nonpulmonary organ dysfunction, and a family history of respiratory disease. A detailed feeding history and up-to-date growth chart may provide valuable information because growth failure may increase the need for oxygen. Usually, 1% to 2% of the total oxygen consumed is used for breathing. During respiratory illnesses, as much as 50% of the total oxygen consumption may be used for breathing. Infants and children with respiratory failure often have intercostal and suprasternal retractions, signs that the work of breathing and oxygen consumption are increased. Patients grunt during expiration in an attempt to maintain FRC. Most infants and children have tachypnea, which also helps maintain FRC by decreasing the time for exhalation. Less energy is required to breathe rapidly and shallowly than to take deep breaths. Infants with respiratory failure often have cyanotic lips, skin, and mucous membranes; however, it is often difficult to recognize skin color changes unless the $PaO_2 < 70$ mm Hg. Symmetry of chest movement should be noted. Differences in movement may indicate pneumothorax or blockage of a bronchus. The small thoracic volume allows easy transmission of breath sounds from one side to the other. Breath sound may be normal, even when pneumothorax is present. Abdominal distention can dramatically impede breathing in infants and young children.

MONITORING OF RESPIRATORY FUNCTION

An arterial blood gas is considered the gold standard to measure oxygenation as PaO_2 is measured directly from blood. The percent oxygen saturation of hemoglobin can be measured directly or calculated from PaO_2, pH, $PaCO_2$,

and temperature. Venous and capillary blood gases do not predict PaO_2. Use of arterial lines has decreased in pediatric ICUs over time. Pulse oximeters are ubiquitous. Pulse oximeters can provide continuous estimations of arterial oxygen saturations when the saturation is less than 97%; this is due to the shape of the oxygen dissociation curve. Pulse oximeters pass at least two wavelengths of light through the patient and the change in the absorbance of light is compared to an algorithm that produces the oxygen saturation. In the saturation range of 91% to 97%, pulse oximeters read higher than measured arterial saturations by approximately 1%.[253] However, in the saturation range of 76% to 90%, pulse oximeters read higher than measured arterial saturations by approximately 5% with wide confidence intervals.[253] Pulse oximeters can also have poorer performance when there is decreased perfusion to the extremity with the sensor. Lastly, most pulse oximeters have difficulty detecting abnormal forms of hemoglobin such as methemoglobin or carboxyhemoglobin and will produce erroneous results in their presence.

$Paco_2$ is used as a measure of the adequacy of ventilation. Analysis of ABGs is the gold standard, although $Paco_2$ obtained from capillary or venous blood gases can also provide valuable information. CO_2 values obtained from capnography or transcutaneous CO_2 monitoring (TCOM) can provide continuous information in a manner similar to pulse oximeters. Capnographs produce a waveform displaying exhaled CO_2 that can be either time-based or volumetric. Time-based capnography is much more common. Capnographs can either be an aspirating or nonaspirating system. An aspirating system takes gas from the ventilator circuit to measure the CO_2. A nonaspirating system has an exhalation chamber placed in line with the ventilator circuit. The system uses an infrared light source and detector that measures the exhaled CO_2. There is a great amount of information that can come from capnography including the end-tidal CO_2 ($ETCO_2$) value, respiratory rate, dead space calculations, cardiac output, and detection of obstruction of the airways.

For time-based capnography, the plateau of the slope will always be lower than $Paco_2$. Increases in $ETCO_2$ must be investigated as they signal a change in ventilation. For individuals with healthy lungs, this $ETCO_2$-to-$Paco_2$ gradient is usually 2 to 5 mm Hg. The gradient increases with increased dead space, abnormalities in the pulmonary vasculature, decreased cardiac output, and pulmonary over distension. $ETCO_2$ from capnography can be used clinically to calculate the approximate alveolar dead space by the alveolar dead space fraction (AVDSf). AVDSf = ($Paco_2$ – $P_{et}CO_2$) / $Paco_2$. AVDSf is a reasonable indicator of alveolar dead space[254] and, in a study by Ghuman and associates[255] for pediatric patients with acute hypoxemic respiratory failure, is found to be independently associated with mortality. Other valuable information is available from the waveform produced by time-based capnography. As an example, a rising upslope to the exhalation phase can indicate obstructive airways disease. Time-based capnography is more accurate with slower respiratory rates and when there is minimal leak around the ETT.

Volumetric capnography traces the CO_2 concentration against the exhaled volume and is appearing as a feature on some ventilators. Free-standing monitors that provide the same measure are also available. Volumetric capnography provides direct information for dead space calculations. Clinically volumetric capnography is helpful in setting the optimal PEEP. In this way PEEP can be titrated to balance improved oxygenation through alveolar recruitment and decreased dead space by not causing over-distension. Volumetric capnography can also be used to demonstrate a response to bronchodilator therapy.

In circumstances such as high frequency ventilation, the use of TCOM provides a continuous measure of ventilation. The TCOM module heats the skin underneath a small sensor. There is increased diffusion of CO_2 across the skin as the capillary bed dilates from the heat. The diffused CO_2 is then measured. When the TCOM is first set up, it should be calibrated against a capillary or arterial blood gas. There can be drift of calibration over time but newer modules have improved stability.

Effort of breathing with or without a ventilator can be obtained by the objective measurement value of the pressure-rate product (PRP). The pressure is measured with a balloon-tipped catheter placed into the distal one third of the esophagus and can be used as a surrogate for pleural pressure. The PRP is the change in esophageal pressure (Pes) multiplied by the respiratory rate (RR). PRP = Pes × RR. The PRP has been used as an objective measure of effort of breathing in studies: before and after extubation[256] with PEEP and obstructed airways disease,[257] evaluating increasing inspiratory load,[258] and evaluating effectiveness of high-flow nasal cannula.[259] Some ventilators can measure esophageal pressure, or it can be obtained with separate devices. In addition to measuring the PRP, the esophageal pressure is very important in measuring the pressure across the lungs or the transpulmonary pressures. Many adult studies are appearing demonstrating the benefits of titrating ventilator settings to trans-pulmonary pressure for patients with ARDS.[260-262] The transpulmonary pressure may have particular benefit in patients who are obese and require mechanical ventilation for respiratory failure[263] in which the decreased compliance of the chest wall might cause practitioners to limit ventilator pressures.

The phase of breathing or the synchrony between movement of the abdomen and the chest wall can be measured with respiratory inductance plethysmography (RIP). This noninvasive measure uses elastic bands placed around the abdomen and chest. Movement of the abdomen and chest changes the inductance of a small wire in the bands. Movement of the abdomen relative to the chest can be presented graphically or measured as the phase angle. When there is obstruction to breathing, such as with upper airway obstruction, there is a lag in the movement of the abdomen and chest wall that is identified as an increasing phase angle. The phase angle obtained by RIP is an objective measure of the degree of upper airway obstruction[258,264] and can be used to evaluate the effectiveness of therapy.[265,266] This is a valuable tool for research in the area of causes and treatment of upper airway obstruction as there is increasing interobserver variability in the clinician's assessment of this process.[267] RIP can be measured easily with free-standing devices, and it may have a more prominent role in future pediatric studies.

Much information on the respiratory effort of patients receiving mechanical ventilation can be obtained from respiratory spirometry. Spirometry can display flow-volume loops, pressure-volume loops, in addition to graphs of flow-time, pressure-time, and volume-time. The characteristic shape of some respiratory flow-volume loops can help with the diagnosis of various respiratory diseases. There is a classic scooped out appearance to the exhalation portion of a flow-volume curve with obstructive lung disease. The pressure-volume loops obtained on the ventilator can be used to increase PEEP to keep lung tissue recruited above an area of potential atelectasis. This can be seen graphically as a lower inflection point on the inspiratory curve. This is where the curve moves from a flat area to an area of maximal compliance where there is the greatest change in volume for a given change in pressure. There is also an upper inflection point on pressure volume loops where over-distension of the lungs can be identified if the inspiratory pressure or volume is too great. The pressure-volume curve with over-distension looks like a bird's beak and ventilator settings should be reduced.

Radiologic evaluation of the nasopharynx, neck, and thorax can provide meaningful information regarding the cause and severity of the respiratory dysfunction. Fluoroscopy can be used to evaluate the airways and movement of the diaphragm in an uncooperative child. Analysis of ABGs is used to determine the effectiveness of gas exchange. PaO_2 measurements allow calculation of the alveolar/arterial oxygen gradient and right-to-left shunting of blood across the lung. Elimination of CO_2 from arterial blood is another indicator of lung function. Failure to remove CO_2 from pulmonary arterial blood indicates maldistribution of blood flow in the lungs; specifically, there is increased dead space.

Umbilical artery cannulation is common in neonates, so those caring for such children can obtain arterial blood and continuously measure arterial blood pressure. These catheters are relatively simple to insert and reasonably easy to maintain.[268] The tip of the catheter ideally should be at or just above the level of the aortic bifurcation and below the level of the renal arteries (L2). Once the child's condition is stable, a peripheral artery catheter should be inserted and the umbilical artery catheter should be removed. All intraarterial catheters have the potential to cause distal thromboembolic disease. Care must be taken to flush arterial catheters gently to prevent cerebral or cardiac emboli. With proper insertion and maintenance, serious complications of arterial lines are rare. Although arteries that are cannulated for a long time may occlude, they recanalize within a short period.

NEONATAL RESPIRATORY FAILURE

The cause of respiratory failure depends to some degree on the age of the patient (see also Chapter 103). Newborn respiratory failure is often the result of congenital anomalies and immaturity of the lungs and their blood vessels. Congenital anomalies can include airway malformations, dysgenesis or malfunction of the lung or nonpulmonary organs, and abnormalities of the pulmonary vessels. Lesions of immaturity include apnea of prematurity, hyaline membrane disease, and abnormalities of surfactant production and secretion. During the perinatal period, neonates are subject to infections and stress. Persistent pulmonary hypertension can complicate neonatal pulmonary and nonpulmonary problems. These and other important causes of respiratory failure in the newborn are listed in (Table 95-5). A wide variety of disorders cause respiratory failure in older children

TABLE 95-5 **CAUSE OF NEONATAL RESPIRATORY DISTRESS**

Location	Congenital Abnormalities	Developmental Immaturity	Specific Neonatal Stress
Impaired control of ventilation	Central nervous system dysgenesis Ondine's curse	Apnea of prematurity Intracranial hemorrhage	Drug intoxication (note maternal drugs) Sepsis Central nervous system infection Seizures
Neuromuscular disorders	Congenital myopathies		High cervical cord injuries
Structural impairment	Thoracic deformities Lung hypoplasia Diaphragmatic hernia Potter syndrome Abdominal malfunction Gastroschisis Omphalocele		Severe abdominal distention Pneumothorax or other leak
Airway obstruction Upper airway	Choanal atresia Pierre Robin syndrome Laryngeal web/cleft Congenital tracheal/laryngeal stenosis Recurrent laryngeal palsy Hemangioma Lymphangioma		Massive meconium aspiration Vocal cord paralysis is secondary to myelodysplasia
Lower airway	Tracheoesophageal fistula Lobar emphysema		Meconium/blood aspiration
Alveolar disorders		Respiratory distress syndrome	Bronchopulmonary dysplasia

(Box 95-2). Regardless of the specific cause, respiratory failure can be categorized as hypoventilation syndromes in patients with normal lungs, intrinsic alveolar and interstitial disease, and obstructive airway disease.

Hypoventilation Syndromes in Children with Normal Lungs

Causes of hypoventilation include neuromuscular disease, central hypoventilation, and structural or anatomic impairment of lung expansion (e.g., upper airway obstruction, massive abdominal distention). These clinical conditions are characterized by inadequate lung expansion, secondary atelectasis, intrapulmonary right-to-left shunting, and systemic hypoxia. Atelectasis and the secondary reduction in FRC increase the work of breathing. The child's response to the increased work of breathing and lower lung volumes is to breathe faster with a smaller tidal volume. This pattern of breathing eventually increases the amount of atelectasis and shunting. As a result, children with intrinsically normal lungs and hypoventilation syndromes exhibit tachypnea, small tidal volumes, increased work of breathing, and cyanosis. Chest radiographs reveal small lung volumes and miliary or lobar atelectasis. Positive-pressure ventilation and PEEP quickly reverse the pathologic processes.

Primary Pulmonary Alveolar or Interstitial Disorders

Intrinsic lung disease involving the alveoli or pulmonary interstitium decreases lung compliance and increases airway closure, both of which cause atelectasis and increase the work of breathing. Edema or inflammation of the alveoli or fibrosis of the interstitium decreases lung compliance. The stiffer lung requires a greater negative intrapleural pressure for air movement, thereby increasing the work of breathing and the risk for pneumothorax.

Obstructive Airway Disease

Airway obstruction can be extrinsic or intrinsic. Intrinsic small airway obstruction commonly occurs with bronchiolitis, bronchopneumonia, asthma, and bronchopulmonary dysplasia (BPD). Airway obstruction decreases conductance and increases airway resistance and the work of breathing. Partial obstruction impedes expiration more than inspiration and causes gas trapping or regional emphysema. Complete airway obstruction results in atelectasis and right-to-left shunting of blood within the lung. Patients with disease of the small airways usually have a mixture of total and partial airway obstruction and inhomogeneous collapse and overdistention of the lung. The areas of collapse cause intrapulmonary right-to-left shunting of blood, and the overdistended areas increase the amount of dead space. If the entire lung is overdistended, compliance is decreased and the work of breathing is increased. The clinical and radiographic picture varies with the different degrees of collapse and overdistention of the lung. In summary, all causes of respiratory failure share similar pathophysiology: atelectasis and decreased FRC with intrapulmonary right-to-left shunting of blood or alveolar overdistention with increased dead space and decreased CO_2 elimination, or both. The increased work of breathing associated with all forms of respiratory dysfunction can cause fatigue and a breathing pattern that further complicates the initial process. It may also lead to apnea, hypoxia, and cardiac arrest in young children if the increased work of breathing is not quickly detected and treated.

BOX 95-2 *Causes of Respiratory Failure in Children*

1. Impaired control of ventilation
   - Head trauma
   - Intracranial hemorrhage
   - Increase intracranial pressure secondary to tumor, edema, hydrocephalus, Reye syndrome
   - Central nervous system infections
   - Drug intoxication
   - Status epilepticus
2. Neuromuscular disorders
   - High cervical cord injury
   - Poliomyelitis
   - Guillain-Barré syndrome
   - Neurodegenerative disease (e.g., Werdnig-Hoffman syndrome)
   - Muscular dystrophies and myopathies
   - Myasthenia gravis
   - Botulism
   - Tetanus
   - Phrenic nerve injury
3. Structural impairment
   - Severe kyphoscoliosis
   - Flail chest
   - Large intrathoracic tumor
   - Pneumothorax or pneumomediastinum
   - Large pleural effusion, hemothorax, empyema
   - Severe abdominal distention
   - Severe obesity (pickwickian syndrome)
4. Airway obstruction
   - Upper airway
   - Congenital anomalies
   - Tumor, intrinsic or extrinsic
   - Epiglottitis
   - Croup (laryngotracheobronchitis)
   - Foreign body
   - Postintubation edema, granulation tissue, or scarring
   - Vocal cord paralysis
   - Burns
   - Vascular ring
   - Lower airway
   - Asthma
   - Bronchiolitis
   - Foreign body
   - Lobar emphysema
   - Cystic fibrosis
5. Alveolar disorders, pneumonia
   - Infectious: bacteria, virus, fungus, *Pneumocystis* species
   - Chemical: aspiration, hydrocarbon, smoke inhalation
   - Pulmonary edema: cardiogenic, near-drowning, capillary leak syndrome
6. Massive atelectasis
7. Oxygen toxicity
8. Pulmonary confusion
9. Pulmonary hemorrhage

RESPIRATORY CARE

The fraction of inspired oxygen (FiO_2) can be increased by a number of means including nasal cannula or mask. The FiO_2 can be increased up to approximately 40% with nasal cannula oxygen at 5 L/min; however, this rapid rate of flow can become uncomfortable. As room air is entrained around the cannula during inspiration, the FiO_2 cannot be increased further with nasal cannula. It should be noted that the size of the patient correlates with the inspiratory volume with each breath. The larger the patient, the larger the inspiratory volume is relative to flow from the cannula and the larger volume of room air that is entrained. In turn, the smaller a patient the less room air is entrained and there may be a greater impact on FiO_2.

The FiO_2 can be increased further with a properly fitted facemask. The open holes of a Venturi or simple facemask allow for greater entrainment of room air as compared to a nonrebreather facemask that has no holes. An FiO_2 approaching 1 can be obtained with a nonrebreather facemask with an oxygen reservoir and one-way valve. Patients with respiratory distress while on the pediatric ward may temporarily require a nonrebreather facemask at high flows. If there is no significant improvement to immediate interventions, arrangements should be made to transfer the patient to the PICU. Nonrebreathing facemask systems can be humidified for comfort, but they do not provide any positive pressure to the airways.

High-flow humidified nasal cannula (HFHNC) oxygen can provide a higher FiO_2, and it is more readily tolerated than standard nasal cannula. The gas in HFHNC is heated to body temperature and nearly completely humidified with water vapor. HFHNC can be delivered with flow rates in pediatric patients up to 10 L/min. It was shown by Rubin and associates[259] that higher flow rates with HFHNC decreased the effort of breathing in critically ill children; this has been used frequently to support patients with bronchiolitis.[269,270] It is unclear whether the significant benefits of HFHNC come from washing out CO_2 from the airways or from the generation of positive pressure. The potential for complications exists with higher gas flow rates. Air leak syndrome was reported in three patients by Hegde and associates.[271] As the use of HFHNC increases, other problems may be identified. Given that the amount of FiO_2 delivered approaches 1.0, use of HFHNC is typically restricted to an emergency department or ICU setting. The high degree of respiratory support provided can mask a significant degree of respiratory distress.

Noninvasive ventilation can be supplied with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). This is typically delivered with a tight fitting nasal or face mask, which allows for the development of positive airway pressure. Most modern ventilators can be set to deliver this therapy, but specific free-standing BiPAP machines are more often used. BiPAP therapy is best for short-term use and in patients with the ability to cough and protect their airway. It is not an absolute that the patient initiates every breath, because a back-up rate can be set. However, if the patient is completely reliant on the rate set on the machine, intubation should be considered. Other indications for conversion from BiPAP to endotracheal intubation include pressure-related tissue breakdown on the face from constantly wearing the mask, the need to initiate enteral feedings as patients are typically nil per os (nothing by mouth) status while receiving BiPAP, and increasing pressure settings on the BiPAP machine.

CPAP reduces the patient's work of breathing by providing airway pressure, reducing atelectasis, decreasing dead space, and improving the balance of ventilation to perfusion. An initial CPAP pressure is typically 4 to 6 mm Hg and is then increased as needed and as the patient tolerates the therapy. Given that the feeling of positive airway pressure is a bit foreign, starting with lower pressures and increasing them gradually gives the patient a chance to adapt. The authors typically start CPAP therapy for several minutes even if the patient will ultimately receive BiPAP. For BiPAP the expiratory pressure is also initially at 4 to 6 mm Hg, and the inspiratory pressure is set at 4 to 6 mm Hg above that. The inspiratory and expiratory pressures are adjusted as well as the rise time to inspiratory flow. All these changes can help the patients tolerate therapy. With the tight seal, an FiO_2 of 1.0 can be delivered. Use of the full facemask can put patients at risk for aspiration if they vomit. BiPAP therapy is being used in status asthmaticus,[272,273] and it may provide a more effective means of delivering aerosolized medication. The use of BiPAP therapy for this indication could increase over time, as it is being recommended in current guidelines.[274,275] BiPAP can also be used as an ongoing therapy for chronic respiratory failure, such as for central hypoventilation or restrictive lung disease. These patients may be able to receive their therapy at home and are typically followed by the hospital's pulmonary service.

The size of ETT required should be selected carefully. One formula that estimates the appropriately sized tube for children older than 2 years is $(Age + 16) / 4$. This formula provides the internal diameter of the appropriately sized ETT. The correct size should have a slight air leak when a positive pressure of 20 to 30 cm H_2O is applied. Serious lifelong laryngeal and subglottic damage can result from using inappropriately large ETTs, particularly in children with inflammatory lesions of the upper airway such as laryngotracheobronchitis. Because of the more flexible tracheal cartilage and the relative subglottic narrowing of children, uncuffed ETTs generally provide an adequate seal in those younger than 5 years. However, if the patient has lung disease that requires high ventilation pressure, a cuffed tube is more appropriate. Small cuffed ETTs are frequently used in the ICU in younger patients,[252] but a small leak of air at 25 to 30 cm H_2O should be present. Cuffed tubes will usually eliminate the air leak around an ETT, but overinflation of the cuff may occlude venous flow and injure the airway. The long-term safety of using cuffed ETTs in young children is not known.

With endotracheal intubation, the position of the ETT should be correct so chest movements are symmetric, and breath sounds should be equal when auscultated in the axillae. An electronic or colorimetric CO_2 detection system helps confirm whether the ETT is in the trachea or the esophagus.[276] If the double lines on the ETT are at the level of the vocal cords, the ETT is usually in the correct

position. Another way to position the ETT correctly is to advance it into the right mainstem bronchus and listen for breath sounds in the left axilla. Breath sounds will be diminished. Withdraw the ETT slowly. When breath sounds are heard on the left, pull the tube out an additional 1 to 2 cm, depending on the size of the child. When the breath sounds are equal, fix the tube in place. The tip of the ETT should be midway between the vocal cords and the carina on the chest radiograph. In small infants, the distance between the carina and the vocal cords is very short. Consequently, it is easy to place the ETT inadvertently in a mainstem bronchus. Flexion of the head moves the ETT into the airway. Extension moves it toward the vocal cords. Turning the head to the side can obstruct the tip of the ETT if it contacts the tracheal wall, which can cause CO_2 retention or hypoxemia, or both. A child's trachea can be intubated for more than 2 weeks before performing a tracheostomy. This is possible with proper humidification of the inspired gases, improved endotracheal suctioning and monitoring (Sa_{O_2}), and excellent nursing care. Everyone caring for the child must be constantly alert to the possibility that the ETT will become obstructed by secretions or that accidental extubation or mainstem bronchus intubation will occur. In neonates, ETTs with a "Murphy" eye become obstructed more often with secretions than those without a Murphy eye do. The Murphy eye is near the end of the ETT. Once the ETT enters the mainstem bronchus, it is impossible for the infant to breathe effectively through the "eye." Because the ETT is almost the same size as the trachea, it is nearly impossible for the infant to breath around the tube. Thus, ETTs with Murphy eyes are dangerous and probably should not be used in young infants. Tracheostomy is indicated when children require a long-term artificial airway for mechanical ventilation, for endotracheal suctioning, or to bypass an upper airway obstruction. Accidental dislodgement of the tracheostomy tube before the tract is well healed can be life threatening. Reinsertion of a tracheostomy tube during the first 72 hours after insertion can be extremely difficult and can create false passages that can make it impossible to ventilate the lungs or can cause pneumothorax.

Intubation and mechanical ventilation can provide significant elevations in airway pressure as compared to noninvasive ventilation and an FiO_2 of 1.0. There can be regional variation to the mode of mechanical ventilation chosen, but there is likely a greater use of pressure-controlled ventilation rather than volume-controlled ventilation in PICUs. With pressure-controlled ventilation, pressure is set and the tidal volume can change as the pulmonary compliance changes. With volume-controlled ventilation, tidal volume is set and the pressure needed to deliver that may change as the pulmonary compliance changes. These are likely the two main modes of mechanical ventilation in pediatric ICUs. For the majority of intubated children who have reasonable pulmonary compliance, there are little differences between the two modes. One potential advantage of pressure-controlled ventilation for patients who are sicker with poorer pulmonary compliance is that most ventilators in this mode use a decelerating inspiratory flow pattern. As a result, the flow of gas is greatest early in inspiration and then decelerates to zero flow when the peak pressure is achieved. This can result in the delivery of a larger tidal volume for a lower peak pressure as compared with the same pressure that might be required in a tidal volume mode.

There are additional modes available on modern ventilators that may have benefit for patients with lung injury. The names of the modes will differ between the ventilator manufacturers. Many will have a mode where a desired tidal volume is guaranteed and the lowest pressure necessary to achieve that is used. The terms to define this are *pressure-regulated volume control* and *volume guarantee*. These modes can reduce the pressure used, but they work best when the patient is well sedated and not competing with the ventilator.

Airway pressure-release ventilation (APRV) is a newer mode of mechanical ventilation that is used at a limited number of centers. There are few published pediatric studies using this mode,[277-279] and its benefits and limitations continue to be explored. Neurally adjusted ventilatory assist (NAVA) is a newer method of triggering ventilator synchrony available on the Servo-i ventilators by Maquet (Rastatt, Germany). This method uses a small esophageal probe that can sense the electrical activity of the diaphragm and use that activity to synchronize the ventilator. The potential benefits of improved triggering such as improved comfort, lower ventilator settings, and increased minute ventilation have been shown in some studies.[280,281] APRV is essentially CPAP with brief, intermittent release coupled with spontaneous ventilation. The high CPAP level (P_{high}) maintains alveolar recruitment and aids in oxygenation over a period of time (T_{high}), and the timed release to a low pressure (P_{low}) minimizes resistance to expiratory flow and carbon dioxide removal. In addition, the patient is able to breathe spontaneously during all phases, P_{high} and P_{low}, potentially allowing for improved pulmonary mechanics and gas exchange. APRV differs from other modes of ventilation because it relies on an intermittent decrease in airway pressure, instead of an increase in airway pressure to maintain an open lung strategy for ventilation. Therefore, the release time (T_{low}) should be set long enough to allow for an adequate tidal volume (6-8 mL/kg), but short enough to avoid alveolar collapse and atelectrauma. In summary, the operator-controlled parameters in APRV are P_{high}, T_{high}, P_{low}, T_{low}, and FiO_2. Recommendations for implementing APRV are limited in pediatrics, and thus extrapolated from adult recommendations.[282] P_{low} is initially set at zero. P_{high} can be set by several methods, such as plateau pressures or 75% of peak inspiratory pressure; however, when transitioning from conventional modes of ventilation P_{high} is often determined by mP_{AW} pressure formula where the mP_{AW} is set 2 to 3 cm H_2O above conventional mP_{AW}: $(P_{high} \times T_{high}) + (P_{low} \times T_{low}) / (T_{high} + T_{low})$. To determine T_{high} and T_{low}, first determine the total cycle time according to a normal respiratory rate range for the patient's age; that is, a respiratory rate of 20 yields a total cycle time of 3 seconds. T_{high} will be the total cycle time minus a T_{low} of 0.2 to 0.6 seconds, initially starting at 0.4 seconds; that is, total cycle time of 3 seconds yields a T_{high} of 2.6 seconds and T_{low} of 0.4 seconds; or, Number of cycles (respiratory rate) = 60 seconds / $(T_{high} + T_{low})$. Transitioning to APRV, like transitioning to high-frequency oscillating

ventilator (HFOV), will take time for optimal lung recruitment. After several hours if the patient continues to have severe hypoxemia, T_{high} can be increased to aid in oxygenation. Once established, P_{low} and T_{low} usually do not require additional changes; however, as lung compliance improves P_{high} and T_{high}, can be decreased and increased, respectively, to wean a patient toward a target of a continual CPAP of 5 to 6 cm H_2O in preparation for extubation of the trachea. APRV may be advantageous to other modes of advanced mechanical ventilation because of the patient's ability to breathe spontaneously throughout the entire ventilatory cycle, improving respiratory mechanics and reducing the need for sedation and neuromuscular blockade. However, some authors are concerned that there may be a more frequent incidence of cyclic alveolar collapse during airway release leading to a greater degree of atelectrauma, as compared with HFOV.[279,283]

High-frequency ventilation describes a type of mechanical ventilation in which the respiratory rate of the ventilator is much greater than a normal physiologic rate. By maintaining the same minute ventilation, these ventilation modes produce low tidal volumes. There are several different types with the most commonly used in pediatrics being the HFOV. Use of the HFOV was first described by Lunkenheimer in 1972.[284] This type of ventilator houses a piston that is attached to semirigid connecting tubing that attaches to the ETT. This circuit can be pressurized to a set mean airway pressure. The piston then oscillates up to 840 times per minute, creating small positive and negative respiratory cycles. The mean airway pressure is higher as compared with conventional ventilation, and this prevents atelectasis and shear forces from opening and closing alveoli with each respiratory cycle. The FiO_2 is set as in a conventional ventilator. The frequency of oscillation of the piston is adjusted to remove carbon dioxide and can vary between 6 and 14 Hertz. (Hertz [Hz] is 1 cycle/second, 6 Hz equals 360 cycles or breaths per minute.) The amplitude of the ventilator is the distance the piston moves with each excursion and by these excursions small breaths are propelled down the tubing. Several proposed mechanisms for the method of gas transport during HFOV have been proposed, but none have been proven definitively. Tidal volumes are dependent on the patient's compliance, ETT size, device frequency, and device amplitude. Tidal volume is inversely related to cyclic frequency: $VCO_2 = \text{Frequency} \times VT^2$. When transitioning from conventional modes of ventilation to HFOV, the initial power setting (referred to as *delta P, power,* or *amplitude*) is adjusted to visible chest "wiggle" from the clavicles to the abdomen or pelvis. The mean airway pressure (mP_{AW}) is initially set approximately 5 cm H_2O greater than the last mP_{AW} on conventional ventilation just prior to the initiation of HFOV. Traditionally, tidal volumes in HFOV are considered to be just above functional residual capacity (FRC); however, it is difficult to measure actual tidal volumes and provide precise "optimal" lung volumes strategy. Clinically, mean airway pressure (mP_{AW}) is titrated upward by 1 to 2 cm H_2O until oxygenation improves and inspired oxygen concentrations can be weaned to less toxic levels of below 0.60. While titrating mP_{AW}, overdistention is assessed with chest radiographs; overdistention or hyperinflation are determined by more than nine posterior ribs or flattened hemi-diaphragms on chest radiographs. Initial frequency settings, measured in hertz, can be found in (Table 95-6). HFOV is the only mode of ventilation with active expiration. If hypercarbia leads to profound respiratory acidosis and patient instability, despite allowances for permissible hypercapnia, then minute ventilation can be improved by several means during HFOV. First, the patient should be suctioned. One of the drawbacks of HFOV is the lack of spontaneous ventilation and adequate airway clearance; therefore, inline suction (without breaking into the circuit causing derecruitment) should be used to ensure adequate airway, ETT patency, and lung recruitment. Second, ΔP/amplitude should be increased to maximize lung recruitment and increase minute ventilation. Third, frequency (Hz) can be slowly decreased to enhance lung recruitment and increase minute ventilation. Finally, the ETT cuff should be deflated to allow additional escape of CO_2 around the ETT. Disadvantages of HFOV include no partial ventilatory support leading to increased requirements for sedation and paralysis, cardiopulmonary interactions owing to higher mP_{AW} and decreased venous return, and loss of alveolar recruitment if the circuit is detached for suctioning of manual ventilation.

HFOV is being used in pediatrics as a rescue therapy for acute lung injury (ALI) or ARDS. A 1994 publication by Arnold and associates[285] is the only multicenter randomized trial of HFOV. This study showed lower use of oxygen supplementation in the HFOV group at 30 days. There have been other pediatric studies showing positive benefit of HFOV, such as a single-center retrospective study by Babbitt and colleagues.[286] The conclusion that could be drawn by many studies with HFOV in pediatrics is that for disease processes with significant mortality, rescue therapy with HFOV may be appropriate and may show improved outcomes. In some of the most critically ill patients with a very high mortality, such as immunocompromised children with ARDS, the use of HFOV has been as a diagnostic criteria to identify survivors from nonsurvivors.[279] A Cochrane review by Sud and associates[287] in adult patients with ARDS summarized the effectiveness of therapy: "The findings of this systematic review suggest that HFO was a promising treatment for ALI and ARDS prior to the uptake of current lung protective ventilation strategies." The recently published results of the adult OSCILLATE trial[288] (The Oscillation of ARDS Treated Early Trial) could further limit the use of HFOV. This multicenter randomized controlled trial was stopped early after 548 patients were enrolled. The in-hospital mortality was 47% in the group receiving HFOV versus 35% in the patients receiving conventional ventilation. It is unclear whether these findings can be

TABLE 95-6 INITIAL FREQUENCY SETTINGS IN HIGH-FREQUENCY OSCILLATORY VENTILATION

31-50	6
>50	5

translated to pediatric patients. The disease processes and the condition of pediatric patients can be extremely different as compared with adults. However, with these findings it is unclear whether the motivation is present to perform a multicenter HFOV trial in pediatrics. There may continue to be other indications for HFOV in pediatrics, such as air leak syndrome or congenital diaphragmatic hernia.

High-frequency percussive ventilation (HFPV) pneumatically stacks subtidal volume breaths at a set rapid rate superimposed upon conventional cyclic rates. HFPV as a mode of ventilation allows for a progressive stepwise inflation of the lung to a set peak pressure while allowing for passive exhalation to a preset lower pressure. HFPV has been well described in the inhalational injury population for its ability to safely oxygenate and ventilate with continuous, pneumatically powered, high-frequency percussions to facilitate clearance of airway debris.[289-292] These properties may be particularly useful in pediatric patients with acute respiratory failure, by improving oxygenation and ventilation while maintaining lung protective strategies.[293]

ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

The 1994 American-European Consensus Conference[294] established clinical criteria to diagnose ARDS. The criteria were widely used in research studies to assure consistent severity of illness and then to study the effect of various interventions. ARDS diagnostic criteria have been revised recently and are known as the *Berlin Definition*.[295,296] By this definition, ARDS is separated into three mutually exclusive categories based on the degree of hypoxia. *Mild* is PaO_2/FiO_2 = 201 to 300, with PEEP > 5; *moderate* is Pa_{O_2}/FiO_2 = 100 to 200, with PEEP > 5; and *severe* is PaO_2/FiO_2 < 100, with PEEP > 10. The Berlin Definition resulted from consensus opinion and from evaluation of criteria performance using two large datasets. Additional components of the criteria include the timing of onset, bilateral opacities on chest radiograph, and respiratory failure not fully explained by cardiac failure. Performance of the Berlin Definition in pediatrics has been evaluated by De Luca and colleagues[297] with validity similar to that presented in adults. As pointed out by Khemani and associates[298] in the accompanying editorial, the new definition was reapplied to patients already classified by the older American-European Consensus Conference definition. The editorial also describes several areas in which research in pediatric ARDS, such as the decreased use of arterial catheters, will differ from adults. Specific diagnostic criteria that address the unique aspects of pediatric ARDS are needed for future research.

Clinical features of lung injury can vary from mild, self-limiting dyspnea to rapidly progressive and fatal respiratory failure. The clinical course of ALI can be generalized in four phases (Box 95-3); however, not every patient passes through all these phases, and the condition may resolve at any stage. Extensive research continues to try to develop predictive biomarkers and genomic arrays for severity and resolution of lung injury; however, to date there are no useful clinical biomarkers or genomic readouts for prediction or goal directed therapy.

BOX 95-3 ***Four Phases in the Clinical Development of Lung Injury***

1. Dyspnea and tachypnea with no other abnormalities on chest radiographs
2. Hypoxemia with normal or subnormal $Paco_2$ with possible minor consolidation or effusions on chest radiographs within the last 24-48 hours
3. Diagnostic criteria of acute lung injury established—severe arterial hypoxemia, decreased pulmonary compliance with characteristic bilateral diffuse infiltrates on chest radiographs
4. Massive bilateral consolidation with unremitting hypoxemia; increased deadspace ventilation; rising $Paco_2$; often terminal

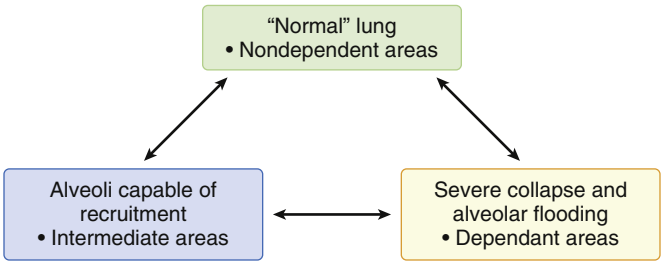

Figure 95-4. For the purposes of lung protective ventilator strategies, the lung can be divided into three hypothetical areas.

PRINCIPLES OF LUNG PROTECTIVE STRATEGIES: LIMITING VENTILATOR ASSOCIATED LUNG INJURY

As lung injury progresses, in response to pulmonary or extrapulmonary injury, the lungs can be divided into three hypothetical regions (Fig. 95-4):

1. Areas with severe collapse and alveolar flooding (dependent areas)
2. Recruitable areas with alveolar atelectasis (intermediate areas)
3. Normal lung (nondependent areas)

The goal of mechanical ventilation is to recruit intermediate areas allowing improved gas exchange, spare normal areas of lung from ventilator-associated lung injury, while giving dependent collapsed regions of lung with alveolar flooding time to recover from the primary process (i.e., pneumonia, sepsis). Lung recruitment of intermediate areas and prevention of ventilator-associated lung injury is accomplished by using PEEP and limiting tidal volume and plateau pressures. This potentially complicated task can be simplified by first looking at Figure 95-5 and conceptualizing a theoretical pressure-volume curve of the lung. As alveolar airway pressure increases, there is an opening pressure (P_{flex}) required to overcome airway resistance and alveolar compliance (Compliance = $\Delta V / \Delta P$). Pressures below P_{flex} will lead to alveolar collapse, termed *atelectasis*. If airway pressure cycles above and below P_{flex}, alveoli will continually open and collapse, leading to wall shear stress and eventual damage, or atelectrauma. Following the hysteresis curve to the upper extent of the inspiratory limb, as pressure increases, there comes a point, termed P_{max}, whereby the alveoli start to become

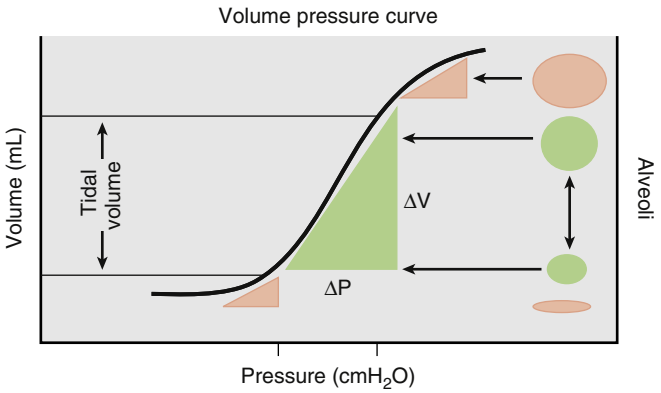

Figure 95-5. Volume pressure curve.

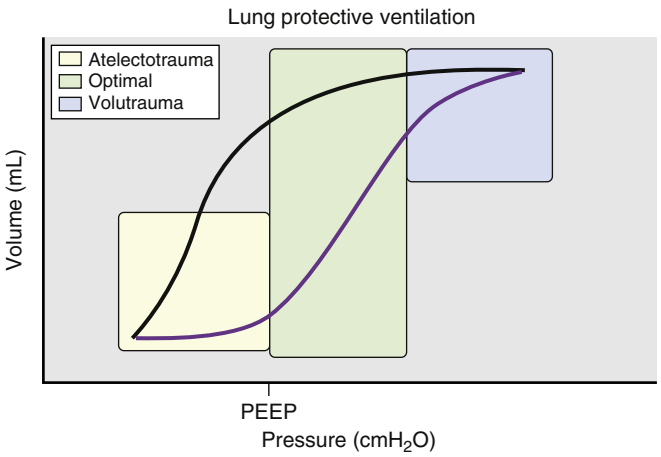

Figure 95-6. Lung protective ventilation strategy. *PEEP,* Positive end-expiratory pressure.

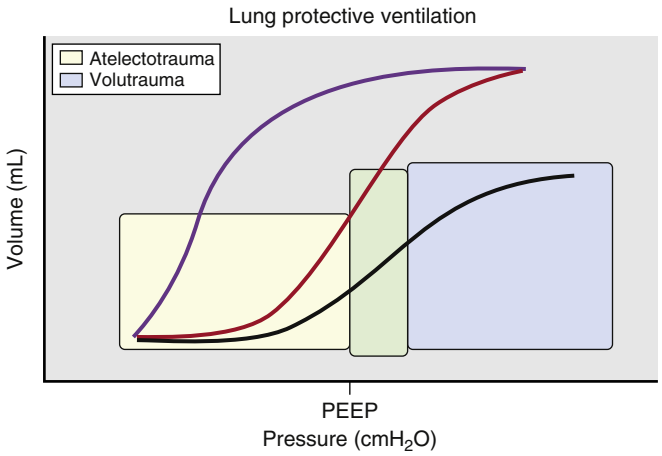

Figure 95-7. Lung protective ventilation with worsening lung compliance. *PEEP,* Positive end-expiratory pressure.

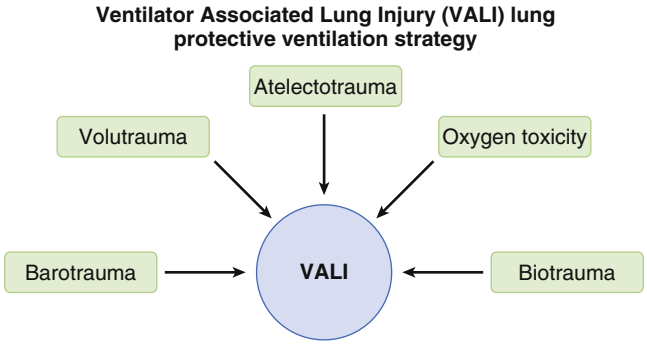

Figure 95-8. Tenets of ventilator associated lung injury.

overdistended. Above P_{max}, shear stress again leads to alveolar damage, this time termed volutrauma. Therefore, in theory, we attempt to keep tidal volumes on the most compliant part of the volume-pressure curve, above P_{flex} and below P_{max}, leading to the idea called *open-lung ventilation*. Triggered by the ARDSNet initial study, the use of low tidal volumes (6 to 8 mL/kg) with the addition of PEEP (open-lung strategy) can reduce morbidity and mortality in patients with ARDS (Fig. 95-6).[299] However, as lung injury to the normal and intermediate areas of the lungs progresses the volume-pressure curve moves to the right as the compliance of the lungs decreases, leaving a smaller therapeutic window requiring an increase in PEEP, resulting in higher mean airway pressure to maintain recruitment of areas of normal and recruitable lung (Fig. 95-7).

Lung protective strategy attempts to decrease ventilator associated lung injury by inhibiting volutrauma, barotrauma, atelectrauma, oxygen toxicity, and biotrauma (Fig. 95-8). Despite using usual control groups in the ARDSNet original study, using a low tidal volume approach of 6 to 8 mL/kg has become a standard of care. The advantages of PEEP as a distending pressure include increase in functional residual capacity, improvement of respiratory compliance, improvement of ventilation/perfusion mismatch, redistribution of lung water/edema. PEEP ultimately improves arterial oxygenation. The use of low tidal volumes has been consistent across multiple recent trials, but the selection of PEEP in these trials has been highly variable. Animal models have shown that setting PEEP just above P_{flex} minimizes lung injury and inflammation.[300] It can be difficult to determine the critical opening pressure of alveoli clinically. Therefore, most clinicians initially use a minimal distension strategy by setting PEEP between 5 and 9 cm H_2O, as lung injury progresses and hypoxemia worsens, PEEP may be increased to increase mean plateau pressures and aid in recruitment. These strategies generally recommend keeping mean plateau pressure less than 30 to 35 cm H_2O. These strategies have yet to show a decrease in mortality, but have shown improvement in secondary outcomes.[301] More precise methods of determining optimal PEEP in patients with ARDS, include titration using dynamic compliance or static pressure-volume loops to identifying the critical opening pressure. Other methods to determine optimal PEEP in a patient with ARDS include titration with dynamic compliance or static pressure-volume curve. It is important to remember that as PEEP is increased and lung is recruited, intrathoracic pressure is also increased and may inhibit cardiac output by reducing venous return. Therefore, despite an improvement in oxygenation, oxygen delivery to vital organs may be compromised.

PLATEAU AIRWAY PRESSURES

Sustained plateau airway pressures greater than 35 cm H_2O can lead to barotrauma: pneumothorax, pneumomediastinum, and subcutaneous emphysema. In an attempt to limit barotrauma, $Paco_2$ is allowed to increase in the face of inadequate minute ventilation. This permissible hypercapnia can be used as long as the patient tolerates the acidosis and is able to buffer with the renal retention of HCO_3 and there are no contraindications from coexisting disease.

PARTIAL VENTILATORY SUPPORT

By avoiding neuromuscular blockade and paralysis of the muscles of the diaphragm, spontaneous ventilation can occur during mechanical ventilation. Partial ventilatory support can lead to improved alveolar recruitment and ventilation/perfusion ratio (V/Q) mismatch, improved venous return and cardiac output, and enhanced weaning from mechanical ventilation. Avoidance of neuromuscular blockade can also lead to decreased needs for sedation.

ADJUVANT THERAPIES FOR ACUTE RESPIRATORY DISTRESS SYNDROME

Prone Positioning

Prone positioning can improve oxygenation in patients with ARDS, and it has been applied safely in pediatric patients (see also Chapter 41). Prone positioning improves lung recruitment in select patients. Patient selection and duration of prone positioning is unclear; however, it is likely that a subgroup of patients responds to prone positioning early after lung injury, and immediate responders may benefit from a prolonged prone positioning.[302] In adults Guerin and colleagues[303] performed a multicenter prospective randomized control trial of patients with severe ARDS (PROSEVA) which showed that early administration of prone positioning (after stabilization of 12 to 24 hours) sessions for several hours per day (16 consecutive hours) for up to 28 days significantly decreased 28- and 90-day mortality.[303] While prone positioning improves oxygenation, a change in mortality has not been shown in pediatrics. In pediatric patients with brain injury and worsening hypoxemia, prone positioning can be attempted with careful monitoring of ICP.[304,305]

Surfactant Therapy

Exogenous surfactant therapy is the standard of care in neonates suffering from respiratory distress syndrome (RDS); however, the utility of surfactant therapy in the treatment of ALI and ARDS is uncertain. An immediate improvement in oxygenation and a trend toward improved survival occurred with exogenous surfactant therapy, calfactant; however, in a recent randomized control trial, Willson and coworkers[306] found that surfactant did not improve outcomes relative to placebo administration.[306] Clinicians still feel that there may be a specific pediatric patient population (i.e., near drowning victims) that may benefit from exogenous surfactant administration, and research is being performed to determine patient selection, timing, and the combinations with other therapies for treatment of ALI/ARDS.

Nitric Oxide

Inhaled nitric oxide (iNO) acts as a selective pulmonary vasodilator to improve V/Q mismatch, decrease pulmonary hypertension, and reduce right ventricular cardiac work (see also Chapter 104). NO upregulates cGMP, ultimately resulting in smooth muscle relaxation and pulmonary arteriolar vasodilatation. iNO is delivered directly to ventilated lung units and improves perfusion in these areas of lung without significant effects on the rest of the pulmonary vascular bed, thereby improving V/Q mismatch and oxygenation in patients with ARDS. Much like prone positioning and surfactant therapy, NO can result in transient improvements in oxygenation. A systemic review and meta-analysis performed by Adhikari and coworkers[306a] reveals that iNO does not reduce mortality in adult patients with ARDS, regardless of severity of illness. In pediatrics, a small, randomized trial by Bronicki and colleagues showed that pediatric patients with ARDS randomized to receive iNO had significantly improved survival, ECMO free survival, and ventilator-free days at 28 days. This trial was small, but it encourages further study in the pediatric population and continues to be the main adjuvant therapy at many major pediatric centers (Bronicki and colleagues, manuscript in preparation).

Extracorporeal Membrane Oxygenation

ECMO remains a rescue strategy for pediatric patients with ARDS who fail to respond to advanced modes of mechanical ventilation. Brodie and associates[307] suggest that in adults with ARDS, ECMO criteria: (1) should be considered when P/F ratio is less than 150, (2) are indicated when P/F ratio is less than 80, (3) should be considered if $Paco_2$ is greater than 80 mm Hg, and (4) should be considered if the end-expiratory plateau pressure is greater than 30 cm H_2O.[307] The CESAR Trial in adults demonstrated improved outcomes in adults treated with ECMO; however, this trial had significant methodological flaws.[308] Currently, there is an ongoing trial in adults that randomizes patients to ECMO or standardized ventilation protocols: ECMO to rescue lung injury in severe ARDS (EOLIA; clinicaltrials.gov identifier: NCT01470703).[309] It is unclear at this time whether ECMO improves outcomes in pediatric patients with ARDS; however, with the increasing use of bicaval dual lumen venovenous cannulas, research is underway to define patient population, timing, and adjuvant therapies.[310]

ADJUNCTIVE PHARMACOLOGIC THERAPY: SEDATIVES AND ANALGESICS

Sedation is often required to help conscious children cooperate with mechanical ventilation. The amount of sedation required depends on the child's age, size, underlying disease, and amount of respiratory support needed. Some infants are sufficiently depressed and require no sedation. Sedation allows patients to breathe "in phase" with the ventilator, which reduces the peak airway pressure and eliminates coughing and straining, all of which can cause

pulmonary gas leaks. A continuous infusion of fentanyl (1 to 2 μg/kg/hr) provides pain relief and sedation. However, the infusion rate of fentanyl on subsequent days may need to be increased to maintain the same level of sedation.[94] Other drugs, such as lorazepam (0.1 to 0.2 mg/kg administered intravenously every 4 to 6 hours) or an infusion of midazolam (0.05 to 0.2 mg/kg/hr), can be useful adjuncts to opioid administration. These drugs usually have minimal cardiovascular effects if intravascular volume is adequate.[95] However, administering lorazepam to premature neonates for several days can cause steroid-responsive hypotension because of buildup of drug in the body. The half-life of lorazepam is approximately 72 hours in premature infants. Giving the drug every 4 to 6 hours causes accumulation of the drug in blood and tissues.

Neuromuscular blocking drugs (see also Chapter 34) increase chest wall compliance, reduce oxygen consumption,[311] and facilitate mechanical ventilation. If neuromuscular blocking drugs are used, they should be administered in conjunction with medications that cause amnesia and anxiolysis and control pain.

Pancuronium and vecuronium are the most commonly administered muscle relaxants used in the PICU. The usual dose of pancuronium is 0.1 mg/kg administered intravenously every 1 to 2 hours or 40 to 100 μg/kg/hr as an infusion. The tachycardia associated with pancuronium is an undesired side effect in adults, but it is generally desirable in infants and children because it helps to maintain cardiac output. Vecuronium (0.08 to 0.2 mg/kg, followed by an infusion of 60 to 150 μg/kg/hr) produces less tachycardia than pancuronium does. Cisatracurium (0.1 to 0.2 mg/kg followed by an infusion of 60 to 120 μg/kg/hr) is often useful because its elimination is not dependent on renal or hepatic function. If these drugs are given for more than 1 day, provision of regular drug holidays should be considered to avoid serum buildup of the drug and prolonged paralysis.

WEANING FROM MECHANICAL VENTILATION

The pediatric literature falls behind adult publications in regard to guidance in tracheal extubation and weaning from mechanical ventilation. A 2009 review by Newth and associates[312] addressed what was known at the time. Attempts have been made to develop predictive indices identifying which children can be successfully weaned from mechanical ventilation. Most of the indices are used in research but do have clinical applications, such as the Rapid Shallow Breathing Index (RSBI) from Yang and Tobin.[313] The RSBI is equal to the respiratory rate/tidal volume ratio. When patients are breathing comfortably, they have a slower respiratory rate with larger tidal volumes. In this circumstance, the RSBI is a low number. Furthermore, patients with respiratory distress tend to breathe more rapidly with smaller tidal volumes, hence a higher RSBI. There are several different techniques for weaning from mechanical ventilation. These techniques include slowing the set ventilator rate over time, performing a daily spontaneous breathing trial, or increasing pressure support or CPAP sprints.[314] The ideal mechanism of weaning is not yet clear, but weaning protocols will likely reduce time on mechanical ventilation.[315] Currently, the best solution seems to be to ask on a daily basis whether the patient is able to be extubated tracheally. More frequent evaluation leads to detecting more patients who are ready for extubation.[316]

However, there is an anticipated extubation failure rate. If mechanical ventilation is continued until we are absolutely certain a patient will not fail, many patients will be ventilated longer than necessary. A 2003 review[317] of 16 ICUs showed an extubation failure rate of 6.2% (range, 1.5% to 8.8%) for patients requiring mechanical ventilation longer than 48 hours. Many hospitals are initiating daily spontaneous breathing trials (SBTs) for their patients. These are periods of decreased ventilatory support while the patient is observed for evidence of respiratory distress. The decreased support can be pressure support, CPAP, or T-piece ventilation. Patients are observed to see that there is no significant increase in respiratory rate, decrease in saturations, diaphoresis, hemodynamic compromise, or evidence of increased work of breathing. The successful completion of an SBT will initiate plans for extubation. Depending on the ICU, SBTs are performed under direction of the physicians, or they can be performed independently by the respiratory therapist.

Regarding the degree of decreased ventilatory support during an SBT, the use of CPAP does not put patients under increased stress. The work of Manczur and associates,[318] Willis and associates,[256] and Hammer and associates[319] demonstrate that infants or children with smaller ETTs are not "breathing through a straw" when administered by CPAP or T-piece. Relative to an adult, the ETT may be smaller in diameter, but it is also shorter and the inspiratory flow rate in infants is low compared to an adult. Flow rates are measured to be approximately 0.5 L/kg/min.[320] Therefore, a 3-kg infant has a flow velocity of 1.5 L/min, and a 60-kg adult has a flow velocity of 30 L/min. If patients are unable to successfully complete the SBT, then it is possible that they would not manage the work of breathing after extubation of the trachea.

Overall, the criteria for extubation readiness include intact airway reflexes, hemodynamic stability, manageable secretions, and an appropriate level of alertness. The amount of negative inspiratory force (NIF) the patient can generate can be measured. NIF should be measured with a calibrated manometer and inspiration from residual volume. Typically, NIF of –30 or greater is associated with extubation success. The presence of a leak around the ETT may be supportive of extubation; however, there is research showing the absence of a leak around the ETT does not predict extubation failure.[321,322] Extubation failure is typically defined as reintubation less than 24 hours after a scheduled extubation attempt. Extubation failure can be caused by a multitude of reasons, but a large category is postextubation upper airway obstruction. In a 2003 study,[317] upper airway obstruction was the stated cause of extubation failure in 37% of patients. Unfortunately, there is significant interobserver variability[267] in the clinical assessment of upper airway obstruction that may be limiting research. Objective measures of airway obstruction may be necessary before there is a definitive answer as to which therapies reduce subglottic narrowing and reduce obstruction.

RESPIRATORY DISORDERS

Laryngotracheobronchitis (Croup)

Croup occurs most frequently in the 3-month-old to 3-year-old age group. Croup is a viral infection (parainfluenza, influenza, adenovirus) that causes edema of the tissues in the upper airway, particularly in the immediate subglottic region. There is usually a history of a few days of upper respiratory tract infection symptoms followed by hoarseness, a croupy cough, and possibly stridor. The degree of respiratory distress and the child's ability to compensate for the increased work of breathing are best assessed clinically. These patients are initially treated with mist and aerosolized racemic epinephrine to reduce swelling of upper airway mucosa.[323] Steroid administration is common yet controversial.[77] Tracheal intubation is required when the child can no longer sustain the increased work of breathing and CO_2 increases. When the trachea is intubated, the ETT should be 0.5 to 1.0 mm smaller than usual for age. The ETT must be of sufficient size that the patient can breathe easily during spontaneous ventilation and the nurses can effectively suction secretions from the airways. Croup usually resolves spontaneously in 3 to 7 days. The average duration of tracheal intubation is approximately 5 days. Laryngotracheobronchitis is less common in children older than 4 years.

Epiglottitis

Epiglottitis is an inflammation of the mucosa of the supraglottic structures that was previously caused by *Haemophilus influenzae* type B, but is now commonly caused by *Staphylococcus aureus* and streptococcal organisms because immunization against the *Haemophilus* organism has been so effective. In the past, epiglottitis was a disease of 4- to 6-year-old children. Now, it occurs more commonly at older ages (even in adults).[324] In young children, epiglottitis is a true airway emergency because it can progress rapidly to complete and fatal airway obstruction. Providing a secure airway is the first priority. Children with epiglottitis appear toxic and have a fulminant onset of fever and respiratory distress. Tracheal intubation is commonly required until antibiotic therapy (ampicillin and chloramphenicol or ceftriaxone) is initiated and the signs of systemic toxicity subside. Introduction of the *H. influenzae* vaccine has dramatically decreased the incidence of *H. influenzae* infection, as well as that of other *H. influenzae* processes.[111]

Bronchiolitis

Bronchiolitis is an acute viral infection of the lower respiratory tract that occurs primarily during the first 2 years of life. The signs and symptoms of this malady are air trapping, wheezing, mild to moderate systemic hypoxemia, increased work of breathing, and increased airway resistance. The cause is usually an infection with respiratory syncytial virus (RSV).[325] Patients at high risk for respiratory failure from this disease include infants and young children with a history of prematurity, chronic lung disease, or congenital heart disease. Apnea is frequently the first sign of decompensation in neonates, which often occurs before significant hypercapnia appears. Fatigue is a common indication for mechanical ventilation. Treatment is primarily supportive and includes endotracheal intubation and mechanical ventilation for respiratory failure.[326] Palivizumab (Synagis [MedImmune, Gaithersburg, MD] is a monoclonal antibody administered to patients at risk for seasonal RSV disease (premature infants, infants with congenital heart disease, immunosuppressed patients, or those with multiple congenital anomalies); it has dramatically decreased the incidence of illness in this population. Ribavirin is a virostatic drug available for the treatment of children with RSV and congenital heart disease, immunosuppressive disease, or multiple congenital anomalies.

Cystic Fibrosis

Cystic fibrosis is a fatal autosomal recessive disease carried on chromosome 7. Although it affects the pancreatic, hepatic, pulmonary, GI tract, and reproductive systems, 90% of the reported morbidity and mortality is pulmonary. The pulmonary pathology consists of severe airway obstruction, bronchiectasis, emphysema, and terminal respiratory failure.

Survival of patients with cystic fibrosis has improved dramatically over the past 30 years. More than one third of patients survive to older than 30 years of age.[123] This change is the result of improved antibiotic therapy, nutritional support, and aggressive treatment of complications. Lung transplantation has been performed in patients with chronic respiratory failure with varied success.[327,328]

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia is a form of chronic lung disease that occurs in patients who have survived severe neonatal lung disease. The cause of this disease is uncertain, but usually patients were born premature, had hyaline membrane disease, and required prolonged and aggressive respiratory support with high inflating and distending pressure and high oxygen concentrations. Inflammation appears to be an important component of this disease.[329] Children with BPD have decreased dynamic compliance, increased airway resistance, increased physiologic dead space, and markedly increased work of breathing. The lungs are hyperinflated, and there are intercostal retractions, nasal flaring, and wheezing. Chest radiographs demonstrate large lung volumes and fibrosis as well as cystic and atelectatic areas. Hypercapnia and hypoxia are present to varying degrees.[330,331] Therapy for BPD includes providing sufficient calories to meet the higher energy expenditure required for the increased work of breathing. Respiratory support (mechanical ventilation, CPAP) is required for some patients. Diuretics and bronchodilators are frequently used and may be associated with electrolyte abnormalities. Most long-term survivors have subjectively normal pulmonary function; however, some survivors have severe chronic physiologic changes.[332,333] During the first years of life, viral or bacterial pulmonary infections often increase the need for respiratory support; these infections may prove to be fatal. Great effort is being made to prevent BPD. Because the trauma of mechanical ventilation on an immature lung is thought to be the major cause of BPD, alternative

modes of ventilatory support are being evaluated, including exogenous surfactant, high-frequency ventilation (especially HFOV),[334] ECMO, and liquid ventilation.[330,335]

Sleep Apnea

Normal ventilation during sleep requires normal upper airway anatomy and normal intact reflexes. The latter include central responses to hypercapnia and hypoxia, response to airway irritation, and dynamic phasic contraction of the pharyngeal and hypopharyngeal muscles. Sleep apnea usually occurs when one or more of these protective responses are abnormal. In infancy, sleep apnea is relatively common. Numerous causes have been postulated, the most attractive of which is immaturity of the medullary chemoreceptors. Patients with Ondine's curse, the most severe form of central apnea, have complete apnea when asleep. Lesser breathing disorders may be present during sleep in patients with sudden infant death syndrome. Treatment of sleep apnea consists of respiratory stimulants (theophylline), cardiorespiratory monitoring during sleep, and in some severe cases, tracheotomy and nighttime mechanical ventilation.[132] Obstructive sleep apnea occurs in all pediatric age groups. It may be associated with an identifiable anatomic disorder, such as enlarged tonsils and adenoids, Pierre Robin syndrome, and tracheal and laryngeal malacia. Signs and symptoms of obstructive sleep apnea include loud snoring, obstructive episodes with frequent arousal, behavior disorders caused by sleep deprivation, and cor pulmonale. The diagnosis is made with the history, electrocardiogram, and formal sleep studies. Bronchoscopy can also be helpful in defining the problem. In young children, an enlarged liver might suggest that the child has pulmonary hypertension. Treatment of sleep apnea includes removal or bypass of an obstruction. Although tonsillectomy and adenoidectomy can improve the airway, there may still be significant airway obstruction for the first few days after surgery. Tracheostomy is rarely required in these children.

Foreign Body Aspiration

Foreign body aspiration is a relatively common and often catastrophic event in children. Although it can occur at any age, the peak incidence of foreign body aspiration occurs at 6 months to 3 years of age. Vegetable matter (e.g., peanuts), other foodstuff (e.g., hot dogs), coins, and small pieces of toys are the most commonly aspirated material. Many of these objects are radiolucent. The symptoms of aspiration are related to the location of the foreign body within the airway and the time since the object was aspirated. Acute symptoms can include total airway obstruction, stridor, wheezing, or acute onset of coughing. Chronic symptoms include bloody sputum and chronic cough. Wheezing can occur as a chronic symptom as well as acute. The diagnosis of a foreign body in the airway is made from the history and physical examination and, in some cases, by radiologic imaging. The efficacy and safety of abdominal thrusts have been questioned. The Heimlich maneuver and back slaps are reserved for acute upper airway obstruction with no air movement. Treatment of less acute or lower airway foreign body aspiration includes bronchoscopy, postural drainage, chest physical therapy, bronchodilators, and surgical removal of the object.[336]

Upper Airway Obstruction and Meningomyelocele

Vocal cord paralysis is a common result of several disorders, including brainstem abnormalities and myelodysplasia. Children with meningomyelocele usually have an Arnold-Chiari malformation and may have stridor. This lesion allows caudal displacement of the medulla, stretching of the cranial nerve tracts, and abnormal arterial architecture of the brainstem. Vocal cord paralysis can result from pressure on the brainstem (i.e., with hydrocephalus) or from focal infarcts of the brainstem. Treatment of these brainstem abnormalities includes relief of the hydrocephalus and, if the paralysis persists, cervical decompression of the Arnold-Chiari lesion. Despite these surgical procedures, some children require a tracheotomy and long-term mechanical ventilation.

ASTHMA

The prevalence of childhood asthma is increasing over time. Estimates from the Centers for Disease Control and Prevention placed the percentage of children with asthma at 3.6% in 1980, 5.8% in 2003, and 9.5% in 2011 (www.cdc.gov/nchs/fastats/asthma.htm). Thankfully, the majority of children with asthma will never require intensive care. However, for the children who do, there can be significant morbidity and a risk of mortality. In a 2012 study by Newth and associates[337] of fatal and near-fatal asthma in an ICU setting, 12% of patients had complications and the mortality was 4%. Cardiac arrest before admission occurred in 10 of the 11 patients who died. For the purposes of this section, *critical asthma* is defined as an asthma exacerbation requiring ICU admission.

Asthma is a disease of inflammation. There is infiltration of the submucosal area of the airways with mast cells, eosinophils, and CD4 lymphocytes. Degranulation of mast cells releases leukotrienes and histamine (causing edema), increases in mucus production, and chemotaxis of white blood cells. Multiple factors can trigger asthma attacks and degranulations of mast cells. Such factors include allergens, infections (viral more than bacterial), changes in the weather, and strong emotions. Inflammation increases irritability of the airway as well as airway hyperresponsiveness. The airway lumen is decreased by spasm of the bronchial muscles, edema and mucus. Decreases in the airway lumen significantly increase airway resistance. For laminar airflow, airway resistance is related to the third power of the radius, but with turbulent airflow it is related to the fourth power. Because of the smaller lumen of their airways, children experience much greater changes in airway resistance during asthma attacks than adults do. Because of resistance in exhalation, an expiratory wheeze is typically noted. Bronchospasm, edema, or mucus plugging can lead to complete obstruction of small airways. Hypoxemia occurs because of a mismatch in ventilation and perfusion. Airway dead space is increased by obstruction of the airways. To maintain ventilation, the respiratory rate is typically increased. In turn, the initial $Paco_2$ is usually low. Respiratory fatigue or impending failure may be identified by a normal or elevated $Paco_2$.

Asthma can occur without wheezing, which is the sound that is produced when there is obstruction to airflow. Wheezing can be caused by pneumonia, upper airway obstruction, foreign body aspiration, or CHF and each requires different therapy. A sudden onset of wheezing in a toddler should prompt evaluation for foreign body aspiration. The history should be addressed for recent choking or coughing episodes. Even the presence of a history of reactive airways or atopy does not rule out aspiration. A high index of suspicion should be maintained. Intermittently a chest radiograph obtained for a child who is wheezing shows cardiomegaly rather than peribronchial cuffing. Asthma is statistically more likely, but this can be the presentation of heart failure. A chest radiograph is warranted for any patient with their first presentation of wheezing, and certainly for any child who is admitted to the ICU for wheezing. Severe asthma exacerbations can occur without wheezing, as the movement of air is required to hear wheezing. It is possible for a patient to have significant airflow restrictions that do not produce audible wheezing. Patients with a quiet chest or limited airflow on auscultation require immediate action.

Children with an asthma exacerbation may have a few days of upper respiratory infection symptoms followed by increased work of breathing. The patient may have low room air oxygen saturations. The patient's position of comfort may be sitting up to support their muscles of respiration. Accessory muscle use is noted. There is a prolonged expiratory phase on auscultation. In an effort to increase airway pressure, some children may be breathing out with pursed lips, or grunting may be noted in smaller children. The child might not be able to speak more than one- or two-word phrases. Therapy should be started immediately, first with supplemental oxygen to address hypoxemia. If the child is in mild respiratory distress, nasal cannula oxygen may be sufficient. If the child has moderate or severe respiratory distress, oxygen should be delivered by either facemask or nonrebreather facemask. Inhaled β-agonists, such as albuterol, are given to relax bronchial smooth muscles. Intravenous or subcutaneous terbutaline or epinephrine may be required if there is not enough air movement to deliver inhaled medications. Steroids should be given early because their effect will take some time. If there is limited improvement with initial therapy, arrangements should be made for ICU admission. Many emergency departments will attempt to obtain ABGs; however, the clinical picture alone may provide enough information to guide therapy.

Asthma Therapy

Supplemental Oxygen. Oxygen can be delivered with a standard nasal cannula, but the fraction of inspired oxygen (Fio_2) is limited. Standard nasal cannula might provide up to 40% Fio_2. Increasing the flow of oxygen with a standard cannula larger than 4 to 5 L/min is not usually tolerated. A simple facemask might increase the Fio_2 to 50%. A tightly sealed nonrebreather facemasks might be able to provide Fio_2 closer to 1. Providing oxygen with a high-flow humidified nasal cannula (HFHNC) may provide nearly complete humidification of the airway gases and the Fio_2 also approaches 1. A study in 2014 by Rubin and associates[259] demonstrated a decrease in effort of breathing in patients receiving HFHNC. The mechanism of its effect is not elucidated. Some clinicians have begun using HFHNC as a mechanism for delivery of β-agonists or other aerosolized medications, but there are no data to support its use.

Inhaled β-Agonists. Inhaled β-agonists are used to relax bronchial smooth muscles. The most commonly used β-agonists is albuterol, which is a racemic mixture of the active R and inactive S enantiomer. Levalbuterol, the active R enantiomer, is available as a separate preparation, but recent studies have not shown it to be more effective[338] or to have less elevations in heart rate.[339] Albuterol is β_2 selective and comes as a metered-dose inhaler or solution for nebulization. For initial therapy in the ICU, continuous albuterol is preferred, and the usual dose is 0.15 to 0.5 mg/kg/hr or 10 to 20 mg/hr. After improvement in air movement with decreased respiratory distress, intermittent doses can be given every 1 to 2 hours. Terbutaline as an inhaled medication is less β_2 selective compared with albuterol and therefore is used less commonly. Terbutaline remains as an important intravenous medication. Tachycardia is commonly associated with albuterol use. At times, it is unclear whether the elevated heart rate is related to toxicity of medications or to ongoing respiratory distress. Arrhythmias may be seen with albuterol use, but this is usually just an increased frequency of premature ventricular contractions. Diastolic hypotension is observed with larger doses of albuterol, although this can be related to decreased intravascular volume and increased intrathoracic pressure. Agitation and tremors can be seen with CNS stimulation. Hypokalemia may be noted as the β-adrenergic agonists drive potassium into cells. Ipratropium bromide, an inhaled anticholinergic, is sometimes paired with intermittent albuterol doses. Ipratropium bromide has the benefit of promoting bronchodilation without decreasing mucociliary clearance.

Corticosteroids. Intravenous steroids are preferred to oral dosing in the ICU because of the possibility of decreased absorption or delayed onset. Methylprednisolone is commonly used because of its limited mineralocorticoid effects. The initial dose is 2 mg/kg and then 0.5 to 1 mg/kg every 6 hours. There may be regional preference for dexamethasone or hydrocortisone. Steroids are typically given for the duration of the acute asthma phase. If steroids are given for 5 days or less, they are not usually tapered. Systemic steroid use is associated with hyperglycemia, hypertension, and occasional agitation. During initial ICU care, inhaled steroids are of no benefit.

Intravenous Fluids. Children admitted to the ICU with critical asthma will likely be dehydrated from limited oral intake during their illness and increased insensible losses from the higher respiratory rate. The patient's circulating volume should be supported with fluid boluses if needed. However, excessive fluids should be avoided, because this could lead to pulmonary edema. Pulmonary edema could worsen both oxygenation and airway resistance. Fluid boluses may also be needed for children whose respiratory distress progresses require mechanical ventilation. Hypotension often occurs during intubation of the trachea.

Intravenous and Subcutaneous β-adrenergic Agonists. A significant decrease in air exchange can result in poor delivery of inhaled medications, and intravenous β-agonists may be required. Terbutaline is often the first choice and relatively β_2 selective as compared to isoproterenol and epinephrine. Terbutaline can be given subcutaneously for children without intravenous access as a dose of 0.01 mg/kg up to a maximum of 0.3 mg. Intravenous terbutaline at a dose of 10 μg/kg over 10 to 20 minutes is followed by a continuous infusion of terbutaline in a range of 0.1 to 10 μg/kg/min. The infusion can be titrated to effect. Subcutaneous epinephrine may be given for severe asthma exacerbation with limited intravenous access with a dose of 0.01 mg/kg of to the 1:1000 solution with a maximum dose of 0.5 mg. Absorption of the drug may be limited by poor perfusion to extremities. Intravenous epinephrine may be an ideal drug for mechanically ventilated patients with hypotension. The use of isoproterenol in critical asthma has decreased over time.

Methylxanthines. There is regional variation in the use of the methylxanthine aminophylline in place of intravenous terbutaline as a second line drug for critical asthma. Fewer children with asthma are admitted to the ICU with methylxanthine as a chronic medication. There are improved controller medications including the leukotriene inhibitors; therefore, fewer children are receiving oral theophylline. The methylxanthines promote bronchial smooth muscle relaxation, but the exact mechanism of action is not known. Intravenous aminophylline is loaded at a dose of 5 to 7 mg/kg over 30 minutes followed by a continuous infusion in the range of 0.5 to 0.9 mg/kg/hr. If the patient has taken oral theophylline in the past 24 hours, the loading dose is reduced by 50% or the aminophylline dosing is adjusted based on a serum theophylline level. In general, an aminophylline loading dose of 1 mg/kg will raise the serum theophylline level by 2 μg/mL. The target range for serum theophylline in acute asthma is 10 to 20 μg/mL. Theophylline has a very narrow therapeutic window. Theophylline levels higher than 20 μg/mL are associated with nausea, tachycardia, restlessness, or irritability. Higher theophylline levels can cause seizure activity.

Magnesium. Magnesium can be given as an inhaled or intravenous medication to relax bronchial muscles. Smooth muscle relaxation occurs because of magnesium's effect as a calcium channel blocker. Results from the 2013 Magnesium Trial in Children[340] indicate nebulized magnesium may be beneficial in an acute severe asthma exacerbation. Intravenous magnesium may also be beneficial in severe asthma.[341,342] As there is still regional variation to magnesium, at the least a magnesium level should be checked with the initial set of electrolytes, and hypomagnesemia should be treated. The dose for critical asthma and hypomagnesemia can be the same 25 to 45 mg/kg given over 30 minutes. Magnesium toxicity can include muscle weakness, cardiac arrhythmias, decreased reflexes, and respiratory depression.

Helium. Mixtures of helium and oxygen (heliox) can be used to improve laminar gas flow. This occurs because of the decreased density of helium as compared with nitrogen (approximately 1/7). For helium to be beneficial in small airways, it must occur in a high ratio with oxygen. The most benefit may be seen with an 80:20 or 70:30 ratio of helium to oxygen; therefore, hypoxemia and the need for increased supplemental oxygen may limit heliox use. Heliox can be used to deliver inhaled β_2 agonists.[343] As with other advanced therapy, helium might not have a role in routine care, but there may be benefit from its use in severe critical asthma.

Ketamine. Ketamine is a noncompetitive *N*-methyl-D-aspartate receptor antagonist that can produce a state of dissociative anesthesia. An additional effect of ketamine is bronchodilation; it is a useful medication for sedation in the ICU because it has a limited effect on the respiratory drive. In usual doses, hemodynamics are not usually affected. For patients with asthma whose tracheas are intubated and mechanically ventilated, ketamine may be a good choice for sedation along with a benzodiazepine. Furthermore, one pediatric study[344] showed an improvement in the PaO_2/FiO_2 ratio as well as dynamic compliance in mechanically ventilated children with refractory bronchospasm who were receiving a continuous infusion of ketamine. There has been no study to show whether ketamine used to treat anxiety is beneficial in preventing intubation in patients during an asthma attack. For nontracheally intubated patients, a recent Cochrane Database Review[345] did not show significant benefit in severe acute asthma. If a decision is made to use ketamine for a procedure or a means of sedation, the bolus dose is usually 1 mg/kg, allowing time for effect before repeating. Ketamine is given as a continuous infusion at the dose of 5 to 30 μg/kg/min titrated to effect. One of the additional side effects of ketamine can be dysphoria, and as such, it is usually given with a benzodiazepine.

Noninvasive Ventilation. There is limited evidence that noninvasive ventilation is effective in children with asthma.[272] Clinically, patients with effective air exchange and who fight the mask and positive pressure do not benefit from noninvasive ventilation. Nevertheless, some children with limited air exchange and fatigue take to noninvasive ventilation easily and appear more comfortable. Noninvasive ventilation can allow time for therapies to become effective (steroids) and can reduce the need for intubation. It should not be used when the level of alertness or ability to protect the airway is diminished.

Intubation of the Trachea. By the time patients with asthma require endotracheal intubation and mechanical ventilation, they are hypoxemic, acidotic, and fatigued, and they have limited reserve. The most experienced person available should perform the intubation of the trachea procedure. Appropriate venous access is required and intravenously administered fluid boluses may be necessary. Ketamine and a benzodiazepine can be used. Ketamine can produce increased secretions; therefore, atropine should be considered. Ketamine can also produce dysphoria; therefore, the benzodiazepine is given for its amnestic effects. The management style in the authors' ICU is to get the patient back to breathing spontaneously

or initiating their own breathing as soon as possible after intubation. In turn, rocuronium can be considered as a medium short-acting muscle relaxant. Succinylcholine can be used, but the other side effects of this medication, including hyperkalemia, should be considered. A cuffed ETT is recommended because ventilator settings may require high peak pressures. Immediately after intubation, adequate ventilation should be achieved with a slow respiratory rate to prevent alveolar overdistention and to reduce the risk of pneumothorax. There can be acute decompensation following intubation. Hypovolemia and increased intrathoracic pressures may be an issue. Following the DOPE acronym, one should also look for *displacement* or *obstruction* of the endotracheal tube and rule out *pneumothorax* or *equipment* failure.

Mechanical Ventilation (Also see Chapter 103). There can be controversy regarding the best means for mechanical ventilation for patients with asthma (see also Chapter 103). The argument against setting the ventilator in a pressure control mode is that changes in airway resistance that occur with asthma can result in delivery of an inadequate tidal volume. The argument against the ventilator in a volume control mode is that due to flow patterns of the ventilator the same tidal volume can be delivered with a higher peak pressure as compared to a pressure control mode. As stated previously, the authors' management style is to get intubated asthmatics breathing spontaneously as soon as possible. This allows them to set their own breathing rate, and on pressure support and PEEP they can set their own inspiratory-to-expiratory ratio. Pressure support has been recommended because it is patient initiated, even if not patient limited.[346] There may be initial elevations in $Paco_2$, but the carbon dioxide elevation is usually will tolerated if the patient is well oxygenated.

Historically, clinicians set zero or low PEEP for intubated asthmatics because of the perceived risk of hyperinflation[347] and barotrauma. However, since 1988 there have been four adult studies[348-351] and one pediatric study[257] strongly suggesting the benefits of extrinsic PEEP during mechanical ventilation for intubated asthmatics. These studies demonstrated that extrinsic PEEP, up to a level to matching intrinsic PEEP, improves the triggering sensitivity of the ventilator, diminishes ventilatory work, and reduces mechanical work of breathing for patients spontaneously breathing with assisted ventilation. As the work of breathing is reduced, there is improved patient comfort and potentially a reduced need for sedation. Matching extrinsic PEEP applied with the ventilator to the intrinsic PEEP developed by the patient with asthma may improve delivery of aerosol therapy via the ETT. Matching PEEP can possibly result in earlier liberation from mechanical ventilation. It should be noted that some clinicians believe that attempts to match PEEP may include the risk that extrinsic PEEP will cause overdistention of the lungs. Overdistention of the lungs can increase the risk of hyperinflation and air leak syndrome.[347] Spontaneous breathing with pressure support and PEEP lowers WOB.[256,257] For the individual patient, the level of extrinsic PEEP at which hyperinflation will occur is unknown. Theoretically, for the spontaneously breathing patient, extrinsic PEEP applied to counteract intrinsic PEEP should not cause an increase in end-expiratory lung volume until extrinsic PEEP exceeds intrinsic PEEP.[352] Furthermore, the end-expiratory lung volume can even decrease, leading to decreased dead space and increased compliance. In the authors' ICU, intrinsic PEEP is measured during a ventilator pause, allowing the patient to exhale completely and measuring the pressure before the next breath. Extrinsic PEEP is added gradually with the ventilator, and respiratory rate and clinical work of breathing are observed. Extrinsic PEEP is maintained at a level below intrinsic PEEP, extrinsic and intrinsic PEEP are reassessed continually as the patient responds to therapy. Further research is needed to determine the best practice of mechanical ventilation for intubated asthmatics, but this is limited by the small number requiring intubation each year.

Inhaled Anesthetics. One of the properties of inhaled anesthetics is bronchodilation. In turn, inhaled anesthetics have been used as rescue therapy in children with critical asthma who are intubated. Isoflurane has been used in the authors' ICU for its reduction in bronchospasm with the added benefit of a decreased sedation requirement. However, inhaled anesthetics are difficult to use in an ICU setting. Modern ICU ventilators are not designed to accept a vaporizer. There is no circle system in ICU ventilators, so there is a tremendous use of anesthetic vapor. There is no primary means of gas scavenging in an ICU ventilator; therefore, significant steps must be taken to avoid contamination of the patient's room. A case series of six patients was reported by Wheeler and colleagues,[353] and Tobias[354-356] has published several articles detailing the use of inhaled anesthetics in asthma and other clinical conditions. A recent retrospective cohort study by Char and associates[357] in intubated asthmatics did not demonstrate a difference in mortality between centers that did or did not use inhaled anesthetics. There was significantly greater length of mechanical ventilation, length of stay, and hospital charges in the centers using inhaled anesthetics. The significant expertise needed to deliver inhaled anesthetics safely can limit its use to a few centers. An anesthetic-conserving device (AnaConDa; Sedana Medical, Uppsala, Sweden) is available in Europe, but not the United States. The device is a miniature vaporizer and a conserving medium or reflective filter that keeps the inhaled anesthetic on the patient side of the device. This device can be used with a normal ventilator. Finally, as the scientific community learns more about the potential neurotoxicity with inhaled anesthetics, the physician must weigh the risk-and-benefit profile of long-term inhalational anesthetics for the management of status asthmaticus.

Extracorporeal Life Support for Status Asthmaticus. Extracorporeal life support (ECLS) has been used as a rescue therapy in near fatal asthma. As with inhaled anesthetics, the use of ECLS for this indication is likely limited to a small number of centers. One single center study reports[25] their use, but the number of patients (n = 13) is too small to determine whether this therapy has advantages over mechanical ventilation or conventional therapy.

TABLE 95-7 **NORMAL AGES FOR MAJOR DEVELOPMENTAL MILESTONES**

Age	Motor Function	Language	Adaptive Behavior
4-6 wk	Lifts head from prone position and turns from side to side	Cries	Smiles
4 mo	Shows no head lag when pulled to sitting from supine position; tries to grasp large objects	Utters sounds of pleasure	Smiles, laughs aloud, and shows pleasure from familiar objects or persons
5 mo	Grasps voluntarily with both hands; plays with toes	Makes primitive sounds	Smiles at self in mirror (ah, goo)
6 mo	Grasps with one hand; rolls prone to supine; sits with support	His increased range of sounds	Expresses displeasure and food preferences
8 mo	Sits without support; transfers objects from hand to hand; rolls supine to prone	Combines syllables (baba, dada, mama)	Responds to "No"
10 mo	Sits well; crawls; stands holding; finger-thumb apposition in picking up small objects		Waves goodbye; plays patty-cake and peek-a-boo
12 mo	Stands holding; walks with support	Says two or three words with meaning	Understands names of objects; shows interest in pictures
15 mo	Walks alone	Utters several intelligible words	Requests by pointing; imitates
18 mo	Walks up and down stairs holding; removes clothes	Says many intelligible words	Carries out simple commands
2 yr	Walks up and down stairs by self; runs	Makes two- or three-word phrases	Engages in organized play; points to some parts of the body

CENTRAL NERVOUS SYSTEM

Systemic illness is a common cause of CNS dysfunction in infants and children. Seizures, head trauma, CNS infections, and hypoxic or metabolic encephalopathy commonly cause acute neurologic dysfunction in the PICU. Assessment of neurologic function depends on an understanding of the age-dependent progression of motor and cognitive skills. Table 95-7 lists the developmental milestones.

FUNCTIONAL POSTNATAL NEUROLOGIC DEVELOPMENT

Motor function in the newborn depends on gestational rather than postnatal age. That is, an infant born at 28 weeks' gestation exhibits motor responses similar to those of a full-term newborn when the former is 3 months old. Although potentially modifiable by cortical influence, most neonatal motor behavior is controlled subcortically, which permits normal motor behavior in newborns who have severe cortical damage. Assessment of intellectual development is difficult in a newborn. Initially, assessment is based on the absence of reflexes and the acquisition of new motor skills. Adaptive or interactive behavior is first seen with accommodation to repeated stimuli and eye contact. The infant's intellectual development depends on the presence of external stimulation and social interaction, preferably from one or a few individuals. This is why infants and children who require long-term intensive care must have parental input and developmental stimulus.

ASSESSMENT OF NEUROLOGIC FUNCTION

Clinical examination is the most important tool we have for assessing neurologic function in children. In an awake child, interactions with the examiner and caretakers are sensitive indicators of high or integrative cortical function. When the child's cognitive function is depressed from disease or drugs, examination of the general level of activity and peripheral and brainstem reflexes becomes an important, albeit crude, measure of CNS function. A detailed examination includes an evaluation of the level of consciousness and alertness in the context of sedative medications. The Glasgow Coma Scale (GCS; Table 95-8) is a commonly accepted tool to evaluate the level of function of neurologically impaired patients; however, it was not developed for this purpose, and extensive research needs to continue on directed scales and noninvasive means to improve assessment consciousness in critically ill children.[358] Painful stimulation can stimulate both decorticate or decerebrate posturing; these responses likely indicate significant CNS malfunction and should trigger further investigation. Decerebrate posturing is an extension at the elbows with the arms and hands pronated. Decorticate posturing of the upper extremities is flexion at the elbows with the hands clenched. These responses to painful stimuli or no response at all should (in combination with attempts to elicit a cough, gag, or ability to handle oral secretions) make the practitioner question whether the patient can protect the airway. Pupillary reflex is a well-preserved function; therefore, unreactive pupils are highly concerning. Large reactive pupils can be caused by tricyclic antidepressant ingestion, atropine administration, or a symptom of pharmacologic withdrawal. Small, reactive pupils can indicate damage at the level of the pons, but usually indicate the presence of opioids or barbiturates. Funduscopic examination is important to assess for signs of increased ICP or retinal hemorrhage; however, the bedside practitioner may have difficulty with these assessments, and an ophthalmologist consultation may be required.

LABORATORY ASSESSMENT OF NEUROLOGIC FUNCTION (ALSO SEE CHAPTER 49)

The EEG is used to diagnose seizures and isoelectric brain death and to monitor the effects of barbiturates

TABLE 95-8 **GLASGOW COMA SCALE FOR INFANTS AND CHILDREN**

Activity	Adult/Child Response	Infant Response	Score
Eye opening (E)	Spontaneous	Spontaneous	4
	To verbal stimuli	To verbal stimuli	3
	To pain	To pain	2
	None	None	1
Best verbal response (V)	Oriented, appropriate	Coos and babbles	5
	Confused conversation	Irritable cries	4
	Inappropriate words	Cries to pain	3
	Incomprehensible words	Moans to pain	2
	None	None	1
Best motor response (M)	Obeys verbal command	Normal movement	6
	Localizes stimulus	Withdraws upon touch	5
	Withdraws from noxious stimulus	Withdraws upon pain	4
	Decorticate flexion	Decorticate flexion	3
	Decerebrate extension	Decerebrate extension	2
	None (flaccid)	None (flaccid)	1

administered to induce coma (see also Chapter 49). In addition, continuous EEG monitoring is often used to detect nonconvulsive seizure activity in critically ill children.[206,359,360] This monitoring system is resource intensive but has now shown that outcomes are improved; however, its use continues to increase in neonatal and pediatric critical care, and further study is needed for this promising, noninvasive tool. Computed tomography (CT) enables rapid detection of CNS lesions, the extent of structural injury, and noninvasive assessment of ICP. Cranial ultrasound is a bedside technique used to assess ventricular size and intracranial anatomy in infants with nonfused cranial sutures. MRI permits intraorbital and ocular injuries and brainstem and spinal cord lesions to be examined; it is also good for defining soft tissue abnormalities.[361] The major drawback of MRI is the length of time required for each examination and the relative inaccessibility of the patient while inside the scanner. Maintaining body temperature can also be a problem in small children during MRI scanning because the room must be cold. It may be difficult to perform MRI safely in patients who have significant cardiorespiratory compromise, because many of the pumps and ventilators cannot enter the scanner. Doppler ultrasound allows bedside assessment of cerebral blood flow (CBF) velocity in the ICU. Although it does not directly measure CBF, Doppler ultrasound is a useful bedside guide to therapy. CBF scans are the gold standard and are usually required to diagnose brain death during barbiturate coma. ICP can be monitored by inserting a catheter into a lateral ventricle or by inserting a subarachnoid screw or transducer into the epidural space or cerebral parenchyma. The ventricular catheter provides an accurate waveform and permits withdrawal of cerebrospinal fluid (CSF) to reduce ICP. The other devices used to measure ICP provide less consistent pressure waves and do not permit removal of CSF.

TRAUMATIC BRAIN INJURY

Despite advances in resuscitation care, morbidity following pediatric traumatic brain injury (TBI) remains high (see Chapters 49 and 81). TBI is composed of two components: an initial primary injury caused by direct mechanical deformation of brain parenchyma and a subsequent secondary injury that can develop over hours to days. Secondary injury may be the result of multiple mechanisms including ischemia, excitotoxicity, metabolic failure and eventual apoptosis, cerebral swelling, axonal injury, and inflammation and regeneration.[362] For improvements in outcome to be achieved in the pediatric critical care setting, secondary brain injury must be prevented or minimized.

Conventional wisdom about TBI has dictated that ischemia plays a major role in secondary brain injury. While reversal of ischemia is crucial, simply delivering oxygen to injured areas of the brain does not abate the onslaught of secondary injury cascades destroying vulnerable areas of the brain following TBI. Recent evidence suggests that secondary injury persists despite adequate oxygen delivery to brain tissue because of persistent metabolic crisis.[363,364] Furthermore, hyperoxia is not effective in completely reversing metabolic crisis and may lead to persistent secondary injury due to superoxide and free radical generation. There is widespread heterogeneity of metabolism following TBI, with some regional areas of increased glucose and oxygen utilization (likely due to electrical instability); however, in large regions of brain oxidative metabolism is reduced to a critical threshold with critically low rates of cerebral metabolic rate of oxygen ($CMRO_2$).[365] This reduction, coupled with ongoing low cerebral blood flow following TBI, places viable brain tissue at risk.[365,366] How the neurovascular bundle regulates the delivery of blood flow to regions gripped in metabolic crisis in ongoing secondary crisis and how to manipulate cerebral blood flow remains an important avenue of study in the immature brain.

CEREBRAL PERFUSION PRESSURE AND CEREBRAL BLOOD FLOW

In children, developing effective treatments for TBI is complicated by the rapid changing responses of the immature brain to each type of brain injury during development from infancy through childhood.[367,368] Therefore, evaluation of therapies for children with brain injury must use immature animal models as a translational pathway to human trials in children. Unfortunately, most of the

principles being used have come from adult clinical studies and adult aged small animal research. How this evidence translates to the child provides some direction, but should catalyze further research focusing on the immature brain. This is especially true when the practitioner must indirectly target metabolic delivery in the face of secondary brain injury by attempting to modulate CBF and predict regulation or lack of regulation in the neurovascular bundle. Even in the healthy brain, cerebrovascular response (CVR) regulation is complex and poorly understood.[369-371] To add to this layer of complexity, CVR is likely heterogenous following brain injury dependent on the mechanisms of injury, age, and even sex. Optimal global CBF is an elusive clinical target, with a lower inflection point associated with ischemic injury and an upper inflection point associated with hyperemia increasing cerebral blood volume and ICP. In early post-traumatic brain injury cerebral, hypoperfusion can contribute greatly to secondary brain injury, ultimately increasing morbidity and mortality.[366,372] In adults, areas of contusions have low cerebral blood flow similar to the ischemic penumbral zones surrounding areas of acute ischemic stroke.[373,374] Low cerebral blood flow states have been demonstrated in children by xenon CT scans following TBI within 24 hours of the initial injury, but by 48 hours these patients had normal or supernormal blood flows.[372] Furthermore, CBF in pediatric patients as a target for neuroresuscitation is a theoretical point of manipulation because of limited options of continuous measurement in the clinical setting; therefore, CPP (Mean arterial pressure [MAP] – ICP = CPP) is a commonly used surrogate.

When cerebral autoregulation is impaired, cerebral blood flow and the metabolic needs of the injured brain may depend on maintaining adequate CPP. The difficulty comes in identifying the term *adequate*. Currently, pediatric CPP thresholds (40 to 60 mm Hg) have been extrapolated from adult experimental and clinical TBI and stroke studies.[373,375] However, recently it has been reported in adults that ischemia following TBI can occur at much higher levels of CBF compared with stroke.[373] Chambers and colleagues[376-378] have published much needed age-specific pediatric thresholds for critical CPP, below which cerebral ischemia occurs with unfavorable neurologic outcomes and increased mortality. These studies identified inadequate CPP levels but did not identify an "optimal treatment" CPP, and therefore assumed that these CPP levels were equivalent to brain injury insult thresholds.

It is not clear whether a CPP of 40 mm Hg is a minimal threshold or that an optimal CPP to prevent brain injury may be higher.[379] Using currently accepted pediatric CPP guidelines (CPP > 40 mm Hg) might not ensure adequate oxygen delivery to brain tissue.[380,381] This raises the question: is a CPP > 40 mm Hg in the pediatric TBI patient high enough? Mild induced hypertension after ischemic stroke has shown promise in animal models but remains controversial in the clinical setting.[382,383] Adult TBI studies have observed an increased risk of adult respiratory distress syndrome associated with targeting a CPP > 70 mm Hg, but it is unclear how applicable this is to pediatric neurocritical care.[384,385] A retrospective study of 146 pediatric TBI patients observed a strong association of poor outcome at discharge with hypotension within the first 6 hours of injury.[386] The window for treatment of hypoperfusion appears to be early after pediatric TBI, and may be of relatively short duration in children. It is the authors' belief that early, aggressive intervention of blood pressure support especially during early critical periods, such as initial resuscitation of a patient with multiple trauma, intubation, and placement of support lines and neuromonitoring devices, is critical to neuroresuscitation. Guidelines released in 2012, based on class III evidence for pediatric traumatic brain injury, suggest that a minimum cerebral perfusion pressure of 40 mm Hg should be maintained and that 50 mm Hg for a minimum CPP in older children may be required.[387] However, data regarding large animal models of TBI may support the use of higher CPP support (>70 mm Hg) in severe TBI.[388]

Targeting cerebral perfusion pressure often requires vasopressor support. While central venous access should not delay administration of vasopressor support, it is important to understand the risks of extravasation of these infusions and have qualified individuals place central venous access as soon as possible to mitigate these risks. Initial stabilization of the pediatric TBI patient can occur in limited resource environments where complex invasive intracranial monitoring might not be available. Early stabilization of cerebrovascular hemodynamics with phenylephrine and targeting a higher MAP or CPP can reduce brain injury and improve long-term outcomes. A common first-line vasopressor to improve MAP in pediatric brain injury is phenylephrine, an α-adrenergic agonist that could have little or no effect on cerebral vasculature resistance.[389-392] Another vasoactive medication gaining favor is norepinephrine (NE). NE primarily targets α-receptors for peripheral vasoconstriction, but has additional effects on β-receptors increasing inotropy. Now NE is viewed as a preferred vasoactive medication, and may provide more predictable CPP augmentation when compared to dopamine.[393-395] Prathep and colleagues[396] have reported that adults with isolated traumatic brain injury and cardiac dysfunction have a higher incidence of in-hospital mortality. Further research is critical to determine the degree of cardiovascular compromise following TBI in children and which vasopressor should be considered a first line agent in pediatric brain injury and currently should be determined by local experience and comfort of use. We believe that the next generation of treatments will build on the tenets of ischemic neuroresuscitation and combine early, directed metabolic neuroresuscitation.[397]

RESPIRATORY MANAGEMENT IN THE BRAIN-INJURED CHILD

Airway Management

The comatose and brain-injured patient is at severe risk for respiratory failure owing to loss of airway protective reflexes and impaired central regulation of respiratory function. In addition, progression of ALI and ARDS can be exacerbated by concomitant injuries (pulmonary contusions, aspiration, left ventricular dysfunction or failure, and inflammation owing to systemic inflammation following trauma or infection) and treatments to improve cerebral perfusion (e.g., crystalloid administration, hyperchloremic

metabolic acidosis, hypernatremia, and vasopressor therapy). It is critical that the physician caring for these patients have a neuroprotective plan in place for induction of anesthesia and intubation of the trachea, in addition to adequate training and skill to obtain an artificial airway. The physician also needs to be adept at ongoing neuroresuscitation in the face of progressive lung disease and hemodynamic instability from systemic inflammatory response syndrome and increasing mean airway pressures impeding cardiac preload. The initial step in treating the head-injured pediatric patient is always to promote adequate oxygenation and ventilation and to prevent or treat hypotension, thereby limiting ischemia. Criteria for tracheal intubation include hypoxemia not resolved with supplemental oxygen, apnea, hypercarbia ($Paco_2$ > 45 mm Hg), GCS ≤ 8, and an incremental decrease in GCS score greater than 3 (independent of the initial GCS) combined with clinical correlation, anisocoria greater than 1 mm, cervical spine injury compromising ventilation, loss of pharyngeal reflex, and any clinical evidence of a herniation pattern or Cushing's triad.[398]

Induction of Anesthesia and Intubation of the Trachea

Patients with neurologic injury are at a frequent risk for aspiration of gastric contents during induction of anesthesia, because of loss of airway protective reflexes. In addition, there is a heightened risk of cervical spine injury because of trauma, and most patients will be in a cervical collar requiring manual in-line stabilization. The goal of tracheal intubation in the neurologically impaired patients should be (1) rapid sequence from induction to placement of an ETT to reduce the risk of pulmonary aspiration of gastric contents; (2) blunt nociceptive reflexes that might further increase ICP or cerebral hypertension that may exacerbate intracranial hemorrhage or facilitate herniation; (3) maintain adequate, age-appropriate cerebral perfusion pressure; and (4) limit ischemia by maximizing adequate oxygen delivery and maintaining $Paco_2$ in a normal range to ensure appropriate cerebral blood flow.[399] All patients are at risk for a full stomach and cervical spine injury; therefore, intubation should be performed using a neuroprotective, rapid-sequence induction of anesthesia whenever possible. Supplemental oxygen (100%) should be delivered with a facemask to allow nitrogen washout from the patient's functional residual capacity to allow sufficient oxygenation prior to tracheal intubation attempts. To avoid risk of aspiration of gastric contents, bag-valve-mask ventilation should not be used unless the patient has signs and symptoms of impending herniation or life threatening desaturation events. Outside of impending herniation, if bag-valve-mask ventilation is conducted, it is imperative not to overventilate the patient's lungs, decreasing $Paco_2$ and thereby increasing cerebral vascular resistance, resulting in decreased cerebral blood flow and metabolic delivery in a brain-injured patient. A separate health care professional's sole responsibility is to maintain the child's neck in a neutral position by mild axial traction during airway maneuvers to prevent or perpetuate cervical spinal injury. Cricoid pressure should be done by a third individual only if the individual is appropriately trained in the technique and it should be abandoned if it hinders a rapid intubation attempt. Orotracheal intubation by direct laryngoscopy should be performed, and nasotracheal intubation should be avoided because of the potential for direct intracranial damage in a patient with a basilar skull fracture.

Because tracheal intubation is a noxious stimulus and can increase ICP, appropriate sedative and analgesic medications should be administered during rapid-sequence induction. The hemodynamic and neurologic status of the patient dictates the choice of agents. Patients usually receive lidocaine (1-1.5 mg/kg) intravenously (IV) before intubation to help blunt the rise in ICP that occurs during direct laryngoscopy.[73] For the hemodynamically unstable patient, the combination of lidocaine, etomidate (0.2-0.6 mg/kg), and neuromuscular blockade with rocuronium (1 mg/kg) or succinylcholine (1 mg/kg) IV is a popular choice. The authors believe that succinylcholine may still be an option for rapid sequence intubation (RSI) in children who might have a difficult airway because of its rapid recovery, as opposed to the nondepolarizing intermediate neuromuscular blockade of rocuronium. There are several choices for drugs and techniques to use for the induction of anesthesia in the critically ill child with acute brain injury. In the following sections, we will discuss the pros and cons of each anesthetic. It remains unclear whether any of these anesthetics have particular advantages or disadvantages for patients with brain injury; all have been implicated in animal studies as neuroprotectants and neurotoxins. What is clear is that they are essential to the care of these patients, and practitioners should stay current with literature and consider the pharmacodynamics of each drug.

Etomidate

Etomidate is a short-acting intravenous drug that produces sedation, anxiolysis, and amnesia. Side effects include respiratory depression, hypotension, myoclonus, and adrenal suppression; it should not be used in children with suspected adrenal insufficiency and sepsis.[400] Etomidate has the benefits of decreasing ICP by reductions in CBF and $CMRO_2$ and has the advantage of producing less cardiovascular depression than barbiturates or propofol, preserving cerebral perfusion pressure.[401,402] These neuroprotective qualities are counterbalanced by its ability to increase cerebral vascular resistance by a greater magnitude than its reduction of $CMRO_2$ resulting in an increased metabolic deficit.[403,404] The increased metabolic deficit has the potential expand the ischemic core and penumbra in brain injured tissue. This increase in cerebrovascular tone is attributed to the inhibition of nitric oxide synthase by etomidate.[405] Particular attention should also be paid to the rapid recovery of etomidate; once the airway is secured, the effects of etomidate on consciousness dissipate quickly, principally because of the redistribution of the drug from the brain to inactive tissue sites. Recovery of consciousness can take 5 to 15 minutes, and if rocuronium (paralyzed for approximately 45 minutes) is used in combination for rapid sequence intubation, the patient will need ongoing sedation while paralyzed. The addition of a short-acting opioid such as fentanyl may be necessary especially if the patient has concomitant injuries, such as bone fractures.

An alternative is the combination of lidocaine, fentanyl (1-4 μg/kg), and rocuronium. In the hemodynamically stable patient, either of the above combination with fast-acting benzodiazepine, midazolam (0.05-0.2 mg/kg) can be added. In addition, the short-acting narcotic fentanyl, when used with lidocaine, can decrease the catecholamine release associated with direct laryngoscopy.[406]

Ketamine

Ketamine is a phencyclidine derivative typically formulated as a mixture of two enantiomers in a hydrochloride salt form. It has a low pH of around 4, which can produce pain at the injection site when administered intramuscularly or intravenously. Ketamine is an *N*-methyl-D-aspartate antagonist that produces increases in CBF and $CMRO_2$.[407,408] Early studies in patients with obstructed CSF pathways reported that ketamine administration increased ICP with reductions in CPP.[409,410] Recent studies in adult patients with severe head injury have demonstrated improvements in cerebral perfusion pressure and minimal increases in ICP with ketamine.[411-413] One recent report of 30 intubated pediatric patients with head injury observed that single doses of ketamine lowered ICP without producing decreases in blood pressure or cerebral perfusion pressure.[414] It is still unclear what ketamine's effect is on neurologic outcome in these patients or in patients in whom ventilation is not being tightly controlled. However, ketamine can possibly be used in the brain-injured patient, especially in patients with multiple trauma and if etomidate is not indicated.

Propofol

Propofol is a short-acting, sedative-hypnotic intravenous agent that can be used to provide moderate or deep sedation. Propofol can induce a deep state of sedation rapidly, provide a short duration of effect, and have a pleasant recovery phase. Propofol is a popular agent for sedating pediatric patients with neurologic conditions for noninvasive diagnostic imaging, such as a CT scan or MRI. Because of the fast onset and recovery following administration, repeated neurologic examinations are easy, such as assessing a child with sickle cell disease who comes in with altered mental status because of a stroke. Propofol also has anticonvulsant properties and reduces ICP, which can be advantageous in sedating a patient with epilepsy or a patient with concerns for obstructive hydrocephalus owing to a malfunctioning ventriculoperitoneal shunt to obtain diagnostic neuroradiologic imaging.[415] While there have been cases of propofol providing adequate sedation and successfully treating intracranial hypertension,[415,416] several pediatric traumatic brain injury case reports have reported metabolic acidosis and death in patients on prolonged (24 hours) continuous infusion of propofol.[417-421] Furthermore, a rare but potentially fatal "propofol infusion syndrome," associated with lactic acidosis, hyperlipidemia, and multiple-organ system failure was first described in pediatric patients who received prolonged (24 hours) continuous infusion and with larger dosages (>4.5 mg/kg/hr).[422] Current guidelines suggest, that in the care of pediatric traumatic brain-injured patients, "continuous infusion of propofol is not recommended."[423] Adverse effects of propofol include pain at the injection site, apnea or respiratory depression, hypotension, and bradycardia, which can be detrimental in a patient at risk for brain ischemia. If used, particular attention should be paid to the decrease in mean arterial blood pressure with the administration of propofol. Intravenous crystalloid boluses and vasopressor administration will likely be needed to counteract the effects of propofol to maintain proper cerebral perfusion pressure and avoid ischemic insult. Propofol does not provide any analgesia.

Dexmedetomidine

Dexmedetomidine, a centrally acting α_2-adrenergic agonist, is approved by the U.S. Food and Drug Administration for short-term (<24 hours) continuous IV sedation of adults who are tracheally intubated.[424] Like propofol, it has a rapid onset and a relatively rapid elimination half-life and is administered as a loading dose followed by continuous IV infusion. One of the advantages is that it provides sedation with a lower risk of respiratory depression than many other sedative medications. There is increased interest with this agent as a sedative during noninvasive neuroradiologic imaging studies in children who are not intubated. In one study, dexmedetomidine was compared to propofol in children undergoing magnetic resonance imaging studies.[425] While the onset of sedation and recovery time were significantly shorter in the children that received propofol, hypotension, respiratory depression and desaturation were more common compared to the children receiving dexmedetomidine.[425]

There is increased interest in the use of dexmedetomidine as a sedative and potential neuroprotective agent in both adults and children, as animal studies revealed neuroprotection from hypoxia-ischemia and decreased apoptosis. Also, adult human studies in healthy volunteers demonstrated parallel decrease in cerebral metabolic rate for oxygen and cerebral blood flow, which may potentially be helpful in briefly sedating patients who are at risk for intracranial hypertension such as head trauma, brain tumor, or obstructive hydrocephalus.[426] In pediatric TBI case reports, no detrimental effects on ICP were observed. Systemic hypertension was observed in one child who was receiving dexmedetomidine with other sedatives, and bradycardia was observed in two other children who were receiving dexmedetomidine, other sedatives, and therapeutic hypothermia.[427,428] Further study is warranted for the potential use of this agent in children at risk for intracranial hypertension. The most common adverse side effects of dexmedetomidine appear to be cardiovascular. Bradycardia with rare reports of sinus pause or cardiac arrest has been reported. Hypotension and hypertension have been reported, the latter thought to be due to peripheral α_{2B} agonism with peripheral vasoconstriction. Mild respiratory depression is likely. Although ICP does not increase, cerebral perfusion pressure and cerebral blood flow decrease. The effects on seizure threshold appear to be mixed.[429] The authors do not recommend dexmedetomidine as an anesthetic to induce anesthesia; however, it may be a useful agent for patients with brain injury and ongoing sedation needs. Further study in pediatric patients is needed.

After Tracheal Intubation

After successful tracheal intubation, oxygen saturation of 100%, normocarbia (35-39 mm Hg confirmed by arterial

blood gas and trended with an $ETCO_2$), and a chest radiograph showing the tracheal tube in good position above the carina (right mainstem tracheal intubation is common in pediatrics) should be confirmed. Unless the patient has signs or symptoms of herniation, prophylactic hyperventilation ($Paco_2$ < 35 mmHg) should be avoided. Hyperventilation causes cerebral vasoconstriction, which decreases cerebral blood flow and subsequent cerebral blood volume; this will decrease ICP but can lead to ischemia.[430] In the presence of signs and symptoms of herniation, such as Cushing triad (irregular respirations, bradycardia, systemic hypertension), pupillary dysfunction, lateralizing extremity weakness, or extensor posturing, hyperventilation with 100% oxygen can be a life-saving maneuver. Hyperoxia is to be avoided, once a stable airway is obtained, and Fio_2 should be titrated to maintain Sao_2 greater than 90%. Elevating the head to 30 degrees (with cervical spine precautions) increases venous drainage and decreases ICP.[431,432] Furthermore, the head should be midline to prevent obstruction of venous return from the brain. If these maneuvers do not relieve the signs and symptoms of herniation, then additional sedative and analgesic agents can be administered as long as hypotension is avoided.

Supraglottic Airway Devices

While supraglottic airways are not considered a permanent airway in critically ill patients, competency in placement is critical for all individuals participating in resuscitation of a brain-injured child. Supraglottic airway devices, such as an LMA device, can be life-saving. When there is difficulty with direct laryngoscopy and inadequate bag-mask-ventilation (BMV), an LMA should be placed to limit hypoxia and control ventilation until a physician with advanced airway skills can arrive to place an ETT.

Postintubation Stabilization

After successful intubation of the trachea, inspired oxygen should be titrated to maintain oxygen saturation greater than 90% and normocarbia (35-39 mm Hg) confirmed by analysis of ABGs and trends followed with $ETCO_2$. If herniation is impending, then moderate hyperventilation (to 30-35 mm Hg) and confirmation of ETT position with a portable chest radiograph[430] can be performed. The head of the bed should be elevated to 30 degrees, and the patient's head should remain mid-line to improve venous drainage and lower ICP.[431]

Neurologic Monitoring (Also see Chapter 49)

Recent guidelines published by Kohaneck and associates provide an update on treatment for infants, children, and adolescents with TBI[433] (see also Chapter 49). ICP increases when the intracranial volume of one of the four compartments (CSF, blood, brain, and supporting tissues) within the cranial vault increases. An increase in one compartment can occur without raising ICP if an equal volume is displaced from another compartment. When displacement is no longer possible, ICP rises in proportion to the added volume. In older children and adults who have a rigid calvaria, the cranial cavity is a closed container, and the contents are noncompressible. With patients with a GCS score of 8, there is grade III evidence to place an ICP monitor.[433] Treatment of ICP should be considered when pressure is greater than 20 mm Hg; however, absolute goals are unclear, and intermittent increases in ICP greater than 20 mm Hg may be associated with autonomic instability. Chestnut and associates[434] have recently reported in a randomized control trial comparing intracranial monitoring with a strategy of imaging and clinical examination in adults with severe TBI. While aspects of the study and recent evidence in adult severe TBI calls into question the utility of treating an ICP goal of 20 mm Hg, these goals should likely be used as a component of multimodal monitoring.[377] The most common monitor used in TBI as an adjuvant monitor for multimodal monitoring (MMM) is brain tissue oxygenation (Licox, Integra); however, brain tissue oxygen monitoring is also used in children with severe TBI.[381,435] If brain tissue oxygenation is used, maintain partial pressure of brain tissue oxygen greater than 10 to 15 mm Hg. It is unclear how multimodal neurologic monitoring, both invasive (brain tissue oxygenation, microdialysis, cerebral blood flow, intracranial EEG) and noninvasive, should be considered for advanced neuroresuscitation, but studies including the one by Chestnut and associates[434] prove that future research is critical to understanding the mechanisms, timing, and monitoring of the brain to limit secondary injury.

Adjuvant First- and Second-Tier Therapies for Intracranial Hypertension and Secondary Injury

In the 2012 guidelines,[433] the use of hypertonic saline for intracranial hypertension is grade II evidence and should be considered to reduce ICP in pediatric TBI. Use of 3% saline to treat increased ICP is gaining in popularity,[436] because the sodium does not cross the blood-brain barrier quickly and it has an osmolar gradient similar to that of mannitol. Three percent saline has additional theoretical beneficial effects, including enhancement of cardiac output, reduction of inflammation, restoration of normal cellular resting membrane potential and cell volume, and stimulation of the release of atrial natriuretic peptide. The recommended dosing is 6.5 to 10 mL/kg intravenous bolus, but the practitioner may consider starting with small boluses and titrate to pharmacodynamics response. Repeated doses can be given, but it is recommended to keep serum osmolality less than 320 mOsm/L. Prophylactic hyperventilation less to a $Paco_2$ less than 30 mm Hg should be avoided. Mannitol reduces ICP by decreasing blood viscosity and transiently increasing CBF and oxygen transport. The adenosine concentration decreases, and CBF is maintained in areas that have intact autoregulation. CBF remains constant despite a decrease in cerebral blood volume and ICP. Mannitol also reduces ICP by withdrawing water from the brain parenchyma and excreting the water as urine.[437] It takes 20 to 30 minutes for this osmotic effect of the drug to develop. Intermittent boluses of 0.25 to 1 g/kg of mannitol are administered intravenously to control ICP. The drug eventually enters the CSF and can increase ICP. Barbiturates should only be considered for refractory intracranial hypertension.

There is no evidence to recommend tight glucose control in head-injured patients, nor is there evidence suggesting the use of immune-modulating diets at this time. There is grade II evidence to suggest that antiepileptic therapy should be initiated in patients with severe traumatic brain injury. In the authors' institution, it is standard practice to place continuous EEG monitoring and start prophylactic levetiracetam. Elevating the head of the bed 30 degrees while keeping it in the midline position enhances cerebral venous outflow. Even slight movement of the head to a few degrees off midline can double the ICP.

Hypothermia for Severe Traumatic Brain Injury

Hutchinson and colleagues[438] published a multicenter randomized controlled trial to investigate the use of hypothermia as a neuroprotective strategy in children.[8] This trial concluded that in children with severe TBI for whom therapeutic hypothermia (32.5° C for 24 hours) was initiated within 8 hours of injury, there was no improvement in neurologic outcome, and the hypothermic group had an increase in mortality. Subsequent analysis of this study suggests that the hypothermia group had a significant increase in hypotension and decreased cerebral perfusion pressure that might have contributed to the increase in mortality.[439] A second phase 3 randomized control trial was initiated to compare hypothermia and normothermia after severe TBI in children with a prolonged hypothermia window (48-72 hours) and a slower rewarming phase.[440] The study was terminated early for futility after interim analysis; therefore, it is believed that normothermia is the current standard of care for TBI in children.

Decompressive Craniectomy

In the 2012 guidelines,[433] there is grade III evidence to suggest that decompressive craniectomy with duraplasty can be considered for pediatric patients with TBI who display early signs of deterioration, herniation, or refractory hypertension. Currently, there is an ongoing study in adults to investigate surgical decompression for severe TBI.

Environment

Care of patients with TBI within an organized trauma center has been shown to reduce mortality associate with severe injury.[441] Unfortunately, most severe TBIs occur in regions lacking in prehospital and advanced care in an intensive care unit.[442] Critically injured children with TBI should be stabilized and transferred to a level 1 trauma center as soon as possible.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

There is little evidence that increased ICP or correction of ICP alters the outcome of patients with hypoxic-ischemic encephalopathy. The clinical impression is that the outcome is less favorable in patients who have trauma or metabolic encephalopathy and that aggressive management of ICP, at best, prevents further CNS damage, which is important.[443] The GCS score provides a reasonable assessment of neurologic function in these patients.

HYDROCEPHALUS

Another cause of increased ICP is an increase in CSF volume (i.e., hydrocephalus). Common causes of hydrocephalus include obstructed ventricular shunts, aqueductal stenosis or compression as a result of congenital malformations, infection, posterior fossa tumors, or intracranial bleeding. Inserting an external or internal shunt to reduce the volume of CSF can be lifesaving.

TUMORS

Brain tumors are common in children, and approximately 70% of them occur in the posterior fossa. The most common tumor type is astrocytoma. The initial symptoms can include focal deficits, ataxia, or symptoms of increased ICP. A change in condition following tumor resection requires an immediate neurologic evaluation and possibly a brain CT scan. After a posterior fossa craniectomy, hemorrhage into the posterior fossa can compromise respiration. If an externalized ventricular drain is present, then output should be carefully inspected. Postoperatively the patient should be followed closely for syndrome of inappropriate antidiuretic hormone secretion (SIADH), diabetes insipidus, and cerebral salt wasting. SIADH usually occurs within 24 to 48 hours following surgery and results in the retention of free water and a decrease in serum electrolytes, which can rapidly worsen cerebral edema. Central diabetes insipidus (DI) usually follows the removal of a suprasellar tumor and results in significant diuresis when antidiuretic stores are exhausted, with a resulting increased serum osmolality and a low urine osmolality and urine specific gravity (<1.005). DI is part of a typical triphasic (SIADH to DI to SIADH) response following suprasellar surgery and is treated with volume replacement and a vasopressin infusion may be required.

STATUS EPILEPTICUS IN CHILDREN

Status epilepticus is a continuous motor seizure that lasts for more than 20 minutes or a series of seizures without intercurrent awakening. Although it is common for physicians to never find a cause of the seizures, the most commonly diagnosed causes are infections (meningitis or encephalitis) and metabolic abnormalities (toxins, head trauma, and hypoxic and ischemic injury). Because seizure activity increases with status epilepticus, brain and skeletal muscle metabolism and oxygen consumption increase and place the child at risk for cellular hypoxia. During a seizure, airway obstruction and ineffective chest wall and diaphragmatic excursion can limit ventilation and worsen arterial hypoxemia and hypercapnia. Treatment of a seizure begins with establishing a patent airway, administering oxygen, and ensuring adequate ventilation. Intravenous anticonvulsant drugs are given to stop the seizure. Commonly used anticonvulsants include lorazepam, phenobarbital, paraldehyde, and phenytoin. Lorazepam is a rapid and reliable drug used to stop seizures. Boluses of 0.1 mg/kg are given intravenously or rectally when there is no intravenous access. Phenobarbital, 5- to 10- mg/kg boluses (maximal dose of 20 mg/kg), also stops seizures. The main

complication of lorazepam is respiratory depression when administered in high doses. Giving both phenobarbital and lorazepam together exaggerates the respiratory depression. Fosphenytoin is also given intravenously in doses of up to 20 mg/kg and should be administered slowly to avoid cardiovascular depression. Paraldehyde (0.3 mL/kg) can be given rectally. Finally, an intravenous injection of 1 to 4 mg/kg of sodium thiopental stops most intractable seizures; higher doses of the drug can cause apnea, and the risk of vomiting and aspiration of gastric contents is real. Further, there may be future difficulty in obtaining sodium thiopental. Once the seizures are under control, the cause of the seizures must be determined.

RENAL SYSTEM

Functional Development of the Renal System

Embryologic development of the renal system begins in the middle of the third week of gestation with development of the pronephric tubules. By 10 weeks' gestation, a functioning kidney and collection system exist, and fetal urine is discharged into the bladder. At 32 to 36 weeks' gestation, each kidney has a full complement of nephrons. Because the placenta is the major excretory organ of the fetus, renal growth is not governed by functional requirements. Renal growth increases linearly with body weight and body surface area during the third trimester of pregnancy. The glomerular filtration rate (GFR) increases rapidly from 28 to 35 weeks' gestation. At term, the GFR is 10 mL/min/m^2 and increases to 20 mL/min/m^2 by 2 weeks of age. Although the GFR of premature infants is lower, the rate of increase is the same as that in a term infant.[444] Tubular function is not fully mature in full-term newborns. The newborn kidney is sensitive to antidiuretic hormone (ADH) and vasopressin, and urine osmolarity can vary from 50 to 780 mOsm/L.[445] The tubular function of premature infants is less mature.

The newborn's renal threshold for bicarbonate is approximately 20 mEq/L, which means that standard acid-base nomograms do not apply to infants because their serum bicarbonate concentration of 20 mEq/L is not indicative of metabolic acidosis. The renal tubular glucose threshold of term infants is similar to that of adults, but it is only 125 to 150 mg/dL in premature infants. A full-term infant has 1% or less fractional excretion of sodium by the third day of life. Fractional excretion of sodium can be much higher (5%) in premature infants. Renin, angiotensin, and aldosterone concentrations are high in newborns and decrease over the first few weeks of life.

Assessment of Renal Function

In the resting state, the kidney receives 20% to 25% of the cardiac output, and because of autoregulation the kidney maintains near constant renal blood flow and glomerular filtration rate. Creatinine is an end product of skeletal muscle catabolism and is excreted solely by the kidneys, and blood urea nitrogen is a byproduct of protein metabolism. Values for BUN can increase independent of renal function because of dehydration, high protein intake, and degradation of blood from the GI tract.

Renal Pharmacology

An important aspect of critical care is the maintenance of appropriate fluid balance in the critically ill child. Even in patients who have normal renal function, such as patients with ARDS, chronic lung disease, or CHF, diuretics are often used to limit lung edema and to help with cardiorespiratory dysfunction. The ascending loop diuretic furosemide is likely one of the most widely used drugs in pediatric intensive care. Furosemide reaches the ascending loop of Henle by the way of the tubular fluid. A prescribed starting dose of furosemide is typically 0.5-1 mg/kg up to approximately 10 mg total dose for patients who are naive to diuretic therapy. The smallest dose necessary to increase urine output should be used, to limit toxicity, including electrolyte imbalance and ototoxicity.[446] With progressive renal dysfunction, escalating doses of furosemide may be required to maintain the same clinical response. Electrolyte and renal function need to be monitored frequently, because diuretic therapy frequently causes significant hypokalemia and hypochloremia, as well as other electrolyte wasting. Furosemide is albumin-bound and in low albumin states, often found in critical illness, the delivery of furosemide to renal secretory sites is decreased. Improved delivery and diuresis is often improved with the administration of 25% albumin just before or with the diuretic. The typical dose is 0.5-1 g albumin/kg body weight. Additional diuretics acting at other locations such as hydrochlorothiazide (distal tubule) are often used as adjuvant medications to improve diuresis. The drug spironolactone, which blocks the hormone aldosterone, is a weak diuretic but may prevent spare potassium loss. Failure of increasing amounts of diuretics to be effective likely represents worsening renal perfusion and or renal failure.

Renal Failure

Acute renal failure is defined as an abrupt, often temporary loss of renal function (see Chapters 72 and 74), where there is insufficient removal of nitrogenous wastes and problems with fluid and electrolyte balance. Acute renal failure is described by: (1) the area of obstruction (prerenal, postrenal (obstructive), or intrinsic renal disorders) and (2) the urine volume (oliguria, polyuria, and anuria). Urine composition is often altered, and fluid, electrolyte, and acid-base disorders are common in acute renal failure. Common causes include hypoperfusion, obstruction, toxins, drugs, inflammation, and autoimmune disorders.

Prerenal causes are common in critically ill children because of systemic hypoperfusion and reduced renal blood flow, resulting in reduced urine output, azotemia, and ischemic renal damage. *Azotemia* is the term for the accumulation of nitrogenous byproducts of protein metabolism. Intravascular fluids in the case of dehydration or fluids and inotropic support may be needed to reverse prerenal renal failure. The adequacy of circulating blood volume is assessed by CVP and cardiac output measurements and by estimating renal blood flow with Doppler flow studies or nuclear imaging techniques.

Intrinsic renal failure is caused by disorders of the renal glomeruli, tubules, or blood vessels. Glomerular diseases include hemolytic-uremic syndrome (HUS),

poststreptococcal glomerulonephritis, Henoch-Schönlein purpura, and other inflammatory and immune complex diseases. Acute tubular injury is most commonly caused by hypoxia and ischemia; other causes are rhabdomyolysis, sepsis, hyperthermia, hemolysis, and a myriad of nephrotoxins, including mercury, carbon tetrachloride, and ethylene glycol.

Postrenal obstruction of urine flow can occur anywhere within the collecting system, but it occurs most commonly as a partial obstruction of the bladder neck or the ureterovesical or ureteropelvic junction. All these malformations cause obstructive nephropathy and renal injury or renal failure. Signs of obstruction may be subtle and require radiologic, ultrasonic, or endoscopic evaluation to detect. Recurrent urinary tract infections are frequent clinical manifestations of obstructive lesions.[447] Vascular diseases, including arterial embolism, venous thrombosis, and congenital malformations, are also causes of acute renal failure.

Hyperkalemia and Abnormalities of Sodium

With increasing renal dysfunction, there is a continued decrease in excretion of potassium. Hyperkalemia can lead to life-threatening cardiac arrhythmias and requires immediate treatment. Electrocardiographic presentation demonstrates a peak in the T wave at moderately elevated potassium levels. As hyperkalemia increases, there may be ST segment depression, and widening of the QRS complex, leading to conduction abnormalities, bradycardia, ventricular fibrillations, or asystole. Treatment includes removal of exogenous potassium administration should be discontinued immediately, and calcium in the form of intravenous CaCl (10 to 20 mg/kg) or CaGluconate (30 to 60 mg/kg) to stabilize the cardiac cell membrane. Intravenous sodium bicarbonate (1 to 2 mEq/kg) will drive potassium into the intracellular fluid by increasing blood pH. Glucose and insulin also drive K+ into cells. Glucose is given as 1 to 2 g/kg IV with insulin 1 unit per 4 g of glucose IV If the patient is intubated increasing respiratory rate makes blood more basic driving K+ into the cells. It is important to note, that none of these efforts will remove potassium from the body. Prior to the initiation of dialysis, potassium removal may be attempted with the ion exchange resin Kayexalate, a sodium polystyrene sulfate, which can bind potassium. It is given orally or rectally in suspension, but does require excretion from the body. The dose is 1 g/kg orally, and it can be given every 6 hours; rectally it can be given every 2 to 6 hours. The enema route is less effective than oral administration.

Severe hyponatremia and hypernatremia can be another electrolyte disturbance seen in the critically ill child. Hyponatremia can present with seizure activity, often when serum sodium is less than 120 mEq/L. In the presence of hyponatremic seizures, the initial treatment is the administration of 3% hypertonic saline with a goal to terminate seizure activity and raise serum sodium to greater than 124 mEq/L. However, in the absence of seizures, if a patient reached this low value slowly it has to be corrected slowly, to potentially avoid osmotic demyelination. The same condition applies to hypernatremia. Rapid correction of elevated serum sodium is likely more harmful than the value itself.

BOX 95-4 *Indications for Dialysis*

1. Severe hyperkalemia
2. Metabolic acidosis unresponsive to therapy
3. Fluid overload with or without severe hypertension
4. Fluid overload with or without congestive heart failure
5. Uremia causing encephalopathy, pericarditis, or bleeding
6. Nonobstructive anuria
7. Inborn errors of metabolism
8. Certain drug overdoses
9. Significantly elevated (>100) blood urea nitrogen possibly a relative indication
10. Potential treatment can reduce inflammation with sepsis or systemic inflammatory response syndrome

Renal Replacement Therapy

Renal replacement therapy may be required to improve ongoing fluid shifts and significant electrolyte disturbance. Usual indications for dialysis are shown in Box 95-4. Modalities for renal replacement therapy are commonly peritoneal dialysis, hemodialysis, or continuous venovenous dialysis. Modality often depends on the size of the patient and the experience and resources of the institution.

Peritoneal dialysis (PD) has the benefits of being relatively low cost, causing less hemodynamic compromise compared with venovenous filtration, requiring no central venous line, and being technically simpler. This technique is especially effective in infants and smaller children. Peritoneal dialysis requires the insertion of a soft, multihole catheter into the peritoneal cavity. When patency of the catheter is confirmed, a dialysate solution is infused that equilibrates with plasma and extracellular fluids. The parietal and visceral surfaces function as semipermeable dialysis membranes. The composition of the dialysis fluid is similar to that of plasma and consists of approximately 130 mEq/L of sodium, 100 mEq/L of chloride, 35 mEq/L of acetate or lactate as a buffer, 3.5 mEq/L of calcium, and 1.5 mEq/L of magnesium. The glucose concentration of the solution can be isosmotic or hyperosmotic. Hyperosmotic solutions remove fluid and electrolytes. Respiratory compromise can occur with peritoneal dialysis because the increased abdominal pressure caused by the dialysate in the abdomen can prevent effective spontaneous ventilation. Mechanical ventilation will be required if this occurs. Bacterial or fungal peritonitis is common. Severe dehydration, circulatory collapse, and metabolic derangements are other complications of peritoneal dialysis.

The principles of hemodialysis are essentially the same as those of peritoneal dialysis, except the blood interfaces with a semipermeable membrane rather than with the peritoneum. Hemodialysis is more appropriate in the acute setting with life-threatening electrolyte disturbances, fluid overload, and toxic ingestions. Hemodialysis is more efficient than peritoneal dialysis. Hemofiltration and ultrafiltration is a process of convective solute transport. An ultrafiltrate of plasma is created by hydrostatic pressure exerted across a highly permeable membrane, with simultaneous blood volume replacement with modified lactated Ringer solution.[448] Continuous venovenous hemofiltration (CVVH) is a common form of CRRT, which

provides isotonic fluid removal but minimal solute clearance; however, these circuits can be easily converted to perform dialysis, termed *continuous venovenous hemodialysis,* providing more solute clearance. In smaller patients, accurate flow rates are important when more than 15% of the patient's circulating blood volume can be in the CVVH tubing. Furthermore, technical challenges occur in smaller patients because of flow characteristics of smaller dialysis catheters. Hemodialysis can be performed with two separate 5-French single-lumen catheters, but typically a dual-lumen 7-French catheter at a minimum is required. Anticoagulation for CVVH can be either with heparin or with regional citrate administration. Citrate can be given in a stopcock before the machine, which creates a regional area of hypocalcia in the circuit, leading to relative anticoagulation in the circuit, while intravenous calcium is given back to the patient via a central line. The use of regional anticoagulation with citrate avoids the concerns of systemic anticoagulation, and it can reduce the risk of systemic bleeding

Renal Failure Outcomes

The prognosis with acute renal failure depends on the patient's age, underlying disease, and the extent of the precipitating insult (see also Chapter 23). In general, children fare better than adults; in fact, children usually recover completely from a renal insult if the hypoxia or ischemia lasted only a short time and other organ systems are not involved. Children with chronic renal failure require long-term outpatient peritoneal dialysis or hemodialysis until they can undergo renal transplantation.[449] It has been demonstrated that the degree of fluid overload at initiation of CRRT is associated with patient mortality.[124] This has been found to be independent of patient severity of illness scoring.

Hemolytic-Uremic Syndrome

Hemolytic-uremic syndrome (HUS) is one of the most common causes of acute renal failure in children. This syndrome is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal injury. In North America, HUS is most often associated with infection by cytotoxin-producing *Escherichia coli* O157, but other serotypes and other Shiga-like toxin–producing bacteria have been implicated.[450] *E. coli* O157 resides in the intestinal tract of cattle, and it can contaminate beef during processing.[451] The organism is killed by cooking. Infections can be spread by person-to-person contact in daycare centers, institutions, and the military. There is also a familial form of the disease that accounts for a small percentage of the total cases. HUS is seen predominately in 0.5- to 4-year-old children, but it can occur in all age groups.[170] It shares many laboratory and clinical features with the adult disease, thrombotic thrombocytopenic purpura. In fact, some investigators consider the two disorders a continuum of the same disease. The abnormalities that develop in HUS are believed to be caused by cytotoxins and lipopolysaccharide, a bacterial endotoxin. Toxin-induced damage to renal endothelial cells, the vasculature, and other organs is directly or indirectly associated with the activation of leukocytes.[452] Cytokines such as interleukin-1 and tumor necrosis factor, prostaglandin I_2, thromboxane A_2, and von Willebrand factor multimers probably play a role in the pathogenesis of this disease.[453] The time from exposure to the organism to initial presentation and evaluation of the patient varies from 3 to 12 days. Symptoms last for approximately 1 week. Patients usually have abdominal cramping, bloody diarrhea, tenesmus, and vomiting.[454] On average, approximately 10% of children with *E. coli* O157–induced bloody diarrhea progress to HUS. Mildly affected patients exhibit anemia, thrombocytopenia, azotemia, and decreased urine output and have an uncomplicated course. In severely affected patients, anuria is common, hypertension and seizures can occur, and the duration of illness is prolonged. A small number of children exhibit progressive and permanent renal insufficiency, severe and recurrent hemolysis, thrombocytopenia, and neurologic impairment. Hematologic abnormalities include hemolysis and thrombocytopenia. Hemolysis often causes hyperbilirubinemia and, despite reticulocytosis, severe anemia with hemoglobin concentrations of 4 to 5 g/dL. Thrombocytopenia is the result of platelet destruction and sequestration in the liver and spleen.[455] The remaining platelets show evidence of impaired aggregation.[456] Disseminated intravascular coagulation (DIC) is relatively common. Glomerular capillary endothelial injury is the most consistent renal finding in HUS. Acute renal failure with oliguria or anuria usually lasts less than 1 week but can linger for more than 10 weeks.[457] Glomerular or arterial injury, or both, may predominate, depending on the presence and extent of renal insufficiency (glomerular injury) and hemolysis and hypertension (arterial injury). CNS abnormalities are manifested as decreased levels of consciousness, seizures, irritability, ataxia, hypotonia, hemiparesis, hyperreflexia, and hallucinations; these problems may be caused by severe hypertension, electrolyte disturbances, microthrombi, or cerebral edema and increased ICP.[458] Abdominal cramping is common and may be difficult to distinguish from intussusception, intestinal stricture or bowel perforation, colonic gangrene, or other surgical emergencies.[459] Pancreatitis is common in patients with HUS. CHF can occur if there is fluid overload, hypertension, anemia, or myocardial depression caused by circulating endotoxins. Treatment of HUS is primarily supportive. Meticulous attention should be paid to volume status, electrolyte and acid-base balance, nutrition, antisepsis, and treatment of hypertension and coagulopathies. Enteric isolation is mandatory to prevent secondary spread of the disease. Accurate fluid intake and output measurements and frequent assessment of weight and volume status are important for management of these patients. A central venous catheter is useful for CVP measurements, blood sampling, and administration of intravenous medications and nutrition. Nephrotoxic drugs should be avoided if possible. If nephrotoxic drugs must be given, the drug dose should be adjusted and serum concentrations should be monitored closely. Daily fluids should be restricted to the amounts required to replace insensible losses, urine output, and other ongoing losses. Fluids administered should reflect the electrolyte content of the fluid losses. Caloric support is essential. Enteral feedings are preferred, but parenteral feeding may be necessary if ileus develops. Antidiarrheal medications prolong the duration of colitis, and antibiotics may increase the risk for HUS.[460,461] No specific treatment has been effective to date.

Heparin, fibrinolytic agents, aspirin, dipyridamole, corticosteroids, vitamin E, and furosemide have not affected the outcome of HUS.[181] Immunoglobulin therapy, plasmapheresis, and infusions of fresh frozen plasma have had mixed results, but no long-term therapeutic benefit has been demonstrated. Dialysis, improved nutrition, and supportive care have decreased the mortality rate from 100% in the original report to less than 10% in the last 30 years. Mortality rates remain high in developing countries and in children with a genetic predisposition for HUS.

ENDOCRINE SYSTEM

ADRENAL AXIS

Abnormalities of the adrenal axis result in deficient or excessive production of glucocorticoids, mineralocorticoids, or both. Many of these disorders are diagnosed and treated as they are in adults. Congenital adrenal hyperplasia, pheochromocytoma, and iatrogenic chronic adrenal insufficiency will be discussed briefly.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia is an autosomal recessive disorder that is associated with deficiencies in either 21-, 11-, or 17-hydroxylase. 21-Hydroxylase deficiency in children can be partial (simple virilizing form) or more complete (salt-losing form). At birth, affected children demonstrate masculinization of the external genitalia, and those with the more complete deficiency show a progressive salt-losing state (i.e., loss of sodium and elevation of potassium). This condition is usually manifested in the first few weeks of life as feeding difficulty, vomiting, and failure to thrive. The clinical and historical course is suggestive of pyloric stenosis. If the deficiency is not diagnosed and treated early in life, affected children can suffer severe cardiovascular collapse. A blood sample should be obtained for electrolytes, glucose, and if the diagnosis has not been established, adrenocorticotropic hormone (ACTH), cortisol, aldosterone, and plasma renin activity.

Treatment requires aggressive support of intravascular volume and myocardial function, glucose, and replacement of the deficient hormones. For emergency therapy, hydrocortisone acetate is used intravenously at a bolus dose of 1.5 to 2.0 mg/kg and then 25 to 250 mg/day in divided doses. Mineralocorticoid is replaced with cortisone acetate, 0.05 to 0.2 mg/day orally; these patients usually require the addition of salt to their diet. Deficiencies of 11- and 17-hydroxylase do not result in salt wasting; masculinization and hypertension are the common initial signs.

PHEOCHROMOCYTOMA

Less than 5% of pheochromocytomas are diagnosed in childhood. As a rule, these tumors are confined to the adrenal medulla, but they can occur anywhere throughout the sympathetic chain. The clinical signs and symptoms of excessive catecholamines are the same as those in adults. Preoperative, intraoperative, and postoperative therapy is similar to that for adults.

IATROGENIC CHRONIC ADRENAL INSUFFICIENCY

Long-term daily use of steroids for the treatment of asthma, nephrotic syndrome, and malignancies is common. Such use can cause a hypoadrenal state and increase the risk for cardiovascular collapse during a severe illness or stress. In children, topical steroids can also depress the production of ACTH. Replacement of stress-level steroids (threefold the daily replacement dose) is required.

ANTERIOR PITUITARY

Panhypopituitarism is usually secondary to a tumor or aggressive dissection of a tumor.[462] Acute ICU problems related to this lesion include support of the adrenal axis and abnormalities of ADH.

DIABETES INSIPIDUS

Diabetes insipidus can be of central, renal, or psychogenic origin. The central mechanism is the most common form in ICU patients. Absence of ADH results in polyuria and polydipsia; patients with a severe form of this disease might not be able to drink sufficiently to meet their requirement, and severe hypovolemia can develop. Diabetes insipidus is precipitated by brain tumors, head trauma, neurosurgery, and clinical brain death.[463,464] Treatment, in the setting of the ICU, is fluid replacement or, if unwieldy, hormone replacement with aqueous vasopressin (Pitressin). The clinical syndrome may be transient or chronic. In either case, close supervision of fluid intake and output is essential.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE

The syndrome of inappropriate ADH secretion is associated with hyponatremia and hypoosmolality caused by inappropriate urinary loss of sodium and free water in patients with normal kidneys. Urine osmolality is greater than serum osmolality. This syndrome is precipitated by a number of mechanisms, including head trauma, neurosurgery, meningitis, hypoxia, and any major surgical procedure in which there is large-volume fluid shifts and fluid replacement.[465] This disease is usually self-limited, and the only real problem occurs if the diagnosis is not considered and the level of hyponatremia is low enough to cause CNS dysfunction. Seizures are rare unless serum sodium is less than 120 mEq/dL. Care should be taken to raise the serum concentration of sodium slowly. This syndrome is treated by fluid restriction and, in severe cases, by the infusion of hypertonic or isotonic saline.

PANCREAS AND INSULIN (ALSO SEE CHAPTER 39)

Hypoglycemia

Hypoglycemia is a common problem in patients in the ICU. What constitutes hypoglycemia in children

has been disputed. However, it is uncommon to find a blood glucose level less than 40 mg/dL in normal, nourished premature, or term neonates. The usual symptoms of hypoglycemia include tachycardia, diaphoresis, weakness, mental clouding, seizures, and coma. The causes of hypoglycemia can be subdivided into disorders of increased utilization and disorders of decreased production. Transient hypoglycemia of the newborn is caused by decreased or immature hepatic gluconeogenesis, and it self-corrects within hours to days. If the hypoglycemia persists, hepatic enzyme deficiencies, endocrine problems, or hyperinsulinism (i.e., pancreatic cell abnormalities, infants of diabetic mothers) must be considered. Other causes of hypoglycemia in the neonatal period include sepsis, hypothermia, hypoxia, and transplacental exposure to maternal hypoglycemic drugs. In older children, hypoglycemia is associated with ketotic hypoglycemia,[466] hepatic enzyme abnormalities, hyperinsulinism, hepatic failure, and Reye syndrome, and it is a side effect of certain drugs. Regardless of cause, the initial treatment of hypoglycemia is glucose administration. The initial dose is 0.5 g/kg given as 50% dextrose in water ($D_{50}W$). This dose should be followed by an infusion of dextrose that is sufficient to meet the metabolic requirements of the child (see the later section on the GI system).

Hyperglycemia

Hyperglycemia in the pediatric ICU can be separated into two main categories with distinct concerns and outcomes. Patients with type 1 diabetes mellitus are often admitted to the ICU, with either initial presentation of the disease or those patients with known diabetes who are exhibiting recurrent problems of insulin balance. The second category of patients with hyperglycemia in critically ill children are those who develop elevated glucose during treatment for their underlying disease process, likely because of stress biology.

Diabetic Ketoacidosis

The most serious acute complication of diabetes mellitus is diabetic ketoacidosis (DKA), a syndrome of glucose and ketone overproduction and underutilization that causes hyperglycemic ketoacidosis (see also Chapter 39). The clinical syndrome includes dehydration and hypovolemic shock from hyperglycemic osmotic diuresis, compensatory hyperventilation (Kussmaul pattern), life-threatening electrolyte depletion, and in cases of severe metabolic imbalance, neurologic obtundation, and coma.[467] Laboratory evaluation demonstrates elevated blood glucose concentrations, severe metabolic acidosis and compensatory hypocapnia, increased osmolality, hyperlipidemia, and a normal or low sodium level (usually fictitiously low because of the hyperlipidemia). Total-body depletion of potassium and possibly phosphate occurs. Levels of both may be falsely normal because of the metabolic acidosis.

Treatment of DKA requires careful correction of the metabolic derangements with meticulous monitoring of the multisystem complications of DKA, as well as the complications of therapy. Adequate intravascular volume is restored with an isotonic glucose-free solution, combined with exogenous insulin administration, commonly referred to as a *two-bag system*.[468] Regular insulin is given as an intravenous infusion of 0.1 U/kg/hr. The goal is to decrease blood glucose by 75 to 100 mg/dL/hr. This infusion is continued until the blood glucose reaches 250 to 300 mg/dL, at which time 5% dextrose in normal saline (D_5NS) is added to the infusate. This regimen of simultaneous glucose and insulin infusion can be continued until the patient can tolerate oral feedings and routine subcutaneous insulin administration. Most clinicians continue the insulin infusion until the acidosis is nearly corrected. Potassium concentrations should be monitored closely. These children have total-body potassium depletion, but potassium should not be added to any infusion until there is urine output. The need for phosphate may be more theoretical than real, but in most situations, half the potassium is given as a phosphate salt. The severe metabolic acidosis is usually corrected with volume and insulin administration. The use of bicarbonate to correct acidosis is generally avoided because bicarbonate can precipitate or worsen the child's neurologic dysfunction. In severe DKA, the intracellular volume of brain cells is reduced by hyperosmolar dehydration. In an attempt to maintain their normal size, brain cells generate osmotically active idiogenic osmoles (e.g., inositol) that attract more water into the intracellular compartment. As systemic rehydration and correction of the hyperosmolar state begin, the brain cells may swell until the idiogenic osmoles are metabolized or cleared. Consequently, rapid correction of osmolarity can cause significant brain edema[469] and can also worsen the neurologic dysfunction, which may require invasive neuromonitoring.[443] The pH of the brain is determined by the CSF bicarbonate level and by the CO_2 content. The CSF CO_2 content equilibrates much more rapidly with the vascular space than bicarbonate does; therefore, correcting the systemic acidosis decreases the level of hyperventilation and causes a rise in $Paco_2$; if this rise is precipitous, the CSF acidosis could worsen before the bicarbonate equilibrates with CSF. Because rapid correction of pH is problematic, bicarbonate administration is not advocated in DKA unless cardiovascular instability is present. Even then, the doses are small. Unfortunately, despite careful and slow correction of the hyperosmolar and acidotic state, hyperosmolar coma and fulminant brain edema can occur.[470] The pathophysiology of brain swelling in DKA is poorly understood. Subclinical brain swelling may be relatively common in children with DKA.[471] If the swelling is significant, mannitol should be administered immediately and therapy for intracranial hypertension begun. The goal is to prevent secondary injury to the brain.

GASTROINTESTINAL SYSTEM

Gastrointestinal problems in the ICU include organ dysfunction and failure from acquired disease and from congenital anatomic malformations and dysfunction. Delivery of adequate nutrition to critically ill patients is necessary.

STRUCTURAL AND FUNCTIONAL DEVELOPMENT OF THE INTESTINE

Knowledge of fetal mid-gut development makes it easier to understand a number of severe congenital anomalies. Although the intestine begins as a hollow tube, it is occluded by 7 to 10 weeks' gestation by rapidly growing epithelial cells. The lumen is later reconstituted when vacuoles within the epithelial cells coalesce. Some of the neonatal intestinal atresias are the result of abnormalities of this recanalization process. At 3 to 10 weeks' gestation, the mid-gut lies outside the abdominal cavity, with only the hindgut fixed in the left side of the abdomen. The gut rotates 270 degrees counterclockwise and reenters the abdominal cavity at 10 weeks' gestation. If the midgut fails to migrate back into the abdominal cavity, an omphalocele occurs. Abnormalities in midgut rotation result in abnormal intraabdominal relationships, the most important being malrotation and volvulus of the intestine.

DEVELOPMENT OF THE LIVER

The liver begins as an outgrowth of the foregut at approximately 3 weeks' gestation. During fetal life, it is relatively large in comparison with the adult liver. Although the fetus relies on the maternal liver and placenta for detoxification and excretory function in utero, the fetal liver is necessary for both prenatal and postnatal survival. As early as 10 to 12 weeks' gestation, the fetal liver is involved in glucose regulation, protein synthesis, and lipid synthesis and is capable of some drug metabolism. The fetal liver contains approximately threefold the amount of glycogen as the adult liver, but the glycogen is nearly completely released within hours of birth to compensate for interruption of the placental supply of nutrients.[472] It takes several weeks for the newborn to reestablish the store of liver glycogen, putting the infant at risk for hypoglycemia during this vulnerable period.

CONGENITAL MALFORMATIONS

Gross anatomic malformations are usually diagnosed during the first few days of life. Some, such as omphalocele, gastroschisis, diaphragmatic hernia, and imperforate anus, are apparent on the initial physical examination. Others manifest themselves in the first few days of life as failure to feed enterally, intestinal atresia, microcolon, tracheoesophageal fistula, and meconium ileus. Other malformations present difficult diagnostic and therapeutic dilemmas after the neonatal period. Specific clinical problems are discussed in the following sections.

Intestinal Malrotation and Midgut Volvulus

Malrotation of the intestine is caused by incomplete rotation of the fetal midgut when the gut migrates into the abdominal cavity. This abnormal rotation can cause partial or complete duodenal obstruction by peritoneal (Ladd) bands or, more importantly, midgut volvulus. The mid-gut (duodenum to transverse colon) and its vascular supply hang on a single pedicle; if the pedicle twists, the entire midgut may infarct. Infants with omphalocele almost invariably have associated malrotation of the gut. Symptomatic infants and children have signs of high intestinal obstruction (bilious vomiting) or signs of an acute abdomen, intestinal perforation, and sepsis. Treatment is surgical reduction and fixation of the volvulus and resection of nonviable bowel. Postoperative respiratory support and total parenteral nutrition are often necessary in infants who were severely compromised before surgery.

Meckel Diverticulum

Meckel diverticulum represents persistence of the omphalomesenteric or vitelline duct and is brought to the attention of the physician because of painless lower GI bleeding. The bleeding site is due to ulceration of the bowel mucosa caused by secretion of gastric acid. Although usually self-limited, massive and life-threatening hemorrhage has been reported.[473] The diagnosis can be difficult to make because it is often one of exclusion. The technetium pertechnetate isotope scan demonstrates gastric mucosa in the diverticulum. Therapy is supportive, but particular attention must be paid to blood replacement. Definitive therapy is surgical resection.

Hirschsprung Disease

Hirschsprung disease (congenital aganglionic megacolon) is characterized by the absence of parasympathetic ganglion cells in the rectum and colon and occasionally in the small bowel.[198] Lack of ganglia cause narrowing of the distal bowel and distention of the normal proximal bowel. The clinical symptoms can be relatively minor, with abdominal distention and stool retention, or severe, with toxic megacolon, peritonitis, and intestinal perforation. Toxic megacolon is usually manifested in younger children; reported mortality rates are as high as 75% with toxic megacolon. The diagnosis of Hirschsprung disease is occasionally made with the history and physical examination. A barium enema reveals a narrowed segment with ballooning of the proximal part of the bowel. The definitive diagnosis is made by finding no ganglion cells on rectal or colon biopsy (or both). Treatment of toxic megacolon is both supportive (volume reexpansion and antibiotic administration) and definitive (surgical decompression via colostomy).

Other Intestinal Disorders

Intestinal disorders can cause bleeding, obstruction, or inflammation, and there can be secondary problems such as malabsorption and bowel perforation. GI bleeding in children is caused by inflammatory diseases (gastritis), ulcers, varices, or vascular malformations. Although ulcer disease is an uncommon initial complaint in pediatric patients, stress gastritis or stress ulcers occur in critically ill children. Prophylactic antacids or an H_2 antagonist should be considered. Bowel obstruction can be caused by intussusception, twisting of the bowel around congenital or postsurgical bands, and twisting of the bowel on itself (volvulus). Intussusception is relatively common in the pediatric age group and usually occurs in the distal part of the ileum. In

only a few cases can a leading point, such as a polyp or localized edema (as seen in Henoch-Schönlein purpura) be identified. Treatment of intussusception can be surgical or, in patients with no evidence of necrotic bowel, with barium, air, or saline enema.[474] Inflammatory bowel diseases include Crohn's disease and regional enteritis.[475] Infectious agents to be considered include *Salmonella*, *Shigella*, and *Yersinia* species. These patients often have diarrhea, malabsorption (especially lactose intolerance), and bloody diarrhea. They also can have a toxic acute abdomen.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a frequently fulminant neonatal disease characterized by ulceration and necrosis of the small bowel and colon. Its cause is unknown but is probably multifactorial. Prematurity is the greatest risk factor for NEC. It is probably due to a combination of intestinal ischemia, oral feeding, and pathogenic organisms. Umbilical artery catheters, perinatal asphyxia, respiratory distress syndrome, and persistent patent ductus arteriosus have all been implicated.[476] The incidence of NEC is on the rise, with 1% to 5% of infants in neonatal ICUs affected. The most common initial signs are feeding intolerance, abdominal distention, and bloody stools. Intestinal obstruction, bowel perforation, and sepsis may follow. Treatment consists of withholding enteral feeding, nasogastric decompression, intravenous fluids, hemodynamic support, administration of appropriate antibiotics, and surgical exploration if there is evidence of an acute abdomen with free air. Peritoneal drainage can be helpful for very-low-birth-weight babies and for those in extremis.[477] Total parenteral nutrition is frequently required for several weeks, and intestinal obstruction can occur weeks to months after a relatively benign course.[478]

Hepatic Failure

Hepatic failure occurs with chronic or acute liver disease. Chronic liver failure can be caused by biliary atresia, inborn errors of metabolism (tyrosinosis, Wilson disease, galactosemia, cystic fibrosis), or chronic inflammatory hepatitis. Children with chronic disease often have signs and symptoms of synthetic dysfunction (malnutrition, hypoalbuminemia, abnormal coagulation), degradation dysfunction (icterus and hyperammonemia), and portal hypertension (hypersplenism and varices). Acute liver failure is most commonly caused by infectious hepatitis A and B. Evidence of bleeding, edema, and other organ dysfunction, including identification of liver and spleen size, is sought on physical examination. Laboratory evaluation should include screening for synthetic function (albumin, prothrombin time [PT], partial thromboplastin time [PTT]), degradation products (bilirubin, ammonia), and liver enzyme concentrations. Hepatic ultrasound, radiographic contrast studies, and liver biopsy are indicated on an individual basis. Life-threatening complications of liver failure include acute bleeding and cardiovascular compromise (from massive intravascular hypovolemia caused by fluid shifts) and intracranial hypertension from toxic encephalopathy. Treatment is expectant and supportive. A 10% dextrose infusion will provide adequate carbohydrate intake. Low-protein diets minimize ammonia production. Coagulation is supported with vitamin K, fresh frozen plasma, and platelets as required. Plasmapheresis with fresh frozen plasma and platelets improves coagulation and maintains normovolemia. Oral lactulose and neomycin enemas decrease the enterohepatic cycle of ammonia production and absorption.[479] Cardiovascular and respiratory function should be monitored closely and supported as required. The development of intracranial hypertension must be anticipated. Serum ammonia levels are used to monitor neurologic dysfunction,[479] but it is unknown whether ammonia is the primary CNS toxin or whether it is just one of many chemical markers. Steroids have been used for some forms of inflammatory hepatitis. Exchange transfusions and plasmapheresis have been used to decrease the toxin load,[480] but there is no strong evidence that such measures reduce morbidity and mortality.[481] Patients with certain forms of acute hepatic failure, including those resulting from toxic and infectious causes, may be considered candidates for liver transplantation.[482]

Extrahepatic Biliary Atresia

Extrahepatic biliary atresia occurs once in every 8,000 to 10,000 live births.[483] The extent of atresia differs from patient to patient and involves variable degrees of obstruction or discontinuity of the biliary tree between the duodenum and the proximal branches of the hepatic ducts. Treatment is surgical (jejunal Roux-en-Y and portoenterostomy) and is tailored to the amount of extrahepatic bile duct present. The Kasai procedure is most successful in patients operated on before they are 6 to 9 months old. However, this procedure is associated with many acute and chronic complications, including hepatic failure, ascending cholangitis, and cirrhosis with portal hypertension and varices. Despite these complications, the Kasai procedure persists because there are not enough suitable donor organs.[484]

Liver Transplants

Improved immunosuppressive drugs and surgical techniques have increased the success of liver transplantation (see also Chapter 74). For transplantation to be successful, the perioperative and postoperative periods require a coordinated approach among surgery, gastroenterology, anesthesia, immunology, and the ICU staff. Most of the clinical issues that arise can be anticipated. Large blood losses occur and massive replacement therapy is required in the operating room. Accordingly, intravascular volume status, renal status, and hematology/coagulation profiles must be closely monitored. The immunosuppression required puts the patient at risk for infection with both "normal" and opportunistic organisms. Surveillance cultures and early aggressive antibiotic therapy are indicated. Systemic hypertension, which appears to be unrelated to elevated CVP or pulmonary capillary wedge pressure, is due to the antirejection drugs. Many patients require aggressive antihypertensive therapy (e.g., hydralazine, diazoxide, captopril).[485,486]

ENTERAL AND PARENTERAL NUTRITION FOR THE CRITICALLY ILL CHILD

Nutritional support of a patient in the PICU may be less of a concern to health care providers when there are neurologic, respiratory, and cardiovascular issues to be addressed; however, not addressing the nutritional needs of pediatric patients misses an important opportunity to improve their care and outcome (see also Chapter 106). There are the potential benefits of reduced translocation of gut bacteria, reduced constipation, and reduced infectious risks as compared with parental nutrition. Research by Khorasani and associates[487] published in 2010 in a single-center study showed decreased mortality in children with burns who received early enteral nutrition (8.5%) as compared with late enteral nutrition (12%). In a 2012 international multicenter cohort study published by Mehta and associates,[488] there was a less frequent 60-day mortality associated with a higher percentage of goal energy intake via an enteral route. The consecutively enrolled cohort consisted of 500 children aged 1 month to 18 years who required mechanical ventilation longer than 48 hours in a PICU. Mortality was more frequent in the patients who received parenteral nutrition. This research demonstrating early enteral nutrition improves outcome in critically ill children is further supported by the 2013 work of Mikhailov and associates.[488] The study was a multicenter retrospective study with 12 participating centers. Pediatric patients aged 1 month to 18 years were included if they had a PICU length of stay of 96 hours or longer, and a total of 5105 patients were identified. The study defined *early enteral nutrition* as obtaining 25% of goal calories enterally within the first 48 hours of ICU admission. The study noted that children who received early enteral nutrition were less likely to die as compared with those who did not (odds ratio, 0.51; 95% confidence interval, 0.34-0.76; $p = 0.001$). This was after adjusting for severity of illness, age, and participating center. There were nonsignificant increases in length of stay and duration of mechanical ventilation.

Given the increasing evidence supporting early enteral nutrition, it is important to consider daily whether it is possible to start feedings. It is also important to consider placing feedings tubes beyond the pylorus so that enteral nutrition can proceed during ICU procedures. Mehta and colleagues[489] showed significant interruptions in enteral feedings even after they had been initiated. Feedings were stopped on average for 2 days in 71% of their patients. While it may be difficult for each clinician to individually advance the feeding of their patients, there is good information that adoption of a feeding protocol in an ICU setting increases goal enteral nutrition.[490] It is possible that 25% to 30% of the patients admitted to the PICU are malnourished.[489] Smaller children and those with chronic illness have limited energy reserves, and early enteral feeding should be targeted. If enteral nutrition is not a possibility, then parenteral nutritional should be considered despite its risks. Higher dextrose solutions increase the risk of phlebitis or complications, should there be an infiltrate of a peripheral IV catheter. Higher dextrose concentration parenteral nutrition also requires placement of a central venous catheter. The central venous catheter is separately associated with risk during placement and ongoing risks of infection. Additional risks of parenteral nutrition include infection, cholestasis, hepatic stenosis, electrolyte disturbance, and elevated triglycerides. Until there is further evidence showing harm for malnourished children, the initiation of parenteral nutrition should be considered if enteral feeding is not an option.

HEMATOLOGY

Hematologic emergencies in the ICU include abnormalities in coagulation, immunity, and red blood cell mass. They can be primary isolated defects, or they can be caused by multiorgan system failure. The immune system is discussed in the section on infectious disease.

Coagulation System

Normal clotting includes initial platelet hemostatic plug formation and fibrin production (intrinsic or extrinsic pathways). For both to occur, platelets, coagulation factors, and an intact blood vessel are essential (see also Chapter 62). Neonates have a number of measurable coagulation abnormalities that rarely have clinical manifestations. Full-term and most preterm infants have normal platelet-vessel interaction, but platelet aggregation is transiently impaired. In addition, many coagulation factors show decreased activity or concentration in the fetus and newborn. Of greatest importance are the vitamin K–dependent factors: factors II, VII, IX, and X. These factors are low at birth and decrease to even lower levels during the first week of life unless vitamin K is administered. The amounts of factor V and VIII are close to adult levels in all but the most premature of infants. Although routine screening tests for coagulation activity are prolonged in infants, the newborn's blood clots more rapidly in vitro because neonates lack sufficient naturally occurring protease inhibitors, principally antithrombin III.[216]

Transfusion Therapy

Many PICU patients require blood transfusions during their hospitalization (Table 95-9; see also Chapter 61). Decreased red blood cells may be secondary to decreased production or ongoing losses to frequent laboratory testing. Decreased platelets may be secondary to decreased production or sequestration in the spleen. Thrombocytopenia from frequent laboratory testing is less common. Decreased production of coagulation factors in the setting of liver failure may predispose

TABLE 95-9 BLOOD COMPONENT THERAPY

Blood Component	Dose	Comments
Packed red blood cells	10-20 mL/kg	Raises hemoglobin 2-4 g/dL
Random donor platelets	1 unit/10 kg or 5-10 mL/kg	Pooled units from multiple donors
Apheresis platelets	10 mL/kg	Donation from single donor
Fresh frozen plasma	10-20 mL/kg	Provides 20%-30% of coagulation factors
Cryoprecipitate	1 unit/10 kg	Significant amount of fibrinogen (50-80 mg/dL)

patients to further blood loss. The transfusion of blood products in any setting carries associated risks. Transfusion reactions can be separated into nonimmune and immune-mediated problems. The nonimmune reactions include transmission of viral or bacterial infections through blood components, circulatory overload, coagulopathy, hypothermia, and changes in electrolytes. Hemolysis of erythrocytes in PRBCs is increased by prolonged storage. The potassium levels can be quite elevated in older units. In trauma or situations of acute blood loss, rapid transfusion of red blood cells can lead to hyperkalemia. This is typically not a problem in an ICU setting where PRBCs are transfused over 2 to 4 hours. The immune-mediated reactions include intravascular and extravascular hemolysis. Hemolytic transfusion reactions can be severe and life threatening. Cross-matching blood products can reduce hemolytic reactions, but there must also be careful identification of the patient and the blood unit to be transfused. Nonhemolytic immune-mediated reactions include febrile reactions, mild allergic, anaphylactic reactions, and transfusion-related acute lung injury (TRALI).

Transfusion-Related Acute Lung

Transfusion-related acute lung injury previously may have been an underreported complication of transfusion, but awareness is improving (see also Chapter 61). The number of studies on TRALI in pediatric ICU patients is increasing.[491-497] The diagnosis of TRALI following a blood transfusion relies on excluding other causes of pulmonary edema. This includes eliminating volume overload, sepsis, and cardiogenic pulmonary edema as causes of the patient's pulmonary edema. It is proposed that there is a two-hit model of TRALI. The first hit is an underlying component of inflammation in the lungs. The second hit is transfusion of a blood product that results in the development of TRALI. It is still not clear whether the damage is caused by the presence of neutrophils, HLA antibodies, or biologically active lipids present in older blood units. A study by Church and colleagues[498] showed an association with increased mortality for pediatric patients with ALI who received fresh frozen plasma. This group already has the first hit because of the ALI. The mortality association was independent of the severity of hypoxemia, the presence of disseminated intravascular coagulopathy, or the presence of multiple-organ dysfunction syndrome. Blood transfusion has associated risks, and these risks should be considered before any transfusion. In some clinical scenarios, pediatric patients will tolerate a greater degree of anemia than would have previously been considered. In 2007, Lacroix and colleagues[499] with the Transfusion Requirements in Pediatric Intensive Care Units (TRIPICU) study demonstrated that by adopting a restrictive transfusion strategy, they were able to reduce transfusion of PRBCs to PICU. A hemoglobin threshold of 7 g was targeted in one group and 10 g in another. In the restrictive threshold group, there was a 44% reduction in PRBC transfusion without an increase in adverse outcomes. This information might not be applicable to all groups in the ICU, such as those with ongoing blood loss. The patients in the TRIPICU study did not have arterial blood pressure lower than 2 SD below an age appropriate mean, and they did not require increasing doses of inotropic medication. Subgroup analysis of the original TRIPICU study in general pediatric surgery[500] and cardiac surgery patients[23] did not show a significant difference in the development of multiple-organ dysfunction syndrome.

Coagulopathy

Coagulation defects can occur due to many conditions in PICU patients, such as sepsis, trauma, malignancy, pancreatitis, and liver failure (see also Chapter 62). As a reminder, the prothrombin time (PT) tests the extrinsic and common pathways of coagulation. The PT is prolonged in liver failure, vitamin K deficiency, and DIC. The activated partial thromboplastin time (aPTT) tests the intrinsic and common pathways of coagulation. The aPTT is prolonged in liver failure, hemophilia A, von Willebrand disease, and DIC. One major concern in a PICU setting is that the underlying inflammatory state in some patients can activate coagulation and inhibit the natural anticoagulation mechanisms. This concern is the basis for DIC. In 2001, the International Society of Thrombosis and Hemostasis[501] published a DIC scoring system. Their DIC score uses platelet count, fibrin-related markers, prothrombin time, and fibrinogen. They separated DIC into nonovert DIC and overt DIC. In nonovert DIC, the balance of hemostasis is stressed by inflammation or noninflammatory disorders of the microvasculature stress hemostasis, but compensation is maintained. In overt DIC, the hemostatic system can no longer compensate. A DIC scoring system such as this allows for ongoing research and a measure of response to therapy. In 2009, Khemani and associates[502] demonstrated the association between an elevated DIC score and mortality in 132 PICU patients with sepsis or shock. There are a maximum of 8 total points on the DIC score. Points are assessed for lower platelet counts and fibrinogen, prolongation of the prothrombin time, and evidence of fibrin degradation. There was a 50% mortality for patients with overt DIC (DIC score ≥ 5). The mortality was 20% for patients with a DIC score less than 5. This association between elevated DIC score and mortality remained even when controlling for severity of illness and use of inotropic medications. The treatment of DIC is supposed to treat the underlying condition that is causing imbalance of the coagulation system. A future goal of research will be to study patient outcomes as DIC is corrected and even caused by FFP. As Church and associates[498] found an increased mortality associated with FFP transfusion, it is not clear what the balance will be between the risk of DIC or the risk of transfusion.

Sickle Cell Disease

Hemoglobin S, or sickle cell trait, is the most common of the hemoglobinopathies. There are also significant regional variations on the concentration of patients with different thalassemias. Hemoglobin S is caused by a point mutation in the β-chain at codon position 6, which results in a substitution of valine for the normal glutamine. Hemoglobin S is formed from the combination of an abnormal β-chains with the valine with normal α-chains. When two copies of the abnormal gene are present, hemoglobin SS (HbSS; or sickle cell disease)

is produced. Complications from Hb SS cause the most frequent PICU admissions of the hemoglobinopathies. Deoxygenation of the Hb SS erythrocytes causes intracellular hemoglobin polymerization, which leads to loss of deformability and changes in the erythrocyte morphology. In a deoxygenated state, the abnormal erythrocytes change from a biconcave configuration to the classic sickle cell shape. The abnormal erythrocytes have a much shorter lifespan and hemolyze more readily. In turn, patients with sickle cell disease have a chronic severe hemolytic anemia.

Sickle Cell Crisis

There are three types of sickle cell crisis that can occur: hemolytic, aplastic, and vasoocclusive. A hemolytic crisis is characterized by increased hemolysis that results in an acute drop in hematocrit and hemoglobin. This drop is typically accompanied by a significant increase in red cell production or reticulocytosis. Alternatively, in an aplastic crisis there is a drop in hematocrit and hemoglobin, but there is no associated reticulocytosis. The production of red cell precursors in the bone marrow has slowed or stopped. The cause of an aplastic crisis is often infectious with greater than 90% of cases caused by parvovirus B19. A vascular occlusive crisis is what is typically known as the classic sickle cell crisis. A vascular occlusive crisis can be initiated by infection, dehydration acidosis, or hypoxia. The erythrocytes assume a sickled configuration that blocks small vessels, leading to infarction. The infarcts can occur in any organ, but are frequent in the, lungs, kidney, bones, skin, spleen, eyes, and CNS.

Acute Chest Syndrome

A vascular occlusive crisis in the lungs leads to acute chest syndrome (ACS). Acute chest syndrome is a leading cause of death and is the second most common complication in sickle cell disease. ACS is defined as a new pulmonary infiltrate on a chest radiograph in association with a fever, respiratory symptoms, or chest pain. There is great variability to the clinical course in ACS. The National Acute Chest Syndrome Study Group[503] issued a multicenter report showing that almost 50% of patients later diagnosed with ACS presented initially with another symptom, mostly typically being pain. The presence of a pulmonary fat embolism is frequently reported and is associated with a particularly severe course. The cause of the pulmonary fat embolism is most likely bone marrow necrosis with release of necrotic bone marrow fat into the blood stream. A common etiology of ACS is infection. *Chlamydia pneumonia* and *Mycoplasma* species are the most commonly identified pathogens. The goal for management of ACS is early recognition. As children with sickle cell disease may have few initial symptom, there should be a high index of suspicion. All febrile children with sickle cell disease should have a chest radiograph obtained. If there are any positive radiologic findings, therapy should begin immediately. Initial antibiotic treatment is cefuroxime or cefotaxime with a macrolide. The patient should be adequately hydrated. The patient should be observed closely and if the patient becomes fluid overloaded, diuretic therapy should be started. Patients should receive oxygen therapy even if there are normal oxygen saturations. Incentive spirometry should be used by every child who is able to do so. There should be consideration given to the use of bronchodilators. Every effort should be made to see that pain is adequately controlled. A simple red cell transfusion may be helpful if the patient is anemic, but an exchange transfusion may be needed. There is some regional variation in this practice. The reason to perform an exchange transfusion is that as the hemoglobin rises the blood viscosity will increase. Further, sickle cell blood has a high viscosity in the deoxygenated state. Performing a red cell exchange can reduce blood viscosity and improve oxygenation.[501] An exchange transfusion can improve perfusion in the microvascular perfusion and cause a reduction in inflammatory mediators. In patients with sickle cell disease, red cell exchange has been shown to reduce white blood count, platelet count, and soluble vascular cell adhesion molecule-1 in patients.[28] However, there was no effect on interleukin-1α, interleukin-1β, interleukn-8, or tumor necrosis factor-α and the reductions that occurred were short lived. In the National Acute Chest Syndrome Study Group publication,[504] 13% of patients required mechanical ventilation, and the mortality rate was 19% in the group that required intubation.

Neurologic Complications

Exchange transfusion has a vital role in the treatment of neurologic complications from sickle cell disease. In a population of patients less than 20 years of age with sickle cell disease, the incidence of stroke was measured at 0.44 per 100 patient-years.[505] Studies have been performed to identify at risk patients and initiate therapy before the development of stroke. The Stroke Prevention Trial in Sickle Cell Anemia (STOP) was to evaluate whether chronic transfusion therapy could prevent an initial stroke in children with sickle cell disease. Transcranial Doppler was used to identify patients at increased risk for stroke. A hemoglobin S concentration of less than 30% was maintained in the study group.[506] The risk for stroke development was reduced by 90% in the chronic transfusion group as compared with the patients receiving standard of care. The trial was stopped 16 months early because of these findings. Chronic transfusion therapy does carry the long-term side effects of alloimmunization and iron overload.[507] The information available would indicate that transfusion should be performed for a child with sickle cell disease and an acute neurologic change exchange. While there is a significant need with acute chest syndrome or neurologic change for an exchange transfusion, it is not without risks. Depending on regional variation, central venous or arterial access is needed. Patients need to be followed closely for the development of fluid overload or hypovolemia during the exchange. There are the risks of blood products. Small children are at risk for hypothermia if the blood is not warmed. The best location and method to handle exchange transfusion will depend on the resources of the ICU, blood bank, and hematology department.

Acquired Disorders

A variety of circumstances can impair the production of coagulation factors. The vitamin K–dependent factors are

most commonly affected. These factors are decreased with liver disease, warfarin therapy, and malabsorption syndromes secondary to either bowel disease or altered bowel flora caused by long-term antibiotic therapy. In addition, untreated neonatal vitamin K deficiency results in hemorrhagic disease of the newborn. In these disorders, the PT is prolonged and there are low levels of factors II, VII, IX, and X. Administration of vitamin K usually reverses these deficiencies unless the synthetic function of the liver is markedly compromised.

Acquired platelet abnormalities include decreased production, increased destruction, and decreased function. Decreased production or hypoproliferative states include marrow diseases, such as leukemia and aplastic anemia, and the side effects of chemotherapeutic agents. Increased destruction can be immune mediated (i.e., idiopathic thrombocytopenic purpura)[508] or the result of consumption (i.e., microangiopathic states, HUS, or thrombotic thrombocytopenic purpura).[509] Finally, platelet dysfunction has been found with uremia and chronic polycythemia in patients with cyanotic heart disease.[510] Treatment of acquired thrombocytopenia includes platelet transfusions and, if possible, correction of the underlying disorder. Therapeutic splenectomy will increase platelet survival in some patients with severe immune-mediated diseases.

ONCOLOGY

Over the past several decades, there has been significant improvement in survival of pediatric cancers. A great amount of information demonstrating this effect is available from the Surveillance, Epidemiology, and End Results Program at http://www.seer.cancer.gov. Furthermore, there has been an increase in the number and types of diseases treated with hematopoietic stem cell transplantation (HSCT). These facts have resulted in an increasing volume of oncology patients in the pediatric ICU. This patient population received highly specialized, detailed care on specialized oncology wards or bone marrow transplant units. The care delivered in these areas as well as the strict isolation procedures used there are difficult to replicate in other locations in the hospital. In an effort to keep oncology patients in oncology wards, some hospitals have policies allowing the use of low amounts of inotropic support in these areas, such as dopamine up to 5 μg/kg/min. This may mean that some oncology patients are transferred to the ICU when they have exceeded this level of support. They may have sepsis and shock not responding to fluid resuscitation and low inotropic support. Other patients may require respiratory support that cannot be delivered on the ward. Finally, there is early literature indicating that earlier initiation of CRRT to treat or prevent fluid overload[511,512] has benefits in HSCT with other studies showing no benefit.[513] However, the positive literature has prompted earlier admission to the ICU for HSCT patients who become fluid overloaded. Overall, there is evidence showing improved outcomes for pediatric oncology patients requiring ICU care.[514-517] For patients following HSCT after controlling for severity of illness a temporal improvement in mortality is less evident.[518] Furthermore, for patients requiring mechanical ventilation the mortality is greater following HSCT compared with non-HSCT oncology patients.[519]

Because of the disease and therapy at times during their illness, oncology patients are profoundly immunocompromised. There is an increased risk of sepsis during periods of neutropenia. Fever may be the first indication of sepsis and studies have looked at predicting which patients will go on to be bacteremic.[520,521] The outcome of sepsis and oncologic disease is an ongoing concern. A study by Pound and colleagues[514] showed that ICU mortality for patients with septic shock was not significantly different between oncology patients (15.9%) compared with matched controls (11.6%). There was no significant survival difference between groups in the first 6 months following discharge from the ICU. A 2005 study by Fiser and colleagues[517] showed an overall mortality of 17% for pediatric oncology patients with severe sepsis. The mortality in the HSCT group (30%) was greater than in the non-HSCT group (12%). For patients who required both mechanical ventilation and inotropic support, there was a high mortality (64%).

LEUKOSTASIS

Leukostasis (vascular obstruction) results from high viscosity caused by elevated cell counts or by the white blood cells (WBCs) themselves. This syndrome is anticipated in patients with acute lymphoblastic leukemia when the WBC count exceeds 500,000 and in AML patients with WBC counts greater than 200,000/mm^3. In AML, leukemic cells are less deformable than lymphoblasts; therefore, a lower WBC count produces the same syndrome.

The brain and lungs are the two major target organs for leukostasis; vascular plugging and organ infarction are the usual manifestations. Initial symptoms include tachypnea, cyanosis, increased work of breathing, altered mental status, and focal neurologic deficits. Besides supportive therapy, reducing the circulating tumor load and viscosity are the primary goals of therapy. Leukapheresis and exchange transfusion transiently accomplish these goals. Cranial irradiation can reduce the CNS tumor load, and chemotherapy will interrupt cell production and possibly destroy circulating cells. The initial goal of chemotherapy is to stop cell production without producing massive cell lysis; this halts the increase in tumor load without causing a severe metabolic crisis before adequate perfusion is reestablished.[522,523]

TUMOR LYSIS SYNDROME

Tumor lysis syndrome is a metabolic crisis precipitated by acute lysis of a large number of tumor cells. Serum uric acid, potassium, and phosphate concentrations are elevated; the elevated phosphate concentrations cause hypocalcemia. Hyperkalemia and hypocalcemia can be life threatening; increased uric acid may cause acute renal failure.[524] Therapy for tumor lysis syndrome consists of alkalinization of urine, fluid administration, and diuresis. Before any chemotherapy is administered, the patient's renal function should be assessed. If renal function is normal, allopurinol or rasburicase therapy is begun. In most cases, this conservative approach of forced diuresis and

allopurinol or rasburicase will prevent renal failure, but occasionally dialysis must be instituted. Indications for the initiation of dialysis include:

1. Potassium > 6 mEq/L and rising despite resin exchange
2. Uric acid > 19 mg/L
3. Creatinine > 10 mg/L
4. Phosphorus > 10 mg/L or rapidly rising
5. Volume overload
6. Symptomatic hypocalcemia

MEDIASTINAL MASS

Children with a mediastinal mass and respiratory distress often complain of coughing, difficulty breathing, stridor, and shortness of breath. They prefer to sit upright and cannot lie supine. The chest radiograph usually shows a large mediastinal mass, often with obliteration or obscuring of the tracheal air column. These masses can also cause positional obstruction of vascular structures such as the superior vena cava or a pulmonary artery. Lam and colleagues[525] reported that clinical presentation is often nonspecific or often times incidental and that patients with airway compromise often also exhibited symptoms of superior vena cava syndrome.[525] These symptoms are often referred to as *critical mediastinal mass syndrome* and requires the care of an experienced multidisciplinary team. These tumors can be malignant (87% Hodgkin and non-Hodgkin lymphoma) or benign; the prognosis and therapy rely on adequate diagnosis, which is best made by obtaining a tissue sample before treatment is begun.[526] However, obtaining a sample of the mediastinal mass may require anesthesia and surgery, and the airway must be manipulated and instrumented. All these maneuvers can cause the patient to die. Local anesthesia with fine-needle biopsy under radiographic guidance allows tissue sampling without anesthesia in some patients. Irradiation of the tumor before obtaining a tissue sample can reduce the size of the tumor and make biopsy easier and safer with anesthesia. Obstruction of the intrathoracic trachea is a major anesthetic risk for these patients; it is often impossible to maintain a patent airway when the patient lies supine, is deeply anesthetized, or is paralyzed with muscle relaxants.[525,527] However, the patient must cooperate sufficiently to perform the test, which is often difficult for them because of respiratory distress. Induction of anesthesia and tracheal intubation are usually done with the patient in the sitting position and breathing spontaneously. If the airway compromise is severe, the tumor should be irradiated and the child should be given steroids before a tissue diagnosis is made; however, these treatments could alter diagnosis and should be discussed with an oncology consultant before initiating them. Sometimes, a peripheral node or mass can be biopsied under local anesthesia. If the tumor mass is large, some of the tumor can remain outside the field of radiation. Sticker and colleagues[527] report that, in a single-center review of 46 cases, patients with symptomatic anterior mediastinal mass underwent biopsy with general anesthesia while maintaining spontaneous ventilation without serious complications.[527] In summary, although diagnosis is the key to treatment of neoplastic disease, the risk associated with biopsy can far outweigh the benefit of tissue diagnosis.

IMMUNITY AND INFECTION

EMPIRIC ANTIBIOTIC COVERAGE

It is difficult to make empiric recommendations for antibiotic coverage for the pediatric ICU. Antibiotic resistance can result from use of broad-spectrum antibiotics without some degree of stewardship. Furthermore, empiric antibiotics should be based on the susceptibility profile of the common bacteria within each hospital and patient population. In the authors' practice, for patients presenting with sepsis, vancomycin and a third-generation cephalosporin in combination are the antibiotics of first choice; this is due to a rising incidence of methicillin-resistant *Staphylococcus aureus* (MRSA). To reduce the spread of MRSA, all patients are screened on admission for colonization and isolated if MRSA is found. Antibiotic coverage can be more specific and narrowed as culture results and sensitivities return. Likely the best recommendation to be made regarding empiric antibiotic coverage is to meet with the infectious disease specialists and discuss the current hospital culture isolates and their antibiotic resistance. Decisions regarding empiric antibiotics are best made in advance of the situation.

PREVENTION OF HEALTH CARE–ASSOCIATED INFECTIONS

The effects of hospital-acquired infections (HAIs) on the medical system are significant and on the individual patient level can be deadly. A 2007 article from Klevens and associates[528] estimated the number of HAIs in U.S. hospitals in the year 2002 at 1.7 million. Of these, 417,946 HAIs occurred among adults and children in an ICU setting. The estimated deaths associated with the HAIs in this period were 98,987. Likely the best thing to protect patients is to wash hands or use alcohol-based gels and encourage others to do so. Encouraging others or providing a positive role model can have a broader effect than anticipated. A 2009 study by Schneider and associates[529] paired trainees who were critical care fellows or nurse orientees with senior supervisors and evaluated compliance with hand hygiene. In the control phase, the senior supervisors were unaware of the study and had a hand hygiene compliance of 20%. The trainees that were being mentored had a hand hygiene compliance of 22%. When the senior supervisors were recruited into the study, there was a hand hygiene compliance of 94%. The trainees who were still blinded to the study had an increase in the hand hygiene compliance to 56%. Certainly it is anticipated that there will be better compliance with hand hygiene if health care providers know that they are being observed. The Schneider study shows the importance of role modeling positive behavior.[529] Ongoing audits of hand hygiene compliance are recommended. Auditors should patient's parents to remind health care providers to wash if they have not observed it. Although it may be difficult, it is important to be willing to remind others to wash their hands.

VENTILATOR-ASSOCIATED PNEUMONIA

Intubation and mechanical ventilation is necessary for patients with respiratory failure. Unfortunately, an ETT

prevents airway protective mechanisms and increases the risk of ventilator-associated pneumonia (VAP). Patients who need mechanical ventilation but who do not have a pulmonary infection can develop pneumonia, and patients who need mechanical ventilation for pneumonia can develop a secondary infection. VAP can increase morbidity and mortality. A 2009 study by Srinivasan and associates[530] demonstrated that patients with VAP had increased length of mechanical ventilation, prolonged stays in the ICU, and more importantly a significant increase in mortality. There was 2.4% mortality in the patients who did not develop VAP as compared with 10.5% mortality in the patients who did. VAP has been defined as the new onset of a lower respiratory tract infection for patients who have required mechanical ventilation for greater than 48 hours. The diagnostic criteria include a new infiltrate on chest radiograph, a positive respiratory culture, a low or elevated white blood cell count, and fever or instability in temperature.

In January 2005, the nonprofit Institute for Healthcare Improvement (IHI) started the *100,000 Lives* campaign. The goal was to save the lives of 100,000 patients in a period of 18 months by six specific, evidence-based clinical interventions. They encouraged hospitals to deploy rapid response teams, deliver evidenced-based care for acute myocardial infarction, prevent adverse drug events, prevent surgical site infections, prevent central line infections, and prevent VAP. The last two incorporated the use of bundles or collections of scientifically grounded interventions that were implemented collectively. These interventions have been successful. From the VAP standpoint the pre-bundle VAP incidence for PICU patients was reported in 2002 as 11.6/1000 ventilator days. [531] The VAP bundle has been tailored to pediatric patients,[532] and there have been significant improvements in VAP incidence. In a 2009 study showing the benefit of bundle implementation, Bigham and colleagues[533] showed a significant reduction in VAP incidence from 5.6 to 0.3 per 1000 ventilator days. This single-center study also showed a reduction in length of mechanical ventilation, length of stay, and mortality. This positive benefit of bundle initiation has been shown in other pediatric studies as well.[534,535]

In an effort to reduce incidence of new bacterial infection while patients are mechanically ventilated, the components of the VAP bundle aim to reduce bacterial colonization and prevent aspiration of contaminated secretions. To reduce the amount of bacteria present in the mouth and sinuses, mouth care is performed with a chlorhexidine rinse every 2 to 4 hours. Several things are done to reduce the risk of aspiration of contaminated secretions. First, suction the oropharynx before suctioning the ETT or deflating the ETT cuff. Second, drain the condensation that occurs in the ventilator tubing every 2 to 4 hours and before repositioning the patient; this should be done without disconnecting the ventilator circuit. Third, use inline suction catheters such that the ETT can be suctioned without disconnecting the ventilator circuit. Finally, by maintaining the head of the bed greater than 30 degrees there is a decreased risk of secretions in the ventilator tubing draining passively into the ETT.

The measures included in a VAP bundle are not difficult to perform and become routine practice quite quickly. More interesting is synergy that occurs with a bundle in that the effect of the combined interventions seems to be greater than any individual component. A strong adherence to a bundle of preventive measures has also been significantly helpful in the prevention of blood stream infection because of the presence of a central line.

CATHETER-ASSOCIATED BLOOD STREAM INFECTIONS

The development of catheter-associated bloodstream infection (CA-BSI) has received national recognition in both adults and pediatrics. It is one of the indicators by which hospitals are evaluated, and with CA-BSI there is a significant increase in hospital stay, morbidity, mortality, and cost. In a prospective study performed in a pediatric cardiac ICU, Abou and associates[536] showed 11% mortality in patients who developed a blood stream infection as compared with 2% mortality in patients who did not. It has been said by many that the best way to reduce a CA-BSI is never to place a central venous catheter. There is benefit to continually reviewing a patient's requirements for central venous access and when possible only using peripheral catheters. Unfortunately, there are many instances, such as the need for vasoactive medications, when central venous catheters cannot be avoided. The implementation of bundles to care for central venous catheters can significantly reduce the development of bloodstream infections and reduce the mortality and morbidity for each patient.

Implementation of preventive bundles during the insertion of, and ongoing maintenance of, central venous catheters will reduce infections. In a 2010 study in 29 PICUs,[537] there was a 43% reduction in the development of CA-BSI when bundles were used. These results are sustainable and continue to improve. The 2011 follow-up by the same group showed a further reduction in the incidence of CA-BSI.[538] The bundle can be broken down into two parts: central line insertion and maintenance. During the insertion of the central venous catheter, the goal of the bundle is to maintain complete sterility of the field. Chlorhexidine is used as the skin preparation for patients older than 2 months. All people in the room wear caps and masks. The persons performing the procedure wear these, as well as a sterile gown and gloves. A large, sterile barrier covering the entire bed is used. The second phase of the bundle is ongoing maintenance of the central venous catheter. There are strict guidelines for the care of the intravenous tubing, hub, and catheter insertion site. When dressing changes are performed, sterile gloves are used, the area is scrubbed for 30 seconds with chlorhexidine, and it is allowed to air dry for 30 seconds. Strict adherence to the same maintenance guidelines throughout the entire hospital is necessary to prevent CA-BSI. In many institutions, the number of infections has dropped so low that each event can be individually reviewed.

URINARY TRACT INFECTION

Catheter-associated urinary tract infections is the most common health-care–related infection. Removing a bladder catheter if it is not needed can significantly reduce the

risk of developing a urinary tract infection. In some cases, the catheter cannot be removed, and efforts should be made to prevent infection. Institution of a bladder-care bundle as a quality improvement measure can significantly reduce infection rates. In a 2013 study by Esteban and coworkers,[539] implementation of quality improvement interventions decreased the number of catheter-associated urinary tract infections from 23.3 to 5.8 per 1,000 urinary catheter days. The goals of a bladder catheter bundle are to reduce the bacterial colonization and to reduce the reflux of urine back into the bladder. Catheters are inserted in a sterile fashion, and periurethral cleaning is performed with a chlorhexidine cloth at least once per shift. To prevent reflux the collection bag is always kept below the level of the bladder and is drained completely or clamped before moving the patient.

INFECTIONS IN THE NEWBORN

Neonates with developmental immunologic deficiencies have increased susceptibility to infection. Depressed cell-mediated immunity makes the fetus and infant more susceptible to viral and fungal infection. In addition, infants have depressed B cell function and diminished production of immunoglobulins. The latter is partially offset by increased maternal immunoglobulin G. By 2 to 3 months of age, which is before infants can adequately produce their own antibodies in sufficient quantity, the level of maternal antibodies reaches a nadir.[540] The time during which the circulating antibody concentration is low is a time when the risk for infections is increased. Perinatal infections are acquired congenitally or postnatally. Congenital infections occur with prenatal exposure to viral, protozoal, or rarely, bacterial pathogens. Common diseases include the TORCH infections: *Toxoplasma gondii* (T); "other" (O), including human immunodeficiency virus (HIV), syphilis, and tuberculosis; rubella (R); cytomegalovirus (C); and herpes simplex virus type 2 (H). Rarely do these infections cause overwhelming sepsis, but they can be confused with bacterial infection when profound CNS depression, circulatory collapse, or thrombocytopenia occurs. When a TORCH infection develops in the first trimester of pregnancy, it causes fetal wastage or major organ malformation. Premature infants have a high incidence of acute infections in the newborn period. Regardless of gestational age, the signs and symptoms of infection are often subtle. Therefore, a high index of suspicion and low threshold for diagnosing and treating infection are required.[541] The most common acquired pathogens are those that colonize the mother's genital tract: group B streptococci, *E. coli*, *Listeria monocytogenes*, and herpesvirus. Herpes is such a fulminant infection in neonates that the presence of active herpes lesions in the birth canal is an indication for cesarean section, although this may not prevent herpes in all children. Group B *Streptococcus* is the most common bacterial pathogen that causes neonatal sepsis. Infection with group B streptococci is manifested as severe cardiorespiratory instability and meningitis in 30% of cases. By 2 to 3 weeks of age, this organism is more commonly associated with meningitis and less commonly with pulmonary disease. Whenever sepsis is suspected, cultures of blood, urine, and CSF should be obtained. Because it is difficult for the physician to localize the infection in an infant, repeated complete sepsis workups are often required. When appropriate cultures are obtained, treatment with ampicillin and an aminoglycoside, such as gentamicin, is usually begun until specific bacteriologic information becomes available. Approximately 50% of neonates thought to be septic have positive cultures.

PEDIATRIC TRAUMA

PRENATAL AND PERINATAL INJURIES

Perinatal trauma occurs before or immediately after birth (see Chapter 81). The most common prenatal injuries are due to maternal gunshot wounds and blunt trauma. Fetal mortality in both cases is at least twofold that of the mother,[542] with fetal death being attributable to maternal shock and fetal oxygen deprivation rather than direct injury. Birth injuries occur more commonly in large, full-term infants and in infants born by breech presentation. Injuries to the head include linear or depressed skull fractures, cephalohematomas, subdural or subarachnoid hematomas, and intraparenchymal or intraventricular hemorrhage. Intracranial injuries can increase ICP and cause cerebral ischemia, neurologic injury, and death. Injury to the sternocleidomastoid muscle can cause torticollis; traction on the neck can transect the cervical spinal cord. Less devastating nerve injuries caused by cervical traction are phrenic nerve paralysis and Erb or Klumpke palsy, which is caused by brachial plexus stretching or tearing (or both). Shoulder dystocia is commonly associated with clavicular and humoral fractures; femoral shaft fractures occur with breech deliveries. Injuries to the liver, spleen, adrenal glands, and kidneys can cause life-threatening hemorrhage or thrombosis. Vasoocclusion causes tissue loss in the cerebral, coronary, or renal vascular beds. Emergency instrumentation of the airway in the delivery room on rare occasion leads to tracheal and esophageal perforation, particularly in a premature infant.

TRAUMA IN CHILDREN

Accidents and trauma are the leading causes of death in children 1 to 14 years of age.[543] Children are frequently victims of falling or being dropped, drowning, near drowning, motor vehicle crashes (pedestrian), ingestions, and burns. Head injuries are common, especially in younger children, who have disproportionately large heads and relatively poor neck muscle support.[544] Young children are less likely to be victims of gunshot or knife attacks; blunt injuries are more common. Blunt trauma to the abdomen can cause solid organ injury (liver and spleen) rather than a perforated viscus. Hypothermia is a frequent complication of trauma; children lose heat rapidly because they have a relatively large surface-to-volume ratio. Drowning and near-drowning are the prototypical hypothermic injuries. Management of trauma patients of all ages requires an organized approach that permits rapid diagnosis and treatment. Most preventable deaths

in pediatric trauma patients are caused by airway obstruction, pneumothorax, and shock. Shock is often the result of inadequate treatment of bleeding or secondary brain injury from an expanding intracranial hematoma.[545] The American College of Surgeons recommends a four-step approach to pediatric trauma patients: (1) primary survey, (2) resuscitation, (3) secondary survey, and (4) definitive care.[250] The primary survey requires rapid assessment of the airway, breathing, and circulation (ABCs). A disproportionately large tongue, in relation to a narrow oropharynx, easily obstructs the airway in an unconscious child. Proper jaw positioning enables bag-valve-mask ventilation until the trachea is intubated. Ventilation through an inadequate airway can lead to gaseous distention of the stomach, vomiting, and aspiration of gastric contents. Cervical spine injuries are less common in children than in adults, but the child's neck should be immobilized until spinal injury is excluded. After establishing an airway, adequacy of respiration should be verified by observation of symmetric chest movement, auscultation of normal and equal breath sounds, and an early chest radiograph. Tension hemopneumothorax can be diagnosed clinically and treated by needle aspiration. Aspiration will alleviate the tension and stabilize the patient's condition until a chest tube can be inserted. Circulation can be assessed quickly by looking for tachycardia, poor peripheral perfusion, weak peripheral pulses, and hypotension (which might not occur until blood loss exceeds 25% of the circulating blood volume).[546] A severely hypovolemic child requires rapid insertion of a central venous catheter. If a peripheral venous catheter cannot be inserted expeditiously, an intraosseous cannula should be placed.[547] The amount of volume resuscitation is dictated by the clinical condition of the child and the estimated volume of blood or plasma lost. During the secondary survey, a thorough head-to-toe examination is performed, and a plan of definitive treatment is developed. Diagnostic measures in a pediatric trauma patient are similar to those in adult patients, but there should be consideration of special problems that occur in children. Most intraabdominal injuries requiring laparotomy are recognized clinically because they produce peritonitis or cause increasing abdominal girth.[548] Diagnostic peritoneal lavage can be of help in children who are hemodynamically unstable despite administering more than 40 mL/kg of blood. Peritoneal lavage can locate the site of occult bleeding in a child who is too unstable to undergo CT, or it can be used to evaluate abdominal injury in a child about to undergo emergency surgery that is not abdominal. Many practitioners forego this procedure if surgery is imminent. Indications for surgical intervention for abdominal trauma include free peritoneal air, evidence of a ruptured viscus, and acute uncontrolled bleeding. A ruptured spleen or a liver laceration is not an indication for surgery in and of itself; the preferred treatment is supportive care, blood volume replacement, and reevaluation.[549] A careful head and neurologic examination is done to detect intracranial trauma quickly. The most important indicator of intracranial trauma is a decrease in the level of consciousness. Rapid diagnosis and treatment of intracranial mass lesions will reduce ICP and may prevent secondary brain injury.

CHILD ABUSE

The diagnosis of child abuse is made by finding an acute injury that might have a plausible explanation and signs of past trauma, including healing bruises, contusions, and fractures. Child abuse can also take the form of psychological or sexual abuse and failure to meet a child's need for food, clothing, shelter, hygiene, medical care, education, or supervision. Suspicion of child abuse begins with an inappropriate or inadequate explanation for the child's injuries or when the degree of trauma exceeds the stated cause. Multiple hospital admissions, emergency department visits, doctor or hospital "shopping," and a history of previous trauma should be of concern. Frequently, the story regarding the injury changes over time. Certain clinical features are common to child abuse, but they are by no means pathognomonic. Most abused children are older than 3 years; they sometimes have poor hygiene and delayed somatic or psychological development. The injuries most commonly include bruises, welts, lacerations, scalds, and burns from cigarettes, stoves, heating grates, or irons. Long-bone fractures, often of varying age, abdominal injuries, signs of smothering, and multiple soft tissue or genital bruises are also common. Head injuries can occur. Shaking an infant can cause neck injuries, intracranial hemorrhage, and contrecoup injuries without necessarily producing external manifestations of trauma. The approach to a possible victim of child abuse includes a meticulous and nonjudgmental history, written in detail in the chart. All allegations are recorded and changes in the reported history are documented. The physical examination includes growth parameters, descriptions of soft tissue bruising or burns, and diagrams or preferably photographs of all injuries. The color, shape, placement, and estimated age of all injuries should be catalogued. Laboratory studies should include the following: a skeletal survey of all long bones, ribs, and the skull; a coagulation profile, including hematocrit, platelet count, PT, and PTT; and genital and throat cultures for venereal disease if sexual abuse is suspected. If child abuse is suspected, it must be reported to the authorities.

INGESTION INJURY

Despite the success of various preventive public health programs, poisoning continues to occur commonly in pediatric patients. Fortunately, the vast majority of presumed poisonings in young children can be managed by telephone consultation with a regional poison control center. In one study, acute poisoning accounted for approximately 5% of all medical admissions to a PICU.[550] Approximately half of these admissions were accidental ingestions, and half were attempted suicides. The median age for the accidental poisoning group was 2 years; it was 15 years for the suicide group. Although many different toxic substances are ingested by children and adolescents, management of poisoning has three main goals: (1) identifying, decontaminating, and eliminating the toxic agents[551]; (2) minimizing the toxic effects on the child; and (3) providing close observation and organ system support until detoxification is complete. Procedures

for drug elimination include emesis, gastric lavage, activated charcoal, and magnesium citrate. Toxic effects can be minimized with specific antidotes when available, by hemodialysis, or by charcoal hemoperfusion. Examples of specific antidotes are deferoxamine for iron ingestion, ethanol infusion for methanol ingestion, naloxone for narcotic overdose, and *N*-acetylcysteine for acetaminophen ingestion. Because many ingestions, particularly those for attempted suicide, include multiple drugs, specific antidote therapy is only occasionally successful. Organ system support usually includes airway protection and mechanical ventilation, intravenous fluids, cardiovascular monitoring for arrhythmias and myocardial depression, and anticonvulsive therapy for patients who are seizing. Consultation with clinical pharmacologists or with the regional poison control center and contacting a social worker or psychiatrist are essential aspects of the care of an acutely toxic child. Common complications of ingestions and their therapy include aspiration pneumonia with hydrocarbon ingestion or loss of glottic function, sepsis, respiratory depression, myocardial depression, arrhythmias, seizures, and coma. The psychosocial environment that allowed or precipitated the ingestion must also be considered. Families should be counseled about proper supervision and "child-proofing" their home. Psychiatric intervention should be introduced early; unsuccessful suicide attempts are often repeated.

TRANSPORT OF THE CRITICALLY ILL CHILD

Transport of critically ill children can be intrahospital or interhospital. Intrahospital transport of patients is necessary when moving to and from the operating room; however, this also includes transport for radiologic procedures and studies throughout the hospital. In this circumstance, the clinician who ordered the test must understand the balance of risk and benefit. Is the information that can be obtained by an MRI worth the transport, changes in monitoring, and the time away from the ICU? In the case of a brain MRI, a patient may be away from the unit for 90 to 120 minutes with transport. There are significant differences in the ability to monitor and provide care to those patients. CT scans are shorter but still entail many of the same risks. The severity of the patient's illness must be considered. Any patient with an ETT is at risk for obstruction or dislodgement. Any patient requiring inotropic support is at risk for those medications being interrupted. Depending on the hospital, the team transporting the patient may include a respiratory therapist, bedside nurse, and transport nurse. Some hospitals will send their ICU fellows, and some have a dedicated intrahospital transport team. When new equipment is purchased, transport monitors should be considered that have the ability to monitor $ETCO_2$. In the smallest patients, maintenance of body temperature can be difficult during transport.

Interhospital transport systems are typically established by a tertiary care hospital. Smaller community hospitals may use outside resources. One should investigate the capabilities of the transport team available. Details to understand include the availability of helicopter and fixed-wing flight, types of practitioners on the transport team, coverage in the circumstance where the primary team is out on a transport, and the ability to provide interventions when the transport team arrives at the outside facility. Many transport care physicians will be able to intubate, place arterial and venous lines, and place chest tubes at an outside facility. All this information is valuable when speaking to the referring hospital. In that regard, the person receiving the transport request may need to assess whether the patient is safe to transfer by a team that provides only basic life-support resuscitation. For hospitals unfamiliar with caring for critically ill children, it may be foremost in their mind to get the child to a higher level of care, and out of their hospital. They may not have considered what support is available during the transport if the patient deteriorates. They may be unwilling to wait for arrival of a transport team, but make the overall needs of the child must be the focus of the discussion. When deciding on the make-up of the transport team, the distance of the referring hospital, condition of the child, ongoing resuscitation efforts and chance of change in condition need to be considered. While the transport team is en route, the referring hospital should continue to support and resuscitate the child with advice from the receiving hospital. Further information regarding the development of a transport team are beyond the scope of this chapter. One excellent resource is the Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients available through the American Academy of Pediatrics. An understanding of altitude physiology is necessary when considering transport by helicopter. One may not give much thought to the barometric pressure in the alveolar gas equation:

$$PAO_2 = (P_B - P_{H_2O}) \times FiO_2 - (PaCO_2/R)$$

This is because at sea level P_B is 760 mm Hg; however at 8,000 feet P_B is 565 mm Hg. Supplemental oxygen may be needed in flight, and low saturation may remain even with supplemental oxygen for patients with significant lung disease. From Boyles law ($Pressure_1 \times Volume_1 = Pressure_2 \times Volume_2$) there will be expansion of gas with the decreased pressure of altitude; this means that a small pneumothorax can expand to a large pneumothorax. The size of an ETT cuff can expand, putting significant pressure on the trachea. The PICU relies significantly on the skills of the transport team. To maintain proficiency, the providers will need to practice intubation and other procedures. It is important to consider helping when asked to be shadowed by a transport physician or nurse in the operating room to gain practice with intubation.

Chapter 96

The Postanesthesia Care Unit

THEODORA KATHERINE NICHOLAU

Key Points

- Emergence from general anesthesia and surgery may be accompanied by a number of physiologic disturbances that affect multiple organ systems. Most common are postoperative nausea and vomiting (PONV), hypoxia, hypothermia and shivering, and cardiovascular instability.
- In a prospective study of more than 18,000 consecutive admissions to the postanesthesia care unit (PACU), the complication rate was found to be as frequent as 24%. Nausea and vomiting (9.8%), the need for upper airway support (6.8%), and hypotension (2.7%) were the most common problems.
- The most frequent cause of airway obstruction in the immediate postoperative period is the loss of pharyngeal muscle tone in a patient who is sedated or obtunded. The persisting effects of inhaled and intravenous anesthetics, neuromuscular blocking drugs, and opioids all contribute to the loss of pharyngeal tone in the patient in the PACU.
- The oropharyngeal muscles are the last muscle group to recover from neuromuscular blockade. Routine monitoring by the train-of-four (TOF) ratio does not accurately reflect the return of pharyngeal muscle tone.
- The use of intermediate-acting neuromuscular blocking agents is associated with an increased incidence of postoperative respiratory complications. Reversal with the anticholinesterase neostigmine does not prevent and may in fact increase the incidence of postoperative pulmonary complications.
- An estimated 8% to 10% of patients who undergo abdominal surgery subsequently require intubation and mechanical ventilation in the PACU. Respiratory failure in the immediate postoperative period is often due to transient and rapidly reversible conditions such as splinting from pain, diaphragmatic dysfunction, muscular weakness, and a pharmacologically depressed respiratory drive.
- Although a combination of leads II and V_5 will reflect 80% of the ischemic events detected on a 12-lead electrocardiogram (ECG), visual interpretation of the cardiac monitor is often inaccurate. Because of human error, guidelines from the American College of Cardiology recommend that computerized ST-segment analysis be used (if available) to monitor patients at high risk for cardiac complications in the immediate postoperative period.
- In one study, the incidence of postoperative urinary retention, defined as bladder volume greater than 600 mL in conjunction with an inability to void within 30 minutes, was 16%. The most significant predictive factors were age older than 50 years, intraoperative fluid greater than 750 mL, and bladder volume on entry to the PACU greater than 270 mL.
- Perioperative attention to adequate intravenous hydration is indicated in any patient who has received an intravenous contrast agent. Aggressive hydration with normal saline provides the single most effective protection against contrast nephropathy.
- Rhabdomyolysis has been reported to occur in 22.7% of 66 consecutive patients undergoing laparoscopic bariatric surgery. Risk factors include increased body mass index (BMI) and duration of surgery.
- The incidence of postoperative shivering may be as high as 65% (ranging from 5% to 65%) after general anesthesia and 33% after epidural anesthesia. Identified risk factors include male gender and the choice of induction agent; propofol is more commonly associated with shivering than is pentothal.

KEY POINTS—cont'd

- Approximately 10% of adult patients older than age 50 years who undergo elective surgery will experience some degree of postoperative delirium within the first 5 postoperative days. The incidence is significantly higher for certain procedures, such as repair of hip fracture (>35%) and bilateral knee replacement (41%).
- PACU Standards of Care require that a physician accept responsibility for the discharge of patients from the unit (Standard V), even when the decision to discharge the patient is made at the bedside by the PACU nurse in accordance with hospital-sanctioned discharge criteria or scoring systems.

The postanesthesia care unit (PACU) is designed and staffed to monitor and care for patients who are recovering from the immediate physiologic effects of anesthesia and surgery. PACU care spans the transition from one-on-one monitoring in the surgical unit to the less acute monitoring on the hospital ward or, in some cases, independent function of the patient at home. To serve this unique transition period, the PACU is equipped to resuscitate patients who are unstable while providing a tranquil environment for the "recovery" and comfort of patients who are stable. Its location, which is in close proximity to the surgical department, facilitates rapid access to anesthesiologists for consultation and assistance.

ADMISSION TO THE PACU

Specially trained nurses skilled in the prompt recognition of postoperative complications make up the staff of the PACU. On arrival of a patient to the PACU, the anesthesiologist provides the PACU nurse with pertinent details of the patient's history, medical condition, anesthesia, and surgery. Particular attention is directed toward monitoring oxygenation (pulse oximetry), ventilation (breathing frequency, airway patency, capnography), and circulation (systemic blood pressure, heart rate, electrocardiogram [ECG]). Vital signs are recorded as often as necessary but at least every 15 minutes while the patient is in the unit. Vital signs and other pertinent information are recorded as part of the patient's medical record. Specific requirements and recommendations for patient monitoring and therapeutic intervention can be found in the Practice Standards and Guidelines drafted by the American Society of Anesthesiologists (ASA).

STANDARDS FOR POSTANESTHESIA CARE

Practice Standards delineate the required *obligation* of *minimal* care in the clinical setting. As such, they serve as a threshold that can be exceeded when indicated by the clinical judgment of the practitioner. The Standards for Postanesthesia Care are updated on a regular basis to keep up with changing practice parameters and technologic advances. The most recent revision, published in 2009, is summarized here.[1]

I. All patients who have received general anesthesia, regional anesthesia or monitored anesthesia care shall receive appropriate postanesthesia management.
II. A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.
III. Upon arrival in the PACU, the patient shall be re-evaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.
IV. The patient's condition shall be evaluated continually in the PACU. The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, level of consciousness, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery.*
V. A physician is responsible for the discharge of the patient from the postanesthesia care unit.

Unlike Practice Standards, Practice Guidelines are not requirements. They are recommendations designed to assist the health care provider in clinical decision making. The ASA Practice Guidelines for Postanesthetic Care are the result of a multiple-step process that incorporates input from three groups: (1) an ASA-appointed taskforce consisting of private practice and academic anesthesiologists and epidemiologists; (2) PACU consultants; and (3) ASA members at large. These Guidelines are based on literature review, expert opinion, open forum commentary, and clinical feasibility. They recommend the appropriate assessment, monitoring, and treatment of the major organ system functions during recovery from anesthesia and surgery (Box 96-1).[2]

*Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

BOX 96-1 *Summary of Recommendations for Patient Assessment and Monitoring in the Postanesthesia Care Unit*

Respiratory

Assessment of airway patency, respiratory rate, and oxygen saturation should be periodically performed. Particular attention should be given to monitoring oxygenation and ventilation.

Cardiovascular

Heart rate and blood pressure should be routinely monitored. Electrocardiographic monitors should be immediately available.

Neuromuscular

Assessment of neuromuscular function should be performed for all patients who received nondepolarizing neuromuscular blocking drugs or who have medical conditions associated with neuromuscular dysfunction (also see Chapter 53).

Mental Status

Mental status should be periodically assessed.

Temperature

Patient temperature should be periodically assessed.

Pain

Pain should be periodically assessed.

Nausea and Vomiting

Periodic assessment of postoperative nausea and vomiting should be routinely performed

Hydration

Postoperative hydration should be assessed and managed accordingly. Certain procedures may involve significant blood loss and require additional intravenous fluids management.

Urine

Assessment of urine output and of urinary voiding should be performed on a case-by-case basis for selected patients or selected procedures.

Drainage and Bleeding

Assessment of drainage and bleeding should be performed periodically as needed

From Apfelbaum JL, Silverstein JH, Chung FF, et al: Practice guidelines for postanesthetic care: an updated report by the American Society of Anesthesiologists Task Force on Postanesthetic Care, Anesthesiology *118:291-307, 2013.*

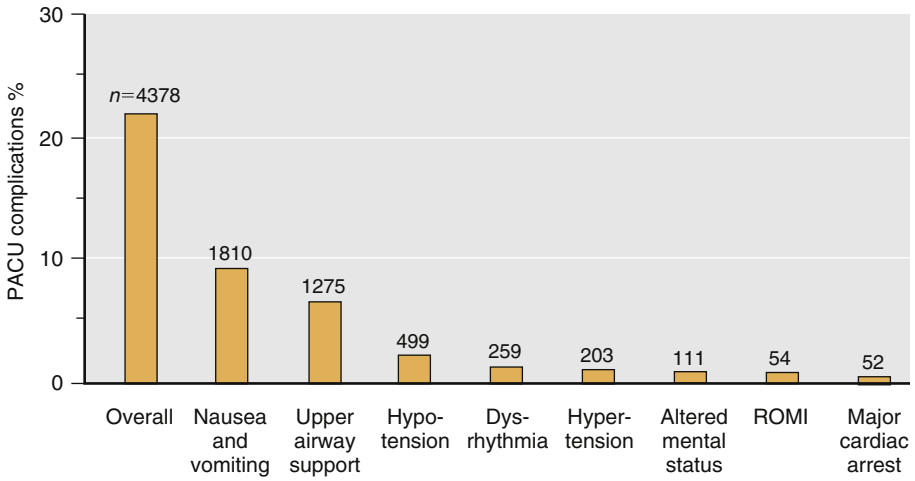

Figure 96-1. The overall complication rate in 18,473 consecutive admissions to a postanesthesia care unit (PACU) was 23.7%. Nausea and vomiting, the need for upper airway support, and hypotension were the most frequent individual complications. *ROMI,* Rule out myocardial infarction. *(From Hines HR, Barash PG, Watrous G, et al: Complications occurring in the postanesthesia care unit: a survey,* Anesth Analg *74:503-509, 1992. Used with permission.)*

In addition to the recommendations for patient assessment and monitoring in the PACU summarized in Box 96-1, other recommendations include the following:

- Multiple antiemetic agents are used for the prevention or treatment of postoperative nausea and vomiting (PONV).
- Oxygen is administered for patients at risk of hypoxemia.
- When available, forced air warmers should be used to reach the goal of normothermia.
- Demerol or other opioid agonists should be used for the treatment of postoperative shivering but not replace treating hypothermia by rewarming.
- Specific antagonists should be available whenever benzodiazepines, opioids, or neuromuscular blockers have been administered.
- The requirement for urination or drinking clear liquids should not be part of a discharge protocol but may be necessary for selected patients.
- ALL patients should be required to have a responsible individual to accompany them home.
- A mandatory minimum stay should not be required, but patients should be observed until they are no longer at risk for cardiopulmonary depression.

EARLY POSTOPERATIVE PHYSIOLOGIC CHANGES

A number of physiologic disturbances that affect multiple organ systems may accompany the patient's emergence from general anesthesia and surgery. Most common are PONV, hypoxia, hypothermia and shivering, and cardiovascular instability. In a prospective study of more than 18,000 consecutive admissions to the PACU, the complication rate was found to be as high as 24%. Nausea and vomiting (9.8%), the need for upper airway support (6.8%), and hypotension (2.7%) were the most common (Fig. 96-1).[3]

TABLE 96-1 **PRIMARY PRESENTING PROBLEM IN 419 RECOVERY ROOM INCIDENTS REPORTED TO AUSTRALIAN INCIDENT MONITORING STUDY**

Primary Presenting Problem	No. (%)

Renal	1 (0.2)
Skin	1 (0.2)
Blood transfusion	1 (0.2)
Facility limitations	1 (0.2)
Gastrointestinal problems	1 (0.2)

From Kluger MT Bullock MF: Recovery room incidents: a review of the Anesthetic Incident Monitoring Study (AIMS), Anesthesia *57:1060-1066, 2002.*

Over a 4-year period ending in 1989, 7.1% of the 1175 anesthesia-related malpractice claims in the United States were attributed to recovery incidents.[4] Despite the significant incidence of nausea and vomiting in the PACU, serious adverse outcomes correlate more closely with airway, respiratory, and cardiovascular compromise. In 2002, airway and respiratory problems (183, 43%) and cardiovascular events (99, 24%) accounted for the majority of 419 recovery room incidents reported to the Australian Incident Monitoring Study (AIMS) database (Table 96-1).[5] Similar data were obtained from the United States closed claims database in 1989, in which critical respiratory incidents accounted for more than one half of the recovery room malpractice claims.[4]

TRANSPORT TO THE PACU

Upper airway patency and the effectiveness of the patient's respiratory efforts must be monitored when transporting the patient from the surgical department to the PACU. Watching for the appropriate rise and fall of the chest wall with inspiration, listening for breath sounds, or simply feeling for exhaled breath with the palm of one's hand over the patient's nose and mouth can confirm adequate ventilation.

With rare exceptions, all patients who undergo general anesthesia should receive supplemental oxygen during their transport to the PACU. In an observational study of 502 patients admitted to the PACU, breathing room air during transport was the single most significant factor to correlate with hypoxemia (oxygen saturation < 90%) on arrival. Other significant factors included elevated body mass index (BMI), sedation score, and respiratory rate.[6]

Although the majority of otherwise healthy patients undergoing ambulatory surgery can be safely transported breathing room air, the decision to do so must be made on a case-by-case basis. In the ambulatory setting, advanced age (>60 years) (see Chapters 80 and 89) and weight (>100 kg) identifies adults who are at increased risk for oxygen desaturation when breathing room air on transport to the PACU.[7] Hypoventilation alone may cause hypoxemia even in healthy patients who undergo minor procedures.

UPPER AIRWAY OBSTRUCTION

LOSS OF PHARYNGEAL MUSCLE TONE

The most frequent cause of airway obstruction in the immediate postoperative period is the loss of pharyngeal muscle tone in a patient who is sedated or obtunded. The persistent effects of inhaled and intravenous anesthetics, neuromuscular blocking drugs, and opioids all contribute to the loss of pharyngeal tone in the patient in the PACU.

In an awake patient, the pharyngeal muscles contract at the same time that negative inspiratory pressure is generated by the diaphragm, facilitating opening of the upper airway. As a result, the tongue and soft palate are pulled forward, tenting the airway open during inspiration. This pharyngeal muscle activity is depressed during sleep, and the resulting decrease in tone can promote airway obstruction. A vicious cycle then ensues in which the collapse of compliant pharyngeal tissue during inspiration produces a reflex compensatory increase in respiratory effort and negative inspiratory pressure that promotes further airway obstruction.[8]

A paradoxical breathing pattern consisting of retraction of the sternal notch and exaggerated abdominal muscle activity characterizes the effort to breathe against an obstructed airway. Collapse of the chest wall and protrusion of the abdomen with inspiratory effort produce a rocking motion that becomes more prominent with increasing airway obstruction. Simply opening the airway with the *jaw thrust maneuver* or continuous positive airway pressure (CPAP) applied via a facemask (or both) can relieve airway obstruction secondary to the loss of pharyngeal tone. Support of the airway is needed until the patient has adequately recovered from the effects of drugs administered during anesthesia. In selected patients, placement of an oral or nasal airway, laryngeal mask airway, or endotracheal tube may be required.

RESIDUAL NEUROMUSCULAR BLOCKADE

When evaluating upper airway obstruction in the PACU, the possibility of residual neuromuscular blockade should be considered in any patient who received neuromuscular blocking drugs during anesthesia (Box 96-2)[9,10] (see also Chapter 35). Residual neuromuscular blockade may not be evident on arrival in the PACU because the diaphragm recovers from neuromuscular blockade before the pharyngeal muscles do. With an endotracheal tube in place, end-tidal carbon dioxide concentrations and tidal volumes may indicate adequate ventilation while the ability to maintain a patent upper airway and clear upper airway secretions remains compromised. The stimulation associated with tracheal extubation, followed by the activity of

BOX 96-2 *Factors Contributing to Prolonged Nondepolarizing Neuromuscular Blockade*

Drugs

Inhaled anesthetic drugs
Local anesthetics (lidocaine)
Cardiac antiarrhythmics (procainamide)
Antibiotics (polymyxins, aminoglycosides, lincosamines [clindamycin], metronidazole [Flagyl], tetracyclines)
Corticosteroid agents
Calcium channel blockers
Dantrolene

Metabolic and Physiologic States

Hypermagnesemia
Hypocalcemia
Hypothermia
Respiratory acidosis
Hepatic or renal failure
Myasthenia syndromes

Factors Contributing to Prolonged Depolarizing Blockade

Excessive dose of succinylcholine
Reduced plasma cholinesterase activity
Decreased levels
- Extremes of age (newborn, old age)
- Disease states (hepatic disease, uremia, malnutrition, plasmapheresis)
- Hormonal changes
- Pregnancy
- Contraceptives
- Glucocorticoids

Inhibited activity
- Irreversible (echothiophate)
- Reversible (edrophonium, neostigmine, pyridostigmine)

Genetic variant (atypical plasma cholinesterase)

patient transfer to the gurney and subsequent mask airway support, may keep the airway open during transport to the PACU. Only after the patient is calmly resting in the PACU does upper airway obstruction become evident. Even patients treated with intermediate- and short-acting neuromuscular blocking drugs may exhibit residual paralysis in the PACU, despite what was deemed clinically adequate pharmacologic reversal in the surgical unit.

The train-of-four (TOF) ratio routinely used to evaluate neuromuscular function in anesthetized patients is unreliable.[11] Measurement of the TOF ratio is a subjective assessment that is often misleading when performed by touch or visual observation alone. A decline in the TOF ratio may not be appreciated until it reaches a value less than 0.4 to 0.5, whereas significant signs and symptoms of clinical weakness persist to a ratio of 0.7.[12] Furthermore, pharyngeal function is not restored to normal until an adductor pollicis TOF ratio is greater than 0.9.[13] Although 5 seconds of sustained tetanus to 100-Hz stimulation has been regarded as the most reliable indicator of adequate reversal of drug-induced neuromuscular blockade,[12,14] it is fraught with the same errors in interpretation as the TOF ratio.

Particular attention should be paid to patients who have received neuromuscular blockade even when the reversal agent neostigmine is administered. A prospective study of over 18,000 surgical patients who received intermediate-acting neuromuscular blocking drugs and their matched cohorts showed that paralysis with intermediate-acting neuromuscular blockade is associated with an increased risk of clinically meaningful postoperative respiratory complications, regardless of anticholinesterase reversal.[11]

In an awake patient, clinical assessment of reversal of neuromuscular blockade is preferred to the application of painful TOF or tetanic stimulation. Clinical evaluation includes grip strength, tongue protrusion, ability to lift the legs off the bed, and ability to lift the head off the bed for a full 5 seconds. Of these maneuvers, the 5-second sustained head lift has been considered to be the standard, reflecting not only generalized motor strength but, more importantly, the patient's ability to maintain and protect the airway. However, the ability to oppose the incisor teeth strongly against a tongue depressor is a more reliable indicator of pharyngeal muscle tone. This maneuver correlates with an average TOF ratio of 0.85, as opposed to 0.60 for the sustained head lift.[12] In a year-long study of 7459 patients who had received general anesthesia, Murphy and colleagues defined critical respiratory events (CREs) in 61 of these patients (see Chapter 35). These events occurred within the first 15 minutes of PACU admission, at which time a TOF ratio was measured. When compared with matched controls, these patients had a significantly lower TOF ratio (0.62 [±0.20]), compared with controls (90.98 [±0.07]).[15]

The manifestation of weakness in the patient in the PACU may be respiratory distress and/or agitation. If one suspects the persistence or return of neuromuscular weakness in the patient, then a prompt review of possible etiologic factors is indicated (see Box 96-2). Common factors include respiratory acidosis and hypothermia, alone or in combination. Upper airway obstruction as a result of the residual depressant effects of volatile anesthetics or opioids (or both) may result in progressive respiratory acidosis after the patient is admitted to the PACU and external stimulation is minimized. Simple measures such as warming the patient, airway support, and correction of electrolyte abnormalities can facilitate recovery from neuromuscular blockade. The use of sugammadex, instead of neostigmine, might possibly lead to a reduced incidence of residual neuromuscular blockade in the PACU. Although reversal with neostigmine requires a baseline twitch response to be effective, sugammadex, a selective rocuronium-binding agent, does not. In a recent study, reversal with sugammadex resulted in a return of TOF ratio to greater than 0.9 within 5 minutes in 85% of patients with no twitches on TOF stimulation.[16] Although the drug has been in use in Europe since 2008, it is currently available only for investigational use in the United States (also see Chapter 35). A United States clinical trial comparing sugammadex with usual care with neostigmine for reversal of neuromuscular blockade induced by rocuronium was conducted in 2012.[17]

LARYNGOSPASM

Laryngospasm refers to a sudden spasm of the vocal cords that completely occludes the laryngeal opening. It typically occurs in the transitional period when the extubated patient is emerging from general anesthesia. Although

laryngospasm is most likely to occur in the operating room at the time of tracheal extubation, patients who arrive in the PACU asleep after general anesthesia are also at risk for laryngospasm on awakening.

Jaw thrust maneuver with CPAP (up to 40 cm water [H_2O]) is often sufficient stimulation to *break* the laryngospasm. If jaw thrust maneuver and CPAP fail, then immediate skeletal muscle relaxation can be achieved with succinylcholine (0.1 to 1.0 mg/kg intravenously [IV] or 4 mg/kg intramuscularly [IM]). Attempting to pass a tracheal tube forcibly through a glottis that is closed because of laryngospasm is not acceptable.

EDEMA OR HEMATOMA

Airway edema is a possible surgical complication in patients undergoing prolonged procedures in the prone or Trendelenburg position. It can be particularly significant in procedures that involve large blood loss and require aggressive fluid resuscitation. Although facial and scleral edema is an important physical sign that can alert the clinician to the presence of airway edema, visible external signs may not accompany significant edema of pharyngeal tissue (see also Chapter 55). In addition to the generalized edema just described, surgical procedures on the tongue, pharynx, and neck, including thyroidectomy,[18,19] carotid endarterectomy,[20] and cervical spine procedures,[21] can produce more localized tissue edema or hematoma. If tracheal extubation is to be attempted in these patients in the PACU, then evaluation of airway patency must precede removal of the endotracheal tube. The patient's ability to breathe around the endotracheal tube can be evaluated by suctioning the oral pharynx and deflating the endotracheal tube cuff. With occlusion of the proximal end of the endotracheal tube, the patient is then asked to breathe around the tube. Good air movement suggests that the patient's airway will remain patent after tracheal extubation.[22] An alternative method involves measuring the intrathoracic pressure required to produce a *leak* around the endotracheal tube with the cuff deflated. This method was originally used to evaluate pediatric patients with croup before extubation.[23] When used in patients with general oropharyngeal edema, the *safe* pressure threshold can be difficult to identify. Lastly, when ventilating patients in the volume control mode, one can measure the exhaled tidal volume before and after cuff deflation. Patients who require reintubation generally have a smaller leak (i.e., less percentage difference between exhaled volume before and after cuff deflation) than those who do not. A difference greater than 15.5% is the advocated cutoff value for extubation of the trachea.[24] The presence of a cuff leak demonstrates the likelihood of successful extubation, not a guarantee, just as a failed cuff leak does not rule out a successful extubation.[25,26] The cuff leak test does not take the place of sound clinical judgment.

Mask ventilation may not be possible in a patient with severe upper airway obstruction resulting from edema or hematoma. In the case of hematoma after thyroid or carotid surgery, an attempt can be made to decompress the airway by releasing the clips or sutures on the wound and evacuating the hematoma. This maneuver is recommended as a temporizing measure, but it will not effectively decompress the airway if a significant amount of fluid or blood (or both) has infiltrated the tissue planes of the pharyngeal wall. If emergency tracheal intubation is required, then ready access to difficult airway equipment and, if possible, surgical backup to perform an emergency tracheostomy are important. If the patient is able to move air by spontaneous ventilation, then an awake technique is preferred because visualization of the cords by direct laryngoscopy may not be possible.

OBSTRUCTIVE SLEEP APNEA

Because most patients with obstructive sleep apnea (OSA) are not obese and the vast majority are undiagnosed at the time of surgery, OSA syndrome is often an overlooked cause of airway obstruction in the PACU [27,28]

Patients with OSA are particularly prone to airway obstruction and should not be extubated until they are fully awake and following commands.[8,29] Any redundant compliant pharyngeal tissue in these patients not only increases the incidence of airway obstruction, but it also often makes intubation by direct laryngoscopy difficult or impossible.[30,31] Once in the PACU, a patient with OSA whose trachea has been extubated is exquisitely sensitive to opioids and, when possible, continuous regional anesthesia techniques should be used to provide postoperative analgesia.[32,33] Interestingly, benzodiazepines can have a greater effect on pharyngeal muscle tone than opioids, and the use of benzodiazepines in the perioperative setting can significantly contribute to airway obstruction in the PACU.[8,34]

When caring for a patient with OSA, plans should be made preoperatively to provide CPAP in the immediate postoperative period. Patients should be asked to bring their CPAP machines with them on the day of surgery to enable the equipment to be set up before the patient's arrival in the PACU. Patients who do not routinely use CPAP at home or who do not have their machines with them may require additional attention from the respiratory therapist to ensure proper fit of the CPAP delivery device (mask or nasal airways) and to determine the amount of positive pressure needed to prevent upper airway obstruction.[35,36]

In patients with OSA who are morbidly obese immediately applying CPAP postextubation in the surgical department rather than waiting to apply positive pressure in the PACU may offer additional benefits. In patients undergoing laparoscopic bariatric surgery, Neligan and colleagues compared the application of 10 cm H_2O CPAP immediately postextubation to instituting the same CPAP 30 minutes later in the PACU. When compared with matched controls, patients who received immediate CPAP demonstrated improved spirometric lung function (i.e., functional residual capacity [FRC], peak expiratory flow [PEF], and forced expiratory volume [FEV]) at 1 hour and 24 hours postoperatively.[37]

MANAGEMENT OF UPPER AIRWAY OBSTRUCTION

An obstructed upper airway requires immediate attention. Efforts to open the airway by noninvasive measures should be attempted before reintubation of the

trachea. Jaw thrust maneuver with CPAP (5 to 15 cm H_2O) is often enough to tent the upper airway open in patients with decreased pharyngeal muscle tone. If CPAP is not effective, then an oral, nasal, or laryngeal mask airway can be rapidly inserted. After successfully opening the upper airway and ensuring adequate ventilation, the cause of the upper airway obstruction should be identified and treated. In adults, the sedating effects of opioids and benzodiazepines can be reversed with persistent stimulation or small, titrated doses of naloxone (0.3 to 0.5 μg/kg IV) or flumazenil (0.2 mg IV to maximum dose of 1 mg), respectively. Residual effects of neuromuscular blocking drugs can be reversed pharmacologically or by correcting contributing factors such as hypothermia.

DIFFERENTIAL DIAGNOSIS OF ARTERIAL HYPOXEMIA IN THE PACU

Atelectasis and alveolar hypoventilation are the most common causes of transient postoperative arterial hypoxemia in the immediate postoperative period.[38] Clinical correlations should guide the postoperative workup of a patient who remains persistently hypoxic.[39] Review of the patient's history, operative course, and clinical signs and symptoms will direct the workup to consider possible causes (Box 96-3).

ALVEOLAR HYPOVENTILATION

A review of the alveolar gas equation demonstrates that hypoventilation alone is sufficient to cause arterial hypoxemia in a patient breathing room air (see also Chapter 19) (Fig. 96-2). At sea level, a normocapnic patient who is breathing room air will have an alveolar oxygen pressure (PAO_2) of 100 mm Hg. Thus a healthy patient without a significant alveolar-arterial gradient will have a PaO_2 near 100 mm Hg. In the same patient, an increase in partial alveolar pressure of carbon dioxide (P_{ACO_2}) from 40 to 80 mm Hg (alveolar hypoventilation) results in a PAO_2 of 50 mm Hg. Hence, even a patient with normal lungs will become hypoxic if allowed to significantly hypoventilate while breathing room air.

Normally, minute ventilation increases linearly by approximately 2 L/min for every 1-mm Hg increase in P_{ACO_2}. In the immediate postoperative period, the residual effects of inhaled anesthetics, opioids, and sedative-hypnotic agents can significantly depress this ventilatory response to carbon dioxide. In addition to depressed respiratory drive, the differential diagnosis of postoperative hypoventilation includes generalized weakness as a result of residual neuromuscular blockade or underlying neuromuscular disease. The presence of restrictive pulmonary conditions, such as preexisting chest wall deformity, postoperative abdominal binding, or abdominal distention, can also contribute to inadequate ventilation.

Arterial hypoxemia secondary to hypercapnia can be reversed by the administration of supplemental oxygen (Fig. 96-3)[40] or by normalizing the patient's P_{ACO_2} by external stimulation of the patient to wakefulness,

BOX 96-3 ***Factors Contributing to Postoperative Arterial Hypoxemia***

- Right-to-left intrapulmonary shunt (atelectasis)
- Mismatching of ventilation to perfusion (decreased functional residual capacity)
- Congestive heart failure
- Pulmonary edema (fluid overload, postobstructive edema)
- Alveolar hypoventilation (residual effects of anesthetics and/or neuromuscular blocking drugs)
- Diffusion hypoxia (unlikely if receiving supplemental oxygen)
- Inhalation of gastric contents (aspiration)
- Pulmonary embolus
- Pneumothorax
- Increased oxygen consumption (shivering)
- Sepsis
- Transfusion-related lung injury
- Adult respiratory distress syndrome
- Advanced age
- Obesity

$$PAO_2 = FiO_2 (PB - PH_2O) - \frac{P_{CO_2}}{RQ}$$

$$P_{ACO_2} = 40 \text{ mm Hg}$$
$$PAO_2 = 21(760 - 47) - \frac{40}{0.8} = 150 - 50 = 100 \text{ mm Hg}$$

$$P_{ACO_2} = 80 \text{ mm Hg}$$
$$PAO_2 = 21(760 - 47) - \frac{80}{0.8} = 150 - 100 = 50 \text{ mm Hg}$$

PAO_2 = alveolar oxygen pressure
P_{ACO_2} = partial pressure of CO_2 in arterial blood
FiO_2 = fraction of inspired oxygen
PB = barometric pressure
PH_2O = vapor pressure of water
RQ = respiratory quotient

Philadelphia, 2005, Butterworth-Heinemann. Used with permission.)*

pharmacologic reversal of opioid or benzodiazepine effect, or controlled mechanical ventilation of the patient's lungs.

DECREASED ALVEOLAR OXYGEN PRESSURE

Diffusion hypoxia refers to the rapid diffusion of nitrous oxide into alveoli at the end of a nitrous oxide anesthetic. Nitrous oxide dilutes the alveolar gas and produces a transient decrease in PAO_2 and $Paco_2$. In a patient breathing room air, the resulting decrease in PAO_2 can produce arterial hypoxemia, whereas decreased $Paco_2$ can depress the respiratory drive. In the absence of supplemental oxygen administration, diffusion hypoxia can persist for 5 to 10 minutes after discontinuing a nitrous oxide anesthetic; therefore it may contribute to arterial hypoxemia in the initial moments in the PACU.

VENTILATION-PERFUSION MISMATCH AND SHUNT

Hypoxic pulmonary vasoconstriction refers to the attempt of normal lungs to match ventilation and perfusion optimally (see also Chapters 19 and 51). This response constricts vessels in poorly ventilated regions of the lung and directs pulmonary blood flow to well-ventilated alveoli. In the PACU, the residual effects of inhaled anesthetics and vasodilators, such as nitroprusside and dobutamine used to treat systemic hypertension or to improve hemodynamics, will blunt hypoxic pulmonary vasoconstriction and contribute to arterial hypoxemia.

Unlike a ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, a true shunt will not respond to supplemental oxygen. Causes of postoperative pulmonary shunt include atelectasis, pulmonary edema, gastric aspiration, pulmonary emboli, and pneumonia. Of these, atelectasis is probably the most common cause of pulmonary shunting in the immediate postoperative period. Mobilization of the patient to the sitting position, incentive spirometry, and positive airway pressure by facemask can be effective in treating atelectasis.

INCREASED VENOUS ADMIXTURE

Increased venous admixture typically refers to low cardiac output states, in which there is mixing of desaturated venous blood with oxygenated arterial blood. Normally, only 2% to 5% of cardiac output is shunted through the lungs, and this shunted blood with a normal mixed venous saturation has a minimal effect on PaO_2. In low cardiac output states, blood returns to the heart severely desaturated. Additionally, the shunt fraction significantly increases in conditions that impede alveolar oxygenation, such as pulmonary edema and atelectasis. Under these conditions, mixing desaturated shunted blood with saturated arterialized blood decreases PaO_2.

DECREASED DIFFUSION CAPACITY

A decreased diffusion capacity may reflect the presence of underlying lung disease such as emphysema, interstitial lung disease, pulmonary fibrosis, or primary pulmonary hypertension. In this regard, the differential diagnosis of arterial hypoxemia in the PACU must include the contribution of any preexisting pulmonary condition.

Finally, the fact that inadequate oxygen delivery may result from an unrecognized disconnection of the oxygen source or empty oxygen tank should be kept in mind.

PULMONARY EDEMA

Pulmonary edema in the immediate postoperative period is often cardiogenic in nature, secondary to intravascular volume overload or congestive heart failure. Less frequently, pulmonary edema may result from airway obstruction (postobstructive pulmonary edema), sepsis, or transfusion (transfusion-related acute lung injury [TRALI]).

POSTOBSTRUCTIVE PULMONARY EDEMA

Postobstructive pulmonary edema and the resulting arterial hypoxemia are rare but significant consequences of upper airway obstruction that may follow tracheal extubation at the conclusion of anesthesia and surgery. Postobstructive pulmonary edema is a transudative edema produced by the exaggerated negative intrathoracic pressure generated by an inspiratory effort against a closed glottis. The resulting negative intrathoracic pressure and increased venous return escalate the hydrostatic pressure gradient across the pulmonary vascular bed, promoting the transudation of fluid. Patients who are muscularly healthy are at increased risk of postobstructive pulmonary edema because of their ability to generate significant inspiratory force.

Laryngospasm is likely the most common cause of postobstructive pulmonary edema in the PACU, but postobstructive pulmonary edema may result from any condition that occludes the upper airway.[41,42] The resultant arterial hypoxemia is usually observed within 90 minutes of the upper airway obstruction and is accompanied by bilateral fluffy infiltrates on the chest radiograph. Treatment is supportive and includes supplemental oxygen, diuresis, and, in severe cases, positive-pressure ventilation of the patient's lungs.

TRANSFUSION-RELATED LUNG INJURY

The differential diagnosis of pulmonary edema in the PACU should include transfusion-related lung injury in any patient who intraoperatively received blood products (see also Chapter 61).[43,44] Transfusion-related lung injury is typically exhibited within 1 to 2 hours after the transfusion of plasma-containing blood products, including packed red blood cells, whole blood, fresh frozen plasma, or platelets. Because reactions can occur up to 6 hours after transfusion, the syndrome may develop during the patient's stay in the PACU after transfusion in the surgical unit. The resulting noncardiogenic pulmonary edema is often associated with fever and systemic hypotension. If a complete blood cell count is obtained with the onset of symptoms, then documenting an acute drop in the white

BOX 96-4 ***Criteria for the Diagnosis of Transfusion-Related Acute Lung Injury: The American-European Consensus Conference Recommendations***

1. Acute lung injury evidenced by:
   a. Acute onset of signs and symptoms
   b. Hypoxemia:
      i. PaO_2/FiO_2 <300, or
      ii. Room air SpO_2 <90%, or
      iii. Other clinical evidence of hypoxemia
   c. Bilateral infiltrates on chest radiography without cardiomegaly
   d. No clinical evidence of left atrial hypertension
2. No preexisting acute lung injury before transfusion
3. Onset of lung dysfunction within 6 hours of transfusion
4. No temporal association of onset to alternative causes of acute lung injury

blood cell count (leukopenia) is possible, reflecting the sequestration of granulocytes within the lung and exudative fluid.[45,46] Treatment is supportive and includes supplemental oxygen and drug-induced diuresis. Mechanical ventilation may be needed to support hypoxemia and respiratory failure. Vasopressors may be required to treat refractory hypotension.[47]

In past years, the lack of specific diagnostic criteria has resulted in the underdiagnosing and underreporting of this syndrome. Recently, a group of transfusion experts in the American-European Consensus Conference developed and implemented diagnostic criteria that have raised the awareness of the syndrome (Box 96-4).[48,49]

MONITORING AND TREATMENT OF HYPOXEMIA

OXYGEN SUPPLEMENTATION

In the era of cost containment, the routine delivery of supplemental oxygen to all patients recovering from general anesthesia is suggested to be a costly and unnecessary practice.[50] The argument against the use of routine oxygen supplementation relies on the fact that continuous pulse oximetry, now a PACU standard, readily identifies those patients who will require oxygen therapy.[51] Supporting this argument is the observation that a majority of patients after general anesthesia do not become hypoxic (63% at a threshold of Sa_{O_2} less than 90% and 83% at a threshold of Sa_{O_2} less than 94%) when breathing room air in the PACU.[51] Although the authors of this observational study predict that the elimination of routine oxygen supplementation in the PACU would result in significant cost savings, others assert that the economic benefit of limited oxygen therapy is likely to be offset by the cost of complications.[52,53]

Although the practice of prophylactic oxygen therapy to all patients after general anesthesia is controversial, most would argue that the benefits outweigh the risks. Even with oxygen supplementation, a significant percentage of patients will become hypoxic at some point during their PACU stay.[54,55] Russell and associates studied 100 patients who were transferred to the PACU breathing room air before receiving at least 40% oxygen by aerosol face tent in the unit. All patients had an Sa_{O_2} greater than 97% before the 2-minute transport to the PACU. Fifteen percent of patients experienced transient desaturation on arrival in the PACU (less than 92% saturation for longer than 30 seconds). This immediate desaturation positively correlated with patient age, body weight, ASA classification, general anesthesia, and increased volume of intravenous fluid greater than 1500 mL. An even larger percentage of patients (25%) desaturated 30 to 50 minutes later in their PACU stay, despite prophylactic oxygen administration. These later desaturations were more severe (71% to 91%) and lasted longer (5.8 ± 12.6 minutes) than those that occurred on admission. Additional correlating factors included duration of anesthesia and female gender.

The safe practice of postanesthesia care without oxygen supplementation requires ideal conditions at all times, such as functioning oxygen delivery apparatus at every bedside and sufficient manpower for observation and immediate intervention. Gravenstein argues that this degree of vigilance is likely unrealistic, and the risk of adverse outcome to even a small number of patients is unwarranted.[56]

LIMITATIONS OF PULSE OXIMETRY

The ASA Standards for Postanesthesia Care require that patients be observed and monitored with "particular attention given to" both oxygenation and ventilation. The pulse oximeter is a standard monitor in the PACU for the detection of hypoxemia, but it does not reflect the adequacy of ventilation.[57] Although several studies have demonstrated oximetry's limited ability to detect hypoventilation in patients breathing room air,[58,59] they confirm that it does not reliably detect hypoventilation in patients breathing oxygen.[59] When monitoring ventilation in the PACU, pulse oximetry is not a substitute for close observation by trained personnel.

OPTIMAL PERIOPERATIVE OXYGENATION

POSTOPERATIVE NAUSEA AND VOMITING

A number of studies have asked whether perioperative supplemental oxygen administration can reduce the incidence of PONV (see also Chapter 97). In the first such study, Grief and colleagues randomized 231 patients undergoing elective colon resection to receive either 30% or 80% oxygen (balanced with nitrogen). In this study, the administration of 80% supplemental oxygen intraoperatively and 2 hours postoperatively reduced the incidence of PONV nearly twofold (30% to 17%).[60] In a subsequent study of 240 patients undergoing laparoscopic

gynecologic surgery, the same group found that perioperative supplemental oxygen (80%) was as effective as ondansetron (with 30% oxygen) in preventing PONV. When compared with 30% oxygen alone, both oxygen and ondansetron decreased the incidence of PONV by 50% in the first 24 hours postoperatively (44% to 22%).[61]

Increased oxygen supplementation did not reduce the incidence of PONV in children undergoing elective dental surgery,[62] adults undergoing thyroid surgery,[63] or patients undergoing strabismus surgery.[64] In 210 patients (4 to 79 years of age) undergoing strabismus surgery, the incidence of PONV was the same among three groups: those who received 30% oxygen or room air plus ondansetron on induction, 80% oxygen or room air, or 30% oxygen or room air. Finally, in patients undergoing laparoscopic cholecystectomy, the elimination of nitrous oxide, not increased oxygen fraction, was found to correlate with decreased PONV. In this study, increasing the oxygen concentration from 40% in air to 80% in air offered no further benefit.[65]

The mechanism by which the elimination of nitrous oxide and increased oxygen fraction may contribute to a reduction in PONV is unknown. Although evidence suggests that perioperative oxygen administration may reduce PONV in patients undergoing colorectal procedures, the data do not support its use for surgical procedures that do not directly involve the bowel.[66] This lack of efficacy of supplemental oxygen in patients undergoing peripheral procedures argues for a local effect on the gastrointestinal tract where the elimination of nitrous oxide and nitrogen, together with hyperoxia, work to decrease bowel distention and reduce gastrointestinal ischemia.

Studying older adult patients transported by ambulance after minor trauma (see also Chapter 80), Kober and colleagues found that hyperoxia reduced the incidence of nausea and vomiting fourfold compared with patients breathing air. In this double-blind study, patients were randomized to receive room air or 100% facemask oxygen delivered at 10 L/min. The authors of this study propose a central mechanism for the effect of oxygen on motion sickness.[67]

WOUND INFECTIONS

Supplemental oxygen appears to reduce the incidence of surgical wound infections in patients undergoing colorectal surgery. Grief and colleagues randomized 500 patients undergoing colon resection to receive either 30% or 80% oxygen (in air). In this study, the higher concentration of oxygen reduced the incidence of surgical site infection by 6% (11.2% to 5.2%).[68] More recently, a randomized controlled multicenter study of 300 patients in 14 Spanish hospitals found that patients who received supplemental oxygen had a 30% reduction in surgical site infections.[69] This study compared 30% to 80% oxygen administration intraoperatively and 6 hours postoperatively. The perioperative care was standardized, and surgical site infections were identified by criteria delineated by the Centers for Disease Control and Prevention.

These results were not consistent with a study of patients undergoing major intraabdominal surgical procedures after which patients who received 80% oxygen had a significantly higher infection rate (25%) than those who received 35% oxygen. It is notable that this study has been widely criticized for its failure of randomization because the patients receiving 80% oxygen were more obese, underwent a longer duration of surgery, and had a larger blood loss than those receiving 35% oxygen. Unlike the Spanish study, the diagnosis of surgical site infection was made by chart review rather than standardized criteria.[70]

NITROUS OXIDE

The role of nitrous oxide in the risk of wound infection remains controversial. When controlling for oxygen concentration (35%) in patients undergoing colon resection, the Outcomes Research Group found that the elimination of nitrous oxide did not decrease the incidence of surgical site infection.[71]

The largest multicenter trial to date comparing nitrous oxide–based anesthesia with nitrous oxide–free general anesthesia included 2050 patients who underwent major surgery. Exclusion criteria included cardiac and thoracic surgery. The exclusion of patients undergoing colon surgery or those who had a history of PONV was left to the discretion of the anesthesiologist. Patients were randomized to receive 30% oxygen with 70% nitrous oxide or 80% oxygen with 20% nitrogen. In this study, the elimination of nitrous oxide significantly decreased the incidence of PONV and major complications within 30 days of surgery. Major complications included pneumonia, pneumothorax, pulmonary embolism, wound infection, myocardial infarction, venous thromboembolism, stroke, and awareness. It did not decrease the length of hospital stay, the study's primary endpoint.[72] Significantly, this study did not control for inspired oxygen concentration; therefore whether the beneficial effects were the result of the elimination of nitrous oxide or the increase in FiO_2 is not clear.[73]

OXYGEN DELIVERY SYSTEMS

SUPPLEMENTAL OXYGEN

The degree of hypoxemia, the surgical procedure, and patient compliance determine the oxygen delivery system of choice in the PACU. Patients who are stable after head and neck surgery may not be candidates for facemask oxygen because of the risk of pressure necrosis on incision sites and microvascular muscle flaps, whereas nasal packing prohibits the use of nasal cannulas in others. Face tent oxygen or blow-by setups are viable alternatives in cases in which tight-fitting masks and straps are contraindicated.

The delivery of oxygen through a traditional nasal cannula with bubble humidifier is usually limited to a maximum flow of 6 L/min to minimize the discomfort and complications that result from inadequate humidification. As a general rule, each liter per minute of oxygen flow through nasal cannula increases the FiO_2 by 0.04, with 6 L/min delivering an FiO_2 of approximately 0.44. Until recently, maximum oxygen delivery to extubated

patients required delivery by facemask through a nonrebreather system or high-flow nebulizer. These systems can be inefficient, however, because of inadequate mask fit and/or high-minute ventilation requirements that result in significant entrainment of room air. The newer high-flow nasal cannula devices can comfortably deliver oxygen at 40 L/min, 37° C, and 99.9% relative humidity.[74] The delivery of high-flow oxygen directly to the nasopharynx produces an FiO_2 equal to that delivered by traditional mask devices. In fact, the Vapotherm system has been shown to deliver a higher FiO_2 than a nonrebreather mask at similar flow ranges (10 to 40 L/min). Unlike the nonrebreather mask, these devices deliver high-flow oxygen directly to the nasopharynx throughout the respiratory cycle. The efficacy of these devices may be enhanced by a CPAP effect resulting from the high gas flow.[75]

CONTINUOUS POSITIVE AIRWAY PRESSURE

An estimated 8% to 10% of patients who undergo abdominal surgery subsequently require intubation and mechanical ventilation in the PACU. As discussed earlier in this chapter, respiratory failure in the immediate postoperative period is often due to transient and rapidly reversible conditions such as splinting from pain, diaphragmatic dysfunction, muscular weakness, and pharmacologically depressed respiratory drive. Readily reversible hypoxemia may be due to hypoventilation, atelectasis, or volume overload. The application of CPAP in this setting can potentially decrease hypoxemia as a result of atelectasis by recruiting alveoli. The resulting increase in functional reserve capacity may also improve pulmonary compliance and decrease the work of breathing. In a recent randomized controlled trial, 209 consecutive patients undergoing major elective abdominal surgery were randomized to receive supplemental oxygen alone or in conjunction with CPAP (at 7.5 cm H_2O pressure) in the PACU. In this study, the application of CPAP in the PACU significantly reduced the incidence of intubation, pneumonia, infection, and sepsis. The study was halted because of efficacy after the enrollment of 209 patients (Table 96-2) (see also Chapter 103).[76]

A large percentage of patients who are obese and undergoing Roux-en-Y gastric bypass surgery have OSA and stand to benefit significantly from postoperative CPAP therapy. Yet surgeons were initially hesitant to embrace this modality for fear that applying positive pressure to the airway would inflate the stomach and proximal intestine and result in anastomotic disruption. In a single center study of 1067 patients undergoing gastrojejunostomy bypass and 420 diagnosed with OSA, CPAP did not increase the risk of postoperative anastomotic leaks.[77]

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Even with the application of CPAP in the PACU, a number of patients will require additional ventilatory support. Noninvasive positive-pressure ventilation (NIPPV) (see also Chapter 103) has been shown to be an effective alternative to endotracheal intubation in the intensive care unit (ICU) setting. Although the use of NIPPV in both chronic and acute respiratory failure is well established, its application in the PACU is limited.

In the past, the use of NIPPV was avoided in the immediate postoperative period because of the potential for gastric distention, aspiration, and wound dehiscence. These potential complications were especially true in patients who had undergone esophageal or gastric surgery. Careful consideration of both the patient and the surgical factors must guide the decision to use noninvasive modes of ventilation in the PACU. Relative contraindications include hemodynamic instability or life-threatening arrhythmias, altered mental status, high risk of aspiration, inability to use nasal or facial mask (head and neck procedures), and refractory hypoxemia.[78] Several case reports describe the successful application of NIPPV in lieu of endotracheal intubation in both adults and children in the PACU. In 2000, Tobias reported the successful application of NIPPV in two patients, one after gastrostomy tube placement and another after cholecystectomy.[79] A larger case series (eight patients) reported by Albala and Ferrigno did not include intraabdominal procedures.[80] The authors of both studies agree that the successful application of NIPPV is dependent on appropriate patient selection and careful instruction.

NIPPV can be delivered by facemask using the pressure support mode of a mechanical ventilator. Alternatively, the use of a biphasic positive airway pressure machine

TABLE 96-2 CONTINUOUS POSITIVE AIRWAY PRESSURE FOR POSTOPERATIVE HYPOXEMIA: SECONDARY OUTCOMES

allows the delivery of positive pressure by either nasal cannula or facemask. An example protocol for instituting NIPPV in patients with acute respiratory failure is shown in Box 96-5.

HEMODYNAMIC INSTABILITY

Hemodynamic compromise in the patient in the PACU is exhibited in a number of ways—systemic hypertension, hypotension, tachycardia, or bradycardia—alone or in combination. Hemodynamic instability in the PACU has a negative impact on long-term outcome. Interestingly, postoperative systemic hypertension and tachycardia are associated with an increased risk of unplanned critical care admission and a higher mortality than hypotension and bradycardia.[81]

SYSTEMIC HYPERTENSION

Patients with a history of essential hypertension are at greatest risk for significant systemic hypertension in the PACU.[82] Additional factors include pain, nausea and vomiting, hypoventilation and associated hypercapnia, emergence excitement, advanced age, urinary retention, and preexisting renal disease (Box 96-6). The surgical procedures most commonly associated with postoperative hypertension are carotid endarterectomy and intracranial procedures. A significant number of patients, especially those with a known history of hypertension, will require pharmacologic blood pressure control in the PACU (see also Chapter 39).

BOX 96-5 *Example Protocol for Instituting Noninvasive Positive-Pressure Ventilation in Patients with Acute Respiratory Failure**

1. Choose the appropriate patient, based on the surgical procedure and the patient's risk of aspiration, ability to protect his or her airway, and ability to comply with the mask fit.
2. Position the head of the bed at ≥45-degree angle.
3. Choose the correct size mask and connect mask to ventilator.
4. Explain the modality to the patient and provide reassurance.
5. Set initial ventilatory settings (CPAP, 0 cm H_2O; pressure support, 10 cm H_2O).
6. Gently hold mask on face until the patient is comfortable and synchronous with ventilation.
7. Apply wound care dressing on nasal bridge and other pressure points.
8. Secure mask with head straps.
9. Slowly increase CPAP.
10. Adjust pressure support to achieve adequate tidal volumes and maximal patient comfort.
11. In patients with hypoxia, increase CPAP in increments of 2 to 3 cm H_2O until FiO_2 is ≤0.6.
12. Avoid peak mask pressures >30 cm H_2O.
13. Set ventilator alarms and apnea backup parameters.
14. Ask the patient and nurse to call for needs (e.g., repositioning mask, pain, discomfort) or if complications occur (e.g., respiratory difficulties, abdominal distention, nausea, vomiting).
15. Monitor with oximetry, and adjust ventilator settings after blood gas results.

SYSTEMIC HYPOTENSION

Postoperative systemic hypotension may be characterized as (1) hypovolemic (decreased preload), (2) distributive (decreased afterload), or (3) cardiogenic (intrinsic pump failure) (Box 96-7).

Hypovolemic (Decreased Preload)

Systemic hypotension in the PACU is often due to decreased intravascular fluid volume and preload, and, as

BOX 96-6 *Factors Leading to Postoperative Hypertension*

  - Tension pneumothorax
  - Drug induced (beta-blockers, calcium channel blockers)
- Decreased vascular tone
  - Sepsis
  - Allergic reactions (anaphylactic, anaphylactoid)
  - Spinal shock (cord injury, iatrogenic high spinal)
  - Adrenal insufficiency

such, it responds favorably to intravenous fluid administration. Common causes of decreased intravascular fluid volume in the immediate postoperative period include ongoing third-space translocation or loss of fluid, inadequate intraoperative fluid replacement (especially in patients who undergo major intraabdominal procedures or preoperative bowel preparation), and loss of sympathetic nervous system tone as a result of neuraxial (spinal or epidural) blockade.

Ongoing bleeding should be ruled out in patients with hypotension who have undergone a surgical procedure in which significant blood loss is possible. Regardless of the estimated intraoperative blood loss, the measured blood loss may be inaccurate. If the patient is unstable, then hemoglobin can be measured at the bedside to eliminate laboratory turnover time. In addition, tachycardia may not be a reliable indicator of hypovolemia or anemia (or both) if the patient is taking beta-blockers or calcium channel blockers.

Distributive (Decreased Afterload)

Distributive shock in the PACU may be the result of a number of physiologic derangements, including iatrogenic sympathectomy, critical illness, allergic reactions, and sepsis. Iatrogenic sympathectomy, secondary to regional anesthetic techniques, is an important cause of hypotension in the perioperative period. A high sympathetic block (to T4) will decrease vascular tone and block the cardioaccelerator fibers. If not treated promptly, then the resulting bradycardia in the presence of severe hypotension can lead to cardiac arrest even in young healthy patients.[83] Vasopressors, including phenylephrine and ephedrine, are pharmacologic treatments of hypotension caused by residual sympathetic nervous system blockade.

Patients who are critically ill may rely on exaggerated sympathetic nervous system tone to maintain systemic blood pressure and heart rate. In these patients, even minimal doses of inhaled anesthetics, opioids, or sedative-hypnotics can decrease sympathetic nervous system tone and produce significant systemic hypotension.

Allergic (anaphylactic or anaphylactoid) reactions may be the cause of hypotension in the PACU. Epinephrine is the drug of choice to treat hypotension secondary to an allergic reaction. Increased serum tryptase concentrations confirm the occurrence of an allergic reaction, but an elevated tryptase level does not differentiate anaphylactic from anaphylactoid reactions. The blood specimen for tryptase determination must be obtained within 30 to 120 minutes after the allergic reaction, but the results may not be available for several days. Neuromuscular blocking drugs are the most common cause of anaphylactic reactions in the surgical setting (Table 96-3).[84,85]

If sepsis is suspected as the cause of hypotension in the PACU, then blood should be obtained for culture, and empirical antibiotic therapy should be initiated before transferring the patient to the assigned unit. Urinary tract manipulation and biliary tract procedures are examples of interventions that can result in a sudden onset of severe systemic hypotension secondary to sepsis. Although fluid resuscitation is the most important immediate intervention, pressor support is often required—at least transiently. Norepinephrine is the pressor of choice in septic patients. Vasopressin deficiency has been shown to contribute to vasodilation in septic shock,[86] and low-dose vasopressin (0.01 to 0.05 unit/min) improves mean arterial pressure, decreases catecholamine vasopressor requirement, and may spare renal function in severe septic shock.[87]

TABLE 96-3 **DRUGS INVOLVED IN PERIOPERATIVE ANAPHYLAXIS**

Substance	Incidence of Perioperative Anaphylaxis (%)	Most Commonly Associated With Perioperative Anaphylaxis
Muscle relaxants	69.2	Succinylcholine, rocuronium, atracurium
Natural rubber latex	12.1	Latex gloves, tourniquets, Foley catheters
Antibiotics	8	Penicillin and other beta-lactams
Hypnotics	3.7	Propofol, thiopental
Colloids	2.7	Dextran, gelatin
Opioids	1.4	Morphine, meperidine
Other substances	2.9	Propacetamol, aprotinin, chymopapain, protamine, bupivacaine

Cardiogenic (Intrinsic Pump Failure)

Significant cardiogenic causes of postoperative hypotension include myocardial ischemia and infarction, cardiomyopathy, cardiac tamponade, and cardiac dysrhythmias. The differential diagnosis depends on the surgical procedure and the patient's preoperative cardiac risk and medical condition. To determine the cause of the hypotension, central venous pressure monitoring, echocardiography, and, rarely, pulmonary artery catheter monitoring may be required.

MYOCARDIAL ISCHEMIA: EVALUATION AND TREATMENT

PATIENTS AT LOW RISK

Interpretation of changes on the ECG in the PACU is influenced by the patient's cardiac history and risk index. In patients at low risk—younger than 45 years of age, with no known cardiac disease, and only one risk factor—postoperative ST-segment changes on the ECG do not usually indicate myocardial ischemia. Relatively benign causes of ST changes in patients at low risk include anxiety, esophageal reflux, hyperventilation, and hypokalemia. In general, these patients require only routine PACU observation unless associated signs and symptoms warrant further clinical evaluation. A more aggressive evaluation

is indicated if the changes are accompanied by cardiac rhythm disturbances or hemodynamic instability (or both) (see also Chapter 39).

PATIENTS AT HIGH RISK

In contrast to patients at low risk, ST-segment and T-wave changes on the ECG in patients at high risk can be significant even in the absence of typical signs or symptoms. In this patient population, any ST or T-wave changes that are compatible with myocardial ischemia should prompt further evaluation to rule out myocardial ischemia. Determination of serum troponin levels is indicated when myocardial ischemia or infarction is suspected in the PACU. Once blood samples for measurement of troponin are obtained and a 12-lead ECG is completed, arrangements must be made for the appropriate cardiac monitoring and cardiology follow-up.

CARDIAC MONITORING

In the immediate postoperative period, myocardial ischemia is rarely accompanied by chest pain, and confirming myocardial ischemia in a patient in the PACU is dependent on the sensitivity of the cardiac monitoring (see also Chapters 45, and 47). Although a combination of leads II and V_5 will reflect 80% of the ischemic events detected on a 12-lead ECG, visual interpretation of the cardiac monitor is often inaccurate. Because of human error, the American College of Cardiology guidelines recommend that computerized ST-segment analysis be used (if available) to monitor this patient population in the immediate postoperative period.[88] A recent small-scale, single-center study by Goldman and associates suggests that a postoperative 12-lead ECG obtained in the PACU may be a valuable tool to adjust risk stratification in patients older than 50 years of age who are at low risk for cardiac ischemia.[89] However, at this time a routine postoperative 12-lead ECG is recommended only for patients with known or suspected coronary artery disease who have undergone high- or intermediate-risk surgery.

CARDIAC DYSRHYTHMIAS

Perioperative cardiac dysrhythmias are frequently transient and multifactorial (see Box 96-6). Reversible causes of cardiac dysrhythmias in the perioperative period include hypoxemia, hypoventilation and associated hypercapnia, endogenous or exogenous catecholamines, electrolyte abnormalities, acidemia, fluid overload, anemia, and substance withdrawal.[90]

TACHYCARDIA

Common causes of sinus tachycardia in the PACU include pain, agitation, hypoventilation with associated hypercapnia, hypovolemia, and shivering. Less common but serious causes include bleeding, cardiogenic or septic shock, pulmonary embolism, thyroid storm, and malignant hyperthermia.

ATRIAL DYSRHYTHMIAS

The incidence of new postoperative atrial dysrhythmias may be as high as 10% after major noncardiothoracic surgery. The incidence is even higher after cardiac and thoracic procedures when the cardiac dysrhythmia is often attributed to atrial irritation.[91] The risk of postoperative atrial fibrillation is increased by preexisting cardiac risk factors, positive fluid balance, electrolyte abnormalities, and oxygen desaturation.[92] These new-onset atrial dysrhythmias are not benign because they are associated with a longer hospital stay and increased mortality.[93]

VENTRICULAR DYSRHYTHMIAS

Premature ventricular contractions (PVCs) and ventricular bigeminy commonly occur in the PACU. PVCs most often reflect increased sympathetic nervous system stimulation that may accompany tracheal intubation, pain, and transient hypercapnia. True ventricular tachycardia is rare and indicative of an underlying cardiac pathologic condition. In the case of torsades de pointes, QT prolongation on the ECG may be intrinsic or drug related (e.g., amiodarone, procainamide, droperidol).

BRADYDYSRHYTHMIAS

Bradycardia in the PACU is often iatrogenic. Drug-related causes include beta-blocker therapy, anticholinesterase reversal of neuromuscular blockade, opioid administration, and treatment with dexmedetomidine. Procedure- and patient-related causes include bowel distention, increased intracranial or intraocular pressure, and spinal anesthesia. A high spinal block that blocks the cardioaccelerator fibers originating from T1 through T4 can produce severe bradycardia. The resulting sympathectomy, bradycardia, and possible intravascular fluid volume depletion and associated decreased venous return can produce sudden bradycardia and cardiac arrest, even in young healthy patients.

ATRIAL FIBRILLATION

Control of the ventricular response rate is the immediate goal in the treatment of new-onset atrial fibrillation. Patients who are hemodynamically unstable may require prompt electrical cardioversion, but most patients can be pharmacologically treated with an intravenous beta-adrenergic blocker or calcium channel blocker.[94] Diltiazem is the calcium channel blocker of choice for patients in whom beta-blockers are contraindicated. If hemodynamic instability is a concern, then the short-acting beta-blocker esmolol is an option. Rate control with these agents is often enough to result in chemical cardioversion for the postoperative patient whose arrhythmia may be catecholamine driven. If the goal of therapy is chemical cardioversion, then an amiodarone load can be initiated in the PACU with the knowledge that QT prolongation, bradycardia, and hypotension may accompany the intravenous infusion of this drug.

TREATMENT

The urgency of treatment of a cardiac dysrhythmia depends on the physiologic consequences of the dysrhythmia, principally hypotension or cardiac ischemia or both. Tachydysrhythmias decrease coronary perfusion time and increase myocardial oxygen consumption. Their impact depends on the patient's underlying cardiac function, and they are most harmful in patients with coronary artery disease. Bradycardia has a more deleterious effect in patients with a fixed stroke volume, such as infants and patients with restrictive pericardial disease or cardiac tamponade. For the most part, treatment relies on identifying and correcting the underlying cause (e.g., hypoxemia, electrolyte abnormalities).[95] The possible role of myocardial ischemia or the occurrence of pulmonary embolism must be considered when contemplating treatment options.

RENAL DYSFUNCTION

The differential diagnosis of postoperative renal dysfunction includes prerenal, intrarenal, and postrenal causes (Box 96-8). Frequently, the cause is multifactorial, with an intraoperative insult exacerbating a preexisting renal insufficiency. In the PACU, diagnostic efforts should focus on the identification and treatment of the readily reversible causes of oliguria (e.g., urine output less than 0.5 mL/kg/hr). For example, urinary catheter obstruction or dislodgment is easily remedied and often overlooked (see Box 96-8). When appropriate, one should confer with the surgical team regarding the details of the surgical procedure (urologic or gynecologic) to rule out anatomic obstruction or disruption of the ureters, bladder, or urethra.

OLIGURIA

Intravascular Volume Depletion

The most common cause of oliguria in the immediate postoperative period is depletion of intravascular fluid volume. In this regard, a fluid challenge (500 to 1000 mL of crystalloid) is usually effective in restoring urine output. A hematocrit measurement is indicated when surgical blood loss is suspected and repeated volume boluses are required to maintain urine output. Volume resuscitation to maximize renal perfusion is particularly important to prevent ongoing ischemic injury and the development of acute tubular necrosis.

A number of perioperative events may alter renal perfusion. Preoperative or intraoperative angiography can result in ischemic injury, secondary to renal vasoconstriction and direct renal tubular injury. Perioperative volume depletion can exacerbate hepatorenal syndrome or acute tubular necrosis caused by sepsis. The surgical procedure, itself, can alter renal vascular patency, decreasing renal perfusion. Finally, increased intraabdominal pressure (IAP) can impair renal perfusion.

If a fluid challenge is contraindicated or oliguria persists, then assessment of intravascular fluid volume status and cardiac function is indicated to differentiate hypovolemia from sepsis and low cardiac output states. Fractional excretion of sodium can be useful in determining the adequacy of renal perfusion, assuming that diuretics have not been given. However, the diagnosis of prerenal azotemia will not differentiate hypovolemia, congestive heart failure, or hepatorenal syndrome. Further evaluation with central venous monitoring or echocardiography, or both, may facilitate the differential diagnosis.

BOX 96-8 *Postoperative Oliguria*

PRERENAL

Hypovolemia (bleeding, sepsis, third-space fluid loss, inadequate volume resuscitation)
Hepatorenal syndrome
Low cardiac output
Renal vascular obstruction or disruption
Intraabdominal hypertension

RENAL

Ischemia (acute tubular necrosis)
Radiographic contrast dyes
Rhabdomyolysis
Tumor lysis
Hemolysis

POSTRENAL

Surgical injury to the ureters
Obstruction of the ureters with clots or stones
Mechanical (urinary catheter obstruction or malposition)

Postoperative Urinary Retention

Postoperative urinary retention can cause bladder overdistention and permanent detrusor damage. Ultrasonography can measure bladder volume and identify urinary retention in the PACU.[96] Using this technique, Keita and associates attempted to identify patients at high risk by measuring bladder volume in 313 adult inpatients on admission to and before discharge from the PACU. They collected data on age, sex, history of urinary retention, intraoperative administration of anticholinergic agents, amount of intraoperative fluid administration, and intravenous use of morphine. Urinary retention was defined as bladder volume greater than 600 mL in conjunction with an inability to void within 30 minutes. In this study, the incidence of postoperative urinary retention in the PACU was 16%. The most significant predictive factors were age older than 50 years, intraoperative fluid more than 750 mL, and bladder volume on entry to the PACU greater than 270 mL.[97] This study argues for the use of ultrasound to identify patients at high risk for possible urinary retention.

CONTRAST NEPHROPATHY

Angiography with intravascular stent placement is replacing open surgical procedures to treat carotid stenosis, aortic aneurysm, and peripheral vascular disease. As a result, contrast nephropathy will be more frequently included in the differential diagnosis of postoperative renal dysfunction. Perioperative attention to adequate hydration is indicated in any patient who has received an intravenous contrast agent. Aggressive hydration with normal saline provides the single most effective protection

against contrast nephropathy. Alkalinization of the urine with sodium bicarbonate has been shown to provide additional protection.[91] If bicarbonate is used for renal protection, then 154 mEq/L should be infused at a rate of 3 mL/kg/hr for 1 hour before injection of a contrast agent, followed by 1 mL/kg/hr for 6 hours.[98] Mucomyst is a relatively inexpensive and easily administered medication (single oral dose before and after procedure) that may also provide protection.[99] Although a number of studies support the efficacy of Mucomyst, meta-analysis does not consistently confirm its usefulness.[100,101]

INTRAABDOMINAL HYPERTENSION

Intraabdominal hypertension should be considered in any patient with oliguria and a tense abdomen on examination after abdominal surgery. Elevated IAP can impede renal perfusion and lead to renal ischemia and postoperative renal dysfunction. Normal IAP in a patient who is not obese is approximately 5 mm Hg. Intraabdominal hypertension is graded into four categories: I: 12 to 15 mm Hg; II: 16 to 20 mm Hg; III: 21 to 25 mm Hg; and IV: greater than 25 mm Hg. Abdominal compartment syndrome is defined as an IAP greater than 20 mm Hg with or without an abdominal perfusion pressure less than 50 mm Hg.[102] In a prospective study of patients undergoing major abdominal surgery, intraabdominal hypertension accounted for 40% of new-onset renal insufficiency. In this study, postoperative renal impairment was independently associated with four factors: hypotension, sepsis, older age, and increased abdominal pressure.[103] Bladder pressure, an indirect measure of IAP, should be measured in patients in whom intraabdominal hypertension is suspected to ensure the initiation of prompt intervention to relieve the pressure and to restore renal perfusion. Bladder pressure is measured at end expiration with the patient in the supine position and in the absence of abdominal muscle contractions. As with arterial pressure measurements, the transducer is placed in the midaxillary line.[103]

RHABDOMYOLYSIS

Rhabdomyolysis may complicate the postoperative course of patients who have suffered major crush or thermal injury. The incidence is also significantly increased in patients who are morbidly obese who undergo bariatric surgery. Rhabdomyolysis has been reported to occur in 22.7% of 66 consecutive patients undergoing laparoscopic bariatric surgery.[104-106] Risk factors include increased BMI and the length of the surgery. Patient history and the operative course should guide the decision to measure creatine phosphokinase in the PACU.[104] Early aggressive hydration to maintain urine output is the mainstay of treatment. Loop diuretics can be used to flush the renal tubules and to avoid fluid overload. The infusion of mannitol to enhance the elimination of myoglobin casts from the renal tubules and bicarbonate to protect against myoglobin toxicity is commonly practiced but may not provide further benefit. In a study of more than 2000 trauma patients with rhabdomyolysis, the infusion of bicarbonate and mannitol did not further decrease the incidence of acute renal failure.[107] No evidence suggests that renal dose dopamine affords renal protection in this setting.[108] In severe cases, an attempt can be made to remove myoglobin by continuous renal replacement therapy. Unlike conventional hemodialysis filters that do not remove circulating myoglobin, high-flux membranes can be effective. Continuous renal replacement modes typically use high-flux membranes. Additionally, convection (i.e., the mechanism of solute removal in continuous hemofiltration) removes larger molecular weight solutes than diffusion (i.e., the mechanism of solute removal in conventional hemodialysis).[109]

BODY TEMPERATURE AND SHIVERING

Postoperative shivering often occurs after general and epidural anesthesia (see also Chapter 54). The incidence of postoperative shivering may be as high as 65% (range, 5% to 65%) after general anesthesia and 33% after epidural anesthesia. Identified risk factors include male gender and the choice of induction agent; propofol is more commonly associated with shivering than is pentothal.[110]

MECHANISM

Postoperative shivering is usually, but not always, associated with hypothermia. Although thermoregulatory mechanisms can explain shivering in the patient with hypothermia, a number of different mechanisms have been proposed to explain shivering in normothermic patients. One proposed mechanism is based on the observation that the brain and spinal cord do not simultaneously recover from general anesthesia. The more rapid recovery of spinal cord function is thought to result in uninhibited spinal reflexes exhibited as clonic activity. This theory is supported by the fact that doxapram, a central nervous system stimulant, is somewhat effective in abolishing postoperative shivering. Other proposed mechanisms include the action of κ- opioid, *N*-methyl-D-aspartate (NMDA), and 5-hydroxytryptamine receptors. The higher incidence of postanesthetic shivering in patients who receive high-dose remifentanil is thought to be by the same mechanism that causes hyperalgesia in these patients; sudden opioid withdrawal resulting in the stimulation of *N*-methyl-D-aspartate receptors.[111] Additional support for this theory comes from the same authors who found that a small dose of intraoperative ketamine reduced the incidence of remifentanil-induced postanesthetic shivering.[112] Tramadol, a weak μ-opioid–receptor agonist and norepinephrine and serotonin reuptake inhibitor, has been shown to be effective in preventing postoperative shivering while also contributing to analgesia.[113]

TREATMENT

Intervention includes the identification and treatment of hypothermia, if present. Accurate core body temperatures can be most easily obtained at the tympanic membrane. Axillary, rectal, and nasopharyngeal temperature measurements are less accurate and may underestimate the

core temperature. Forced air warmers are used to warm the patient with hypothermia. A number of opioids, ondansetron,[114] and clonidine[115] have been shown to be effective in abolishing shivering once it starts; however, in adults, meperidine, 0.35 to 0.4 mg/kg (12.5 to 25 mg IV), is most commonly used. The infusion of low-dose ketamine (0.5 mg/kg IV) before general[116] and regional anesthesia[117] has been shown to be an effective prophylactic measure.

CLINICAL EFFECTS

In addition to significant patient discomfort, postoperative shivering increases oxygen consumption, carbon dioxide production, and sympathetic tone and is associated with increased cardiac output, heart rate, systemic blood pressure, and intraocular pressure. Patients who are hypothermic on arrival in the PACU should be actively warmed to avoid these immediate complications, as well as delayed consequences of hypothermia. Mild-to-moderate hypothermia (33° C to 35° C) inhibits platelet function, coagulation factor activity, and drug metabolism. It exacerbates postoperative bleeding, prolongs neuromuscular blockade, and may delay awakening. Whereas these immediate consequences are associated with a prolonged PACU stay,[118] long-term deleterious effects include an increased incidence of myocardial ischemia and myocardial infarction, delayed wound healing, and increased perioperative mortality.

POSTOPERATIVE NAUSEA AND VOMITING

Without prophylactic intervention, approximately one third of patients who undergo inhalational anesthesia will develop PONV (range, 10% to 80%) (see also Chapter 97).[119] The consequences of PONV include delayed discharge from the PACU, unanticipated hospital admission, increased incidence of pulmonary aspiration, and significant postoperative discomfort. The ability to identify patients at high risk for prophylactic intervention can significantly improve the quality of patient care and satisfaction in the PACU. From a patient's perspective, PONV may be more uncomfortable than postoperative pain.

PREVENTION AND TREATMENT

Prophylactic measures to prevent PONV include modification of the anesthetic technique and pharmacologic intervention. In a randomized controlled multicenter multifactorial trial, Apfel and associates studied the efficacy of six prophylactic interventions in patients at high risk for PONV (greater than 40%).[119] Interventions were both pharmacologic and technique related. Pharmacologic intervention included droperidol, 1.25 mg; dexamethasone, 4 mg; or ondansetron, 4 mg. Anesthetic intervention included propofol in lieu of a volatile anesthetic, nitrogen in lieu of nitrous oxide, or remifentanil in lieu of fentanyl. More than 4000 patients were assigned to 1 of 64 possible combinations. The study found that each of the three antiemetic medications reduced the relative risk of PONV to the same degree (26%). Together, propofol (19% decrease) and nitrogen (12% decrease) reduced the relative risk of PONV to a similar degree.

BOX 96-9 *Commonly Used Antiemetic Medications (Adult Doses)*

Anticholinergics

Scopolamine (0.3-0.65 mg IV)
Scopolamine (1.5 mg) Transdermal patch applied to a hairless area behind the ear before surgery; remove 24 hours postoperatively.

Antihistamines

Hydroxyzine (12.5-25 mg IM)
Phenothiazines
Promethazine (12.5-25 mg IM)

Prokinetics

Metoclopramide (10-20 mg IV) Avoid if any gastrointestinal obstruction is possible.

Serotonin-Receptor Antagonists

Ondansetron (4 mg IV) Administer 30 minutes before the conclusion of surgery.
Anzemet (12.5 mg IV) Administer 15 to 30 minutes before the end of surgery.

Vasopressors

Ephedrine (25 mg IM) with hydroxyzine (25 mg)

Corticosteroids

Dexamethasone (4-8 mg IV) Administer with the induction of anesthesia.

Although prophylactic measures to prevent PONV are more effective than rescue, a subset of patients will require treatment in the PACU even after appropriate prophylactic treatment. No convincing evidence suggests that any of the serotonin-receptor antagonists commonly prescribed at this time are more effective than any others. Box 96-9 lists the different classes of antiemetic medications commonly prescribed in the PACU. If an adequate dose of antiemetic medication given at the appropriate time is ineffective, then simply giving more of the same class of drug in the PACU is unlikely to be of significant benefit.

Aprepitant (Emend), a substance P antagonist that blocks the neurokinin 1 (NK1) receptor, may be effective in very high-risk patients and refractory cases. The recommended dose is 40 mg by mouth before anesthesia. Initial clinical trials have shown the drug to be effective for up to 48 hours after surgery.[120]

DELIRIUM

Approximately 10% of patients older than 50 years of age who undergo elective surgery will experience some degree of postoperative delirium within the first 5 postoperative days (see Chapter 79).[121] The incidence is significantly higher for certain procedures, such as repair of hip fracture (>35%)[122] and bilateral knee replacement (41%).[123] Although the majority of these patients are older adults who develop delirium within the first several postoperative days, the percentage who become delirious while

recovering in the PACU is not well known; many studies of postoperative delirium and postoperative cognitive dysfunction (POCD) do not evaluate the PACU stay.[124] The American Psychiatric Association defines *delirium* as an acute change in cognition or disturbance of consciousness that cannot be attributed to a preexisting medical condition, substance intoxication, or medication[125]; however, preexisting conditions such as age, functional status, and substance abuse influence the risk of immediate postoperative delirium.

RISK FACTORS

Persistent postoperative delirium is generally a condition of older adult patients.[126] It is a costly complication in both human and monetary terms because it increases the length of hospital stay, pharmacy costs, and mortality. Adult patients at risk for postoperative delirium can be identified before surgery. The most significant preoperative risk factors include: (1) advancing age (70 years and older), (2) preoperative cognitive impairment, (3) decreased functional status, (4) alcohol abuse, and (5) history of delirium. Intraoperative factors that are predictive of postoperative delirium include surgical blood loss, hematocrit less than 30%, and the number of intraoperative blood transfusions.[121,126] In adults, intraoperative hemodynamic derangements (hypotension),[127] the administration of nitrous oxide,[128] and the anesthetic technique (general versus regional)[129] have not been shown to increase the risk of postoperative delirium or longer-term POCD.

Clinical evaluation of a patient with delirium in the PACU includes a thorough evaluation of any underlying disease or metabolic derangement, such as hepatic and/or renal encephalopathy. The workup for postoperative delirium must exclude or treat iatrogenic factors, including inadequate hydration, perioperative medications, arterial hypoxemia, hypercapnia, pain, sepsis, and electrolyte abnormalities.

MANAGEMENT

Identifying the patient at high risk for delirium before admission to the PACU is useful.[126,130] Patients who are severely agitated may require restraints and/or additional personnel to control their behavior and to avoid self-inflicted injuries. Early identification of patients at high risk can also guide postoperative pharmacologic therapy. Patients older than 60 years of age who are to undergo minor surgery should be scheduled in an outpatient center whenever possible to minimize the incidence of POCD.[131]

EMERGENCE EXCITEMENT

Persistent postoperative delirium should not be confused with *emergence excitement*, a transient confusional state that is associated with emergence from general anesthesia. Emergence excitement is common in children, with more than 30% experiencing agitation or delirium at some period during their PACU stay. It usually occurs within the first 10 minutes of recovery but can have later onset in children who are brought to the recovery room asleep. The peak age of emergence excitement in children is between 2 and 4 years.[132] Unlike delirium, emergence excitement typically resolves quickly and is followed by an uneventful recovery.[133]

In children, emergence excitement is most frequently associated with rapid "wake up" from inhalational anesthesia. Although it has also been reported after isoflurane[134] and, to a lesser extent, halothane[135] anesthesia, emergence excitement is most often associated with the less-soluble vapors, sevoflurane[136] and desflurane. Several studies suggest that the incidence of emergence excitement is more a reflection of the anesthetic agent used rather than the rapidity of emergence.[137] In studies comparing sevoflurane and propofol, propofol resulted in a significantly smoother awakening than sevoflurane, despite rapid emergence. Furthermore, delaying emergence by a slow reduction in the inhaled concentration of sevoflurane did not reduce the incidence of emergence excitement.[138]

In addition to rapid emergence, the literature supports a number of possible etiologic factors, including intrinsic characteristics of the anesthetic, postoperative pain, type of surgery, age, preoperative anxiety, underlying temperament, and adjunct medications. Awareness of these contributors allows for the identification and treatment of children who are at increased risk.[133]

Simple preventive measures should be taken to treat children at risk. These include reducing preoperative anxiety, treating postoperative pain, and providing a stress-free environment for recovery. Medications that have been used to prevent and treat emergence agitation and delirium in children include midazolam,[139] clonidine,[140-142] dexmedetomidine,[143,144] fentanyl,[145,146] ketorolac,[147] and physostigmine.[148] In children, the most common preoperative anxiolytic, midazolam, has produced conflicting data. Although midazolam is generally associated with a decrease in the incidence and duration of postoperative delirium, not all studies are in agreement. In studies in which midazolam has not been shown to be beneficial, determining whether midazolam is an independent factor or merely a reflection of other preoperative variables remains unclear.[149]

The incidence of emergence excitement in adults is significantly less than in children and estimated to be between 3% and 4.7%.[150] One study found that significant surgical- and anesthesia-related risk factors included preoperative medication with midazolam (odds ratio [OR] 1.9), breast surgery (OR 5.190), abdominal surgery (OR 3.206), and, to a lesser extent, the length of surgery.[150]

DELAYED AWAKENING

Even after prolonged surgery and anesthesia, a response to stimulation in 60 to 90 minutes should occur.[151] When delayed awakening occurs, evaluating the vital signs (e.g., systemic arterial blood pressure, arterial oxygenation, ECG, body temperature) and performing a neurologic examination are important steps; patients may be hyperreflexic in the early postoperative period. Monitoring with pulse oximetry and analysis of arterial blood gases and pH can detect problems of oxygenation and

ventilation. Additional blood studies may be indicated to evaluate possible electrolyte derangements and metabolic disturbances (e.g., blood glucose concentration).

Residual sedation from drugs used during anesthesia is the most frequent cause of delayed awakening in the PACU. If residual effects of opioids are a possible cause of delayed awakening, then titrated intravenous doses of naloxone (20- to 40-μg increments in adults) should be carefully administered while keeping in mind that this treatment will also antagonize opioid-induced analgesia. Physostigmine may be effective in reversing the central nervous system sedative effects of anticholinergic drugs, especially scopolamine. Flumazenil is a specific antagonist for the residual depressant effects of benzodiazepines. In the absence of pharmacologic effects to explain delayed awakening, considering other causes, such as hypothermia (especially a body temperature lower than 33° C), hypoglycemia, and increased intracranial pressure, is important. Computed tomography may be indicated in patients in whom a central nervous system cause of delayed awakening is a consideration. A stat measurement of serum glucose is indicated if hypoglycemia is a possibility, as in patients with known insulin-dependent diabetes mellitus. Residual neuromuscular block may appear to be delayed awakening. Confirmation with peripheral nerve stimulation and administration of a reversal agent should correct this situation.

DISCHARGE CRITERIA

Although specific PACU discharge criteria may vary, certain general principles are universally applicable (Box 96-10).[2] To summarize, a mandatory minimum stay in the PACU is not required. Patients must be observed until they are no longer at risk for ventilatory depression and their mental status is clear or has returned to baseline. Hemodynamic criteria are based on the patient's baseline hemodynamics without specific systemic blood pressure and heart rate requirements.

BOX 96-10 *Summary of Recommendations for Discharge*

1. Patients should be alert and oriented or mental status returned to baseline.
2. A minimum mandatory stay is not required.
3. Vital signs should be stable and within acceptable limits.
4. Discharge should occur after patients have met specified criteria.
5. Use of scoring systems may assist in documenting fitness for discharge.
6. The requirement to urinate before discharge and drink and retain clear liquids should *not* be part of a routine discharge protocol, although these requirements may be appropriate for selected patients.
7. Outpatients should be discharged to a responsible adult who will accompany them home.
8. Outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a telephone number to call in case of emergency.

Modified from American Society of Anesthesiologists Task Force on Postanesthetic Care: Practice Guidelines for Postanesthetic Care, Anesthesiology *96:742-752, 2002.*

An assessment and written documentation of the patient's peripheral nerve function on discharge from the PACU may become useful information should a new peripheral neuropathy develop in the later postoperative period.

POSTANESTHESIA SCORING SYSTEMS

In 1970, Aldrete and Kroulik developed a postanesthesia scoring system to monitor recovery from anesthesia. The original Aldrete score assigned a number of 0, 1, or 2 to five variables: activity, respiration, circulation, consciousness, and color. A score of 9 out of 10 was considered adequate for discharge from the PACU.[152] Over the years, this system has been modified to keep up with advances in technology and anesthesia practice, including the expansion of ambulatory surgery. In 1995, pulse oximetry replaced visual assessment of oxygenation, and additional assessments were added to accommodate patients undergoing ambulatory surgery (Tables 96-4 and 96-5).[153]

With the increase in number and complexity of outpatient surgeries, various authors have amended discharge criteria to include an assessment of home readiness. The resulting postanesthesia discharge scoring system (PADSS) continues to evolve. It was initially based on five criteria: (1) vital signs, (2) ambulation and mental status, (3) pain and nausea and vomiting, (4) surgical bleeding, and (5) fluid intake and output. The current version has been modified to separate pain from nausea and vomiting and to eliminate the need to urinate before discharge.[154-158] In the ambulatory surgical setting, postoperative pain is the most significant cause of delayed discharge and unplanned hospital admission (see

TABLE 96-4 **CRITERIA FOR THE DETERMINATION OF DISCHARGE SCORE FOR RELEASE FROM THE POSTANESTHESIA CARE UNIT**

Variable Evaluated	Score
Activity	
Able to move four extremities on command	2
Able to move two extremities on command	1
Able to move no extremities on command	0
Breathing	
Able to breathe deeply and cough freely	2
Dyspnea	1
Apnea	0
Circulation	
Systemic blood pressure ≤ 20% of the preanesthetic level	2
Systemic blood pressure is 20% to 50% of the preanesthetic level	1
Systemic blood pressure ≥ 50% of the preanesthetic level	0
Consciousness	
Fully awake	2
Arousable	1
Not responding	0
Oxygen Saturation (Pulse Oximetry)	
>92% while breathing room air	2
Needs supplemental oxygen to maintain saturation >90%	1
<90% with supplemental oxygen	0

Modified from Aldrete JA: The postanaesthesia recovery score revisited, J Clin Anesth *7:89-91, 1995.*

Chapter 89). In an effort to improve patient satisfaction and a timely discharge, Chung and associates identified a subset of high-risk patients who are likely to benefit from intense prophylactic analgesic therapy. This study of 10,008 consecutive ambulatory surgical patients found that the incidence and intensity of postoperative pain increased with higher BMIs and duration of anesthesia. Orthopedic and urologic procedures were the most significant surgical factors.[159]

PACU Standards of Care require that a physician accept responsibility for the discharge of patients from the unit (Standard V),[1] even when the decision to discharge the patient is made at the bedside by the PACU nurse in accordance with hospital-sanctioned discharge criteria or scoring systems. If discharge criteria are to be used, then the department of anesthesia and the hospital medical staff must first approve them. A responsible physician's name must be noted on the record.

INFECTION CONTROL

Limitations in space,[148] staffing,[160,161] and time contribute to the transmission of infectious organisms in the PACU. The PACU is typically an open unit without physical barriers between bed stations. Nurses and respiratory therapists simultaneously care for more than one patient, and admissions to the unit are transient with a length of stay measured in hours rather than days. To complicate infection control monitoring, an infection resulting from a lapse in infection control in the PACU might not be identified by routine monitoring until days later on the surgical unit. In 1999, serial hand washing audits in a large metropolitan hospital cited the physical design of the PACU (open patient bays) as a significant barrier to improving hand-washing compliance.[148]

With these limitations in mind, it is not surprising that the PACU has been described as the "weakest link" in the chain of care that bridges the sterile technique practiced in the operating room with infection control protocols practiced on the surgical unit. Despite an awareness of the factors that increase the risk of infection in the PACU, no studies have addressed the problem until recently. A study of hand cleansing during postanesthesia care documents the poor compliance of PACU nurses with this standard infection control procedure.[162,163] In this observational study of 3143 patient care activities, the average compliance with hand cleansing was only 19.6% on patient admission to the unit and 12.5% in patients already admitted to the unit. In this study, the intensity of patient care activities was an independent predictor of noncompliance; that is, the greater the workload, the less likely the nursing staff would comply with infection control measures. Additional independent factors included patients of advanced age (65 years and older) and those recovering from clean surgery (i.e., surgical sites in which the respiratory, alimentary, and urinary tracts are not entered) and clean-contaminated surgery (i.e., surgical sites in which respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions without unusual contamination). As expected, compliance was best in patients with contaminated or known infected wounds.

The installation of bedside alcohol-based cleansers increases compliance of hand hygiene among heath care workers in the ICU.[164-167] Although no equivalent study has been conducted in the PACU, the unit is similar to the ICU in workload and intensity of patient care. The Centers for Disease Control and Prevention's *Guideline for Hand Hygiene in Health-Care Settings* recommends that an "alcohol based hand rub [be made] available at the entrance to the patient's room or at the bedside, in other convenient locations, and in individual pocket-sized containers to be carried by [health care workers] HCWs."[168] Although the convenience of appropriately placed alcohol-based cleansers is expected to improve hand-cleansing compliance, no follow-up studies in the PACU have been published.

TABLE 96-5 CRITERIA FOR DETERMINATION OF DISCHARGE SCORE FOR RELEASE HOME TO A RESPONSIBLE ADULT

Variable Evaluated	Score*
Vital Signs (stable and consistent with age and preanesthetic baseline)	
Systemic blood pressure and heart rate within 20% of the preanesthetic level	2
Systemic blood pressure and heart rate 20% to 40% of the preanesthetic level	1
Systemic blood pressure and heart rate >40% of the preanesthetic level	0
Activity Level (able to ambulate at preoperative level)	
Steady gait without dizziness or meets the preanesthetic level	2
Requires assistance	1
Unable to ambulate	0
Nausea and Vomiting	
None to minimal	2
Moderate	1
Severe (continues after repeated treatment)	0
Pain (minimal to no pain, controllable with oral analgesics; location, type and intensity consistent with anticipated postoperative discomfort)	
Acceptability:	
Yes	2
No	1
Surgical Bleeding (consistent with that expected for the surgical procedure)	
Minimal (does not require dressing change)	2
Moderate (up to two dressing changes required)	1
Severe (more than three dressing changes required)	0

Modified from Marshall SI, Chang F: Discharge criteria and complications after ambulatory surgery, Anesth Analg *88:508-517, 1999.*

* Patients achieving a score of at least 9 are acceptable for discharge.

FUTURE CONSIDERATIONS

INTENSIVE CARE

In recent years, the demand for ICU beds has significantly increased in the United States and in Europe. Because the PACU possesses the equipment and expertise to monitor, ventilate, and resuscitate patients recovering from general anesthesia, it has become the logical choice to provide

care for patients who are critically ill and for whom ICU beds are not available[169] (see also Chapter 101). Although it is now common to care for patients who are critically ill in the PACU, the maintenance of quality patient care continues to challenge hospital administrators and staff.[170]

One obstacle to efficient ICU care in the PACU is the diversity of physician coverage required. Whereas the proximity of the surgical unit and the patient population recovering from anesthesia dictate that an anesthesiologist be the responsible physician for the majority of patients in the unit, patients in a nonsurgical ICU often require physician coverage by specialists who are unfamiliar with the unit and whose practices are located in distant areas of the hospital. As a result, PACU nurses must identify and contact physicians with whom they rarely interact.

Physician coverage (internist, anesthesiologist, or surgeon who is primarily responsible for patient care), privacy for family visitation (lack of space in a traditionally open unit), infection control (proximity of patient beds and rapid turnover of patients), and nursing competencies (ongoing ICU training of staff) are some of the challenges facing the PACU today.[171] In a study of 400 ICU overflow patients admitted to the PACU in the United Kingdom, Ziser and colleagues identified insufficient medical and nursing coverage, inadequate communications, and visiting facilities for patient's families as the most significant problems facing the unit. The patients awaiting placement in the ICU in this study were on average 53 years of age with a mean length of stay of 12.9 hours. Seventy percent were mechanically ventilated, 77.8% required invasive monitoring, and 4.5% died in the PACU while awaiting placement in the ICU. The busiest hours of admission were 1 AM to 11 AM.[172]

In an effort to ensure the quality of patient care in the PACU, the professional societies responsible for the delivery of care in the unit have collaborated to develop standards for the care of ICU overflow patients. The "Joint Position Statement on ICU Overflow Patients" issued in 2000 is the result of this collaboration. It specifically requires that PACU staffing meet the nursing staffing ratios and competencies required in the critical care units.[173]

The Joint Position Statement reproduced here recommends that the following criteria be met:

- It must be recognized that the primary responsibility for Phase 1 PACU is to provide the optimal standard of care to the postanesthesia patient and to effectively maintain the surgery schedule.
- Appropriate staffing requirements should be met to maintain safe, competent nursing care of the postanesthesia patient as well as the ICU patient. Staffing criteria for the ICU patient should be consistent with ICU guidelines and based on individual acuity and needs.
- Phase 1 PACUs are by their nature critical care units and as such should meet the competencies required for the care of the critically ill patient. These competencies should include, but are not limited to, ventilator management, hemodynamic monitoring, and medication administration, as appropriate to their patient population.
- Management should develop and implement a comprehensive resource utilization plan with ongoing assessment that supports the staffing needs for both the PACU and ICU patients when the need for overflow admission arises.
- Management should have a multidisciplinary plan to address appropriate utilization of ICU beds. Admission and discharge criteria should be utilized to evaluate the necessity for critical care and to determine the priority of admission.

In addition to increasing the acuity of patient care in the PACU, the shortage of ICU beds has encouraged the de-escalation of care in selected patient populations. Patients who were historically admitted directly to the ICU after surgery for intensive or specialized monitoring have had successful recovery by routine postoperative care in the PACU. Examples include postoperative craniotomy,[174] liver transplantation,[175,176] and cardiac surgery. The neurosurgical group at the University of Florida has shown that patients with uncomplicated craniotomy can be safely cared for in the PACU at a significant savings of hospital days and cost without increased morbidity or mortality.[163] Likewise, the trend to early extubation of patients after liver transplantation in the surgical unit has led to the successful uncomplicated recovery of these patients in the PACU. Finally, in an effort to protect ICU bed availability and to reduce the number of cardiac surgery cancellations, a group in Melbourne established a cardiac surgery recovery unit within the PACU.[177] Each of these examples requires adequate space and specialized nursing skills to be successful.

OUTPATIENT PROCEDURES

Finally, the PACU has responded to the economic restrictions that currently limit hospital resources by accommodating the performance of simple outpatient procedures (see Chapter 89).[178] The PACU is uniquely equipped to care for patients who are undergoing noninvasive and minimally invasive procedures such as electroconvulsive therapy,[179,180] cardioversion,[181] epidural blood patch,[178] and liver biopsy.[178] Ambulatory patients undergoing such procedures can be directly admitted to the PACU for the procedure and discharged to home after a brief recovery period. To do so, the PACU must be appropriately staffed and scheduled so as to not interfere with routine surgery scheduling and postoperative recovery. Electroconvulsive therapy is somewhat unique in that it requires general anesthesia that is delivered by an anesthesia care practitioner. Typically, these are short procedures that can be scheduled before the routine surgical unit cases. One successful electroconvulsive therapy program schedules the procedure at 5:30 AM with nurse-to-patient ratio of 2:1 and an estimated PACU length of stay of 2 hours.[180]

SUMMARY

The PACU is more than a postanesthesia observation unit. It is unique in its ability to support the care of patients of all ages and in every stage of illness. Since its inception

more than 50 years ago, the PACU has proved to be an exceptionally adaptable unit that is equipped to meet the demands of an evolving health care system.

Chapter 97

Postoperative Nausea and Vomiting

CHRISTIAN C. APFEL

Key Points

- Postoperative nausea and vomiting (PONV) may be triggered by various pathways through peripheral and/or centrally located receptors; however, the exact etiology is unknown.
- Numerous patient-, anesthesia-, and surgery-related risk factors are associated with a high incidence of PONV, but this association may not be causal. For example, the high incidence of PONV after gynecologic surgery is likely observed because the surgical procedures are conducted in women, who are more susceptible to PONV, and not because of the surgical procedures themselves.
- Instead of assessing a wide range of associated risk factors, a patient's risk for PONV is best predicted by a simplified risk score using independent predictors (statistically corrected for confounders).
- In adult inpatients undergoing general inhaled anesthesia, Apfel's simplified risk score for PONV includes female gender, nonsmoking status, history of PONV or motion sickness, and the use of postoperative intravenous opioids as the main independent predictors. When 0, 1, 2, 3, or 4 of these factors are present, the risk for PONV is approximately 10%, 20%, 40%, 60%, or 80%, respectively.
- In adult outpatients undergoing general anesthesia, a simplified risk score for postdischarge nausea and vomiting (PDNV) includes female gender, age less than 50 years, history of PONV, opioid use in the postanesthesia care unit (PACU), and nausea in the PACU. When 0, 1, 2, 3, 4, or 5 of these factors are present, the risk for PDNV is approximately 10%, 20%, 30%, 50%, and 90%, respectively.
- In children, a similar simplified risk score exists for postoperative vomiting (POV) with duration of surgery greater than or equal to 30 minutes, age older than or equal to 3 years, strabismus surgery, and a positive history of POV or POV/PONV in relatives as the main predictors.
- Because the main triggers for PONV appear to be inhaled anesthetics and opioids, strategies to avoid or reduce exposure (e.g., regional anesthesia or total intravenous anesthesia) are effective means to reduce the risk for PONV.
- A PONV prophylaxis strategy should be tailored to a patient's baseline risk, which can be determined using a simplified risk score. Patients at greatest risk experience the greatest absolute risk reduction from interventions (absolute risk reduction = baseline risk × relative risk [RR] reduction).
- Effective antiemetics to reduce PONV are cyclizine, dimenhydrinate, droperidol, dexamethasone, metoclopramide, ondansetron, dolasetron, tropisetron, and granisetron. The RRs of these antiemetics versus placebo for nausea and for vomiting vary between approximately 0.60 and 0.80.
- Neurokinin (NK_1) antagonists are similarly effective against nausea compared with other antiemetics but are considerably more effective against POV.
- Although the minimally effective dose for prophylaxis with ondansetron is 4 mg, the minimally effective dose for rescue treatment with ondansetron is only 1 mg. Based on this observation, many experts assume that the minimally effective dose for rescue treatment is only one quarter of the dose needed for prophylaxis.
- Patients who suffer from PONV in spite of intraoperative prophylaxis with ondansetron do not respond to rescue treatment with a second dose of ondansetron or granisetron in the PACU. It is therefore concluded that rescue treatment targeting an already blocked receptor is ineffective, so an antiemetic strategy using a different mechanism should be used instead.

Nausea and vomiting in the postoperative period occurs in 20% to 30% of patients,[1] and together, nausea and vomiting are the second most common complaints reported (pain is the most common).[2-8] After the landmark 1992 review by Watcha and White,[9] *postoperative nausea and vomiting (PONV)* became the more commonly used clinical term. In 1999, PONV became a medical subject heading in the National Library of Medicine. The term *PONV* is used throughout this chapter to reflect its current widespread usage to describe the composite postoperative symptoms of nausea and/or vomiting and/or retching. However, the description of these symptoms as "postoperative" should not be construed to suggest that surgery is their most important direct cause, even though this is a widely held belief. Several large prospective cohort studies now suggest that the varying incidences of PONV observed after different types of surgical procedures are largely a reflection of important patient-specific and anesthesia-related risk factors, rather than the surgical procedure itself.[4,5,8]

PONV can be such an unpleasant experience that patients often rate it worse than postoperative pain.[10] Patients' "willingness to pay" out of pocket for effective antiemetic treatment of PONV, as measured by well-designed studies, is $56 in the United States[11] and ∈65 in Europe.[12] Prevention of PONV in high-risk patients significantly improves postoperative ratings of well-being and satisfaction.[13] Although the experience of PONV is generally self-limited, postoperative vomiting or retching (POV) can lead to rare but serious medical complications, such as aspiration of gastric contents, suture dehiscence, esophageal rupture, subcutaneous emphysema, or pneumothorax (the actual incidence related to PONV has not been quantified).[14,15] PONV may delay a patient's discharge from postanesthesia care units (PACUs) and can be the leading cause of unexpected hospital admission after ambulatory anesthesia.[16] Annual PONV-related health care costs approach several hundred million dollars in the United States alone.[17,18]

The ongoing need to improve understanding, prevention, and treatment of PONV is reflected in the literature: approximately 3000 randomized controlled trials of PONV have been published in peer-reviewed journals, and almost 300 new studies are published each year. This is in part because of the interest of the pharmaceutical industry in developing new and more effective treatments for this condition. The purpose of this chapter is to provide an up-to-date review of PONV by a deepened methodologic understanding that allows resolution of discrepancies between traditional beliefs and the best available evidence. This more current understanding and knowledge will enable the reader to manage PONV more effectively in daily clinical practice.

ETIOLOGY: PATHWAYS FOR NAUSEA AND VOMITING

Nausea and vomiting may be induced through various pathways (Fig. 97-1).[19,20]

TOXIC MATERIALS IN THE GASTROINTESTINAL LUMEN

Ingestion of toxic substances (e.g., hypertonic saline or copper sulfate) results in the release of serotonin (5-hydroxytryptamine [5-HT]) from enterochromaffin cells in the gut wall.[21] These enterochromaffin cells hold more than 90% of the body's serotonin and appear to release it under various chemical and mechanical stimuli. Serotonin may also be released indirectly through M_3-muscarinic receptors, β-adrenoceptors, and histamine (H_3) receptors; conversely, the stimulation of γ-aminobutyric acid ($GABA_B$) receptors, 5-HT_4 receptors, and α_2-adrenoceptors and the presence of vasoactive intestinal polypeptide and somatostatin have been proposed to reduce the release of serotonin.[19] Serotonin is secreted in close proximity to afferent vagal nerve endings of the gut wall that travel to the dorsal brainstem through the nucleus tractus solitarius, as demonstrated in animal models in which vagotomy blocks cisplatin-induced emesis.[22] However, large amounts of

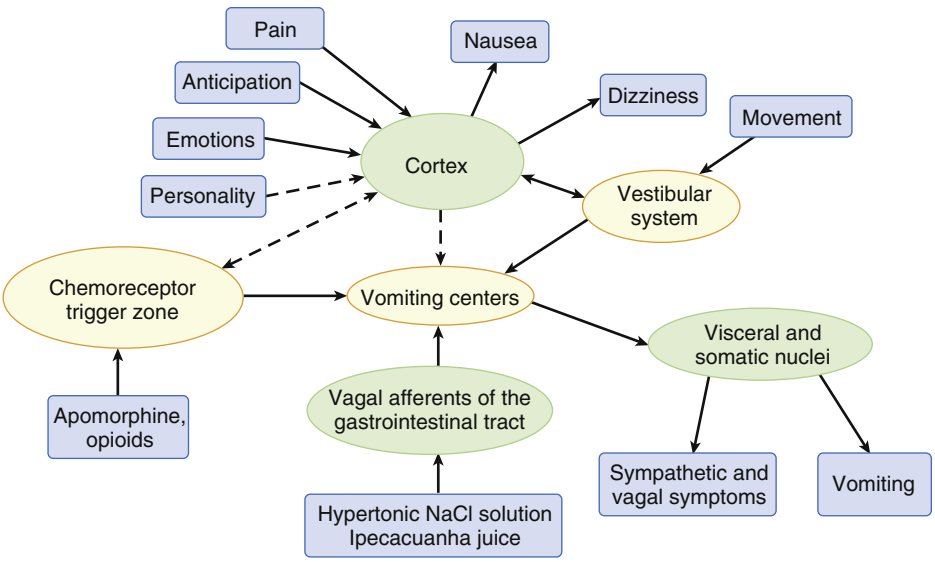

Figure 97-1. Pathways for nausea and vomiting. *Dotted lines* are hypothetic pathways with only indirect evidence. *NaCl*, Sodium chloride. *(Created by Christian Apfel, MD, PhD.)*

serotonin released by neuroendocrine carcinoid tumors lead to flushing, diarrhea, wheezing, and abdominal cramps but typically not to nausea and vomiting. This finding suggests that serotonergic emetogenic stimuli are primarily mediated through the autonomic nervous system rather than the bloodstream. Therefore, even though renal secretion of 5-hydroxyacetic acid (a metabolite of serotonin, with a much longer half-life) is associated with PONV after abdominal surgical procedures,[23] a causal relationship with PONV remains unclear.

ABSORBED TOXINS AND DRUGS

Absorbed toxins or drugs circulating in the blood can cause nausea and vomiting by stimulation of the chemoreceptor trigger zone (CRTZ).[24] The CRTZ is located in the area postrema, a circumventricular organ at the bottom of the fourth ventricle. Even though the CRTZ resides anatomically in the central nervous system, its uniquely permeable endothelium (i.e., lack of a blood-brain barrier) allows it to detect emetogenic substances in the bloodstream as if it were a peripheral organ.[25] Based on a series of articles, Borison and Wang were able to demonstrate in the early 1950s that the CRTZ has an abundance of receptors and that its stimulation can send emetogenic triggers to the brainstem's vomiting center to activate the vomiting reflex (Fig. 97-2).[26-30] Although this mechanism explains how apomorphine (a fairly selective dopamine [D_2] agonist) provokes emesis and why droperidol (a D_2 antagonist) reverses apomorphine's emetogenic effect, it remains unclear how the CRTZ senses or transduces emetic stimuli and why nausea and vomiting are not typical side effects of dopamine infusions. Again, the reasons that certain receptor agonists circulating in the blood fail to trigger nausea and vomiting while corresponding receptor antagonists prevent or reduce nausea and vomiting are unclear.

STIMULATION OF THE VESTIBULAR SYSTEM

The vestibular system is another source of emetogenic stimuli, as observed in motion sickness or Ménière's disease.[31-33] Motion sickness is a risk factor for PONV.[2-8] Whether vestibular input contributes to the emetogenic state in the vomiting center or whether anesthetics or opioid analgesics contribute to the susceptibility of the vestibular organ or signal processing is not clear.

RISK FACTORS AND INDEPENDENT PREDICTORS

DISTINGUISHING ASSOCIATION FROM CAUSALITY

The recognition of risk factors plays a critical role in making diagnostic and therapeutic decisions in medicine. The term *risk factor* was likely first coined in the Framingham study, in which the risk of heart disease was associated with specific conditions such as hypertension, high cholesterol, and smoking. To know which of the risk factors is most likely *causal* or merely *correlational* can be critical for the development of valid risk assessment tools to be used for clinical decisions. For example, women are more susceptible than men to certain emetogenic stimuli (motion, chemotherapy, inhaled anesthetics, and opioids).[34,35] If the average incidence of PONV is considered to be approximately 30% overall and female patients are approximately three times more likely to develop PONV,[3,5] the average incidence in male and female patients should be in the range of 15% and 45% (assuming that the same numbers of men and women are anesthetized).[36] It is therefore not surprising that approximately one in two women undergoing gynecologic surgical procedures suffers from PONV. From this perspective, the type of surgery can be considered a risk factor for PONV. However, establishing a policy for the routine use of antiemetics for the prevention of PONV for women having gynecologic surgery, but not other surgical procedures, would not acknowledge that lengthy nongynecologic surgical procedures in women are associated with incidences of PONV much higher than 50%,[4,5] whereas short gynecologic procedures such as dilatation and curettage may be associated with PONV incidences as low as 7%.[37] Therefore, the current categories of surgical procedures are generally too broadly defined to be reliable predictors of PONV.[38]

It is more useful to consider PONV as multifactorial in its origin, that is, as a consequence of emetogenic agents (inhaled anesthetics, opioids) applied to susceptible patients (female patients, those with a history of motion sickness, nonsmokers). These factors have been shown not only to be associated with an increased incidence of PONV but also to be important independent predictors of PONV. A better prediction can be obtained by focusing on these well-established independent predictors that appear to cause PONV.[38] Therefore, the following text distinguishes between factors that are merely associated with increased risk (risk factors or associated risk factors) and factors that appear to be causally related to PONV (independent risk factors or independent predictors). Table 97-1 lists the relative importance (presented as odds ratios) of independent predictors as determined in large cohort studies.

FACTORS THAT MAY NOT BE RELEVANT

Many reviews or book chapters list large numbers of PONV risk factors, irrespective of the evidence or the magnitude of effect. This approach has contributed to a divergence between commonly held clinical beliefs about PONV risk factors and the published evidence. For example, Eberhart and colleagues reported that more than 80% of German anesthesiologists considered obesity to be a risk factor for PONV.[39] However, Kranke and co-workers found that an increased body mass index was not associated with an increased incidence of PONV.[40] Similar discrepancies exist for the influence of facemask ventilation,[41,42] use of a nasogastric or orogastric tube,[43-46] intravenous use of neostigmine to reverse neuromuscular blockade,[47,48] phase of menstrual cycle,[49] and even weather or phase of the moon.[50,51] Thus, the following discussion of risk factors for PONV focuses on

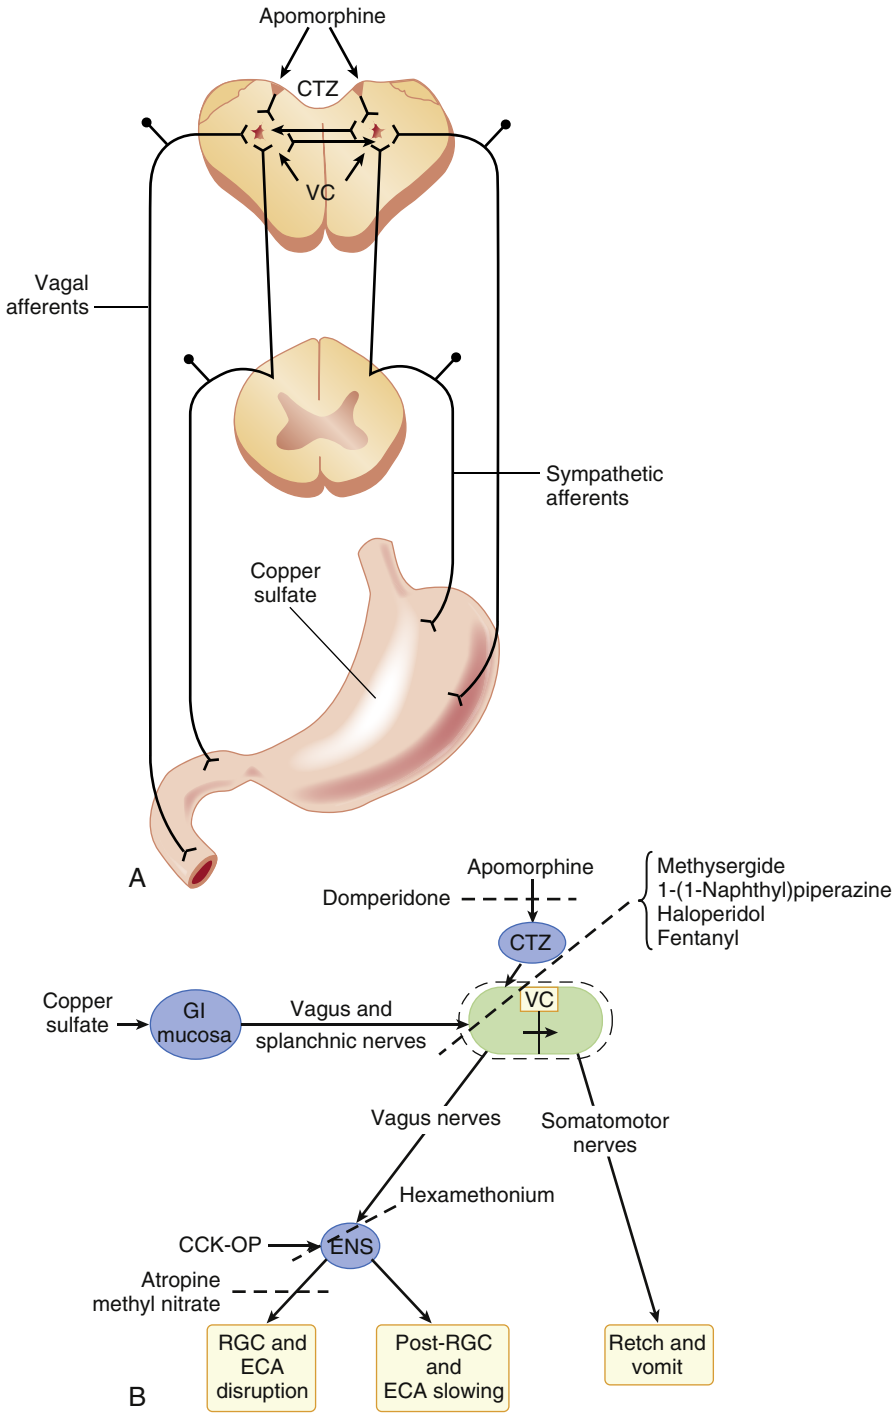

Figure 97-2. Different types of schematic representation of the organization of the emetic reflex from the original Wang and Borison (**A**) 1952 model and Lang and Marvig (**B**) in 1989; Borison and McCarthy (**C**) in 1981; and Andrews, Rapeport, and Sanger (**D**) in 1988. Note that all the models contain essentially the same key elements. *CCK-OP,* Cholecystokinin octapeptide; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *CTZ,* chemoreceptor trigger zone; *ECA,* electrical control activity; *ENS,* enteric nervous system; *GI,* gastrointestinal; 5-HT, 5-hydroxytryptamine; *IV cytotoxic agents,* intravenous cytotoxic agents; *IV vent,* fourth ventricle; *NTS,* nucleus tractus solitarius; *RGC,* retrograde giant contraction; *PCRF,* parvicellular reticular formation; *SP,* substance P; *VC,* vomiting center.

the factors that are well supported in the literature. Of course, other unknown or insufficiently studied PONV risk factors may have yet to be found. For example, it may be possible that rapid patient transport from the operating room to the PACU, especially involving fast turns or decelerations, can trigger nausea and vomiting. However, this factor has never been formally studied, and therefore its importance cannot be determined. Accordingly, the following discussion focuses on the best available evidence.

PATIENT-RELATED INDEPENDENT PREDICTORS

Female Gender

Female gender is the strongest patient-specific predictor of PONV, with an odds ratio of approximately 2.6[52] (see Table 97-1), independent of anesthetic technique. Women can also suffer from hyperemesis gravidarum,[53] and they have a lower threshold for motion sickness than men.[54] The reason for increased female susceptibility to nausea and

vomiting is unclear, but this susceptibility persists well after menopause and for most of the rest of a woman's life.[55]

Not Smoking

Individuals often experience nausea and diarrhea when smoking their first cigarette.[56] This is likely an acute effect of nicotine because nausea is a known side effect of nicotine patches.[57] Although one could predict that smokers would have a higher risk of PONV than nonsmokers,[39] Cohen and associates found that nonsmokers were 1.8 times more likely than smokers to have PONV.[3] This finding was subsequently confirmed in a meta-analysis of large studies of risk factors for PONV.[52] The mechanism by which a smoking habit reduces the risk of PONV is not entirely clear, but one may speculate that long-term smokers are desensitized to nausea. Nicotine

stimulates indirect GABA-mediated cerebral dopamine release,[58] and nicotine withdrawal in the perioperative period may lead to low postoperative cerebral dopamine levels, thus reducing activation of dopaminergic circuits in the CRTZ known to be associated with nausea and vomiting (my conjecture). However, nonsmoking is not a risk factor for nausea and vomiting in the postdischarge period,[59] perhaps because the protective effect of reduced dopaminergic stimulation disappears once discharged patients resume smoking.

History of Postoperative Nausea and Vomiting, Motion Sickness, or Migraine

Susceptibility to emetogenic stimuli varies among individuals according to history of PONV,[2,4,6,8,37,60-62] history of motion sickness,[2,4,6,61,62] and history of migraine.[4,8]

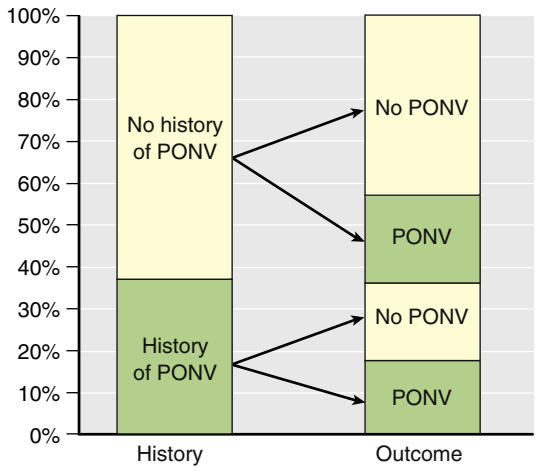

Figure 97-3. Limited sensitivity of a single predictor to identify patients at risk for postoperative nausea and vomiting (PONV), with history of PONV as an example. *(From Apfel CC, Kranke P, Eberhart LH: Comparison of surgical site and patient's history with a simplified risk score for the prediction of postoperative nausea and vomiting,* Anaesthesia *59:1078-1082, 2004.)*

Although one would intuitively expect that a history of PONV is the strongest predictor of subsequent PONV, this is not the case. In fact, in the majority of studies, female gender is a stronger predictor than a history of PONV.

This finding is illustrated by a study of 1566 patients (Fig. 97-3).[38] Approximately one third of these patients (569) presented with a history of PONV, of whom every second patient (280) experienced PONV. Two thirds of patients (997) did not have a history of PONV, of whom one third (320) experienced PONV. Clearly, patients with a history of PONV were at higher risk for experiencing PONV. However, of the total 600 patients who developed PONV, fewer than half (280 of 600) would have been correctly identified if the history of PONV had been used as a single predictor. Indeed, the use of PONV history as a single predictor has been associated with a sensitivity of less than 50% to identify patients at risk for PONV. In other words, fewer than half the patients who develop PONV were correctly identified in advance (less than one would expect from a random guess).[38]

Age

In adults, although the incidence of PONV decreases with age with an odds ratio of 0.88 per decade,[52] age has not always been a strong risk factor.[3,37,55,60,62-66] In children, however, Eberhart and co-workers have shown that an age of 3 years or older is associated with an increased risk for PONV.[67]

Anxiety

Anxiety may influence PONV, although this finding was not supported in a study with a small cohort of children.[68] However, in secondary analyses of a considerably larger randomized controlled trial in adults,[7] anxiety was assessed using two standardized psychometric instruments, and a statistically significant but fairly weak association was demonstrated.[66] Although anxiety increases PONV, a preoperative assessment of anxiety is unlikely to result in a significant improvement in prediction for PONV.

ANESTHESIA-RELATED INDEPENDENT PREDICTORS

Preoperative Opioids

Few studies have compared different opioids given in conjunction with premedication. Eger and colleagues found no difference between morphine and meperidine.[69] In the same study, the $GABA_A$-enhancing drug pentobarbital was associated with a less frequent incidence of PONV compared with placebo.

Intraoperative Opioids

No large prospective cohort study has demonstrated that the type or dose of intraoperative opioid influences PONV in adults. In children, the liberal intraoperative use of morphine (analgesic median effective dose [ED_{50}], 0.18 mg/kg) is associated with a frequent incidence of POV in children undergoing tonsillectomies (see Chapter 93).[70]

Whether the type of intraoperative opioid used is a relevant consideration remains controversial. One article suggested that alfentanil is associated with less PONV compared with fentanyl or sufentanil.[71] Another group hypothesized that the ultrashort half-life of remifentanil would result in less carryover effect in the postoperative period and thereby decrease PONV. However, no significant difference in the overall incidence of PONV was noted when remifentanil was compared with fentanyl, probably because the study design included predominantly larger operations requiring significant amounts of opioids for postoperative pain relief, thus masking any potential benefit.[48] Finally, morphine-6-glucuronide, an active metabolite of morphine, has been reported to be associated with less PONV compared with morphine,[72] although this difference was not statistically significant in another study.[73] In conclusion, regardless of whether opioids are used intraoperatively or postoperatively, the available evidence suggests that the dose of opioid, rather than the type, is one of the main predictors (and/or causes) of PONV.

Postoperative Opioids

Most large studies using multivariable analyses demonstrate that use of postoperative opioids doubles the risk of PONV.* The dose of postoperative opioid appears to be important,[76] but not the type (e.g., morphine versus piritramide).[77] As a consequence, opioid-sparing strategies should reduce the incidence of PONV. Indeed, PONV tends to be decreased when intravenous acetaminophen or cyclooxygenase-2–selective nonsteroidal antiinflammatory drugs (NSAIDs)[78] reduce opioid use by 30% to 50%. In addition, the peripheral opioid antagonist alvimopan appears to reduce nausea severity in the late postoperative period without affecting the central analgesic effects of opioids.[79] Alvimopan appears to work by mitigating postoperative ileus and opioid-induced bowel dysfunction.[80-83]

Propofol and Inhaled Anesthetics

Propofol is widely believed to have antiemetic properties. By using propofol in patient-controlled analgesia (PCA) pumps in the PACU as "patient-controlled antiemesis,"

*References 2, 4, 5, 38, 60, 74, and 75.

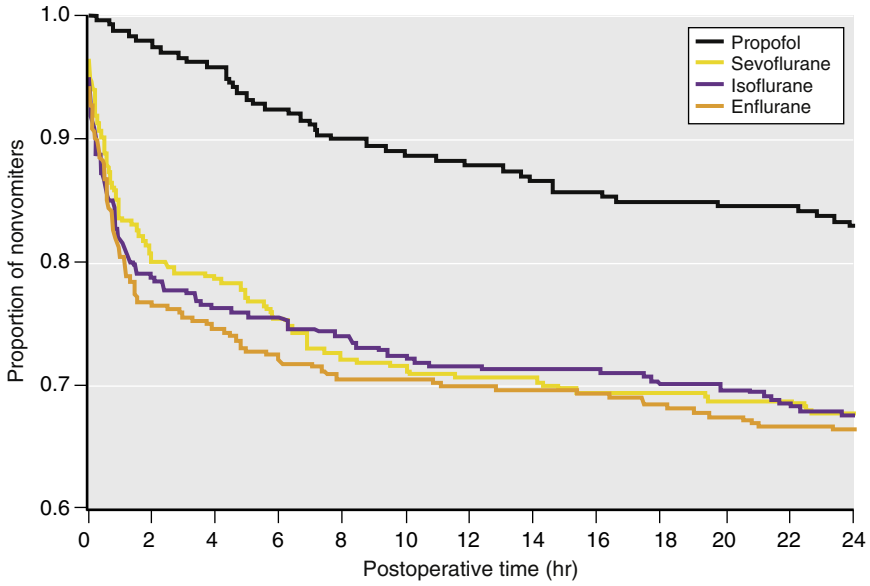

Figure 97-4. Kaplan-Meier chart for postoperative vomiting after isoflurane, enflurane, sevoflurane, and propofol. *(From Apfel CC, Kranke P, Katz MH, et al: Volatile anaesthetics may be the main cause of early but not delayed postoperative vomiting: a randomized controlled trial of factorial design,* Br J Anaesth *88:659-668, 2002.)*

Gan and associates found that "nonsedating" plasma concentrations of 343 ng/mL reduced nausea in 50% of cases.[84,85] However, using a similar design, Scuderi and colleagues were unable to demonstrate any antiemetic effect of propofol.[86] In another study, healthy volunteers were randomized to propofol, midazolam, or placebo and were then exposed to an infusion of apomorphine.[87] At nonsedative doses, neither propofol nor midazolam provided protection. However, at sedative doses, both propofol and midazolam increased the threshold for nausea. As a result, the antiemetic activity of propofol-induced sedation is not clear.

Compared with a purely regional anesthetic technique, general anesthesia is associated with a significantly higher incidence of PONV.[37] This finding raises the question of the individual contribution of the drugs used for the general anesthetic regimen, namely opioids, inhaled anesthetics, and nitrous oxide. Although previous meta-analyses demonstrated a lower incidence of nausea and vomiting with propofol compared with inhaled anesthetics,[88,89] in volunteer studies 8-hour anesthesia with sevoflurane was associated with nausea and vomiting in more than 80%, a finding strongly suggesting the emetogenicity of volatile anesthetics.[90] In addition, a large clinical study demonstrated the following: (1) the difference in vomiting between inhaled anesthetics and propofol occurs predominantly in the first 2 to 6 hours postoperatively (Fig. 97-4); and, more importantly, (2) the difference in early vomiting is clearly dose related (Fig. 97-5), so the difference is not related to propofol but rather to the dose-dependent emetogenic effect of the volatile anesthetics.[75] No differences in PONV have been observed among the volatile anesthetics isoflurane, enflurane, and sevoflurane. This finding is consistent with a meta-analysis by Gupta and co-workers (comparing propofol, isoflurane, sevoflurane, and desflurane),[91] a meta-analysis by Macario and associates (comparing sevoflurane with desflurane),[92] and a study by Wallenborn and colleagues (comparing isoflurane, sevoflurane, and desflurane).[93]

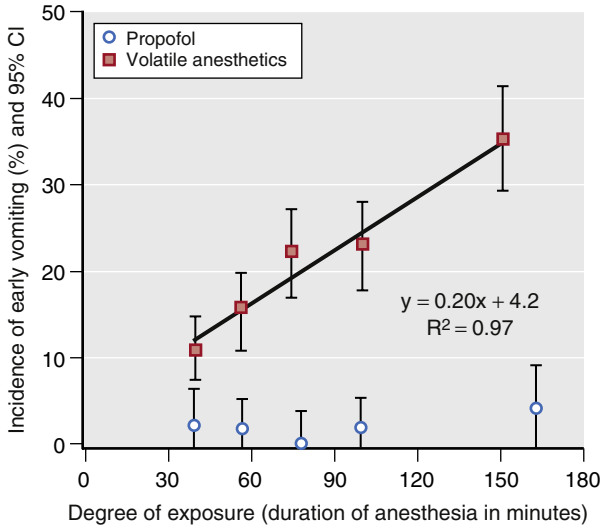

Figure 97-5. Incidence of early vomiting (0 to 2 hours) after maintenance with volatile anesthetics or propofol. *CI,* Confidence interval. *(From Apfel CC, Kranke P, Katz MH, et al: Volatile anaesthetics may be the main cause of early but not delayed postoperative vomiting: a randomized controlled trial of factorial design,* Br J Anaesth *88:659-668, 2002.)*

Nitrous Oxide

Numerous studies in the 1980s and meta-analyses in the 1990s emphasized the emetogenic effect of nitrous oxide.[94,95] However, the emetogenic effect of nitrous oxide may not be quite as strong as that associated with volatile anesthetics.[74] Moreover, the emetogenic effects of nitrous oxide and volatile anesthetics are independent (i.e., they are additive).[74] What is probably more notable than the emetogenic effect of nitrous oxide is the landmark trial comparing a nitrous oxide group (70% N_2O, 30% O_2) with an oxygen-enriched air group (80% O_2, 20% N_2) that found not only more PONV but also significantly more severe adverse events (pulmonary complications, wound infections, and fever) in the nitrous

oxide group.[96] A second large multicenter 5-year study comparing a nitrous oxide group (70% N_2O, 30% O_2) and a nitrous oxide–free group (70% N_2, 30% O_2) may provide further evidence regarding nitrous oxide and its association with more severe medical complications.[97]

Duration of Anesthesia

The effect of duration of anesthesia on PONV has been described in several studies.[4,37,61,74,75,93] The magnitude of this time-dependent dose response varies widely, as reflected in odds ratio per hour ranging from 1.15[74] to 2.53.[37] As referenced earlier, the effect size may be large when inhaled anesthetics are used and small when propofol is used (see Fig. 97-5), and it depends on the amount of opioids used.[74] In any event, it is generally correct to assume that longer and more invasive surgical procedures are associated with more PONV. In fact, in a cross-validation that developed a simplified risk score, a co-linearity was seen between the duration of anesthesia and the postoperative intravenous use of opioids. Because intravenous opioid use was the slightly stronger predictor, that variable remained an independent predictor, as opposed to duration of anesthesia.[5]

SURGERY-RELATED INDEPENDENT PREDICTORS

Many surgical procedures are associated with a high incidence of PONV.[9] This finding has led to many hypothesized causal mechanisms for various types of surgical procedures—tympanoplasty and vestibular stimulation, adenotonsillectomy and swallowed blood, breast surgery and emotional load, laparoscopic surgery and peritoneal irritation, abdominal surgery and serotonin release, and hysterectomy and vagal stimulation[98-100]—all resulting in a tendency to specify the type of surgery narrowly in antiemetic trials. Without question, patients undergoing major abdominal and gynecologic surgical procedures have an increased risk of PONV, with incidences of at least 50%. However, in many instances, these incidences may reflect other underlying factors, such as prolonged exposure to emetogenic volatile anesthetics and/or large doses of intraoperative opioids. In fact, if volunteers are exposed to volatile anesthetics (without any surgical intervention) for an extended period of time, almost all experience nausea or vomiting afterward.[90] Therefore, risk assessment should be based on the underlying independent predictors, rather than the type of surgical procedure. In addition, several studies support the notion that the type of surgery is not an independent predictor of postoperative nausea,[4] vomiting,[4,8,63] PONV,[5,60] or need for rescue treatment (see Table 97-1).[65] However, other studies have identified several types of surgical procedures as independent predictors of postoperative nausea,[3,8] vomiting,[64] or PONV.[37,61,66,74] Nevertheless, most types of surgery have not consistently been shown to be independent predictors of PONV in the majority of studies; possible exceptions to this rule are laparoscopic cholecystectomy and gynecologic procedures.[3,59,74] Although strabismus surgery is not a risk factor in adults,[101] it is a well-established and clinically relevant independent predictor of POV in children.[67,102]

One could argue that it would be enough to know which types of surgical procedures are risk factors, whether or not they are independent predictors of PONV, to decide on the need for prophylactic antiemetics. The incidence of PONV in many so-called emetogenic procedures (laparoscopy, adult strabismus surgery, middle ear surgery, herniorrhaphy, tonsillectomy, adenoidectomy, and uvulopalatopharyngoplasty) is not much higher than for other types of surgery. In fact, when Scuderi and colleagues stratified patients according to "emetogenic procedures," the incidence of PONV in the PACU was 37% (80 of 215) compared with 31% (112 of 360) for all other surgical procedures, an incidence that was not significantly different.[103] These findings are also consistent with a study in which the PONV incidence over 24 hours was 42% (283 of 681) for "emetogenic procedures" and 36% (317 of 885) for other procedures.[38] In conclusion, although certain types of surgical procedures are associated with a more frequent incidence of PONV, causality has not been clearly established. With the exception of strabismus surgery in children, the incidence of PONV with most surgical procedures likely reflects underlying patient- and anesthesia-related factors.

RISK ASSESSMENT

PONV is multifactorial. Therefore, a patient's risk can be better estimated by accounting for several independent predictors simultaneously.

Palazzo and Evans in the United Kingdom were the first to apply multiple logistic regression analysis to 148 patients undergoing minor orthopedic procedures, thus developing a predictive model for "postoperative sickness."[2] One year later, logistic regression analysis was applied to data from a Canadian 4-center survey of 16,000 inpatients.[3] Binary logistic regression analysis is a multivariable statistical method that quantifies the relative impact of *independent* predictors (e.g., female gender, nonsmoking) on a dichotomous outcome (here PONV) by determining their coefficients according to

$$P = 1/\left(1 + e^{-z}\right)$$

with $z = \alpha \bullet x_1 + \beta \bullet x_2 + \gamma \bullet x_3 + \ldots + \omega$, and α, β, γ, and so forth, being the coefficients for the factors x_1, x_2, x_3, etc. These coefficients are directly related to the odds ratio of a predictor through the formula odds $\text{ratio}_{(a)} = e^a$, a measure that is similar to the relative risk or risk ratio, discussed later.

This is important to realize when comparing articles that report coefficients with those that report odds ratios.[8] Table 97-1 displays the odds ratios that quantify the impact of variables as independent predictors, not merely risk factors, for PONV.

Subsequently, two groups independently conducted large surveys and applied logistic regression analyses to develop more generalizable predictive models.[4,63,64] Koivuranta and colleagues were the first to publish predictive models for PONV based on logistic regression analyses, and they developed a simplified model by selecting the five strongest predictors: female gender,

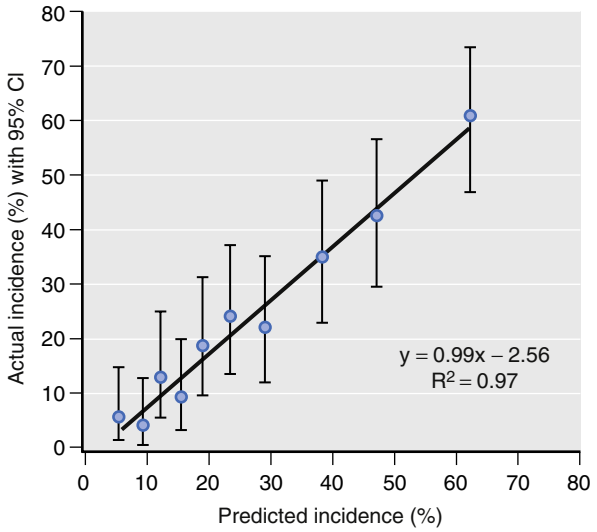

Figure 97-6. Correlation between average predicted and actual incidence of postoperative vomiting in 10 percentile groups. *CI,* Confidence interval. *(From Apfel CC, Greim CA, Haubitz I, et al: The discriminating power of a risk score for postoperative vomiting in adults undergoing various types of surgery,* Acta Anaesthesiol Scand *42: 502-509, 1998.)*

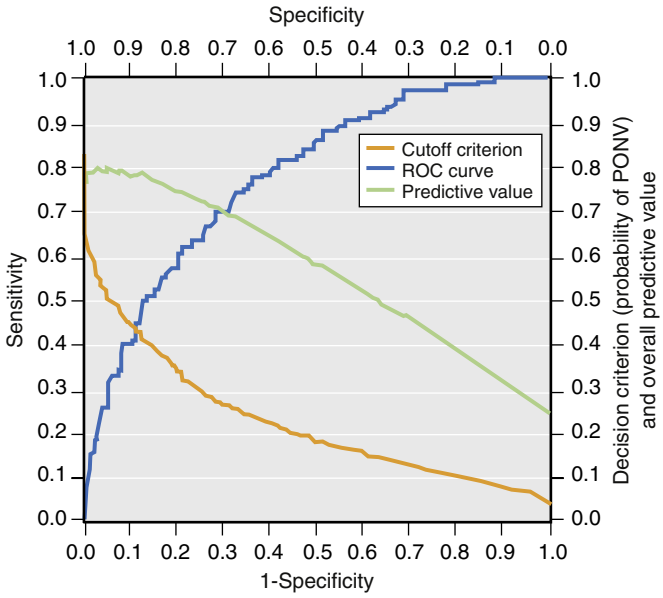

Figure 97-7. Receiver operating characteristic (ROC) curve characterizing the relationship between sensitivity and specificity. *PONV,* Postoperative nausea and vomiting. *(From Apfel CC, Greim CA, Haubitz I, et al: The discriminating power of a risk score for postoperative vomiting in adults undergoing various types of surgery,* Acta Anaesthesiol Scand *42:502-509, 1998.)*

previous PONV, duration of operation longer than 60 minutes, history of motion sickness, and nonsmoking.[4] When 0, 1, 2, 3, 4, or 5 of these independent predictors were present, the risk for PONV was 17%, 18%, 42%, 54%, 74%, and 87%, respectively. Later, a published predictive model for POV in patients undergoing surgical procedures of the ear, nose, and throat (ENT) showed a tight correlation between predicted and observed incidence in a validation cohort (Fig. 97-6).[63] Because the later model was developed in patients undergoing ENT surgical procedures, its applicability to other types of surgical procedures was unclear. In a subsequent study that included a wide range of surgical procedures, the type of surgery turned out to be an *independent* predictor (at the expense of duration of anesthesia), but the discriminating power as described by the area under the receiver operating characteristic (ROC) curve was at least as good using the prior risk score (independent of surgery type). Notably, the area under the ROC curve (ROC-AUC) was 0.77 (Fig. 97-7), meaning that on average the prediction was correct in approximately three of four cases.[64] The two groups then performed a cross-validation and found that risk scores derived from one center were able to predict PONV from the other center (ROC-AUC = 0.65 to 0.75) and that simplification of the score did not weaken the discriminating power (ROC-AUC = 0.63 to 0.73).[5] The final score consisted of four predictors: female gender, history of motion sickness or PONV, nonsmoking status, and the use of postoperative opioids; if 0, 1, 2, 3, or 4 of these risk factors were present, the incidences of PONV were 10%, 21%, 39%, 61%, and 79%, respectively (Fig. 97-8).[5] In countries where opioids are used liberally in the postoperative period, Koivuranta's PONV score shows slightly superior predictive characteristics,[62] although Apfel's PONV score may be preferable for its simplicity.

Whereas this score was developed for the prediction of PONV over 24 hours in inpatients, Chung's group developed a fairly complex predictive model for PONV in outpatients, also known as postdischarge nausea and/or vomiting (PDNV).[37] That score included type of surgery as a predictor, but it appeared to be inferior to the simplified risk scores.[60,61] However, this result may have occurred, in part, because the validations were performed in inpatients. A more recent validation from the Kalkman group in the Netherlands found that the predictive characteristics of the simplified risk scores were rather limited, with ROC-AUCs of only 0.63 to 0.66.[62] In this patient population, however, use of postoperative opioids—invariably shown to affect the risk for PONV in previous studies and a key independent predictor in the simplified risk models—was not associated with an increased incidence of PONV, a feature likely accounting for the limited predictive power. Therefore, a large multicenter study in more than 2000 patients was conducted to develop a predictive risk score for PDNV in ambulatory patients in the United States, where opioids are commonly used in postoperative and postdischarge settings.[59] The incidence of overall PDNV was 37% (Fig. 97-9), and logistic regression analyses identified 5 independent predictors of PDNV, namely female gender, age less than 50 years, history of PONV, opioid use in the PACU, and nausea in the PACU.[59] Simplification of a risk score based on these 5 risk factors led to an ROC-AUC of 0.72, and the incidence of PDNV associated with 0, 1, 2, 3, 4, and 5 factors was 7%, 20%, 28%, 53%, and 89%, respectively (Fig. 97-10).[59]

These models have been developed for prediction in adults and are not applicable to pediatric patients.[104] However, the risk of POV can be predicted with the

Venn diagrams for nausea, vomiting, and retching in patients after general inpatient or outpatient anesthesia with inhalational or propofol anesthesia. *PONV,* Postoperative nausea and vomiting; *TIVA,* total intravenous anesthesia. *(From Visser K, Hassink EA, Bonsel GJ, et al: Randomized controlled trial of total intravenous anesthesia with propofol versus inhalation anesthesia with isoflurane-nitrous oxide: postoperative nausea with vomiting and economic analysis,* Anesthesiology *95:616-626, 2001.)*

vomiting are correlated, they can occur independently and should therefore be assessed and reported separately, so that results can be compared across publications. This is true for both inhaled and intravenous anesthesia in both inpatient and outpatient procedures (Fig. 97-12)[7] Failure to realize this essential point has resulted in difficulties in assessing results for a significant portion of the available literature. Similar difficulties have arisen from the use of various scales that are generally inadequate to properly assess PONV. For example, assessing PONV on a four-point severity scale ranging from "*no symptoms, mild nausea, severe nausea or up to two vomits, or more than two vomits*" fails to reflect the underlying physiology and presentation of these symptoms and does not allow determination of the proportion of patients experiencing nausea, vomiting, or both.[105]

Nausea (from the Greek *nautia* meaning "seasickness") is often described as a "sensation of unease and discomfort in the stomach with an urge to vomit." Nausea may manifest at different intensities, may last a variable period of time, and may wax and wane (change in intensity over time). The intensity of these symptoms is assessed in three ways.

The most widely accepted measurement technique for intensity uses a visual analog scale (VAS). The VAS consists of a 10-cm horizontal line with the left end corresponding to *no nausea* and the right end corresponding to *worst imaginable nausea*. Patients are asked to choose a point on the line that represents the intensity of their current state. The VAS is considered the criterion standard because its reliability and sensitivity have been well established in pain studies.[106] Another common approach is the use of a written or verbal 11-point numeric rating scale (NRS), for which the patient is asked to rate the severity of his or her nausea between 0 and 10, with 0 corresponding to *no symptoms* and 10 corresponding to *worst possible symptoms*. The NRS approach has the advantage of ease of use and maintains a sensitivity similar to the VAS gold standard.[107] The easiest approach appears to be a categorical verbal rating scale (VRS), in which patients describe their symptoms as *none*, *mild*, *moderate,* or *severe*. Unfortunately, even though Boogaerts and colleagues demonstrated a good correlation between the VRS and VAS for nausea,[108] pain studies have found that the VRS is not as sensitive as the VAS.[107] All told, the NRS approach may provide the best balance between sensitivity and ease of use.

Usually, the intensity of nausea varies over time, so repeated measurements would be needed for an overall severity assessment. Thus, nausea assessment may not be accurate if the intervals between assessments are considerably longer than the duration of nausea episodes. As a rule of thumb, it may thus be advantageous to have patients estimate their *average* and/or *most severe* level of nausea, rather than limiting patients to rating the current nausea at the time of questioning. Therefore, assessments of nausea should be performed to cover a time *interval* rather than to assess a time *point*.

Vomiting, as a clinical symptom, is the forceful expulsion of gastric contents through the mouth or nose. *Retching* is similar to vomiting with the exception that no gastric content enters the pharynx (dry heaves). An *emetic*

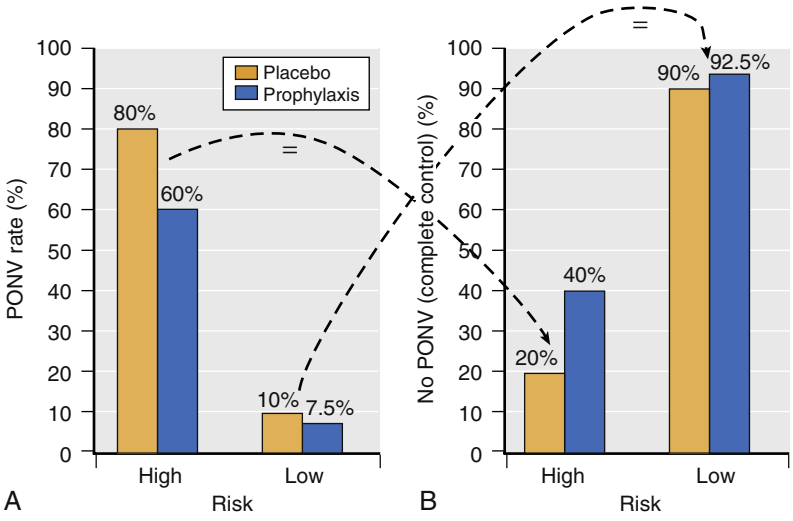

Figure 97-13. A and **B,** Relative risks (risk ratios) or relative risk ratios are independent of the patient's baseline risks. Both **A** and **B** represent the same data, yet efficacy of a drug can be judged only from the risk ratio of the events (e.g., postoperative nausea and vomiting [PONV]), not from the risk ratio of the absence of events (e.g., no PONV).

episode is often operationally defined as one or more instances of vomiting and/or retching separated by no more than 1 minute of respite. However, for the sake of simplicity and because vomiting is much more frequent than retching, many authors' reports of *vomiting* include both vomiting and retching. In such instances, use of the term *emetic episode* is preferable. The measurement of vomiting and emetic episodes is simpler than that of nausea because the former involves a distinctive and recognizable muscular reflex. Severity is therefore best evaluated by number of episodes, and recording the times of individual episodes allows secondary analysis with regard to the time course.

Because no universally accepted standard exists for measuring and reporting nausea and vomiting, publications should at the minimum report separate incidences for nausea and for vomiting, even if the primary outcome is a combined measure such as the incidence of PONV. Whenever possible, the frequency and success of rescue treatment should be reported as well, to allow comparison of treatment effects in subsequent meta-analyses.[105] In addition, patients may experience a benefit as mild (instead of severe) nausea, and this is not reflected by the crude incidence, a dichotomous outcome. This may also be a reason that a joint severity score that considers the severity of nausea and vomiting may be a valuable adjunct to report and analyze with more statistical power than the binary variables.

Measures of Efficacy and Effectiveness. From an epidemiologic perspective, *efficacy* refers to the impact of an intervention in a clinical trial, whereas *effectiveness* refers to the impact in real-world situations. For PONV trials, *efficacy* of a prophylactic strategy is probably best described by the relative risk (a synonym would be the risk ratio [RR is used for either term interchangeably]) or the odds ratio that measures the drug-specific antiemetic potential. In contrast, the *effectiveness* of a prophylactic intervention is probably best measured by the absolute risk difference (ARD; synonym: absolute risk reduction) or number-needed-to-treat (NNT) that describes the actual benefit of that intervention when given to patients of a population with a certain risk for PONV. To appreciate the meaning of the different measures of treatment effects described in the literature fully, it is essential to conceptualize the fundamental differences between measures of *efficacy* and *effectiveness* (i.e., RR and ARD). Understanding this difference is key when comparing efficacy among antiemetic trials and when determining the effectiveness of interventions in specific clinical situations.

Absolute Risk Difference and Number-Needed-to-Treat. When using binary outcomes such as the incidence of PONV, the clinical benefit or *effectiveness* of prophylactically administered antiemetics for an individual (or a population) with a particular underlying risk profile is best described by the ARD. For example, when a patient is at very high risk for PONV, say 80%, the use of an antiemetic such as ondansetron may reduce the risk to 60% (i.e., the ARD is 20%) (Fig. 97-13, A). Thus, ondansetron given to 100 individuals with a baseline risk of 80% will prevent PONV in 20% of cases, and therefore 1 of 5 such patients will benefit from the intervention. To put it another way, 5 high-risk patients would need to be treated prophylactically to prevent 1 of those 5 patients from experiencing PONV: the NNT is 5. Thus, the following formula applies:

$$NNT = 1/ARD$$

However, when ondansetron is given for prophylaxis to patients at low risk for PONV, say 10%, the risk will be reduced only to 7.5%; the ARD is only 2.5%, and the NNT is 40. Thus, ARD and NNT, both measures of *effectiveness,* are critically dependent on the patient's baseline risk. As a corollary, ARD or NNT determined in one study cannot be taken as a measure of *efficacy* for patients in a population with a different (higher or lower) baseline risk. This emphasizes the importance of an objective risk assessment to tailor the use of prophylactic antiemetic treatment to those patients who benefit most.

Relative Risk Reduction and Risk Ratio. The aforementioned examples have one characteristic in common. The use of ondansetron reduced the risk by approximately one fourth. Thus, in both examples the relative risk reduction (RRR) was 25%, and the risk ratio (RR) was 0.75.

$$RR = 1 - RRR$$

The finding that the RR is a relatively robust measure of efficacy for a wide range of baseline event rates has been described in other medical areas,[109] but it was first described in the field of PONV in the IMPACT (*I*nternational *M*ulticenter *P*rotocol to assess *A*ntiemetic *C*ombinations in a controlled Clinical *T*rial of factorial design) study.[74,110] In addition, this study demonstrated that the *efficacy* of each of the three antiemetics tested (ondansetron, dexamethasone, and droperidol) was independent of one another and by and large of other risk factors.[74] In other words, RR and RRR were reliable measures for the *efficacy* of prophylactic antiemetics and were independent of the patient's baseline risk.

As a consequence, the *effectiveness* in terms of an ARD of an antiemetic that can be expected in clinical practice can be estimated from the baseline risk multiplied by the RRR using the formula:

$$\text{ARD} = \text{Baseline risk} \bullet \text{RRR}$$

Alternatively, the remaining risk can be estimated using the formula:

$$\begin{aligned}\text{Remaining risk} &= \text{baseline risk} - \text{ARD}\\ &= \text{baseline risk} \bullet (1 - \text{RRR})\\ &= \text{baseline risk} \bullet \text{RR}\end{aligned}$$

Relative Benefit for Freedom From Symptoms. However, the RRR or RR is independent of the patient's baseline risk only when the outcome is "PONV" but not "no PONV." In the first example (i.e., in the high-risk group), the incidence of no PONV was 20% without prophylaxis and 40% with prophylaxis (Fig. 97-13, *B*). Therefore, twice as many patients were free of PONV; that is, the relative benefit (RB) for no PONV was 2. However, in the second example (i.e., in the low-risk group), the incidence of no PONV was 90% without prevention and 92.5% with prevention; that is, the RB for no PONV was only 1.03 (92.5/90), even though there was a 25% decrease in the incidence of PONV. This demonstrates that the RB for "no PONV" or "freedom from symptoms" is again highly dependent on the patient's baseline risk. Similarly, this applies to complete response (no vomiting and no rescue treatment) or complete control (no nausea, no vomiting, and no rescue treatment). Thus, a ratio cannot be taken as a measure for drug *efficacy* when the reported outcome is a measure of freedom from symptoms such as "no nausea," "no emesis," "complete response," or "complete control." For this reason, future publications should report vomiting or nausea rather than no vomiting or no nausea, and compound measures should report PONV or rescue treatment rather than complete response or complete control.

Generalizability of Study Results. As described earlier, the number of patients required to demonstrate the antiemetic efficacy of a drug in a clinical trial depends critically on the baseline risk (often described as the control event rate). A table for sample size estimations for PONV trials can be found in the article by Apfel and colleagues entitled "How to Study Postoperative Nausea and Vomiting."[105] Fewer patients need to be studied when the control event rate is high (i.e., when patients at high risk are selected). In addition, patients at high risk are much more likely to benefit from prevention given that their absolute risk difference will be larger. Therefore, most PONV trials specify certain types of surgical procedures that are assumed to be "high-risk procedures." However, as pointed out earlier, patients at risk are more reliably identified by using a simplified risk score.[38]

The other rationale for the selection of just one type of surgical procedure is to increase study strength by minimizing heterogeneity. Although this is a well-recognized approach for any continuous outcome, it does not apply to binary outcomes in which the confidence interval is solely a function of the number and proportion of patients.

The third reason that most studies are limited to a certain type of surgical procedure is the notion that the type of surgery may play a critical pathophysiologic role in PONV. If that were true, study results for one type of surgical procedure possibly would not be applicable to other surgical populations. Carlisle and Stevenson addressed this question in a subgroup analysis of their meta-analysis, but they could not find any evidence that the type of surgical procedure affects the efficacy of an antiemetic.[111] One theoretical limitation of their subanalysis is that it is based on interstudy comparisons. However, two sufficiently powered randomized controlled trials were also unable to identify any interaction between antiemetics and type of surgery (Fig. 97-14).[74,75]

In conclusion, currently published data suggest that the efficacy of an antiemetic is independent of the type of surgery. Therefore, the clinician may assume similar antiemetic *efficacy* for other types of surgical procedures or similar settings from those in the randomized trials. For the clinical researcher, it would be better to address more novel questions than to repeat PONV trials that have already been studied in other types of surgical procedures. As a corollary, it appears that separate meta-analyses of PONV for specific types of surgical procedures[112,113] are unlikely to advance our knowledge and understanding.

PERIOPERATIVE PAIN MANAGEMENT
(See also Chapter 98)

Local Anesthesia

Data from multivariable analyses suggest that the main cause of PONV is exposure to emetogenic triggers, namely inhaled anesthetics and opioids. If both these drug classes can be avoided, PONV incidence can be expected to be quite low. In fact, a 5-year review of 1264 cases using an opioid-free propofol/ketamine sedation technique for a wide range of ambulatory surgical procedure performed with local anesthesia reported only 7 patients (0.6%) with vomiting and 21 patients (2%) requiring postoperative antiemetics.[114] However, the lack of a control group in this study necessitates cautious interpretation. Nevertheless, this result is in accordance with small-scale, high-quality randomized controlled trials, such as the comparison of anesthetic techniques by Song and colleagues.[115] In that study, ilioinguinal-hypogastric nerve block, spinal anesthesia, and general anesthesia (with volatile anesthetics and opioids) were associated with PONV incidences of 7%, 12%, and 62%, respectively.

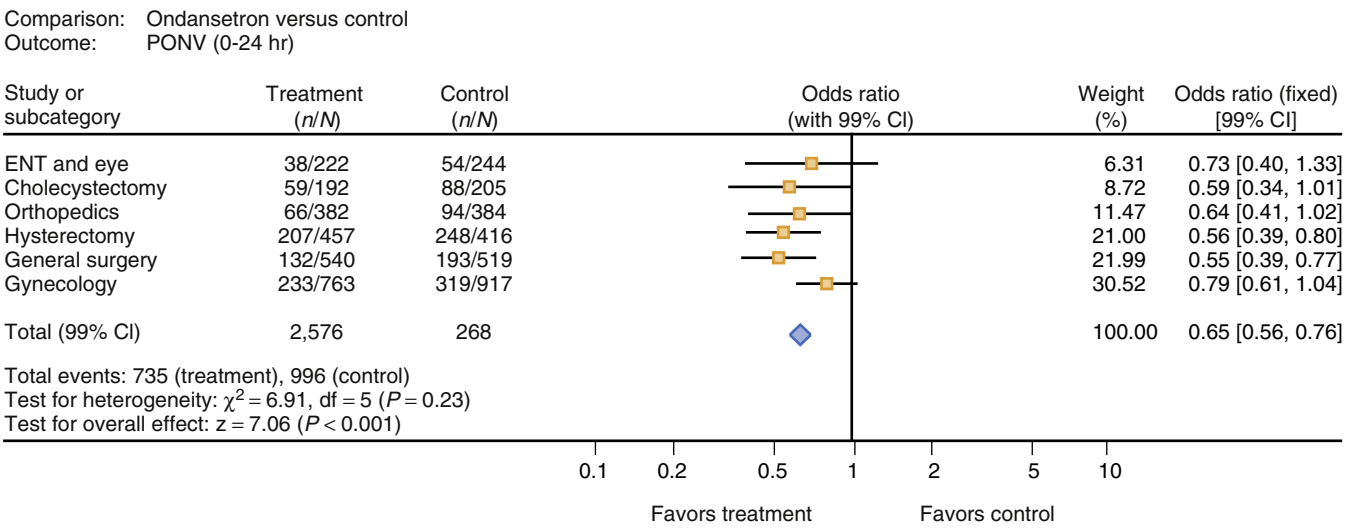

Figure 97-14. Efficacy of ondansetron is independent of the type of surgical procedure. *CI,* Confidence interval; ENT, ear, nose, and throat; *PONV,* postoperative nausea and vomiting. *(Data from Apfel CC, Korttila K, Abdalla M, et al: A factorial trial of six interventions for the prevention of postoperative nausea and vomiting,* N Engl J Med *350:2441-2451, 2004.)*

Regional Anesthesia

Consistent with the low incidence of PONV after primarily regional techniques with or without sedation (see also Chapters 56 and 57) are the results of a meta-analysis that compared single-shot regional anesthesia (peripheral nerve block or central neuraxial blockade) with general anesthesia as the primary anesthetic technique for ambulatory surgery.[116] Patients who were randomized to receive a peripheral nerve block had a more than fourfold lower incidence of nausea than those receiving a general anesthetic regimen (6.8% versus 30%). The RR was 0.23, which corresponds to an RRR of 77%, an antiemetic efficacy that can be achieved only by a quadruple antiemetic combination (see later).[74]

Similarly, central neuraxial blockade was also associated with a numerically lower incidence of nausea (5% versus 14.7%), an RR of 0.34, and an RRR of 66%. However, this incidence failed statistical significance, and further research is needed to confirm this finding ($P < .06$). Anesthetic solutions for epidural anesthesia often contain opioids to increase the density of the block, and this may be the reason that opioid-free paravertebral blocks are associated with a lower incidence of PONV compared with epidural anesthesia.[117]

In this respect, intraoperative nausea and vomiting after spinal anesthesia is different. Two large cohort studies of spinal anesthesia identified the following independent predictors of nausea and vomiting in the perioperative period: female gender, history of motion sickness, preoperative tachycardia, preoperative intravenous opioids, intrathecal procaine, use of phenylephrine or epinephrine, and hypotension or high intrathecal block (T4 or higher).[118,119]

Nonopioid Analgesics

Although individual studies have been able to demonstrate a reduction in pain and/or opioid consumption by NSAIDs (see also Chapter 30), most were unable to demonstrate benefits in their secondary outcomes, such as incidence of PONV. Marret and Bonnet and their colleagues conducted a quantitative systematic review of randomized controlled trials, and although evidence was insufficient to demonstrate a significant reduction of pruritus, urinary retention, or respiratory depression, these investigators were able to demonstrate an RR of 0.7 for PONV (i.e., an RRR of 30%).[78] Although the efficacy of NSAIDs is not as high as that of regional anesthetic techniques, NSAIDs are equal to antiemetics such as 4 mg of ondansetron.

Antiemetics

To date, more than 3000 articles on PONV have been published, with more than 300 articles added yearly. Most are reports of randomized controlled trials for the prevention of PONV, yet it is apparent that the elusive "holy grail" PONV prevention has yet to be found.

One reason could be that relatively little effort has been made to understand the causes of PONV. For example, few reviews acknowledge that the strongest known causes of PONV are inhalational anesthetics and opioids, and that an opioid-free regional anesthetic technique is probably the most effective way to prevent PONV. However, a particular patient may have medical and logistical reasons that a local or regional anesthetic technique would not be practical. Therefore, even though the efficacy of antiemetics is limited, and avoiding the causes for PONV appears to be more effective, antiemetics remain important tools for the prevention of PONV in many clinical situations.

META-ANALYSES

Given the abundance of published PONV studies, it is highly desirable to (1) identify all available evidence, (2) reconcile controversial results if possible, and (3) determine the treatment effect based on the best available evidence. This can be achieved through a systematic review such as a Cochrane review with a prespecified study

question, inclusion and exclusion criteria, and well-established search algorithms to ensure identification of all relevant articles. The term *systematic review* characterizes the scientific rigor to identify and consider all available evidence, whereas the term *meta-analysis* characterizes the statistical approach to synthesize the various study results to come up with the most accurate point estimate for the treatment effect. Thus, a systematic review that uses a meta-analysis to quantify the treatment effect is often described as a quantitative systematic review.

The first systematic review on PONV was by Tramer and associates on the effect of nitrous oxide.[94] Because systematic reviews tend to focus on a well-defined, specific question, dozens of other systematic reviews have been subsequently published, thus requiring reviews of systematic reviews.[120,121]

Fortunately, Carlisle and Stevenson created a comprehensive Cochrane review for all drugs that have been studied for the prevention of PONV.[111] The first edition encompasses 737 studies involving 103,237 patients. It is the largest PONV meta-analysis to date and clearly the most important for clinicians seeking a single reference for drugs that may prevent PONV. In addition, in contrast to many previous systematic reviews that focused on the NNT, which—as described earlier—is not a useful estimate to characterize the efficacy, the Cochrane review from Carlisle and Stevenson used the RR.

ANTIEMETICS

Table 97-2 gives an overview of antiemetic agents.

DOPAMINE ANTAGONISTS

Metoclopramide has been used for decades to prevent PONV. Its antiemetic properties are primarily mediated through its antidopaminergic action and its prokinetic properties.[122] In the past, use of large doses of metoclopramide (e.g., 200 mg every 6 hours) was a mainstay for prevention of chemotherapy-induced nausea and vomiting (CINV). These large doses likely have antiserotoninergic properties.[123] Unfortunately, these large doses cause extrapyramidal side effects in more than 10% of patients; these side effects can be treated with antihistamines and benzodiazepines.[124]

As a result, small doses of metoclopramide (10 mg) became widely used in clinical practice. However, this amount has been proven not to be clinically effective.[125] Consequently, Wallenborn and associates conducted a large randomized placebo-controlled trial comparing 8 mg dexamethasone alone or combined with either 10, 25, or 50 mg metoclopramide.[126] The RRs for the prevention of PONV for these three combinations compared with dexamethasone alone were 0.89, 0.74, and 0.63, respectively. Thus, the efficacy of 25- or 50-mg doses seems to be comparable to that of other well-established antiemetics. Efficacy must be balanced against the potential side effects (the most frequent were treatable hypotension and tachycardia) and the incidence of dyskinetic and/or extrapyramidal symptoms, which were 0.1%, 0.4%, 0.8%, and 0.8%, respectively, in those four groups. In children undergoing tonsillectomies, a moderate dose of 0.5 mg/kg of metoclopramide was not equivalent to 0.1 mg/kg of ondansetron.[127]

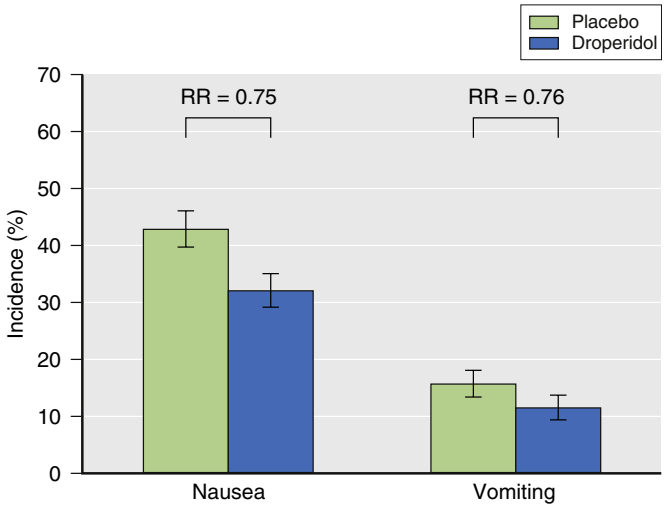

Figure 97-15. Risk ratios (RR) of nausea and vomiting for droperidol versus placebo for 0 to 24 hours. *(Data from IMPACT; figure from Apfel CC, Cakmakkaya OS, Frings G: Droperidol has comparable clinical efficacy against both nausea and vomiting,* Br J Anaesth *103:359-363, 2009.)*

Droperidol is a highly potent D_2-antagonist with well-proven antiemetic properties at intravenous doses as small as 0.625 to 1.25 mg[111,128,129] and an overall RR of 0.75 and 0.76, for nausea and vomiting, respectively.[130] Although droperidol was previously believed to be more effective against nausea than vomiting,[128] IMPACT demonstrated that droperidol has similar efficacy against both outcomes (Fig. 97-15).[130] Furthermore, it is similarly effective compared with ondansetron,[74,131] with an RR for PONV of 0.62.[111] Compared with placebo, droperidol is associated with increased sedation (RR, 1.32) but a decreased incidence of headache (RR, 0.79).[111] Although droperidol has been investigated in more than 400 articles, its minimal effective dose and optimal time of administration have not yet been established. Because of its relatively short plasma half-life of approximately 3 hours, droperidol should be given at the end of the surgical procedure and at the lowest effective dose of 0.625 mg to minimize potential sedative side effects.

For the same pharmacokinetic reason, the supplementation of a morphine-loaded PCA pump with droperidol appears to be a highly effective approach to reduce opioid-induced nausea and vomiting. In a dose-response study, adding 5, 15, or 50 μg to 1 mg of morphine led to an RR of 0.88, 0.63, and 0.44, respectively.[132] Although 50 μg of droperidol per milligram of morphine appears to be the most effective dose, it was associated with sedative side effects, so the authors concluded that a dose of 25 μg droperidol per milligram of morphine was optimal.

Low-dose droperidol has also been reported to lead to anxiety and restlessness,[133] akathisia,[134] and dystonia.[135] However, data are conflicting.[136] In addition, the U.S. Food and Drug Administration (FDA) has received reports of severe arrhythmias (torsades de pointes) and deaths in association with the use of low-dose droperidol, thus leading to the following black box warning:

Droperidol is contraindicated in patients with known or suspected QT prolongation, including patients with congenital long QT syndrome. In patients who fail to show an acceptable response to other adequate treatment, a 12-lead ECG must confirm the absence of QT prolongation (440 msec for males, 450 msec for females) prior to administration of droperidol, and ECG monitoring should be continued for 2 to 3 hours after drug administration. Also, it should be administered with extreme caution to patients who may be at risk for the development of a prolonged QT syndrome, such as in patients with electrolyte disturbances or those receiving volatile anesthetics and intravenous opioids.

The FDA black box warning for droperidol has created controversy among physicians who continue to see a value in its low-dose use for PONV prevention. According to a study by White and associates, general anesthesia itself leads to QT prolongation from approximately 400 to 430 msec, and the mean maximal QT prolongations when placebo, 0.625 mg, or 1.25 mg droperidol was administered during anesthesia were 12, 15, and 22 msec, respectively.[137] The anesthetic had a much stronger overall effect on the average QTc interval compared with droperidol, and it was associated with considerably more interindividual variability. Conversely, one instance of QT prolongation of 133 msec was observed in a single patient who received 1.25 mg of droperidol. Charbit and colleagues investigated the effect of 0.75 mg of droperidol or 4 mg of ondansetron on the QTc interval when these drugs were given as rescue treatment in the PACU.[138] More than 40% of patients had a prolonged QTc interval after anesthesia, and the mean maximal additional QTc prolongation was 17 msec after droperidol and 20 msec after ondansetron (Fig. 97-16). This finding raises a question about the clinical relevance of QT prolongation. In general, the Committee for Proprietary Medicinal Products in the United Kingdom considers QT prolongation of less than 30 msec unlikely to be clinically relevant. Furthermore, based on data from patients with congenital prolonged QT syndrome, a prolongation of 10 msec corresponds to a hazard ratio of 1.056, which translates to an 18% increased risk (RR, 1.18) at 30 msec but double the risk (RR, 2.06) at 133 msec.[139] Based on these data, the risk of droperidol for healthy patients with a normal electrocardiogram appears to be negligible. It is, however, difficult to exclude the possibility that the addition of droperidol in a clinical context of an unrecognized conduction abnormality alongside other QTc-prolonging drugs may trigger a clinically relevant QT prolongation leading to torsades de pointes.[140]

Because of the droperidol black box warning, haloperidol has garnered more interest, and more recent studies have shown an efficacy similar to that of ondansetron.[141,142] However, cardiac arrhythmias and death associated with haloperidol have also been reported to health agencies, so the FDA has issued an alert that haloperidol is approved only for intramuscular administration and that intravenous injection is off-label use.

Alizapride and the highly potent neuroleptics perphenazine (Decentan, Trilafon) and prochlorperazine (Compazine) are less frequently used dopamine antagonists that have additional mechanism of actions. Although their efficacy appears comparable to that of other antiemetics, these drugs have not been studied extensively, such that the limited number of patients provides insufficient power to detect all treatment effects.[111] A main reason for the rather infrequent use of these drugs may be sedative side effects that can delay recovery.

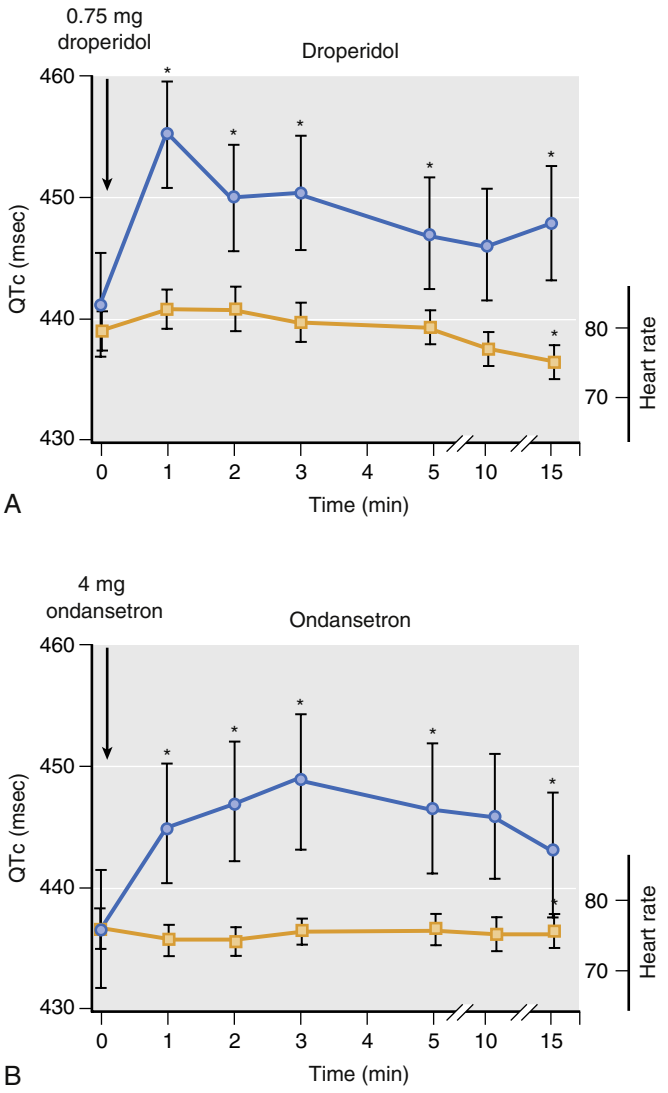

Figure 97-16. Prolongation of QTc interval after postoperative nausea and vomiting treatment by droperidol (**A**) or ondansetron (**B**). *(From Charbit B, Albaladejo P, Funck-Brentano C, et al: Prolongation of QTc interval after postoperative nausea and vomiting treatment by droperidol or ondansetron,* Anesthesiology *102:1094-1100, 2005.)*

HISTAMINE ANTAGONISTS

Diphenhydramine (Benadryl) and dimenhydrinate (an aminophylline salt of diphenhydramine) are histamine (H_1)-receptor antagonists known for their effectiveness against motion sickness and relatively weak anticholinergic (antimuscarinic) activities (see Table 97-2).[111,143] Cyclizine (Marezine) and promethazine (Atosil, Phenergan) seem to have equal antihistaminic and anticholinergic properties, this feature poses a contraindication

TABLE 97-2 **MECHANISMS, DOSES, AND MEASURES OF EFFICACY OF ALL INVESTIGATED ANTIEMETICS WITH STATISTICALLY SIGNIFICANT OUTCOME**

Antiemetic (U.S. Trade Names)	Primary (Other) Mechanisms	Frequently Studied Adult Doses, Given Intravenously Unless Noted Otherwise	Risk Ratio Compared With Placebo That Met Statistical Significance			Comments
			Nausea	Vomiting	PONV

for patients with glaucoma and prostate hypertrophy. All relatively nonspecific histamine receptor antagonists have sedative side effects that may delay recovery when these drugs are given immediately before the end of anesthesia. Diphenhydramine, cyclizine, and promethazine are effective for the prevention of PONV, with RRs of 0.71, 0.67, and 0.46, respectively.[111] Side effects include drowsiness (RR, 9.0),[111] as well as urinary retention, dry mouth, blurred vision, and extrapyramidal symptoms reported too infrequently to draw conclusions.[111,143] Promethazine has also been reported to cause vascular necrosis requiring plastic surgery of skin lesions and/or limb amputations that led to an FDA safety alert in 2006.

ANTICHOLINERGICS

Data on the potential antiemetic properties of atropine are conflicting. For example, when coadministered with neostigmine to reverse neuromuscular blockade, atropine was associated with less postoperative vomiting compared with glycopyrrolate.[48,111] One plausible explanation is that atropine, unlike glycopyrrolate, crosses the blood-brain barrier. However, comparisons of atropine versus placebo have been negative,[111] perhaps because of the drug's short half-life. Scopolamine is another centrally acting anticholinergic (antimuscarinergic) agent that, like atropine, has a relatively short half-life. This limitation is overcome by a transdermal formulation that allows a more favorable pharmacokinetic profile to cover up to 72 hours. The membrane layer of the transdermal patch is required for the slow, sustained release of scopolamine and therefore should not be cut to limit the dose administered. Instead, patients can remove the patch once symptoms have cleared or the highest-risk period (i.e., the first 4 to 6 postoperative hours) has passed. The antiemetic properties of scopolamine are well established for the prevention of motion-induced nausea and vomiting,[144] and the scopolamine patch has also been shown effective for the prevention of PONV in the first 24 postoperative hours, with RRs of 0.59 and 0.68, respectively.[145] Transdermal scopolamine appears to be similarly effective when applied the night before the surgical procedure or the morning of the surgical procedure (RRs = 0.56 and 0.61, respectively).[145] Its long duration of action may be especially useful for the prevention of PDNV in ambulatory patients; data, however, are limited. An increased incidence of visual disturbances at 24 to 48 hours postoperatively appears to be the only side effect associated with its use; an apparent dose-response relationship exists because visual disturbances increase threefold on postoperative day 2 (i.e., after 2 days of exposure to the drug).[145] Although no association with confusion was found in a meta-analysis of more than 3000 patients, further study is needed to determine whether older patients are more susceptible to this adverse event with administration of anticholinergics such as scopolamine.[146] In addition, because transdermal scopolamine can also cause temporary pupil dilation,[146] this drug should be used with caution in the context of neurosurgical procedures for which pupil dilation can be an important indicator of serious complications.

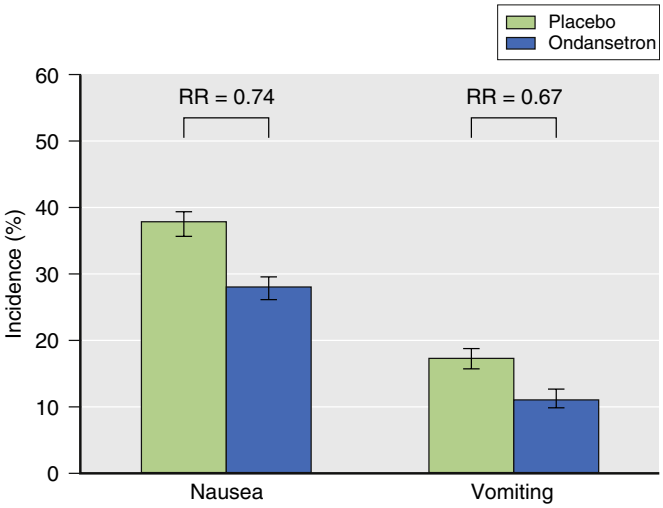

Figure 97-17. Relative risks (RR) of nausea and vomiting for ondansetron versus placebo. The difference of 0.07 in relative risks for the two outcomes is unlikely to be clinically relevant. *(From Jokela RM, Cakmakkaya OS, Danzeisen O: Ondansetron has similar clinical efficacy against both nausea and vomiting,* Anaesthesia *64:147-151, 2009.)*

SEROTONIN ANTAGONISTS

Ondansetron was the first serotonin antagonist, and its introduction was a milestone in the prevention of early CINV. It was considerably more effective and had fewer side effects (no extrapyramidal symptoms or sedation) compared with all previous antiemetics. Given the superior efficacy of ondansetron for CINV, it is not surprising that the drug quickly established a reputation as the most effective antiemetic for prevention of PONV. This perception was further nurtured by duplicate publication of positive studies that, according to analyses by Tramer and co-workers, would lead to a 23% overestimation of ondansetron's effectiveness if included in a meta-analysis.[147] In fact, in the IMPACT trial of more than 5000 patients, the risk reductions for nausea and vomiting were 0.74 and 0.67, respectively.[148] Like droperidol, ondansetron was previously believed to be more effective for one outcome (vomiting) than the other,[149] but IMPACT demonstrated that ondansetron has similar efficacy against both nausea and vomiting (Fig. 97-17).[148] In addition, the same trial showed that the efficacy of ondansetron against PONV is similar to that of other antiemetics.[74] Specifically, 4 mg of ondansetron, 4 mg of dexamethasone, and 1.25 mg of droperidol had RRs of 0.76, 0.76, and 0.74, respectively (i.e., each drug led to an RRR of approximately 25%.)[74] Ondansetron has a plasma half-life of 4 hours and is therefore more effective when it is given at the end of a surgical procedure instead of immediately after induction of anesthesia.[150,151]

Dolasetron mesylate, and its liver-converted active metabolite hydrodolasetron, are highly specific 5-HT_3 antagonists with plasma half-lives roughly twice as long as that of ondansetron. In general, all first-generation serotonin antagonists are considered to be equally effective when given at equipotent doses. For ondansetron, 4 mg is well documented to be the minimal effective dose (the minimal dose at which any further increase fails to

produce additional clinically relevant benefit). For dolasetron, the data from Korttila and associates suggest that 50 mg is superior to 25 mg and equivalent to 4 mg of ondansetron.[152] However, this finding contrasts with a pooled analysis of three trials that suggests that 12.5 mg is the minimum effective dose, which is the dose approved by the FDA for the prevention of PONV.[153]

Granisetron is another highly specific 5-HT_3 antagonist, with a half-life that is approximately twice as long as that of ondansetron. The FDA-approved dose for the prevention of PONV is 1 mg. This is based on a dose range study from Wilson and associates in which 0.1, 1.0, and 3.0 mg were associated with RRs for postoperative vomiting of 0.94 (not significant), 0.56, and 0.66, respectively.[154] A second dose-response study investigated the efficacy of 2, 5, 10, and 20 μg/kg and found that 5 μg/kg appears to be the minimal effective dose, which corresponds to roughly 0.35 mg for a 70-kg adult patient.[155] Despite results from these relatively large randomized controlled trials, some more recent studies re-explored the possibility that doses as low as 0.1 mg are effective for the prevention of PONV. One study compared 0.1, 0.2, and 0.3 mg with placebo in patients undergoing abdominal hysterectomies.[156] Although all three doses were associated with less vomiting within the first 6 hours, no significant difference could be demonstrated over 24 hours. Another study compared the combination of 8 mg of dexamethasone plus either 0.1 mg of granisetron or 4 mg of ondansetron in patients undergoing laparoscopy.[157] However, that study was not sufficiently powered to demonstrate a statistically significant difference for the main outcome of vomiting in the first 2 postoperative hours, which was 6% in the granisetron-treated group and 3% in the ondansetron-treated group. The studies on granisetron that suggested that 3 mg is superior to 1 mg for preventing PONV have been discredited. The current evidence suggests that the FDA approved dose of 1 mg—but not 0.1 mg—is an effective dose for the prevention of PONV.

Whereas all serotonin antagonists are considered to be similarly effective, the second-generation palonosetron may be an exception. Not only does palonosetron have a long half-life of approximately 40 hours, but it also exhibits allosteric binding to 5-HT_3 receptors with subsequent receptor internalization, as well as negative cooperativity with neurokinin-1 (NK1) receptors.[158,159] Perhaps because of these unique properties, palonosetron is the most effective 5-HT_3 receptor antagonist for the prevention of CINV, especially delayed CINV, for which the previous serotonin antagonists are usually ineffective. Whether this will translate into higher efficacy for the prevention of PONV, and perhaps PDNV, is unclear. Like other 5-HT_3 receptor antagonists, palonosetron, at 0.075 mg. has been associated with a RRR of approximately 30% for PONV.[160,161] However, a more recent study in which palonosetron and ondansetron were administered at equipotent doses in conjunction with a fentanyl PCA pump did show superior efficacy against PONV with palonosetron.[162] Beyond the extended half-life and superior efficacy of the drug, palonosetron also does not appear to affect the QT interval and therefore may be safer for patients at risk of cardiac arrhythmias.

DEXAMETHASONE

Dexamethasone is well documented as an effective antiemetic,[74,111] and animal experiments suggest that it exerts its antiemetic effects through central inhibition of the nucleus tractus solitarii but not the area postrema.[163] Most early studies were conducted with 8 to 10 mg of dexamethasone,[129,164] but convincing evidence from several smaller dose-response trials indicates that 2.5 to 5 mg can be considered the minimum effective dose.[165-167] Dexamethasone has a slow onset of action, which may be the reason that its application at the beginning of a case appears to be superior to later use.[168] According to Carlisle and Stevenson, the RR of dexamethasone is 0.57 for nausea and 0.51 for vomiting,[111] and direct head-to-head comparisons suggest that its efficacy is similar to that of ondansetron and droperidol.[74,111]

NEUROKININ ANTAGONISTS

Substance P is a regulatory peptide that binds to NK1 receptors found in vagal afferents in the gastrointestinal tract. More importantly, in the 1950s it was shown to reside in areas of the central nervous system that are thought to be involved in the vomiting reflex.[169] Nevertheless, it took more than 40 years before it became apparent that NK1 antagonists could be highly effective against a wide range of emetic stimuli in animal studies.[170] A few years later, Diemunsch and colleagues showed the clinical feasibility for control of established PONV after major gynecologic surgery in a pilot study with the NK1 antagonist GR205171.[171] This work was followed by a multicenter study with CP-122,721[172] in which 200 mg reduced the incidence of postoperative emesis from 50% to 10%, which corresponds to an RR of 0.2 and an RRR of 80%—significantly more effective against vomiting than all other previous antiemetics.

The strong antiemetic property of NK1 receptor antagonists was confirmed by studies of aprepitant, the first drug in its class approved for clinical use by the FDA. In a three-arm multicenter study, 4 mg of ondansetron, given intravenously, was compared with 40 mg and 125 mg of orally administered aprepitant.[173] Although the incidence of nausea was similar between the groups, the incidences for vomiting were 26%, 10%, and 5%, respectively. Considering that ondansetron reduces the risk of vomiting by approximately 26%,[74] if a placebo group had been included in this study, the incidence in the placebo group would likely have been in the 35% range. In that case, the RRs for 40 and 125 mg of aprepitant would have been in the range of 0.3 and 0.15 compared with placebo, that is, an RRR in the range of 70% or 85%, again clearly more effective than other antiemetics. A similar international trial (again without a placebo control group) yielded similar (though less striking) results for aprepitant.[174] In that study, the incidences of vomiting for 4 mg of ondansetron given intravenously, 40 mg of aprepitant, and 125 mg of aprepitant orally were 29%, 16%, and 14%, respectively. For the prevention of PONV, 40 mg of aprepitant is the dose approved by the FDA.

In the future, it is likely that other NK1 receptor antagonists will appear on the market, such as casopitant[175] and

rolapitant.[176] However, although NK1 receptor antagonists appear to be superior for preventing vomiting, they may not be superior for preventing nausea. Furthermore, aprepitant is rarely used for PONV because of its relatively high cost. Nevertheless, their excellent antiemetic profiles make NK1 antagonists ideal drugs to reduce the medical risk that may be associated with vomiting after certain procedures (e.g., wired jaw, neurosurgical procedures, and upper gastrointestinal surgery).

COMBINATIONS AND MULTIMODAL THERAPY

None of the currently available antiemetics is capable of completely eliminating the incidence of PONV. In fact, according to the meta-analysis from Carlisle and Stevenson, the overall RR for FDA-approved "effective" antiemetics is 0.65, that is, the RRR is 35%.[111] Considering that smaller studies tend to be published more often if the results are positive (publication bias), the "true" RRR is likely to be smaller than 35%. In fact, in a large multicenter trial, the RRs for ondansetron, dexamethasone, and droperidol were in the range of 0.75; that is, the RRR was 25% rather than 35%.[74]

Given the limited antiemetic efficacy of prophylactic antiemetics, Scuderi and co-workers were the first to investigate a multimodal approach.[177] In patients undergoing outpatient laparoscopy, these investigators studied a combination antiemetic regimen (group I, $n = 60$) that consisted of both preoperative interventions (10 to 30 μg/kg midazolam for anxiolysis, 10 mL/kg crystalloid fluid administration) and intraoperative interventions (0.625 mg of droperidol, 10 mg of dexamethasone, induction and maintenance with remifentanil/propofol, gastric decompression, 30 mg of ketorolac, 1 mg of ondansetron at the end of the surgical procedure, and 25 μg of fentanyl 10 minutes before end of the surgical procedure). Patients in groups II and III received balanced anesthesia with sevoflurane/nitrous oxide/fentanyl with ($n = 42$) or without ($n = 37$) 4 mg of ondansetron. With the multimodal group I regimen, no patients vomited, and only 1 of 60 patients (1.7%) experienced nausea before discharge from the hospital. In contrast, 10 patients in group II (24%), and 15 in group III (42%) experienced nausea. Although this study demonstrated an impressive reduction in PONV, the study design could not identify to what extent each individual intervention contributed to the reduction in PONV. Furthermore, it was unclear what interactions may exist among the various antiemetic interventions (e.g., whether a certain synergistic combination contributes the most to these positive results).

This work led to the development of IMPACT.[74,110] In this trial, 4123 patients were randomly assigned to 1 of 64 possible combinations of 6 prophylactic interventions: 4 mg of ondansetron or no ondansetron; 4 mg of dexamethasone or no dexamethasone; 1.25 mg of droperidol or no droperidol; propofol or a volatile anesthetic; nitrogen or nitrous oxide; and remifentanil or fentanyl. Ondansetron, dexamethasone, and droperidol each reduced the risk of PONV by approximately 26% (RR, 0.74).[74] Propofol reduced the risk by 19%, and nitrogen

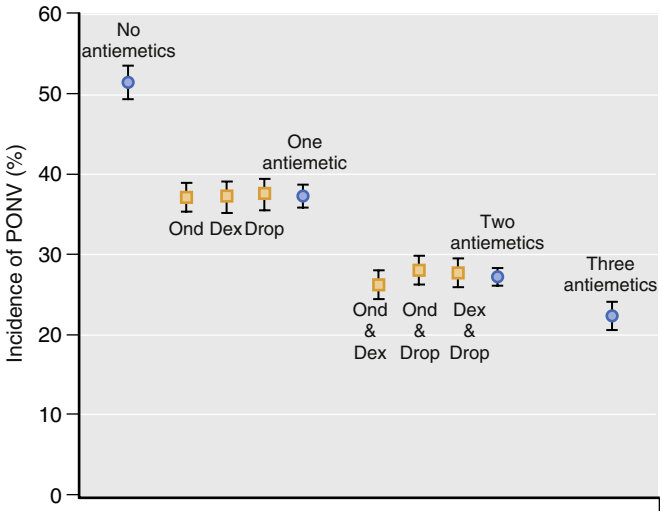

Figure 97-18. Reduction of postoperative nausea and vomiting (PONV) with ondansetron (Ond), dexamethasone (Dex), and droperidol (Drop) when given alone or in combination. *(From Apfel CC, Korttila K, Abdalla M, et al: A factorial trial of six interventions for the prevention of postoperative nausea and vomiting,* N Engl J Med *350:2441-2451, 2004.)*

by 12%; the combined RRR of propofol with no nitrous oxide (i.e., total intravenous anesthesia [TIVA]) was thus similar to that observed with each individual antiemetic. This study provided two major insights. First, it demonstrated that all interventions acted independently of each other; therefore, the RRs associated with combined antiemetic interventions can be estimated by multiplying the RRs associated with each intervention. For example, the RR for a triple combination of ondansetron plus dexamethasone plus droperidol is $0.74 \times 0.74 \times 0.74 = 0.41$; that is, the application of three antiemetics that each reduces the risk by approximately one fourth results in an RRR of $1 - 0.41 = 59\%$. Figure 97-18 demonstrates that all three antiemetics are similarly effective, and all three double combinations are similarly effective because no interactions occur. Second, it was demonstrated that the efficacy of the drugs as measured by the odds ratio or RR is independent of the patient's risk. Therefore, the effectiveness (in terms of absolute risk difference or NNT) primarily depends on the patient's baseline risk rather than on the choice of antiemetic, and each additional antiemetic in a combination regimen adds less and less additional benefit as the patient's risk decreases.

As an example, a female nonsmoker without a history of PONV or motion sickness who is expected to require postoperative opioids has a PONV risk of approximately 60%.[5] If she receives an antiemetic (e.g., 4 mg of dexamethasone), her risk will decrease to 44% (Table 97-3; $0.6 \times 0.74 = 0.44$), which means that the absolute risk difference will be 16%. If she receives a triple antiemetic therapy, her risk will decrease to approximately 24%, and a fourth antiemetic would reduce the risk to 18% (see Table 97-3). Adding a fourth antiemetic would thus result in an absolute risk difference of only 6% (i.e., less than half as much reduction as for the first antiemetic). Apparently, the first antiemetic has the greatest effectiveness, and additional prophylactic antiemetics are

TABLE 97-3 ESTIMATED POSTOPERATIVE NAUSEA AND VOMITING INCIDENCE AS A FUNCTION OF BASELINE RISK, ASSUMING EACH INTERVENTION REDUCES RELATIVE RISK BY 26%

Number of Interventions				
None* (%)	One (%)	Two (%)	Three (%)	Four (%)
10	7	5	4	3
20	15	11	8	6
40	29	22	16	12
60	44	33	24	18
80	59	44	32	24

associated with decreased effectiveness because of the already decreased baseline risk. Another example would be a male smoker who is undergoing a short procedure that will not require postoperative opioids and who will start off with a risk of approximately 10%.[5] Even the first antiemetic will at best reduce the risk by no more than 3% (see Table 97-3). The key message here is that the patient's baseline risk is the main determinant of the effectiveness of antiemetic interventions. Therefore, prophylaxis is rarely justified in patients at low risk, a single antiemetic is likely to be reasonable for patients with a moderate risk, and patients at high risk are likely to benefit from combination treatment.[74]

ALTERNATIVE OR ADJUVANT APPROACHES

Ginger is frequently assumed to have antiemetic properties, even though few studies were conducted, most of which had negative results, and meta-analyses came to conflicting conclusions.[178-180] According to the comprehensive review by Carlisle and Stevenson, evidence that ginger is an effective intervention for the prevention of PONV appears to be lacking.[111]

A meta-analysis of studies on liberal crystalloid fluid supplementation demonstrated that this intervention can be as effective as an antiemetic to reduce PONV outcomes and that its effect on PONV is stronger in the late postoperative period.[181] Supplemental crystalloids were previously believed to reduce PONV by alleviating dehydration and subsequent organ hypoperfusion after overnight fasting; however, surgical patients have been shown to remain normovolemic even after 10 hours of fasting. Therefore, one may speculate that additional fluids may instead alleviate the relative hypovolemia induced by volatile anesthetics, which can trigger the release of emetogenic arginine vasopressin[182-184] from the posterior pituitary. Although crystalloid fluids may be a relatively inexpensive intervention with a safe side effect profile, liberal fluid administration may be detrimental for wound healing and for recovery from larger procedures such as major intraabdominal operations, in which fluid accumulation is more likely.[185-187] In addition, a large, well-designed trial is still needed to confirm the results of this meta-analysis.

Various reports have investigated stimulation of the classic acupuncture P6 point (the sixth point on the pericardial meridian at the volar side of the wrist) for the prevention of PONV.[188-192] A Cochrane review by Lee and associates in 2004 identified 26 trials and found RRs of 0.72 for nausea and 0.71 for vomiting compared with sham.[193] This effect is comparable to that of conventional antiemetics.[194] These positive results bring up the question why P6 stimulation is rarely used for the prevention of PONV. Because most studies were small, Lee and colleagues conducted a secondary simulation analysis that suggested that the effect for nausea, but not for vomiting, may result from publication bias.[195] Based on the published evidence, it appears that stimulation of the P6 wrist point by means of acupuncture, electroacupuncture, transcutaneous nerve stimulation, laser stimulation, acu-stimulation device, and acupressure is an effective measure for the prevention of PONV.

SPECIAL SETTINGS

PEDIATRIC ANESTHESIA

Fewer studies have been conducted in children, and these generally focus on POV because the assessment of nausea can be difficult in younger children (see also Chapter 93).[196,197] A limited number of studies investigated risk factors,[198] but only one well-designed multicenter prospective survey developed a predictive model for POV (see also the earlier section on risk assessment).[67] Although the impact of the type of surgery remains somewhat controversial in adults, strabismus surgery and especially myopexy (Faden surgery)[102,199] appear to be independent predictors of POV in children, as determined by Eberhart and colleagues.[67] At the same time, contrary to widely held belief, little evidence suggests that ENT surgical procedures or appendectomies are independent predictors of POV in children.

Regarding antiemetics, it appears that efficacy is comparable to that known for adults. Few thoroughly conducted dose-response studies for antiemetics exist in adults and even fewer have been conducted in children. Thus, most pediatric doses are arbitrarily set at approximately 1/50th to 1/25th of the common adult per kilogram dose.

POSTDISCHARGE NAUSEA AND VOMITING

In the United States, more than 60% of surgical procedures are now performed on an outpatient basis (ambulatory surgery). In addition to being a major cause of delayed discharge and unanticipated readmissions, PONV may also pose a significant problem to the patient after discharge (see also Chapter 89).[200,201] In fact, PDNV may be of particular concern because it occurs when patients no longer have immediate access to intravenous rescue treatment, and oral medications may be intolerable. A large multicenter trial in patients undergoing general anesthesia for ambulatory surgery in the United States found that PDNV affected 37% of patients in the first

48 postoperative hours,[59] similar to a previous, smaller U.S. study that reported that 35% of patients experienced PDNV severe enough to delay resumption of their normal daily activities.[202] This prevalence is surprisingly high given that ambulatory surgery procedures are generally less invasive and less extensive than inpatient procedures and therefore require less exposure to perioperative triggers of PONV such as inhalational anesthetics and opioids. The multicenter trial identified five independent predictors of PDNV, namely female gender, age less than 50 years, history of PONV after previous anesthesia, opioid administration in the PACU, and nausea in the PACU (see also the earlier section on risk assessment).[59] Therefore, as for PONV, the patient's risk for PDNV can be easily assessed using a simplified predictive risk score.[59]

Interestingly, the RRR of antiemetics seems to be similar for PDNV and for PONV. For example, according to a systematic review from Gupta and colleagues, the RR for postdischarge nausea is 0.77 for 4 mg of ondansetron, 0.68 for more than 1 mg of droperidol, and 0.55 for dexamethasone.[203] Shorter-acting drugs are not as effective, especially when they are used at the minimally effective dose, and antiemetics with a longer duration of action appear favorable. Furthermore, although a trial in more than 2000 patients confirmed that dexamethasone can significantly reduce the incidence of PDNV, ondansetron was found to have no effect.[59] Therefore, dexamethasone, scopolamine (because of the sustained release of the patch), palonosetron, and aprepitant may be reasonable first choices for the prevention of PDNV. Of course, further studies, especially with the novel compounds, are needed to support this hypothesis.

RESCUE TREATMENT

Although numerous studies have investigated antiemetics for the prevention of PONV, relatively few have addressed their use for rescue treatment of established PONV. In fact, when Kazemi-Kjellberg and Tramer and their co-workers conducted a quantitative systematic review of rescue treatments for established nausea and vomiting, only 18 randomized placebo-controlled trials met inclusion criteria.[204] These investigators reported an absolute risk reduction between 20% and 30%, consistent with the 20% to 30% RRR known for the prevention of PONV in large trials[74] (in studies of rescue treatment, absolute risk reduction and RRR are equivalent measures because all patients who receive treatment have prior symptoms). In fact, Scuderi and colleagues demonstrated that early rescue treatment of PONV results in outcomes including time to discharge, unanticipated admission, and time to return to normal daily activities that are similar to those achieved with routine prophylactic treatment.[103] This finding does not, however, account for patients' comfort, even though this may be difficult to measure in terms of patients' satisfaction.

With regard to dosage, early rescue treatment with 1 mg of ondansetron seems to have comparable efficacy and better effectiveness than 4 mg of prophylactic ondansetron.[205,206] Thus only one-quarter dose is needed for rescue compared with preventive treatment.

Serotonin antagonists are not only the most commonly used antiemetics for prevention but also the most commonly used antiemetics for rescue treatment.[207] One reason may be that serotonin antagonists are currently the only class of intravenously available antiemetics that may have a rapid onset for rescue treatment without having sedative side effects. As previously mentioned, serotonin antagonists are highly selective and tend to block almost all available receptors. Therefore, once ondansetron is used for prophylaxis, subsequent use for rescue treatment in the PACU is ineffective.[208] Nevertheless, ondansetron is still commonly used as first-line rescue treatment after previous prophylaxis, even though this practice is contrary to both theoretical considerations and available evidence. Similarly, use of rescue granisetron, another serotonin antagonist, is ineffective in patients who have already received ondansetron for PONV prevention.[209] Therefore, as a rule of thumb, after administering an antiemetic, it is most effective to choose an antiemetic of another class for later rescue treatment. This recommendation is corroborated by a secondary analysis showing that after prophylaxis with either ondansetron and droperidol, promethazine rescue treatment is significantly more effective than repeat dosing with the same agent.[210]

Dexamethasone has been shown to be as effective as ondansetron for the prevention of PONV.[74] Clinically, it appears to have a fairly slow onset, as supported by observations that it has better efficacy when it is given at the beginning than at the end of the procedure.[168] Nevertheless, Rusch and associates were able to show that adding dexamethasone to either ondansetron or haloperidol for rescue treatment increases the overall RRR during a 24-hour period.[211]

In conclusion, drugs for rescue treatment appear to have the same efficacy and thus better effectiveness compared with their use for prevention. In addition, lower doses are needed for rescue treatment than for prevention, and it is preferable to administer drugs that have not been previously used.

A RATIONAL GUIDELINE FOR THE MANAGEMENT OF POSTOPERATIVE NAUSEA AND VOMITING

The wealth of published information poses a challenge for the anesthesia provider who wants to develop a comprehensive and valid strategy for the prevention and treatment of PONV. To this end, consensus guidelines have been developed. However, the fact that a group of individuals agrees or compromises on a certain content or wording does not guarantee infallibility. For example, some guidelines report the NNT for various interventions as if this would allow a comparison of drug efficacy among trials even though that would not be sound methodologically (see the earlier discussion to appreciate the difference between efficacy and effectiveness).

Therefore, instead of summarizing various consensus guidelines, this last section describes a rational approach for the prevention and treatment of PONV that is based

TABLE 97-4 ALGORITHM FOR THE MANAGEMENT OF POSTOPERATIVE NAUSEA AND VOMITING*

	TIVA Preferred	Anticipated Rescue	1 Risk Factor	2 Risk Factors	3 Risk Factors	4 Risk Factors
Inpatients	Yes	Ondansetron	Dex	+TIVA	+D_2-RA	+Aprep
		Non-5-HT_3	Dex	+TIVA	+Ond	+Aprep
	No	Ondansetron	Dex	+D_2-RA	+Aprep	+TIVA
		Non-5-HT_3	Dex	+Ond	+Aprep	+TIVA
	TIVA preferred	**Anticipated Rescue**	**1 Risk Factor**	**2 Risk Factors**	**3 Risk Factors**	**4 to 5 Risk Factors**
Outpatients	Yes	Palo	Dex	+TIVA+TDS	+D_2-RA	+Aprep
		Non-5-HT_3	Dex	+TIVA+TDS	+Palo	+Aprep
	No	Palo	Dex	+TDS	+Aprep	+TIVA
		Non-5-HT_3	Dex	+TDS	+Palo	+Aprep

Aprep, Aprepitant; *D_2,* dopamine-2; *dex,* dexamethasone; *5-HT_3,* 5-hydroxytryptamine 3 (serotonin); *Ond,* ondansetron; *Palo,* palonosetron; *RA,* receptor antagonist; *TDS,* transdermal scopolamine; *TIVA,* total intravenous anesthesia.

*Recommended prophylactic strategy based on patient's risk, inpatient or outpatient status, anticipated rescue treatment, and the preference of the anesthesia provider regarding total intravenous anesthesia.

on the current knowledge and understanding outlined in this chapter. This approach should be taken as a guide for clinicians but not as a rigid rule because other similarly valid approaches certainly exist. To this end, the rule of three would be helpful: (1) assess the need for prevention, (2) titrate preventive measures (that includes a modification of the anesthetic technique) according to the patient's need, and (3) follow up on your patient and use rescue treatment immediately, by targeting mechanisms that have not been tried before.

CONSIDER THE IMPORTANCE OF PREVENTION

This consideration is influenced by the patient's risk for PONV, the potential medical problem associated with it, and the perspective and values of both the patient and the health care provider. It is advisable to estimate the patient's risk by using a risk score, such as the score from Apfel and associates or Koivuranta and colleagues for adults and the score from Eberhart and co-workers for children.[4,5,67] Even though these scores are far from being perfect, they provide a better prediction compared with the history of PONV or the type of surgical procedure.[38]

TITRATE TO THE PATIENT'S NEEDS

Patients With Limited Need for Preventive Measures

In general, the use of prophylactic antiemetics is rarely justified when the patient's risk is low (e.g., 10% to 20%) (Table 97-4).[74] The reasons are that antiemetics have low effectiveness at low risk, so that many patients need to be treated for one patient to benefit, and low-risk patients are unnecessarily exposed to an antiemetic that may have—even rare—associated side effects (e.g., sedation, headache, QT prolongations, torsades de pointes). However, as mentioned earlier, the use of these drugs may be justified if this is a patient's preference or if concerns exist about medical or surgical complications related to vomiting.

Patients Who Require Some Preventive Measures

In patients at moderate risk, one or two antiemetic measures are often appropriate, but these do not need to be antiemetic drugs. One approach could be TIVA (with propofol, air, and fentanyl) and/or the use of 4 mg of dexamethasone after the induction of anesthesia supplemented with measures to minimize opioid consumption (NSAIDs, lidocaine, low-dose ketamine).

PATIENTS IN WHOM SIGNIFICANT PREVENTIVE MEASURES SHOULD BE UNDERTAKEN

In patients at high or very high risk, avoidance of general anesthesia and minimization of perioperative opioids may comprise the most effective approach (e.g., peripheral nerve block, spinal anesthesia).[116] However, if a general anesthetic regimen is needed, a TIVA with 4 mg of dexamethasone[74] and an additional antiemetic (e.g., 12.5 to 25 mg of promethazine, 31.25 to 62.5 mg of dimenhydrinate, or 25 to 50 mg of metoclopramide) can be recommended. Which partner drug to choose is most likely not relevant because most drugs appear similarly effective,[111] and indirect evidence suggests that interventions with different mechanisms are additive (i.e., they work independently).[74] Of course, TIVA could be substituted for an inhaled anesthetic in conjunction with an antiemetic, but this eliminates one rescue treatment option should PONV occur in the PACU. This is particularly true for the use of a serotonin antagonist, which may otherwise be an effective rescue option without sedative side effects.

RESCUE WITHOUT DELAY

Options for rescue treatment are interventions that have not been applied before or when the half-life suggests that the intervention is no longer active.[208] Serotonin antagonists, if not given in the operating room, may be a first choice in the PACU because of their lack of sedative side effects. Moreover, the addition of dexamethasone to

dolasetron or haloperidol could increase the overall risk reduction for rescue treatment (again, if the drug has not been given before).[211] Finally, stimulation of the P6 acupressure point may be another option, given that its efficacy has been demonstrated for the prevention of PONV.

Chapter 98

Acute Postoperative Pain

ROBERT W. HURLEY • JAMIE D. MURPHY • CHRISTOPHER L. WU

Key Points

- Nociception is a dynamic process (i.e., neuroplasticity) with multiple points of modulation. Persistent noxious input may result in relatively rapid neuronal sensitization and possibly persistent pain.
- Postoperative pain, especially when poorly controlled, results in harmful acute effects (i.e., adverse physiologic responses) and chronic effects (i.e., delayed long-term recovery and chronic pain).
- By preventing central sensitization, preventive analgesia may reduce acute and chronic pain. Although studies overwhelmingly support the concept of preemptive analgesia, the evidence from clinical trials is equivocal because of methodologic issues.
- By allowing individual titration of analgesic drugs, use of patient-controlled anesthesia (oral, subcutaneous, iontophoretic, intravenous, paravertebral, or epidural) may provide several advantages over traditional provider-administered analgesia (e.g., intramuscular or intermittent intravenous injections) in the management of postoperative pain.
- The incidence of respiratory depression from opioids is not significantly different among the various routes of administration (i.e., oral, intravenous versus intramuscular versus subcutaneous versus neuraxial). Appropriate monitoring of patients receiving opioid analgesics is essential to detect those with opioid-related side effects, such as respiratory depression.
- Judicious use of adjuvant drugs, such as nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, clonidine, ketamine, and gabapentinoids, may improve postoperative analgesia and potentially diminish analgesic-related side effects.
- When compared with systemic opioids, perioperative epidural analgesia may confer several advantages, including a facilitated return of gastrointestinal function and decrease in the incidence of pulmonary complications, coagulation-related adverse events, and cardiovascular events, especially in higher-risk patients or procedures. However, the risks and benefits of epidural analgesia should be evaluated for each patient, and appropriate monitoring protocols should be used during postoperative epidural analgesia.
- Epidural analgesia is not a generic entity. Perioperative morbidity may vary based on different catheter locations (catheter-incision congruent versus catheter-incision incongruent), durations of postoperative analgesia, and analgesic regimens (local anesthetics versus opioids).
- Postoperative pain management should be tailored to the needs of special populations (e.g., opioid-tolerant, pediatric, and obese patients, as well as those with obstructive sleep apnea) who may have different anatomic, physiologic, pharmacologic, or psychosocial issues.

FUNDAMENTAL CONSIDERATIONS

A revolution in the management of acute postoperative pain has occurred during the past 4 decades. Widespread recognition of the undertreatment of acute pain by clinicians, economists, and health policy experts has led to the development of a national clinical practice guideline for management of acute pain by the Agency for Healthcare Quality and Research (formerly the Agency for Health Care Policy and Research) of the U.S. Department of Health and Human Services.[1] This landmark document includes acknowledgment of the historical inadequacies in perioperative pain management, importance of good pain control, need for accountability for adequate provision of perioperative analgesia by health care institutions, and a statement on the need for involvement of specialists in appropriate cases. In addition, several professional societies (e.g., American Society of Anesthesiologists, The Joint Commission) have developed clinical practice guidelines for acute pain management or provided new pain management standards.

With their knowledge of and familiarity with pharmacology, various regional anesthesia techniques, and the neurobiology of nociception, anesthesiologists are prominently associated with the clinical and research advances in acute postoperative pain management. Anesthesiologists developed the concept of acute postoperative pain services (inpatient pain services), application of evidence-based practice to acute postoperative pain, and creation of innovative approaches to acute pain medicine, all of which are a natural part of the anesthesiologist's functions as a "perioperative physician," consultant, and therapist throughout an institution, as well as a highly skilled expert in the operating room. Provision of effective analgesia for surgical and other medical patients is an important component of this multidimensional role. An area that is often lacking in the acute perioperative pain services is the management of patients with acute surgical pain in addition to a baseline chronic pain. These patients are often not well served by the arbitrary distinction of "acute versus chronic" pain services in hospitals. Anesthesiologists are well trained to manage acute pain in the patient with concomitant chronic pain as a result of the strength of chronic pain curricula in current anesthesiology training programs. Although this chapter focuses on the patient who has acute perioperative pain, acute management of chronic pain in the hospitalized setting is also discussed.

PAIN PATHWAYS AND THE NEUROBIOLOGY OF NOCICEPTION

Surgery produces tissue injury with consequent release of histamine and inflammatory mediators such as peptides (e.g., bradykinin), lipids (e.g., prostaglandins), neurotransmitters (e.g., serotonin), and neurotrophins (e.g., nerve growth factor).[2] Release of inflammatory mediators activates peripheral nociceptors, which initiate transduction and transmission of nociceptive information to the central nervous system (CNS) and the process of neurogenic inflammation, in which release of neurotransmitters (i.e., substance P and calcitonin gene–related peptide) in the periphery induces vasodilatation and plasma extravasation.[2] Noxious stimuli are transduced by peripheral nociceptors and transmitted by A-delta and C nerve fibers from peripheral visceral and somatic sites to the dorsal horn of the spinal cord, where integration of peripheral nociceptive and descending modulatory input (i.e., serotonin, norepinephrine, γ-aminobutyric acid, enkephalin) occurs. Further transmission of nociceptive information is determined by complex modulating influences in the spinal cord. Some impulses pass to the ventral and ventrolateral horns to initiate segmental (spinal) reflex responses, which may be associated with increased skeletal muscle tone, inhibition of phrenic nerve function, or even decreased gastrointestinal motility. Others are transmitted to higher centers through the spinothalamic and spinoreticular tracts, where they induce supraspinal and cortical responses to ultimately produce the perception of and affective component of pain.

Continuous release of inflammatory mediators in the periphery sensitizes functional nociceptors and activates dormant ones. Sensitization of peripheral nociceptors may occur and is marked by a decreased threshold for activation, increased rate of discharge with activation, and increased rate of basal (spontaneous) discharge. Intense noxious input from the periphery may also result in central sensitization ("persistent postinjury changes in the CNS that result in pain hypersensitivity"[3]) and hyperexcitability ("exaggerated and prolonged responsiveness of neurons to normal afferent input after tissue damage"[3]). Such noxious input may lead to functional changes in the dorsal horn of the spinal cord and other consequences that may later cause postoperative pain to be perceived as more painful than it would otherwise have been. The neural circuitry in the dorsal horn is extremely complex, and we are just beginning to elucidate the specific role of the various neurotransmitters and receptors in the process of nociception.[2] However, it seems that certain receptors (e.g., *N*-methyl-D-aspartate [NMDA]) may be especially important for the development of chronic pain after an acute injury, although other neurotransmitters or second messenger effectors (e.g., substance P, protein kinase C) may also play important roles in spinal cord sensitization and chronic pain. Our understanding of the neurobiology of nociception has progressed from the hard-wired system proposed by Descartes in the 17th century to the current view of neuroplasticity in which dynamic integration and modulation of nociceptive transmission take place at several levels. However, many gaps still exist in our knowledge of the specific roles of various receptors, neurotransmitters, and molecular structures in the process of nociception.

An understanding of the neurobiology of nociception is important for appreciating the transition from acute to chronic pain. The traditional dichotomy between acute and chronic pain is arbitrary because acute pain may quickly transition into chronic pain.[4] Noxious stimuli can produce expression of new genes (which are the basis for neuronal sensitization) in the dorsal horn of the spinal cord within 1 hour, and these changes are sufficient to alter behavior within the same time frame.[5] Also, the intensity of acute postoperative pain is a significant predictor of chronic postoperative pain.[6] Control

of perioperative pain (e.g., preventive analgesia) and the manner in which it is implemented (e.g., multimodality perioperative management) may be important in facilitating short- and long-term patient convalescence after surgery.

ACUTE AND CHRONIC EFFECTS OF POSTOPERATIVE PAIN

Uncontrolled postoperative pain may produce a range of detrimental acute and chronic effects. The attenuation of perioperative pathophysiology that occurs during surgery through reduction of nociceptive input to the CNS and optimization of perioperative analgesia may decrease complications and facilitate recovery during the immediate postoperative period[7] and after discharge from the hospital.

Acute Effects

The perioperative period has a variety of pathophysiologic responses that may be initiated or maintained by nociceptive input. At one time these responses may have had a beneficial teleological purpose; however, the same response to the iatrogenic nature of modern-day surgery may be harmful. Uncontrolled perioperative pain may enhance some of these perioperative pathophysiologies and increase patient morbidity and mortality. Attenuation of postoperative pain, especially with certain types of analgesic regimens, may decrease perioperative morbidity and mortality.

Transmission of nociceptive stimuli from the periphery to the CNS results in the neuroendocrine stress response, a combination of local inflammatory substances (e.g., cytokines, prostaglandins, leukotrienes, tumor necrosis factor-α) and systemic mediators of the neuroendocrine response. The dominant neuroendocrine responses to pain involve hypothalamic-pituitary-adrenocortical and sympathoadrenal interactions. Suprasegmental reflex responses to pain result in increased sympathetic tone, increased catecholamine and catabolic hormone secretion (e.g., cortisol, adrenocorticotropic hormone, antidiuretic hormone, glucagon, aldosterone, renin, angiotensin II), and decreased secretion of anabolic hormones.[8] The effects include sodium and water retention and increased levels of blood glucose, free fatty acids, ketone bodies, and lactate. A hypermetabolic, catabolic state occurs as metabolism and oxygen consumption are increased and metabolic substrates are mobilized from storage depots.[8] The extent of the stress response is influenced by many factors, including the type of anesthesia and intensity of the surgical injury, with the extent of the stress response being proportional to the degree of surgical trauma.[9] The negative nitrogen balance and protein catabolism may impede convalescence; however, attenuation of the stress response and postoperative pain may facilitate and accelerate the patient's recovery postoperatively.

The neuroendocrine stress response may enhance detrimental physiologic effects in other areas of the body. The stress response is likely a factor in the postoperative development of hypercoagulability. Enhancement of coagulation (i.e., decreased levels of natural anticoagulants and increased levels of procoagulants), inhibition of fibrinolysis, and increased platelet reactivity and plasma viscosity may enhance the incidence of postoperative hypercoagulable-related events such as deep venous thrombosis, vascular graft failure, and myocardial ischemia.[10] The stress response may also enhance postoperative immunosuppression, the extent of which correlates with the severity of surgical injury.[4] Hyperglycemia from the stress response may contribute to poor wound healing and depression of immune function.

Uncontrolled postoperative pain may activate the sympathetic nervous system and thereby contribute to morbidity or mortality. Sympathetic activation may increase myocardial oxygen consumption, which may be important in the development of myocardial ischemia and infarction,[10] and may decrease myocardial oxygen supply through coronary vasoconstriction and attenuation of local metabolic coronary vasodilation.[11] Activation of the sympathetic nervous system may also delay return of postoperative gastrointestinal motility, which may develop into paralytic ileus. Although postoperative ileus is the result of a combination of inhibitory input from central and local factors,[10,11] an increase in sympathetic efferent activity, such as from uncontrolled pain, may decrease gastrointestinal activity and delay return of gastrointestinal function.

Nociceptors are activated after surgical trauma and may initiate several detrimental spinal reflex arcs. Postoperative respiratory function is markedly decreased, especially after upper abdominal and thoracic surgery. Spinal reflex inhibition of phrenic nerve activity is an important component of this decreased postoperative pulmonary function.[10] However, patients with poor postoperative pain control may breathe less deeply, have an inadequate cough, and be more susceptible to the development of postoperative pulmonary complications.[11] Activation of nociceptors may also initiate spinal reflex inhibition of gastrointestinal tract function and delay return of gastrointestinal motility.[10]

Many detrimental postoperative pathophysiologic effects can occur in the perioperative period and can activate nociceptors and the stress response. Uncontrolled pain may activate the sympathetic nervous system, which can cause a variety of potentially harmful physiologic responses that may adversely increase morbidity and mortality. Nociceptor activation may also result in several detrimental inhibitory spinal reflexes. Control of the pathophysiologic processes associated with acute postoperative pain may attenuate the stress response, sympathetic outflow, and inhibitory spinal reflexes and contribute to improvements in morbidity, mortality, and patient-reported outcomes (e.g., health-related quality of life [HRQL], patient satisfaction).[10]

Chronic Effects

Chronic postsurgical pain (CPSP) is a largely unrecognized problem that may occur in 10% to 65% of postoperative patients (depending on the type of surgery), with 2% to 10% of these patients experiencing severe CPSP.[12] Poorly controlled acute postoperative pain is an important predictive factor in the development of CPSP.[6,13] The transition from acute to chronic pain occurs very quickly, and long-term behavioral and neurobiologic changes occur much sooner than was previously thought.[4] CPSP is relatively

common after procedures such as limb amputation (30% to 83%), thoracotomy (22% to 67%), sternotomy (27%), breast surgery (11% to 57%), and gallbladder surgery (up to 56%).[6] Although the severity of acute postoperative pain may be an important predictor in the development of CPSP,[6] a causal relationship has not been definitively established, and other factors (e.g., area of postoperative hyperalgesia) may be more important in predicting the development of CPSP.[14] One such factor may be the severity of the patient's preoperative pain. Patients with more intense levels of preoperative pain may also develop a degree of CNS sensitization predisposing them to the increased likelihood of higher postoperative pain and the subsequent development of chronic pain.[14] Thus, it is important that acute pain service clinicians understand chronic pain conditions and involve themselves in the patient's preoperative care. The increased involvement of the acute pain medicine team in preoperative anesthesia clinics or services can positively attenuate the incidence and severity of postoperative pain.

Control of acute postoperative pain may improve long-term recovery or patient-reported outcomes (e.g., quality of life). Patients whose pain is controlled in the early postoperative period (especially with the use of continuous epidural or peripheral catheter techniques) may be able to actively participate in postoperative rehabilitation, which may improve short- and long-term recovery after surgery.[15] Optimizing treatment of acute postoperative pain can improve health-related quality of life (HRQL).[16] Postoperative chronic pain that develops as a result of poor postoperative pain control may interfere with patients' activities of daily living.

PREVENTIVE ANALGESIA

The older terminology of "preemptive" analgesia referred to an analgesic intervention that preceded a surgical injury and was more effective in relieving acute postoperative pain than the same treatment following surgery. The precise definition of preemptive analgesia is one of the major controversies in this area of medicine and contributes to the question of whether preemptive analgesia is clinically relevant. Definitions of preemptive analgesia include what is administered before the surgical incision, what prevents the establishment of central sensitization resulting from incisional injury only (i.e., intraoperative period), what prevents central sensitization resulting from incisional and inflammatory injury (i.e., intraoperative and postoperative periods), or the entire perioperative period encompassing preoperative interventions, intraoperative analgesia, and postoperative pain management (i.e., preventive analgesia).[3] The first two definitions are relatively narrow and may contribute to the lack of a detectable effect of preemptive analgesia in clinical trials. The rationale for preemptive analgesia was based on the inhibition of the development of central sensitization. Effectively, noxious input initiated by surgical procedures induced a state of CNS hyperactivity that accentuated pain. Although a very popular and discussed theory, a single analgesic treatment (either peripheral or neuraxial) before the incision does not reduce postoperative pain behaviors beyond the expected duration of the analgesic effect.[17] When the block of nociceptive afferents diminishes, the surgical injury is able to reinitiate central sensitization. Clinical trials have been negative.[18] For these reasons, this terminology has been abandoned.

As stated previously, intense noxious input (e.g., postoperative pain from the periphery) can change the CNS (i.e., central sensitization) to induce pain hypersensitivity and hyperexcitability (i.e., exaggerated and prolonged responsiveness of neurons to normal afferent input after tissue damage). Preventive analgesia is aimed at inhibiting the development of this type of chronic pain. This definition broadly includes any regimen given at any time during the perioperative period that is able to control pain-induced sensitization. Central sensitization and hyperexcitability can develop after the surgical incision in a patient who has no history of preoperative pain.

In contrast, some patients may already have existing acute or chronic pain and developed central sensitization before the surgical incision. These patients with preexisting pain may have even more intense pain in the postoperative period. This augmentation of already preexisting pain can occur in acutely hospitalized patients and even in those patients in subacute or chronic outpatient settings. Preventing the establishment of altered central processing by analgesic treatment may result in short-term (e.g., reduction in postoperative pain and accelerated recovery) and long-term (e.g., reduction in chronic pain and improvement in HRQL[16] benefits during a patient's convalescence. Unfortunately, many clinical studies (e.g., trials) lack clarity of study design and clear terminology of preemptive versus preventative analgesia.[18,19]

Timing of the intervention[18] may not be as clinically important as other aspects of preventive analgesia (i.e., intensity and duration of the intervention). An intervention administered before the surgical incision is not preventative if it is incomplete or insufficient (i.e., central sensitization is not prevented). Incisional and inflammatory injuries are important in initiating and maintaining central sensitization. Confining the definition of preventative analgesia to only the intraoperative (incisional) period is not relevant or appropriate because the inflammatory response lasts well into the postoperative period and continues to maintain central sensitization.

Maximal clinical benefit is observed when complete multisegmental blockade of noxious stimuli occurs, with extension of this effect into the postoperative period. Preventing central sensitization with intensive multimodal analgesic interventions[18] could theoretically reduce the intensity or even eliminate acute postoperative pain/hyperalgesia and chronic pain after surgery.[6]

MULTIMODAL APPROACH TO PERIOPERATIVE RECOVERY

The analgesic benefits of controlling postoperative pain are generally maximized when a multimodal strategy to facilitate the patient's convalescence is implemented. Yet postoperative pain treatment may not provide major improvements in some outcomes because it is unlikely that a unimodal intervention can be effective in addressing a complex problem such as perioperative outcomes.[7,20] Principles of a multimodal strategy include

control of postoperative pain to allow early mobilization, early enteral nutrition, education, and attenuation of the perioperative stress response through the use of regional anesthetic techniques[7] and a combination of analgesic drugs (i.e., multimodal analgesia). Despite the widely publicized case of academic fraud that included[21] many published articles on multimodal analgesia, subsequent carefully performed systematic reviews appeared to be robust enough to support its efficacy.[22] The use of epidural administered analgesics can provide superior analgesia and physiologic benefits and is therefore an integral part of the multimodal approach.

A multimodal approach to perioperative recovery to control postoperative pathophysiology and facilitate rehabilitation may result in accelerated recovery and decreased length of hospitalization.[23] Patients undergoing major abdominal or thoracic procedures and who participate in a multimodal strategy have a reduction in hormonal and metabolic stress, preservation of total-body protein, shorter times to tracheal extubation, lower pain scores, earlier return of bowel function, and earlier fulfillment of intensive care unit discharge criteria.[23] The multimodal approach integrates the most recent data and techniques from surgery, anesthesiology, nociceptive neurobiology, and pain treatment, making it an extension of clinical pathways (Enhanced Recovery After Surgery, or ERAS), or "fast tracks," by revising traditional care programs into effective postoperative rehabilitation pathways.[23] This approach will likely decrease perioperative morbidity, decrease the length of hospital stay, and improve patient satisfaction without compromising safety. However, widespread implementation of these programs requires multidisciplinary collaboration, change in the traditional principles of postoperative care, additional resources, and expansion of the traditional acute pain service, which may be limited in the current economic climate.

BOX 98-1 *Monitoring and Documentation of Postoperative Analgesia*

Analgesic Medication*
- Medication, concentration, and dose of drug
- Settings of PCA device: demand dose, lockout interval, continuous infusion
- Amount of drug administered (including number of unsuccessful and successful doses)
- Limits set (e.g., 1- and 4-hour limits on dose administered)
- Supplemental or breakthrough analgesics

Routine Monitoring
- Vital signs: temperature, heart rate, blood pressure, respiratory rate, average pain score
- Pain score at rest and with activity, pain relief
- Use of breakthrough medication

Side Effects
- Cardiovascular: hypotension, bradycardia, or tachycardia
- Respiratory status: respiratory rate, level of sedation
- Nausea and vomiting, pruritus, urinary retention
- Neurologic examination
- Assessment of motor block or function and sensory level
- Evidence of epidural hematoma

Instructions Provided
- Treatment of side effects
- Concurrent use of other CNS depressants
- Parameters for triggering notification of the covering physician
- Provision of contact information (24 hours/7 days per week) if problems occur
- Emergency analgesic treatment if the PCA device fails

CNS, Central nervous system; *PCA,* patient-controlled analgesia.
*Postoperative analgesia includes systemic opioids and regional analgesic techniques. This list incorporates some of the important elements of preprinted orders, documentation, and intravenous PCA and epidural analgesia daily care described in the ASA Practice Guidelines for Acute Pain Management.[24]

TREATMENT METHODS

Many options are available for the treatment of postoperative pain, including systemic (i.e., opioid and nonopioid) analgesics and regional (i.e., neuraxial and peripheral) analgesic techniques. By considering patients' preferences and making an individualized assessment of the risks and benefits of each treatment modality, the clinician can optimize the postoperative analgesic regimen for each patient. Essential aspects of postoperative monitoring of patients receiving various postoperative analgesic treatment methods are listed in Box 98-1.

SYSTEMIC ANALGESIC TECHNIQUES

OPIOIDS

Advantages and Characteristics

Opioid analgesics are one of the cornerstone options for the treatment of postoperative pain. They generally exert their analgesic effects through μ-receptors in the CNS, although opioids may also act at peripheral opioid receptors. A theoretical advantage of opioid analgesics is that there is no analgesic ceiling. Realistically, the analgesic efficacy of opioids is typically limited by the development of tolerance or opioid-related side effects such as nausea, vomiting, sedation, or respiratory depression. Opioids may be administered by the subcutaneous, transcutaneous, transmucosal, or intramuscular route, but the most common routes of postoperative systemic opioid analgesic administration are oral and intravenous. Opioids may also be administered at specific anatomic sites such as the intrathecal or epidural space (see later sections, "Single-Dose Neuraxial Opioids" and "Continuous Epidural Analgesia").

Wide intersubject and intrasubject variability exists in the relationship of opioid dose, serum concentration, and analgesic response in the treatment of postoperative pain. Serum drug concentrations may exhibit wider variability with certain routes of administration (e.g., intramuscular) than with others (e.g., intravenous). In general, opioids are administered parenterally (intravenously or intramuscularly) for the treatment of moderate to severe postoperative pain, in part because these routes provide a more rapid and reliable onset of analgesic action than the oral route does. Parenteral opioid administration may be necessary in patients who are unable to tolerate oral intake postoperatively. The transition from parenteral to oral administration of opioids usually occurs after the patient

TABLE 98-1 **INTRAVENOUS PATIENT-CONTROLLED ANALGESIA REGIMENS**

Drug Concentration	Size of Bolus*	Lockout Interval (min)	Continuous Infusion
Agonists			
Morphine (1 mg/mL)			
Adult	0.5-2.5 mg	5-10	—
Pediatric	0.01-0.03 mg/kg (max, 0.15 mg/kg/hr)	5-10	0.01-0.03 mg/kg/hr
Fentanyl (0.01 mg/mL)			
Adult	10-20 μg	4-10	—
Pediatric	0.5-1 μg/kg (max, 4 μg/kg/hr)	5-10	0.5-1 μg/kg/hr
Hydromorphone (0.2 mg/mL)			
Adult	0.05-0.25 mg	5-10	—
Pediatric	0.003-0.005 mg/kg (max, 0.02 mg/kg/hr)	5-10	0.003-0.005 mg/kg/hr
Alfentanil (0.1 mg/mL)	0.1-0.2 mg	5-8	—
Methadone (1 mg/mL)	0.5-2.5 mg	8-20	—
Oxymorphone (0.25 mg/mL)	0.2-0.4 mg	8-10	—
Sufentanil (0.002 mg/mL)	2-5 μg	4-10	—
Agonist-Antagonists			
Buprenorphine (0.03 mg/mL)	0.03-0.1 mg	8-20	—
Nalbuphine (1 mg/mL)	1-5 mg	5-15	—
Pentazocine (10 mg/mL)	5-30 mg	5-15	—

*All doses are for adult patients unless noted otherwise. Units vary across agents for size of the bolus (mg versus mg/kg versus μg versus μg/kg) and continuous infusion (mg/kg/hr versus μg/kg/hr). The anesthesiologist should proceed with titrated intravenous loading doses, if necessary, to establish initial analgesia. Individual patient requirements vary widely, with smaller doses typically given to older or compromised patients. Continuous infusions are not initially recommended for opioid-naive adult patients.

initiates oral intake and postoperative pain has been stabilized with parenteral opioids. Although oral opioids (typically formulated as part of a combination product that includes an adjuvant such as acetaminophen) are generally prescribed on an as-needed (PRN) basis postoperatively, there may be a role for sustained-release oral opioids, which may provide analgesia superior to that with conventional PRN regimens, although further studies are needed and these medications should be instituted on a case-by-case basis.[25] Although the traditional form (passive) of transdermal fentanyl is not indicated for the routine treatment of acute postoperative pain, a newer version involving patient-activated electrically facilitated delivery of transdermal fentanyl has been developed for use in hospitalized adult patients.[26]

Intravenous Patient-Controlled Analgesia

Various factors, including the aforementioned wide interpatient and intrapatient variability in analgesic needs, variability in serum drug levels (especially with intramuscular injection), and administrative delays, may contribute to inadequate postoperative analgesia. A traditional PRN analgesic regimen probably cannot compensate for these limitations. By circumventing some of these issues, intravenous patient-controlled analgesia (PCA) optimizes delivery of analgesic opioids and minimizes the effects of pharmacokinetic and pharmacodynamic variability in individual patients. Intravenous PCA is based on the premise that a negative-feedback loop exists; when pain is experienced, analgesic medication is self-administered, and when pain is reduced, there are no further demands. When the negative-feedback loop is violated, excessive sedation or respiratory depression may occur.[27] Although some equipment-related malfunctions can occur, the PCA device itself is relatively free of problems, and most problems related to PCA use result from user or operator error.[28]

A PCA device can be programmed for several variables, including the demand (bolus) dose, lockout interval, and background infusion (Table 98-1). An optimal demand or bolus dose is integral to the efficacy of intravenous PCA because an insufficient demand dose may result in inadequate analgesia, whereas an excessive demand dose may result in a higher incidence of undesirable side effects such as respiratory depression.[27] Although the optimal demand dose is uncertain, the data available suggest that the optimal demand dose is 1 mg for morphine and 40 μg for fentanyl in opioid-naive patients; however, the actual dose for fentanyl (10 to 20 μg) is often less in clinical practice.[28] The lockout interval may also affect the analgesic efficacy of intravenous PCA. A lockout interval that is too long may result in inadequate analgesia and decrease the effectiveness of intravenous PCA. A lockout interval that is too short allows the patient to self-administer another demand dose before feeling the full analgesic effect of the previous dose and thus may contribute to an increase in medication-related side effects. In essence, the lockout interval is a safety feature of intravenous PCA, and although the optimal lockout interval is unknown, most intervals range from 5 to 10 minutes, depending on the medication in the PCA pump; varying the interval within this range appears to have no effect on analgesia or side effects.[28]

Most PCA devices allow administration of a continuous or background infusion in addition to the demand dose. Initially, routine use of a background infusion predicted certain advantages, including improved analgesia, especially during sleep; however, analgesic benefits of a background infusion have not been successful in opioid-naive patients. A background infusion only increases the analgesic dosage used and the incidence of adverse respiratory events in the postoperative period especially in adult subjects. Furthermore, use of a nighttime background infusion does not improve postoperative sleep patterns, analgesia,

or recovery profiles.[29] Although routine use of continuous or background infusion as part of intravenous PCA in adult opioid-naive patients is not recommended, a background infusion in opioid-tolerant or pediatric patients may be effective (see later sections, "Opioid-Tolerant Patients" and "Pediatric Patients").

When compared with traditional PRN analgesic regimens, intravenous PCA provides superior postoperative analgesia and improves patient satisfaction, but the presence of economic benefits is not clear.[30] A meta-analysis revealed that intravenous PCA (versus as-needed opioids) provides significantly better analgesia and patient satisfaction; however, these patients used more opioids and had more frequent incidence of pruritus than those treated with PRN opioids, although no difference was seen in the incidence of adverse events.[30] With regard to economic outcomes, whether intravenous PCA is less expensive than traditional PRN intramuscular opioid administration is not clear because the calculations of cost are complex.

Intravenous PCA may provide advantages when assessing other patient-related outcomes such as patient satisfaction; these outcomes have become more important because health care organizations use them as a measure of quality and a tool for marketing purposes (also see Chapter 6). Patients usually prefer intravenous PCA over intravenously, intramuscularly, or subcutaneously administered PRN opioids. Greater patient satisfaction with intravenous PCA may be the result of superior analgesia and perceived control over the administration of analgesic medications and avoidance of disclosing pain or securing analgesic medication from nurses; however, the reasons for patient satisfaction are complex and many factors may contribute to or predict satisfaction with intravenous PCA. Although intravenous PCA use creates better satisfaction overall, the proper assessment of patient satisfaction can be complex.[31]

The incidence of opioid-related adverse events from intravenous PCA is not different from that of PRN opioids administered intravenously, intramuscularly, or subcutaneously. The rate of respiratory depression associated with intravenous PCA is infrequent (approximately 1.5%) and is not more frequent than that with PRN systemic or neuraxial opioids.[32] Factors that may influence the frequency and intensity of respiratory depression with intravenous PCA include use of a background infusion, advanced age, concomitant administration of sedative or hypnotic drugs, and coexisting pulmonary disease such as obstructive sleep apnea.[33] Intravenous PCA–related respiratory depression may also be caused by errors in programming or administration (i.e., operator error).[34]

NONOPIOIDS

Nonsteroidal Antiinflammatory Agents

Nonsteroidal antiinflammatory drugs (NSAIDs), which include aspirin and acetaminophen, consist of a diverse group of analgesic compounds with different pharmacokinetic properties. The primary mechanism by which NSAIDs exert their analgesic effect is through inhibition of cyclooxygenase (COX) and synthesis of prostaglandins, which are important mediators of peripheral sensitization and hyperalgesia. In addition to being peripherally acting analgesics, NSAIDs can also exert their analgesic effects through inhibition of spinal COX.[35] The discovery of at least two COX isoforms (i.e., COX-1 is constitutive and COX-2 is inducible) with different functions (i.e., COX-1 participates in platelet aggregation, hemostasis, and gastric mucosal protection, whereas COX-2 participates in pain, inflammation, and fever) has led to the development of selective COX-2 inhibitors that differ from traditional NSAIDs, which block both COX-1 and COX-2.[36] The discovery of a COX-3 variant may represent a primary central mechanism by which acetaminophen and other antipyretics decrease pain and fever; however, the precise relationship between COX-3 and acetaminophen is still uncertain.[37]

NSAIDs given alone generally provide effective analgesia for mild to moderate pain. NSAIDs are also traditionally considered a useful adjunct to opioids for the treatment of moderate to severe pain. Yet some quantitative, systematic reviews suggest that NSAIDs, alone or in combination with opioids, may be more beneficial than previously thought (Table 98-2 and Fig. 98-1). NSAIDs may be administered orally or parenterally and are particularly useful as components of a multimodal analgesic regimen by producing analgesia through a different

TABLE 98-2 RELATIVE EFFICACY OF SINGLE-DOSE ANALGESICS IN PROVIDING GREATER THAN 50% RELIEF OF MODERATE TO SEVERE POSTOPERATIVE PAIN

Drug*	Mean NNT†	95% CI
Acetaminophen (1000 mg PO)	3.8	3.4-4.4
Aspirin (600 to 650 mg PO)	4.4	4.0-4.9
Aspirin (1000 mg PO)	4.0	3.2-5.4
Diclofenac (50 mg PO)	2.3	2.0-2.7
Diclofenac (100 mg PO)	1.9	1.6-2.2
Ibuprofen (600 mg PO)	2.4	1.9-3.3
Ketorolac (10 mg PO)	2.6	2.3-3.1
Ketorolac (30 mg IM)	3.4	2.5-4.9
Naproxen (550 mg PO)	2.7	2.3-3.3
Celebrex (200 mg PO)	3.5	2.9-4.4
Celebrex (400 mg PO)	2.1	1.8-2.5
Tramadol (100 mg PO)	4.8	3.8-6.1
Gabapentin (600 mg PO)	11	6.0-35
Codeine (60 mg) acetaminophen (600 to 650 mg PO)	4.2	3.4-5.3
Oxycodone (5 mg) acetaminophen (325 mg PO)	2.5	2.0-3.2
Codeine (60 mg PO)	16.7	11.0-48.0
Morphine (10 mg IM)	2.9	2.6-3.6
Oxycodone (15 mg PO)	2.4	1.5-4.9

CI, Confidence interval; *IM,* intramuscular; *NNT,* number needed to treat; *PO,* oral route.

*Data obtained in part and modified from Bandolier with permission. Available at http://www.medicine.ox.ac.uk/bandolier/.

†NNT in this case refers to the number of patients who must be treated to obtain greater than 50% relief of moderate to severe postoperative pain. NNT conveys statistical and clinical significance, is useful in comparing the efficacy of different interventions, and summarizes treatment effects in a clinically relevant manner. A lower mean NNT implies greater analgesic efficacy in this example. See Figure 98-1 for a graphic presentation of these data.

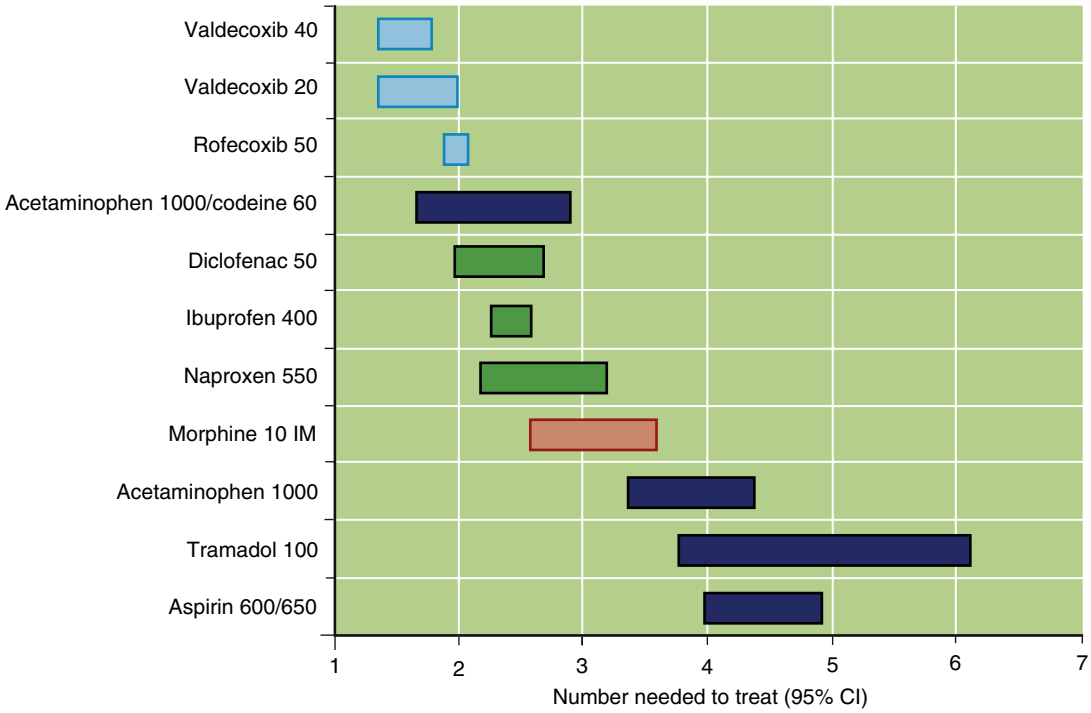

Figure 98-1. Number needed to treat (NNT) for at least 50% pain relief in patients with moderate to severe pain. The mean and 95% confidence interval (CI) for the NNTs are shown for several opioid and nonopioid analgesics from Table 98-2. The NNTs are derived from trials investigating the efficacy of a single dose of nonopioid analgesic versus placebo in providing more than 50% pain relief for moderate to severe postoperative pain. Numbers with drug names are doses in mg. *(From Bandolier. Available at http://www.medicine.ox.ac.uk/bandolier/.)*

mechanism than that of opioids or local anesthetics. Several meta-analyses have examined the analgesic efficacy of NSAIDs (including COX-2 inhibitors) and acetaminophen when added to intravenous PCA with opioids. Surprisingly (and important to note), NSAIDs,[38] not acetaminophen,[39] resulted in a statistically significant (but probably not clinically meaningful) reduction in pain scores.[40,41] Although all regimens significantly decreased morphine consumption, only NSAIDs (but not acetaminophen) reduced the risk for the opioid-related side effects of nausea, vomiting, and sedation.

Perioperative use of NSAIDs may be associated with several side effects, including decreased hemostasis, renal dysfunction, and gastrointestinal hemorrhage. Inhibition of COX and the formation of prostaglandins cause many of the side effects, which mediate many diverse processes throughout the body. Decreased hemostasis from NSAID use is from platelet dysfunction and inhibition of thromboxane A_2 (generated by COX-1), an important mediator of platelet aggregation and vasoconstriction.[42] Evidence of the effect of NSAIDs on perioperative bleeding is equivocal; a surveillance study of perioperative ketorolac administration did not demonstrate a significant increase in operative site bleeding. Whether NSAIDs may also have a deleterious effect on bone healing and osteogenesis is controversial.[43] Although NSAIDs have been used following acetabular/hip fractures and hip replacement surgery to reduce heterotopic ossification, the short-term effects of NSAIDs on other skeletal tissues are less clear.[44] Two recent systematic reviews indicated that when examining the highest-quality studies, there was no increased risk of nonunion with NSAID exposure. Certainly, a short-term NSAID regimen can be used for treatment of postfracture pain without significantly increasing the risk of disrupted healing.[45] A brief (<14 days) exposure to normal-dose NSAIDs (e.g., ketorolac <120 mg/day) was safe after spinal fusion; however, use of large-dose ketorolac (>120 mg/day) increased the risk of nonunion, suggesting a dose-dependent effect of perioperative NSAIDs on spinal fusion healing.[46] Spine surgeons will more commonly err on the conservative side and refuse to have postoperative spine fusion patients receive NSAIDs.

Perioperative NSAID-induced renal dysfunction may occur in high-risk patients, such as those with hypovolemia, abnormal renal function, or abnormal serum electrolytes, because prostaglandins dilate the renal vascular beds and mediate diuretic and natriuretic renal effects. NSAIDs should not be withheld in patients with normal preoperative renal function because euvolemic patients with normal renal function are unlikely to be affected, although NSAIDs may cause a clinically unimportant transient reduction in renal function in the early postoperative period in patients with normal preoperative renal function.[47] Gastrointestinal bleeding[48] may be more likely with NSAID intake because of inhibition of COX-1, which is required for the synthesis of cytoprotective gastric mucosal prostaglandins. Bronchospasm may be induced by NSAIDs (including aspirin) or acetaminophen, and cross-sensitivity may occur with acetaminophen in aspirin-sensitive asthmatic subjects.[49] Because expression of peripheral COX-2 is increased during inflammation, selective inhibition of COX-2 could theoretically

provide analgesia without the side effects associated with COX-1 inhibition. COX-2 inhibitors have a less frequent incidence of gastrointestinal complications[50] and exhibit minimal platelet inhibition, even when administered in supratherapeutic doses.[51] However, long-term use of COX-2 inhibitors has an excess cardiovascular risk; thus, rofecoxib was withdrawn from the market.[52] Although cardiovascular toxicity appears to be a class effect of all COX-2 inhibitors, the cardiovascular risks of COX-2 inhibitors are heterogeneous and influenced by many factors such as the specific medication, dosage, and patient characteristics.[52] Issues surrounding the perioperative use of COX-2 inhibitors are slightly different from those of longer-term use of COX-2 inhibitors.[53] A randomized trial of valdecoxib and its intravenous prodrug parecoxib versus placebo assessed the safety of these drugs in patients undergoing coronary artery bypass grafting (CABG).[54] When compared with the group given placebo alone, both the group given parecoxib and valdecoxib and the group given placebo and valdecoxib had a higher proportion of patients with at least one confirmed adverse event.[54] The use of parecoxib and valdecoxib after CABG was associated with an increased incidence of cardiovascular events, thereby arousing serious concern about the use of these drugs in such circumstances. However, a subsequent randomized controlled trial investigating the safety and efficacy of parecoxib and valdecoxib after major noncardiac surgery found that patients who received the COX-2 inhibitors had similar frequencies of predefined adverse events compared with those who received placebo.[55]

Gabapentanoids

Gabapentin and pregabalin, antiepileptic drugs also used in the treatment of neuropathic pain, interact with calcium channel α_2-δ ligands to inhibit calcium influx and subsequent release of excitatory neurotransmitters. However, oral pregabalin is absorbed more rapidly and has more absolute bioavailability (≥90% versus <60%) than does gabapentin.[56] Despite these differences, oral gabapentin improves the analgesic efficacy of opioids both at rest and with movement, and reduces opioid consumption and opioid-related side effects, but with an increased incidence of side effects such as sedation and dizziness.[57,58,59] The data for the analgesic efficacy for pregabalin is not as convincing as that for gabapentin. A meta-analysis investigating the analgesic efficacy of pregabalin for acute postoperative pain demonstrated use of pregabalin was associated with a decrease in opioid consumption and opioid-related side effects, but no difference in pain intensity.[60] Another meta-analysis suggested that perioperative administration of pregabalin may provide additional analgesia in the short term but also results in an increase in side effects such as dizziness/lightheadedness or visual disturbances.[61] Although further studies are needed to elucidate the specific parameters (e.g., dose, duration of use) for gabapentanoids in the perioperative period, these analgesics can be considered as part of a multimodal approach to postoperative analgesia. Furthermore, perioperative administration of gabapentin and pregabalin may reduce the incidence of CPSP.[62]

Ketamine

Ketamine is traditionally recognized as an intraoperatively administered anesthetic; however, small-dose (analgesic) ketamine can facilitate postoperative analgesia because of its NMDA-antagonistic properties, which may be important in attenuating central sensitization and opioid tolerance.[63] Ketamine can be administered orally, intravenously (PCA or as a continuous infusion), subcutaneously, or intramuscularly. A systematic review of perioperative ketamine use found that perioperative analgesic doses of ketamine reduce rescue analgesic requirements or pain intensity.[64] In addition, perioperative ketamine reduced 24-hour PCA morphine consumption and postoperative nausea or vomiting and had minimal adverse effects.[64] A subsequent systematic review found that intravenous ketamine was an effective adjunct for postoperative analgesia particularly in patients undergoing painful procedures, such as upper abdominal, thoracic, and major orthopedic surgeries.[65] The administration of ketamine in postoperative pediatric patients is also associated with decreased postoperative pain intensity (also see Chapter 93).[66] One potential concern is the possible impact of ketamine's amnestic effects on the neuropharmacologic and cognitive level of patients with use of perioperative ketamine infusions.[67] Although possible, these effects infrequently occur when the medication is given in analgesic doses. Ketamine has also been given epidurally and intrathecally, but racemic mixtures of ketamine are neurotoxic, and therefore the use of neuraxial racemic ketamine is strongly discouraged.

Tramadol

Tramadol is a synthetic opioid that exhibits weak μ-agonist activity and inhibits reuptake of serotonin and norepinephrine, although the relative degree of contribution of each modality to postoperative analgesia is not certain.[68] Although tramadol exerts its analgesic effects primarily through central mechanisms, it may have peripheral local anesthetic properties and has been used as a subcutaneous local anesthetic for minor surgical procedures.[69] Tramadol is effective in treating moderate postoperative pain[70] and is comparable in analgesic efficacy to aspirin (650 mg) with codeine (60 mg) or ibuprofen (400 mg) (see Table 98-2 and Fig. 98-1).[70] The addition of acetaminophen to tramadol (versus tramadol alone) may decrease the incidence of tramadol's side effects without reducing its analgesic efficacy.[71] Use of tramadol in intravenous PCA results in similar pain scores when compared with that from intravenous PCA opioids; however, the side effect profile is different between the two groups (i.e., a more frequent incidence of postoperative nausea/vomiting but lower pruritus with tramadol).[72] Advantages of tramadol for postoperative analgesia include a relative lack of respiratory depression, major organ toxicity, and depression of gastrointestinal motility and a small potential for abuse (1 case per 100,000 patients).[68] Common side effects (overall incidence of 1.6% to 6.1%) include dizziness, drowsiness, sweating, nausea, vomiting, dry mouth, and headache.[70] Tramadol should be used with caution in patients with seizures or increased intracranial pressure (also see Chapter 70) and is contraindicated in those taking monoamine oxidase inhibitors.[70]

REGIONAL ANALGESIC TECHNIQUES

A variety of neuraxial (primarily epidural) and peripheral regional analgesic techniques may be used for the effective treatment of postoperative pain. In general, the analgesia provided by epidural and peripheral techniques (particularly when local anesthetics are used) is superior to that with systemic opioids,[73] and use of these techniques may even reduce morbidity and mortality.[10,74] However, as with all approaches, the risks and benefits should be compared, especially regarding the controversies about the use of these techniques in the presence of various anticoagulants.

Single-Dose Neuraxial Opioids

Administration of a single dose of opioid may be efficacious as a sole or adjuvant analgesic drug when administered intrathecally or epidurally. One of the most important factors in determining the clinical pharmacology for a particular opioid is its degree of lipophilicity (versus hydrophilicity) (Table 98-3). Once they have reacted the cerebrospinal fluid (CSF) through direct intrathecal injection or gradual migration from the epidural space, hydrophilic opioids (i.e., morphine and hydromorphone) tend to remain within the CSF and produce a delayed but longer duration of analgesia, along with a generally more frequent incidence of side effects because of the cephalic or supraspinal spread of these compounds. Neuraxial administration of lipophilic opioids, such as fentanyl and sufentanil, provides a rapid onset of analgesia, and their rapid clearance from CSF may limit cephalic spread and the development of certain side effects such as delayed respiratory depression. The site of analgesic action for hydrophilic opioids is overwhelmingly spinal, but the primary site of action (spinal versus systemic) for single-dose neuraxial lipophilic opioids is not as certain.[75]

TABLE 98-3 **PROPERTIES OF NEURAXIAL OPIOIDS**

Property	Lipophilic Opioids	Hydrophilic Opioids
Common drugs	Fentanyl, sufentanil	Morphine, hydromorphone
Onset of analgesia	Rapid onset (5-10 min)	Delayed onset (30-60 min)
Duration of analgesia*	Shorter duration (2-4 hr)	Longer duration (6-24 hr)
CSF spread	Minimal CSF spread	Extensive CSF spread
Site of action	Spinal ± systemic	Primarily spinal ± supraspinal
Side effects		
Nausea and vomiting	Lower incidence with lipophilic than with hydrophilic opioids	
Pruritus	Lower incidence with lipophilic than with hydrophilic opioids	
Respiratory depression	Primarily early; minimal delay	Both early (<6 hr) and delayed (>6 hr) possible

CSF, Cerebrospinal fluid.
*The duration of analgesia varies.

The differences in pharmacokinetics between lipophilic and hydrophilic opioids may influence the choice of opioid in an attempt to optimize analgesia and minimize side effects for a particular clinical situation. Single-dose intrathecal administration of a lipophilic opioid may be useful in situations (e.g., ambulatory surgical patients) in which rapid analgesic onset (minutes) combined with a moderate duration of action (<4 hours) and minimal risk of respiratory depression is needed.[76] Single-dose hydrophilic opioid administration provides effective postoperative analgesia and may be useful in patients monitored on an inpatient basis, for whom a longer duration of analgesia would be beneficial.

Single-dose epidural administration of lipophilic and hydrophilic opioids is used to provide postoperative analgesia, with considerations generally being similar to those discussed for single-dose intrathecal administration of opioids. A single bolus of epidural fentanyl may be administered to provide rapid postoperative analgesia; however, diluting the epidural dose of fentanyl (typically 50 to 100 μg) in at least 10 mL of preservative-free normal saline will decrease the onset and prolong the duration of analgesia, possibly as a result of an increase in initial spread and diffusion of the lipophilic opioid. Single-dose epidural morphine is effective for postoperative analgesia, and use of a single-dose hydrophilic opioid may be especially helpful in providing postoperative epidural analgesia when the epidural catheter's location is not congruent with the surgical incision (e.g., lumbar epidural catheter for thoracic surgery). Smaller doses of epidural morphine may be required for older patients and for thoracic catheter sites. Commonly used dosages for intrathecal and epidural administration of neuraxial opioids are provided in Table 98-4.

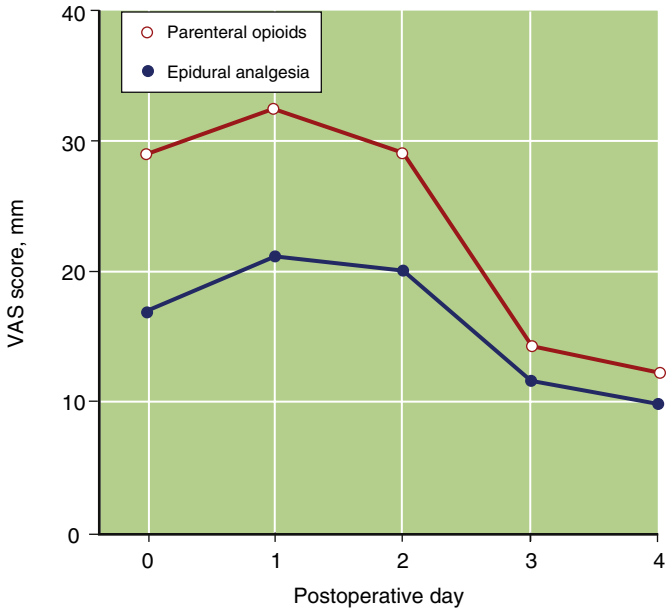
Recently introduced is an extended-release formulation of (single-dose) epidural morphine encapsulated within liposomes that results in up to 48 hours of analgesia.[77] Some precautions are required in using this newer formulation of epidural morphine. To resuspend the particles immediately before withdrawal from the vial, the vial should be gently inverted (but aggressive or excessive agitation must be avoided). Concurrent administration of liposomal extended-release morphine and local anesthetics may increase peak concentrations of morphine. Accordingly, the manufacturer has recommended that clinicians increase the interval between administration of local anesthetic (including test doses) and liposomal extended-release morphine to at least 15 minutes to minimize this pharmacokinetic interaction. In addition, because the liposomal extended-release morphine does not contain any bacteriostatic agents, it should be administered within 4 hours after withdrawal from the vial. Finally, as with traditional single-dose neuraxial opioids, clinicians should administer a smaller dose of liposomal extended-release morphine to older patients or those with decreased physiologic reserve or coexisting disease.

At this time, liposomal extended-release morphine has not been studied or approved in pediatric patients.

Continuous Epidural Analgesia

Analgesia delivered through an indwelling epidural catheter is a safe and effective method for management of acute postoperative pain.[78] Postoperative epidural analgesia can provide analgesia superior to that with systemic opioids (Fig. 98-2).[79,80] Of note, however, *epidural analgesia* is not a generic term but incorporates a wide range of options, including the choice and dose of analgesic agents, location of catheter placement, and onset and duration of perioperative use.[78] Although this section focuses on the postoperative management of epidural analgesia, intraoperative use of the epidural catheter as part of a combined epidural-general anesthetic technique results in less pain and faster patient recovery immediately after surgery than general anesthesia followed by systemic opioids does.[81] Each of these options may affect the quality of postoperative analgesia, patient-reported outcomes, and even rates of morbidity and mortality.

Analgesic Drugs



Local Anesthetics. Epidural infusion of local anesthetic alone may be used for postoperative analgesia, but in general it is not as effective in controlling pain as local anesthetic–opioid epidural analgesic combinations are.[79,80] The precise location of action of local anesthetics in the epidural space is not clear, and potential sites include the spinal nerve roots, dorsal root ganglion, or spinal cord itself.[75] Epidural infusion of local anesthetic alone may be warranted for postoperative analgesia in an attempt to avoid opioid-related side effects; however, the sole use of local anesthetics is less common than the use of a local anesthetic–opioid combination because of a significant failure rate (from regression of sensory blockade and inadequate analgesia) and relatively high incidence of motor block and hypotension.[78]

Opioids for Epidural Infusion. Opioids may be used alone for postoperative epidural infusion and do not generally cause motor block or hypotension from sympathetic blockade.[78] There are differences between continuous

TABLE 98-4 **DOSING OF NEURAXIAL OPIOIDS***

Drug	Intrathecal or Subarachnoid Single Dose	Epidural Single Dose	Epidural Continuous Infusion
Fentanyl	5-25 μg	50-100 μg	25-100 μg /hr
Sufentanil	2-10 μg	10-50 μg	10-20 μg /hr
Alfentanil	—	0.5-1 mg	0.2 mg/hr
Morphine	0.1-0.3 mg	1-5 mg	0.1-1 mg/hr
Hydromorphone	—	0.5-1 mg	0.1-0.2 mg/hr
Extended-release morphine†	Not recommended	5-15 mg	Not recommended

*Doses are based on the use of a neuraxial opioid alone. No continuous intrathecal or subarachnoid infusions are provided. Lower doses may be effective when administered to older patients or when injected in the cervical or thoracic region. Units vary across agents for single dose (mg versus μg) and continuous infusion (mg/hr versus μg/hr).

epidural infusion of lipophilic (e.g., fentanyl, sufentanil) and hydrophilic (e.g., morphine, hydromorphone) opioids. The analgesic site of action (spinal versus systemic) of continuous epidural infusion of lipophilic opioids is not clear. Although some data suggest a benefit from epidural (versus intravenous) infusion of lipophilic opioids,[82] the overall advantage of administering continuous epidural infusion of lipophilic opioids alone is marginal.[78]

The analgesic site of action for continuous hydrophilic opioid infusion is primarily spinal. Continuous infusion of a hydrophilic opioid may be especially useful for providing postoperative analgesia when the site of catheter insertion is not congruent with the site of surgery or when side effects (e.g., hypotension, motor block) are attributed to the epidural local anesthetic. Use of a continuous infusion rather than intermittent boluses of epidural morphine may result in superior analgesia with fewer side effects. Continuous epidural infusion of hydrophilic opioids may provide analgesia superior to that of traditional PRN administration of systemic opioids.

Local Anesthetic–Opioid Combinations. Use of a local anesthetic and an opioid in an epidural infusion may have advantages over infusions consisting of a local anesthetic or opioid alone. When compared with a local anesthetic or opioid alone, a local anesthetic–opioid combination provides superior postoperative analgesia (including improved dynamic pain relief), limits regression of sensory blockade, and possibly decreases the dose of local anesthetic administered, although the effect on the incidence is uncertain.[78] Continuous epidural infusion of a local anesthetic–opioid combination also provides analgesia superior to that of intravenous PCA with opioids.[79] It is unclear whether the analgesic effect of the local anesthetic and opioid in epidural analgesia is additive or synergistic. The choice of local anesthetic for continuous epidural infusion varies. In general, bupivacaine, ropivacaine, or levobupivacaine is chosen because of the differential and preferential clinical sensory blockade with minimal impairment of motor function. Concentrations used for postoperative epidural analgesia are lower than those used for intraoperative anesthesia. The choice of opioid also varies, although many clinicians prefer a lipophilic opioid (e.g., fentanyl, sufentanil) to allow rapid titration of analgesia.[78] Use of a hydrophilic opioid (morphine, hydromorphone) as part of a local anesthetic–opioid epidural analgesic regimen may also provide effective postoperative analgesia. The optimal local anesthetic and opioid dose that provides the lowest pain scores with the fewest medication-related side effects is unknown and further investigation is needed to determine the optimal combinations for other types of surgical procedures with different epidural catheter insertion sites and to compare the efficacy of these optimal continuous infusions with patient-controlled epidural analgesia (PCEA).

Adjuvant Drugs. A variety of adjuvants may be added to epidural infusions to enhance analgesia while minimizing side effects, but none has gained widespread acceptance. Two of the more studied adjuvants are clonidine and epinephrine. Clonidine mediates its analgesic effects primarily through the spinal dorsal horn α_2-receptors on primary afferents and interneurons, as well as the descending noradrenergic pathway, and the epidural dose typically used ranges from 5 to 20 μg/hr.[83,84] Clinical application of clonidine is limited by its side effects: hypotension, bradycardia, and sedation.[85] Hypotension and bradycardia are both dose dependent. Epinephrine may improve epidural analgesia, can increase sensory blockade, and is generally administered at a concentration of 2 to 5 μg/mL.[86,87] Epidural administration of NMDA antagonists, such as ketamine, can theoretically be useful in attenuating central sensitization and potentiating the analgesic effect of epidural opioids, but additional safety and analgesic data are needed.

Location of Catheter Insertion

Insertion of the epidural catheter congruent to the incisional dermatome (i.e., catheter-incision–congruent analgesia) (Table 98-5) results in optimal postoperative epidural analgesia by infusing analgesics to the appropriate incisional dermatomes, providing superior analgesia, minimizing side effects (e.g., lower extremity motor block and urinary retention), and decreasing morbidity.[10,78] When compared with catheter-incision–congruent epidural analgesia, catheter-incision–incongruent epidural analgesia (e.g., low lumbar catheter placement for thoracic procedures) results in increased pain and early removal of the epidural catheter because of ineffective analgesia. By targeting delivery of analgesic drugs to the appropriate dermatomes, catheter-incision–congruent epidural analgesia may result in smaller drug requirements and decreased medication-related side effects. Incidence of lower extremity motor block is more frequent with the use of lumbar epidural catheters, and an earlier-than-anticipated termination of

TABLE 98-5 **RECOMMENDED CATHETER INSERTION SITES FOR SURGICAL PROCEDURES**

Location of Incision	Examples of Surgical Procedures	Congruent Epidural Catheter Placement
Thoracic	Lung reduction, radical mastectomy, thoracotomy, thymectomy	T4-8
Upper abdominal	Cholecystectomy, esophagectomy, gastrectomy, hepatic resection, Whipple procedure	T6-8
Middle abdominal	Cystoprostatectomy, nephrectomy	T7-10
Lower abdominal	Abdominal aortic aneurysm repair, colectomy, radical prostatectomy, total abdominal hysterectomy	T8-11
Lower extremity	Femoral-popliteal bypass, total hip or total knee replacement	L1-4

L, Lumbar level; *T,* thoracic level.

epidural analgesia may also result.[88] Use of a high thoracic epidural for abdominal or thoracic surgery does not inhibit sympathetic nerve activity in the lower extremities and may result in a relatively infrequent incidence of urinary retention, thus diminishing the need for routine bladder catheterization.[83] Placement of thoracic epidural catheters is relatively safe, and a more frequent incidence of neurologic complications is not documented with placement of a thoracic (versus lumbar) epidural catheter. Furthermore, the benefits of epidural analgesia in decreasing morbidity in patients undergoing abdominal and thoracic surgery are seen only with thoracic (congruent), not lumbar (incongruent), epidural catheter placement.[84]

Side Effects of Neuraxial Analgesic Drugs

Many medication-related (opioid and local anesthetic) side effects can occur with the use of postoperative epidural analgesia, but before automatically ascribing the cause to the epidural analgesic regimen, other causes should be considered, such as small intravascular volume, bleeding, and low cardiac output, leading to hypotension and cerebrovascular accident, pulmonary edema, and evolving sepsis, leading to respiratory depression. Standing orders and nursing protocols for analgesic regimens, neurologic monitoring, treatment of side effects, and physician notification about critical variables should be standard for all patients receiving neuraxial and other types of postoperative analgesia (see Box 98-1).

Hypotension. The local anesthetics used in an epidural analgesic regimen may block sympathetic fibers and contribute to postoperative hypotension. Although the incidence of postoperative hypotension with postoperative epidural analgesia may be as frequent as approximately 7%, the average may be closer to 0.7% to 3%.[78,89] A systematic review of studies investigating postoperative analgesia found a mean (95% CI) incidence of hypotension for epidural analgesia of 5.6% (3.0% to 10.2%).[32] Strategies to treat noncritical hypotension caused by epidural analgesia include decreasing the overall dose of local anesthetic administered (by decreasing the rate or concentration), infusing an opioid epidural alone because it is unlikely that neuraxial opioid administration would contribute to postoperative hypotension, and treating the underlying cause of the decrease in blood pressure.[78]

Motor Block. Use of local anesthetics for postoperative epidural analgesia may also contribute to lower extremity motor block in approximately 2% to 3% of patients,[78,89] and this may lead to the development of pressure sores in the heels.[90] A meta-analysis noted a mean incidence of motor block of 3.2% with PCEA.[79] A lower concentration of local anesthetic and catheter-incision–congruent placement of epidural catheters for abdominal or thoracic procedures may decrease the incidence of motor block. Although motor block resolves in most cases after stopping the epidural infusion for approximately 2 hours, persistent or increasing motor block should be evaluated promptly, and spinal hematoma, spinal abscess, and intrathecal catheter migration should be considered as part of the differential diagnosis.[78]

Nausea and Vomiting. Nausea and vomiting associated with neuraxial administration of single-dose opioid occurs in up to 50% of patients, and the cumulative incidence in those receiving continuous infusions of opioid may be as high as 80%. The overall data (neuraxial opioids and/or local anesthetic combined) suggest that the incidence of postoperative vomiting is similar between epidural analgesia and systemic opioids, although female patients will exhibit a more frequent incidence regardless of analgesic modality.[91] The incidence of neuraxial opioid–related nausea and vomiting may be dose dependent, although a recent meta-analysis suggested that a larger dose (≥0.3 mg) of intrathecal morphine did not increase the risk of postoperative nausea or vomiting compared with a smaller dose (<0.3 mg) of intrathecal morphine.[92] Nausea and vomiting from neuraxial opioids may be related to the cephalad migration of opioid within the CSF to the area postrema in the medulla. Use of fentanyl alone or in combination with a local anesthetic in an epidural infusion is associated with less frequent incidence of nausea and vomiting than are infusions of morphine. A variety of drugs have been used successfully to treat neuraxial opioid–induced nausea and vomiting, including naloxone, droperidol, metoclopramide, dexamethasone, ondansetron, and transdermal scopolamine.[93,94]

Pruritus. Pruritus is one of the most common side effects of epidural or intrathecal administration of opioids, with an incidence of approximately 60% versus about 15% to 18% for epidural local anesthetic administration or systemic opioids.[95] A systematic review of studies investigating postoperative analgesia found a mean (95% CI) incidence of pruritus for epidural analgesia of 16.1% (12.8% to 20%) versus 13.8% (10.7% to 17.5%) for intravenous opioid PCA.[91] Although the cause of neuraxial opioid–induced pruritus is uncertain, peripheral histamine release is not the cause but may be related to central activation of an "itch center" in the medulla or activation of opioid receptors in the trigeminal nucleus or nerve roots with cephalad migration of the opioid. It is unclear whether the incidence of neuraxial opioid–related pruritus is dose dependent because a quantitative systematic review[95] suggested no evidence of a relationship, whereas other clinical and experimental studies have indicated a significant correlation.[96] Many drugs have been evaluated for the prevention and treatment of opioid-induced pruritus, which can be difficult to manage and quite bothersome for some patients. Intravenous naloxone, naltrexone, nalbuphine, and droperidol appear to be efficacious for the pharmacologic control of opioid-induced pruritus.[95] Meta-analysis has shown that serotonin receptor antagonists may also be an effective modality in the prevention of neuraxial opioid-induced pruritus.[94] The use of epidural morphine is associated with postpartum reactivation of herpes simplex labialis.

Respiratory Depression. Neuraxial opioids used in appropriate doses are not associated with a more frequent incidence of respiratory depression than that seen with systemic administration of opioids. The incidence

of respiratory depression with neuraxial administration of opioids is dose dependent and typically ranges from 0.1% to 0.9%. The incidence of respiratory depression with neuraxial opioids is no more frequent than that seen after systemic opioid administration. The incidence of respiratory depression, as defined by a slow respiratory rate, should be less than 1%.[32] The precise incidence of respiratory depression in actual clinical practice may be difficult to determine because many criteria (e.g., respiratory rate, oxygen saturation, partial pressure of carbon dioxide, and need to administer respiratory stimulants/reversal drugs) have been used to define respiratory depression.[32] Neuraxial lipophilic opioids cause less delayed respiratory depression than do hydrophilic opioids, although administration of lipophilic opioids may cause early significant respiratory depression. Delayed respiratory depression is primarily associated with the cephalad spread of hydrophilic opioids, which typically occurs within 12 hours after injection of morphine. Risk factors for respiratory depression with neuraxial opioids include increasing dose, increasing age, concomitant use of systemic opioids or sedatives, possibly prolonged or extensive surgery, and the presence of comorbid conditions (e.g., obstructive sleep apnea). Clinical assessments, such as the respiratory rate, may not reliably predict a patient's ventilatory status or impending respiratory depression. Treatment with naloxone (and airway management if necessary) is effective in 0.1- to 0.4-mg increments; however, because its clinical duration of action is relatively short in comparison with the respiratory depressant effect of neuraxial opioids, continuous infusion of naloxone (0.5 to 5 μg/kg/hr) may be needed.[97] Although perioperative single-dose extended-release epidural morphine (versus intravenous opioid PCA) may be effective for postoperative pain relief for up to 48 hours, respiratory depression may be more likely.[98] Practice guidelines for the prevention, detection, and management of respiratory depression associated with neuraxial opioid administration have been published.[99]

Urinary Retention. Urinary retention associated with the neuraxial administration of opioids is the result of an interaction with opioid receptors in the spinal cord that decreases the detrusor muscle's strength of contraction. The incidence of urinary retention is more frequent with neuraxially administered opioids than when given systemically. Urinary retention does not depend on the opioid dose and may be treated with the use of low-dose naloxone, although at the risk of reversing the analgesic effect. Urinary retention occurred in 23.0% of patients, with the most frequent rate in those receiving epidural analgesia.[91] Another review of the literature found an overall incidence of urinary retention of 9%.[100] However, the exact incidence of urinary retention seen clinically may be difficult to determine because patients who undergo major surgical procedures are often routinely catheterized.

Patient-Controlled Epidural Analgesia

Epidural analgesia has traditionally been delivered at a fixed rate or as a continuous epidural infusion (CEI); however, the administration of epidural analgesia through a patient-controlled device (PCEA) has become more common. Like intravenous PCA, PCEA allows individualization of postoperative analgesic requirements and may have several advantages over CEI, including lower drug use and better patient satisfaction. PCEA may also provide analgesia superior to that afforded by intravenous PCA.[79]

PCEA is a relatively safe and effective technique for postoperative analgesia on routine surgical wards. Observational data from two series of over 1000 patients each reveal that more than 90% of patients with PCEA receive adequate analgesia, with a median pain score of 1 (of a possible 10) at rest and 4 with activity.[89,101] The incidence of side effects is 1.8% to 16.7% for pruritus, 3.8% to 14.8% for nausea, 13.2% for sedation, 4.3% to 6.8% for hypotension, 0.1% to 2% for motor block, and 0.2% to 0.3% for respiratory depression.[89,101] These rates are favorable and comparable to those reported with CEI.

The optimal PCEA analgesic solution and delivery parameters are unclear. Use of a continuous or background infusion in addition to the demand dose is more common with PCEA than with intravenous PCA and may provide analgesia superior to that with the use of a demand dose alone.[102] In general, most acute pain specialists have gravitated toward a variety of low-concentration local anesthetic–opioid combinations (Table 98-6) in an attempt to improve analgesia while minimizing side effects, such as motor block and

TABLE 98-6 PATIENT-CONTROLLED EPIDURAL ANALGESIA REGIMENS

Analgesic Solution*	Continuous Rate (mL/hr)	Demand Dose (mL)	Lockout Interval (min)
General Regimens			
0.05% bupivacaine + 4 μg/mL fentanyl	4	2	10-20
0.0625% bupivacaine + 5 μg/mL fentanyl†	4-8	3-5	10-20
0.1% bupivacaine + 5 μg/mL fentanyl	6	2	10-20
0.2% ropivacaine + 5 μg/mL fentanyl	5	2	20
Thoracic Surgery			
0.0625%-0.125% bupivacaine + 5 μg/mL fentanyl†	3-4	2-3	10-20
Abdominal Surgery			
0.0625% bupivacaine + 5 μg/mL fentanyl†	4-8	3-5	10-20
0.125% bupivacaine + 0.5 μg/mL sufentanil	3-5	2-3	10-20
0.1%-0.2% ropivacaine + 2 μg/mL fentanyl	3-5	2-5	10-20
Lower Extremity Surgery			
0.0625%-0.125% bupivacaine + 5 μg/mL fentanyl†	4-8	3-5	10-20

respiratory depression. As for CEI, addition of an opioid to the local anesthetic can provide analgesia superior to that with either analgesic alone. A lipophilic opioid is usually chosen because its rapid analgesic effect and shorter duration of action may be more suitable for use with PCEA.[89] Use of lower concentrations of a local anesthetic (e.g., bupivacaine, ropivacaine) may provide excellent analgesia without significant motor block.[103]

Benefits of Epidural Analgesia

Use of perioperative epidural anesthesia and analgesia, especially with a local anesthetic–based analgesic solution, can attenuate the pathophysiologic response to surgery and may be associated with a reduction in mortality and morbidity when compared with analgesia with systemically administered opioids.[10,11] Meta-analysis of randomized data (141 trials enrolling 9559 subjects) found that perioperative use of neuraxial anesthesia and analgesia (versus general anesthesia and systemic opioids) reduced overall mortality (primarily in orthopedic patients) by approximately 30%.[104] Use of epidural analgesia can decrease the incidence of postoperative gastrointestinal, pulmonary, and possibly cardiac complications.[10,74]

By inhibiting sympathetic outflow, decreasing the total opioid dose, and attenuating spinal reflex inhibition of the gastrointestinal tract, postoperative thoracic epidural analgesia can facilitate return of gastrointestinal motility without contributing to anastomotic bowel dehiscence.[74,105] Randomized clinical trials demonstrate that use of postoperative thoracic epidural analgesia with a local anesthetic–based analgesic solution allows earlier return of gastrointestinal function and fulfillment of discharge criteria.[106] When compared with those who receive epidural opioids for postoperative analgesia, patients who receive epidural local anesthetics have an earlier return of gastrointestinal motility after abdominal surgery.[106]

Perioperative use of epidural analgesia with a local anesthetic–based regimen in patients undergoing abdominal and thoracic surgery decreases postoperative pulmonary complications,[107,108] presumably by preserving postoperative pulmonary function through providing superior analgesia and thus reducing splinting behavior and attenuating the spinal reflex inhibition of diaphragmatic function.[74] A meta-analysis of 48 randomized clinical trials[109] and another large, randomized clinical trial[110] demonstrated that use of thoracic epidural analgesia with a local anesthetic–based regimen decreased the incidence of pulmonary infections and complications. However, patients who received postoperative epidural opioids, intercostal blocks, wound infiltration, or intrapleural analgesia did not have a significant decrease in the incidence of pulmonary complications.[109] A subsequent meta-analysis confirmed the benefits of thoracic epidural analgesia in decreasing perioperative pulmonary complications.[111]

Use of postoperative thoracic, but not lumbar epidural analgesia may decrease the incidence of postoperative myocardial infarction,[84] possibly by attenuating the stress response and hypercoagulability, improving postoperative analgesia, and providing favorable redistribution of coronary blood flow.[74] The finding that only thoracic epidural analgesia decreases the incidence of postoperative myocardial infarction corroborates experimental data on the physiologic benefits of thoracic epidural analgesia, such as a reduction in the severity of myocardial ischemia or size of infarction, attenuation of sympathetically mediated coronary vasoconstriction, and improvement of coronary flow to areas at risk for ischemia.[74] The use of thoracic epidural analgesia in patients undergoing cardiac surgery decreased in the risk of postoperative supraventricular arrhythmias and respiratory complications.[112]

Although postoperative epidural analgesia decreases postoperative gastrointestinal, pulmonary, and possibly cardiac morbidity, the benefits of postoperative epidural analgesia are not as evident in other areas, such as postoperative coagulation, cognitive dysfunction,[113] and immune function. Although the use of *intra*operative regional anesthesia decreases the incidence of hypercoagulable-related events (e.g., deep venous thrombosis, pulmonary embolism, vascular graft failure),[104] *post*operative epidural analgesia does not obviously decrease the incidence of hypercoagulable-related events.

The benefits of postoperative epidural analgesia are optimized when the epidural catheter is inserted in a location corresponding to the dermatomes covered by the surgical incision (i.e., catheter-incision–congruent analgesia), which results in a smaller dose of drug administered and decreased incidence of drug-induced side effects, such as pruritus, nausea, vomiting, urinary retention, motor block, and hypotension.[89] When compared with catheter-incision–incongruent epidural analgesia, catheter-incision–congruent analgesia provides earlier return of gastrointestinal function, a lower incidence of myocardial infarction,[84] and superior analgesia.[74] The ability of postoperative epidural analgesia to attenuate postoperative pathophysiology and improve outcomes also depends on the type of drugs used (opioids versus local anesthetics). Maximal attenuation of perioperative pathophysiology occurs with the use of a local anesthetic–based epidural analgesic solution. The use of a local anesthetic–based (versus opioid-based) analgesic solution is associated with earlier recovery of gastrointestinal motility after abdominal surgery[106] and less frequent occurrence of pulmonary complications.[109] Epidural analgesia is not a generic entity because different catheter locations and analgesic regimens may differentially affect perioperative morbidity.

It is unclear whether perioperative epidural analgesia may improve patient-reported outcomes.[114] Use of postoperative epidural analgesia may be associated with an improvement in postoperative analgesia and patient-reported outcomes such as patient satisfaction[31] and HRQL.[16] When compared with systemic opioids, epidural local anesthetics consistently provide superior analgesia.[79,80] Although the concept of satisfaction is complex and difficult to measure accurately, the analgesic benefits of postoperative epidural analgesia may contribute to greater patient satisfaction[31] and improved HRQL.[16]

A link may exist between the perioperative use of regional anesthesia/analgesia and a decrease in cancer

recurrence.[115] There are several hypothetical reasons why the perioperative use of regional anesthesia and analgesia would be of benefit in patients undergoing cancer surgery, including attenuation of perioperative immunosuppression and decreased use of inhaled anesthetics/opioids. A regional anesthetic-induced sympathectomy should increase blood flow to the extremities with subsequent improvement in tissue oxygenation and a potential favorable local anesthetic effect on tumor cell killing.[116] However, multiple factors may potentially affect cancer recurrence, and the impact of perioperative regional analgesic techniques on a long-term outcome such as cancer recurrence is uncertain at this time. Use of neuraxial anesthesia/analgesia for total hip or knee replacement may decrease the risk of surgical site infections compared with general anesthesia.[117]

Risks With Epidural Analgesia

The benefits of perioperative epidural anesthesia-analgesia must be weighed against the risks associated with this technique. Some complications are associated with placement of an epidural catheter, and several risks related to the use of indwelling epidural catheters (e.g., epidural hematoma and abscess) should be discussed in the context of postoperative epidural analgesia. A review of neurologic complications after regional anesthesia revealed that the rate of neurologic complications after central neuraxial blockade is less than 4 in 10,000 (0.04%); the rate of neuropathy after a peripheral nerve block is less than 3 in 100 (3%).[118] However, permanent neurologic injury after either central neuraxial or peripheral nerve block is rare in contemporary anesthetic practice.[118] Elements of routine monitoring of patients receiving neuraxial analgesia are presented in Box 98-1.

The concurrent use of anticoagulants and neuraxial anesthesia and analgesia has always been a relatively controversial issue but has been highlighted over the past decade by the increased incidence of spinal hematoma after the introduction of low-molecular-weight heparin in North America in 1993.

Different types and classes of anticoagulants have different pharmacokinetic properties that affect the timing of neuraxial catheter or needle insertion and catheter removal. Despite many observational and retrospective studies investigating the incidence of spinal hematoma in the setting of various anticoagulants and neuraxial techniques, no definitive conclusion regarding the absolute safety of neuraxial anesthesia and anticoagulation has been reached. The American Society of Regional Anesthesia and Pain Medicine (ASRA) lists a series of guidelines based on the available literature for administration (insertion and removal) of neuraxial techniques in the presence of various anticoagulants, including oral anticoagulants (warfarin), antiplatelet agents, fibrinolytics-thrombolytics, standard unfractionated heparin, and low-molecular-weight heparin.[119] The ASRA guidelines recommend that the timing of neuraxial needle or catheter insertion or removal reflect the pharmacokinetic properties of the specific anticoagulant. Frequent neurologic monitoring is essential. Concurrent use of multiple anticoagulants may increase the risk of bleeding, and the analgesic regimen should be tailored to facilitate neurologic monitoring, which may be continued in some cases for 24 hours after removal of the epidural catheter. Although the ASRA guidelines were developed with the latest available literature, these guidelines are limited by the relatively rare incidence of epidural hematoma; observational studies have occurred, during which procedures (e.g., epidural catheter removal) were performed outside the boundaries presented in the ASRA guidelines.[120] An updated version of the ASRA guidelines on neuraxial anesthesia and anticoagulation[119] can be found on the ASRA website (www.asra.com), and some of these statements address the newer anticoagulants. Anesthesiology societies outside North America have also put forth their own guidelines for regional anesthesia and different anticoagulants.[121] Finally, the risk of epidural hematoma may be different for obstetric versus surgical patients.[122,123]

Infection associated with postoperative epidural analgesia may result from exogenous or endogenous sources.[78] Serious infections (e.g., meningitis, spinal abscess) associated with epidural analgesics are rare (<1 in 10,000),[124] although a more frequent incidence has been observed (approximately 1 in 1000 to 2000).[124] Closer examination of the studies that reported a more frequent incidence of epidural abscess reveals that the patients had a relatively longer duration of epidural analgesia or coexisting immunocompromising or complicating diseases (e.g., malignancy, trauma).[78] Use of epidural analgesia in the general surgical population with a typical duration of postoperative catheterization (approximately 2 to 4 days) is not generally associated with epidural abscess formation.[89] Even though serious infectious complications are rare after short-term (<4 days) epidural infusions, there may be a relatively more frequent incidence of superficial inflammation or cellulitis (4% to 14%) and an even higher rate of catheter colonization (20% to 35%), with the proportion of positive cultures increasing with longer duration of catheterization; however, the catheter colonization rate may not be a good predictor of infection of the epidural space.[125] A practice advisory from the American Society of Anesthesiologists discussing the prevention, diagnosis, and management of infectious complications associated with neuraxial techniques has been published.[126]

Although epidural analgesia may provide superior postoperative analgesia, migration of the epidural catheter out of the epidural space and into the intrathecal, intravascular, or subcutaneous space decreases the effectiveness of this technique. The failure rate (i.e., earlier-than-anticipated discontinuation of the catheter for any reason, placement of a nonfunctioning epidural catheter or "shamdural") ranges from approximately 6% to 25%, with many centers reporting a rate between 10% and 20%, but the incidence of actual premature epidural catheter dislodgment may be less frequent (mean, 5.7%; 95% CI, 4.0% to 7.4%).[73,89] Fortunately, the rate of intrathecal and intravascular migration of an epidural catheter is most likely much less frequent than the failure rate. Despite the less frequent occurrence of intravascular and intrathecal migration of postoperative epidural catheters, use of an epinephrine-containing test dose, administration of local anesthetic in fractionated doses, and aspiration of the catheter before

bolus administration of local anesthetics may prevent complications (e.g., high or total spinal, seizures, neurotoxicity).[78] The issue of whether lower extremity compartment syndrome can be consistently masked by the use of a local anesthetic–based epidural analgesic regimen is unresolved because use of systemic opioid analgesia has also been associated with a delayed diagnosis of compartment syndrome.[127]

Peripheral Regional Analgesia

The use of peripheral regional analgesic techniques as a single injection or continuous infusion can provide analgesia superior to that with systemic opioids[128] and may even result in improvement in some outcomes.[129] A variety of wound infiltration and peripheral regional techniques (e.g., brachial plexus, lumbar plexus, femoral, sciatic-popliteal, and scalp nerve blocks) can be used to enhance postoperative analgesia. Peripheral regional techniques may have several advantages over systemic opioids (e.g., superior analgesia and decreased opioid-related side effects) and neuraxial techniques (e.g., decreased risk for spinal hematoma).[130]

A one-time injection of local anesthetic for peripheral regional techniques may be used primarily for intraoperative anesthesia or as an adjunct to postoperative analgesia. When compared with placebo, peripheral nerve blocks with local anesthetics provide superior analgesia and are associated with reduced opioid use, decreased opioid-related side effects, and improvement in patient satisfaction.[130] The duration of postoperative analgesia resulting from the local anesthetic in the peripheral nerve block varies but may last up to 24 hours after injection. An earlier systematic review indicated that local anesthetics may also provide effective wound infiltration analgesia postoperatively for a variety of procedures.[131] A more recent meta-analysis suggested that local anesthetic administered via wound catheters may not reduce pain intensity after surgery.[132]

Continuous infusions of local anesthetics can be administered through peripheral nerve catheters. Peripheral nerve catheters may be inserted by several methods, including nerve stimulation, ultrasound guidance, and paresthesia elicitation.[133] Randomized controlled trials suggest that use of peripheral regional analgesia may facilitate postoperative rehabilitation as evidenced by accelerated resumption of passive joint range-of-motion, decrease in time until discharge readiness, and earlier actual discharge from the hospital or rehabilitation center.[133,134] Continuous peripheral nerve blocks may be used in the outpatient (home) setting, typically using a portable ambulatory pump.[133] When compared with systemic opioids, use of continuous infusions or patient-controlled peripheral analgesia results in superior analgesia, decreased opioid-related side effects, and greater patient satisfaction.[128,130] The optimal parameters (i.e., local anesthetic, concentration, opioid, adjuvants, and continuous versus PCA versus intermittent boluses) for peripheral analgesia are still being determined.

Thoracic or Nonepidural Analgesia

Several nonepidural regional analgesic techniques can be used for the management of postoperative thoracic pain, including paravertebral and intercostal blocks, transversus abdominis plane blocks, interpleural (intrapleural) analgesia, and cryoanalgesia. The most promising technique appears to be a thoracic paravertebral block, which has been used for thoracic, breast, and upper abdominal surgery and for the treatment of rib fracture pain.[135] Possible sites of analgesia for a thoracic paravertebral block include direct somatic nerve, sympathetic nerve, and epidural blockade.[135] A thoracic paravertebral block can be administered as a single injection or as continuous infusion through a catheter; it may provide analgesia equal or superior to that with thoracic epidural analgesia and is a valuable alternative to thoracic epidural analgesia.[136,137] Paravertebral blocks may be especially useful in providing postoperative analgesia after breast surgery.[138] When compared with thoracic epidural analgesia, paravertebral analgesia has been shown to provide equivalent analgesia but with a better side effect profile (e.g., lower incidence of hypotension) and also a lower risk of postoperative pulmonary complications.[137,139] Continuous infusions of local anesthetics through a paravertebral catheter are preferable to intermittent boluses because the former is associated with lower pain scores.[140]

Transversus abdominis plane (TAP) nerve block is an approach for blocking the abdominal wall neural afferents to provide postoperative analgesia. Typically performed under ultrasound guidance, TAP blocks have been mostly described in adult patients (with some in pediatric patients) and used in a variety of surgical patients.[141,142] At least two systematic reviews indicate that TAP blocks may reduce postoperative morphine requirements, nausea and vomiting, and possibly the severity of pain after abdominal surgery.[143,144] Although superior early postoperative analgesia appears to occur (within 24 hours of surgery), the surgical procedures, analgesic dosing, techniques, and timing for optimal analgesia following TAP block need further examination.[141]

The analgesic efficacy and the mechanism of interpleural analgesia are no longer controversial (i.e., sensory or sympathetic block, or both). Interpleural analgesia is inferior to epidural and paravertebral analgesia for control of postoperative pain, preservation of lung function after thoracotomy, and reduction of postoperative pulmonary complications.[109] A recent systematic review demonstrated that intrapleural analgesia was inadequate for postoperative pain management.[139] Intercostal blocks may provide short-term postoperative analgesia and may be repeated postoperatively; however, the incidence of pneumothorax increases with each intercostal nerve blocked (1.4% per nerve, with an overall incidence of 8.7% per patient).[145] Like interpleural analgesia, intercostal blocks do not reduce the incidence of pulmonary complications postoperatively when compared with epidural analgesia.[109]

Intraarticular Analgesia

Local peripheral administration of opioids (e.g., intraarticular injection after knee surgery) may theoretically provide analgesia for up to 24 hours after surgery[146] and decrease the incidence of chronic pain[147] as peripheral opioid receptors are found on the peripheral terminals of primary afferent nerves and are up-regulated during

inflammation of peripheral tissues.[148] Results of the several randomized clinical trials investigating this topic have been summarized.[146] Use of a larger dose of intraarticular morphine (5 versus 1 mg) results in superior analgesia; however, there may be no advantage in the degree of analgesia provided between intraarticular and systemic opioids.[146] A subsequent qualitative systematic review found no evidence for analgesic effect of intraarticular morphine after knee arthroscopy.[149] A systemic effect of intraarticularly injected morphine cannot be excluded. A systematic review suggested that intraarticular administration of NSAIDs may provide clinically relevant peripheral analgesia.[150] Intraarticular injection of local anesthetics may provide a limited duration of postoperative analgesia, but the clinical benefit from intraarticular injection of local anesthetics is unclear.[151] Clinicians should be aware that there have been cases of glenohumeral chondrolysis reported in association with postarthroscopy infusion of local anesthetic.[152]

OTHER TECHNIQUES

Other nonpharmacologic techniques, such as transcutaneous electrical nerve stimulation (TENS), acupuncture, exercise/activity, and psychological approaches, can be used in an attempt to alleviate postoperative pain. The mechanism by which TENS produces analgesia is unclear but may be related to modulation of nociceptive impulses in the spinal cord, release of endogenous enkephalins, or a combination of these, and other mechanisms. Although the analgesic efficacy of these techniques is controversial, TENS and acupuncture may provide postoperative analgesia, decrease postoperative opioid requirements, reduce opioid-related side effects, and attenuate activation of the sympathoadrenal system. In general, all of these approaches to postoperative pain are relatively safe, noninvasive, and devoid of the systemic side effects seen with other analgesic treatment options.[153] TENS may be of benefit in providing postoperative analgesia and decreasing analgesic consumption.[154,155] Early mobilization and activity therapy improve functional outcomes following orthopedic surgical procedures[156] and are effective in reducing pain behaviors in animal models of surgical neuropathic pain. [157] Although some methodologic issues have been raised with many of the available trials and the precise role of these treatments in postoperative pain management is not clear, they represent alternative therapies to add to the clinician's armamentarium. In particular, exercise and activity programs are inexpensive and easily available therapies.

Although this chapter has focused on the neurobiology of nociception and pharmacologic treatments available for the treatment of postoperative pain, the experience of pain is complex, multifaceted, and "an unpleasant sensory and emotional experience," as defined in part by the International Association for the Study of Pain. The differential behavior response to surgical incision may be related to global (i.e., personality, gender, age, and culture) and specific (i.e., fear, depression, anger, and coping) psychological factors.[158] Cognitive therapy and behavior therapy may be efficacious in reducing pain and alleviating psychological factors associated with pain.[159] Identifying and addressing psychological factors can reduce pain, improve the efficacy of pharmacologic analgesics, and diminish patients' distress, in part through enhancement of the placebo effect.[158] Although it may have a psychological origin, the placebo response may exert part of its effects through activation of endogenous opioids and may be useful in reducing the intensity of pain.[160]

POSTOPERATIVE ANALGESIA IN SPECIAL POPULATIONS

The foregoing discussion has provided a general approach to the principles and practice of acute postoperative pain management, but this approach may need to be modified for certain populations that have unique anatomic, physiologic, pharmacologic, affective, and cognitive issues. Management of acute pain should be tailored to the specific needs of a particular population. Although each population could merit a separate chapter in some textbooks, this chapter outlines the general principles and issues associated with each population and provides references to other more extensive sources.

OPIOID-TOLERANT PATIENTS: PATIENTS WITH PREEXISTING PAIN

Opioid-tolerant patients can be categorized into three groups: (1) those who have chronic pain for which they receive opioid-based analgesic therapy, (2) those who use opioids recreationally as a result of a substance use disorder, and (3) those who take opioids for a combination of the first two reasons. Regardless of the reason the individual is using opioids, the management of their perioperative pain is considerably more challenging than those who are opioid-naive.

Even though there is no specific threshold or timeframe for when a patient becomes opioid tolerant, the U.S. Food and Drug Administration (FDA) has recently provided guidelines for defining the opioid-tolerant patient.[161] In summary, patients considered opioid tolerant are those who are regularly taking at least one of these: 60 mg oral morphine per day; 25 μg transdermal fentanyl per hour; 30 mg oral oxycodone per day; 8 mg oral hydromorphone per day; 25 mg oral oxymorphone per day; or an equianalgesic dose of another opioid for 1 week or longer.

Postoperative pain may be difficult to manage in opioid-tolerant patients because the standard approaches used for baseline assessment and assessment of response to therapy in opioid-naive or research patients are often less accurate for opioid-tolerant patients. Although opioid-tolerant patients require larger doses of analgesic medications (in addition to their baseline pain medication requirements) in the immediate postoperative period, many health care providers still do not provide adequate postoperative pain relief, in part because of the fear of addiction or medication-related side effects. In dealing with patients with chronic opioid use, health care providers often mistakenly interchange several pharmacologic terms (i.e., tolerance, physical dependence, and

addiction), a practice that may contribute to misunderstanding and inappropriate treatment decisions.

Tolerance refers to the pharmacologic property of an opioid in which an increasing amount is needed to maintain a given level of analgesia. *Physical dependence* is another pharmacologic property of opioids, characterized by the occurrence of a withdrawal syndrome on abrupt discontinuation of the opioid or administration of an antagonist. As pharmacologic properties, tolerance and physical dependence are not synonymous with the aberrant psychological state or behavior associated with *addiction*, a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm. The exaggerated fear of addiction contributes to the undertreatment of postoperative pain by health care providers; however, minimal risk of iatrogenic addiction exists with the use of opioids for pain control in patients who do not have a prior history of addiction.[162,163]

Several principles of pain assessment and treatment can be applied to the postoperative management of opioid-tolerant patients. The physician should expect high self-reported pain scores. Treatment decisions should be based on objective pain assessment (e.g., ability to breathe deeply, cough, ambulate) in conjunction with patients' self-reported pain scores. Physicians should understand the need to identify and treat two major problems—maintenance of a basal opioid requirement and control of incisional pain. Finally, physicians should recognize that detoxification is not usually an appropriate goal in the perioperative period.[164-166]

The treatment of patients with prior opioid use requires the management of the expectations of the patient, the patient's family, and the physician's surgical colleagues. The goal of inpatient management of pain in patients with chronic pain or acute-on-chronic pain is to stabilize and rationalize (if necessary) the patient's outpatient pain medication regimen. The goal is not to treat long-standing persistent pain that has been managed on an outpatient basis, because it is unlikely in the very limited time period in which you are a member of the patient's care team that you will be able to make a substantial positive difference. Therefore, several general strategies can be used for the treatment of postoperative pain in an opioid-tolerant patient or in a patient with chronic pain who is receiving opioids. Although patients with chronic pain are not synonymous with opioid-tolerant patients, many of these patients are also opioid tolerant, and the same general principles and strategies discussed earlier may be applied to these patients as well. The physician can create a treatment plan early and discuss it with the patient, surgical team, and nursing staff; replace the patient's baseline or basal opioid requirements postoperatively; anticipate an increase in postoperative analgesic requirements[167]; maximize the use of adjuvant drugs; consider the use of regional analgesic techniques; and plan for the transition to an oral regimen. The physician, patient and other providers need to be aware that the nonopioid adjuvant medications (not including tramadol, NSAIDs, or acetaminophen) may be started while the patient is an inpatient, but they are unlikely to have substantial impact on the patient's chronic pain while hospitalized. Recognizing and addressing nonnociceptive sources of distress may be especially important for patients with chronic pain.[158]

Administration of a PRN analgesic regimen alone for opioid-tolerant patients is highly discouraged because replacing the basal opioid requirement in the postoperative period can optimize pain relief and possibly prevent opioid withdrawal. Basal opioid requirements can be administered systemically (typically intravenously) until the patient can tolerate an oral analgesic regimen.[28] For example, 50% to 100% of the patient's baseline opioid requirement can be administered by continuous infusion as part of an intravenous PCA regimen, with a demand dose to cover the additional incisional pain. Conversion tables (Table 98-7) may facilitate equianalgesic conversion of opioids (i.e., different routes of administration of one opioid or conversion between two different opioids); however, these tables provide only estimations to assist health care providers in initiating opioid titration.[168]

Opioid-tolerant patients generally require increased postoperative analgesic levels, including a larger demand dose.[28,167] Patients may need frequent adjustment (e.g., two to three times each day) of the intravenous PCA demand dose or continuous infusion, depending on the analgesic requirements. Response to different opioids varies by individual, and if a decision is made to switch opioids, the choice of opioid is probably not as important as using an equianalgesic dose. Patients may experience different side effects with different opioids, and rotating to another opioid may be reasonable if the patient is not tolerating the first opioid.[169] Adjuvant drugs such as NSAIDs should be administered on a regularly scheduled basis to optimize analgesic efficacy and possibly provide

TABLE 98-7 GUIDELINES FOR EQUIANALGESIC DOSING OF OPIOID AGONISTS

Drug	Relative Strength Compared With Morphine	Equianalgesic Dose (mg)	
		Oral	Parenteral
Morphine	--	30	10
Buprenorphine	Much much stronger	N/A	0.4 (7.5 µg/hr TD)
Butorphanol	Much stronger	N/A	2
Codeine	Weaker	200	125
Fentanyl	Much much stronger	N/A	0.1 (16.5 µg/hr TD)
Hydrocodone	Equivalent to mildly weaker	30	N/A
Hydromorphone	Much stronger	7.5	1.5
Levorphanol	Much stronger	4	N/A
Methadone	Stronger	10	5
Nalbuphine	Equivalent	N/A	10
Oxycodone	Stronger	20	N/A
Oxymorphone	Stronger	10	1
Pentazocine	Weaker	150	60
Tapentadol	Weaker	100	N/A
Tramadol	Much Weaker	300	N/A

Equianalgesic doses are approximate and intended to serve only as an estimate of opioid requirements. Actual doses may vary, in part because of wide interpatient variability in response to opioids. Doses should be individualized and gradually titrated to effect. *TD*, Transdermal.

an opioid-sparing effect. Use of regional analgesic techniques with neuraxial opioids may provide excellent analgesia in opioid-tolerant patients while theoretically preventing withdrawal symptoms, although the clinician should be prepared to diagnose and treat perioperative opioid withdrawal in these patients.

After the patient is tolerating oral intake, conversion from intravenous opioids to oral form that would be more suitable for discharge home may be initiated. Opioid-tolerant patients can generally be converted to a combination of a regularly administered, controlled-release formulation of opioid (i.e., sustained-release morphine) and a short-acting, immediate-release opioid on a PRN basis. Although conversion of intravenous opioid to an oral form can be accomplished over a period of 1 to 2 days in opioid-tolerant patients, this process may take several days in extremely difficult cases. In patients with a relatively high basal requirement of intravenous opioid (e.g., high, continuous background infusion of intravenous opioid PCA), clinicians should be aware not to abruptly discontinue the intravenous infusion of opioid during this transition but ideally decrease the high basal requirement of intravenous opioid in a stepwise fashion to account for the slower onset of the sustained release. Converting from an intravenous to an oral form of opioid is not an exact science, and the conversion tables available can serve only as a rough guide because of significant interpatient and intrapatient variability in the sensitivity to opioids, lack of complete cross-tolerance between opioids (which may lead to greater than anticipated potency of a new opioid), and changes in the level of pain, which may rapidly decrease in the immediate postoperative period.[168] Because of these factors, conversion of approximately 50% to 75% of the equianalgesic dose to a sustained-release preparation of opioid or a transdermal fentanyl patch, with the remainder converted to a short-acting opioid delivered on a PRN basis, may be a reasonable starting point in patients whose pain is reasonably controlled, although additional titration may be necessary.

Although opioids are most commonly used in these patients, with consultation of the inpatient pain services (if available), the physicians can consider the use of analgesic (low-dose) ketamine.[170] Ketamine can be given as a basal infusion as a part of the ketamine PCA or a combination ketamine and opioid PCA, subcutaneously, or orally. Ketamine may have significant advantages (such as greater analgesic response, less frequent rates of respiratory depression, and minimal impact on the gastrointestinal system) over further opioid use in the opioid-tolerant or chronic pain patient in the postoperative setting.

Patients taking medications containing buprenorphine have some challenges similar to those of opioid-tolerant or chronic pain patients in the perioperative setting, but these patients also have the added difficulties associated with the partial μ-opioid agonist pharmacodynamics of buprenorphine. Although buprenorphine is a partial agonist, when given in conjunction with a full μ-opioid agonist, it functions as a pharmacologic antagonist. Further, with buprenorphine, the time to dissociation from the opioid receptor is variable; therefore, when used in combination with a full agonist, it is challenging to time the switch from antagonism of the μ-opioid receptor action to the full agonism of the morphine, oxycodone, hydromorphone, and other similar opioids. This can create a dangerous situation in which a previously appropriate dosage of one of the full agonists becomes enough to result in respiratory depression or other dose-related adverse events. Although it is ideal to not take buprenorphine for 2 days before surgery, this is often not feasible in many surgical settings, in which patients are first seen by the anesthesiologist directly before the operation. In situations in which patients have not discontinued their buprenorphine therapy well in advance of their surgery, the patient should receive baseline buprenorphine via sublingual or transdermal routes. Alternatively and if necessary, convert the patient's buprenorphine requirements to an intravenous equivalent while the patient is in the immediate perioperative period. Although the patient is maintained on a stable dosage of buprenorphine, additional full agonist opioids may be titrated to pain reduction, or alternatively, nonopioid adjuvants (including clonidine, ketamine, or dexmedetomidine) can be used instead of opioids for the patient's postoperative pain.

PEDIATRIC PATIENTS

As in adults, undertreatment of acute pain occurs in a substantial percentage of children.[171] Pediatric patients continue to be undertreated.[167] In addition to anatomic, physiologic, pharmacodynamic, and pharmacokinetic differences between children and adults, there are barriers unique to pediatric patients that may interfere with effective postoperative pain control. Control of postoperative pain is important in pediatric patients because poor pain control may result in increased morbidity or mortality.[172]

Some of the most important barriers to pain control in pediatric patients are the myths that children and infants do not feel pain, that pain is not remembered, and that there are no untoward consequences of experiencing pain.[171] These incorrect assumptions may hinder management of pediatric pain. Because of developmental, cognitive, and emotional differences, assessment of pain in pediatric patients can be difficult. Pediatric patients may have difficulty conceptualizing and quantifying a subjective experience such as pain. The lack of routine assessment and reassessment of pain may interfere with effective acute pain management.[171] Special scales are available to assist young children in self-reporting of pain; however, interpretation of behavior and physiologic parameters may be used to estimate pain intensity in preverbal children or those who cannot self-report their pain. Furthermore, assessing pain in children with intellectual disabilities presents unique challenges.[173]

A plan for postoperative pain management should be discussed with the family and patient before surgery because pediatric patients may have many anxieties about pain and analgesic use after surgery. In general, the oral route of analgesic administration is preferred for mild to moderate pain. Intravenous or regional analgesia is appropriate for moderate to severe postoperative pain.[171,174] Use of intramuscular injections is strongly discouraged because of the pain associated with injection and variable absorption of analgesic medications. Fear of needles may

inhibit control of postoperative pain because pediatric patients may choose to suffer in silence rather than receive a painful and anxiety-provoking intramuscular injection. Addressing medication-related side effects is important to alleviate patient-related distress and improve compliance with the postoperative analgesic regimen.

Use of an intravenous PCA device allows individualization of analgesic requirements and offers pediatric patients autonomy. Children as young as 4 years have the cognitive and physical capability to appropriately use an intravenous PCA device.[175] Although morphine is the standard by which other opioids are compared, morphine does not appear to have an analgesic advantage over other opioids (e.g., hydromorphone) when given in equianalgesic doses. Because of toxicity from its metabolite and much better alternatives, meperidine should not be used in the pain management of pediatric (or adult) patients.[171] A meta-analysis examining whether the addition of a background or continuous infusion to an intravenous PCA opioid regimen would be associated with an increased risk of respiratory depression indicated that the addition of a continuous or background infusion was associated with a higher incidence of respiratory events in adult but not in pediatric patients.[29] Nurse- or parent-controlled analgesia is also effective and may be used in certain circumstances, but close monitoring of the patient may be needed because significant respiratory depression occurs in approximately 1.7% of patients (although some data suggest that children receiving PCA by proxy do not have a higher incidence of adverse events compared with those not receiving PCA by proxy[176,177]). For pediatric patients unable to use intravenous PCA, continuous infusions or intermittent intravenous administration of opioids is effective in providing postoperative analgesia.[178] Although respiratory depression may occur with opioids regardless of the route administered, clinically significant respiratory depression in pediatric patients is relatively uncommon.[175] Unlike adults, pediatric patients do not appear to exhibit multiple episodes of clinically significant oxygen desaturation postoperatively when treated with neuraxial, intravenous, or intramuscular opioids.[179] Use of nonopioid analgesic agents, such as NSAIDs or acetaminophen, may improve overall analgesia, reduce the amount of opioid used postoperatively, and decrease some opioid-related side effects such as postoperative nausea and vomiting.[180] For rectal administration of acetaminophen postoperatively, a larger dose (40 mg/kg followed by three doses of 20 mg/kg at 6-hour intervals) than that previously recommended may result in appropriate serum analgesic levels.[181] In addition, other analgesics such as ketamine and tramadol may be considered as adjunct analgesic drugs for the treatment of postoperative pediatric pain in specific clinical situations.[66,182]

Peripheral and neuraxial regional analgesic techniques are commonly used and effective for acute pain management in pediatric patients. The use of ultrasound-guided regional analgesic techniques has been described and may further increase the use of efficacious regional analgesic techniques for pediatric postoperative pain management.[183] One of the more frequently used techniques is epidural analgesia, which can be delivered as a single dose or by using a continuous-infusion catheter technique. The catheter may be inserted (typically using general anesthesia) anywhere along the epidural space (e.g., thoracic, lumbar, caudal), but the caudal approach seems to be the most common technique because the catheter can be easily advanced cephalad to the appropriate dermatome. Local anesthetics or opioids, or both, can be administered through the epidural catheter or needle to provide effective postoperative analgesia. Although epidural (caudal) analgesia may be safely administered to neonates, the clinician should recognize that the maximal continuous infusion dose is probably smaller than that in older children because of lower levels of α_1-acid glycoprotein (which binds local anesthetics) and diminished ability of the relatively immature liver to metabolize amide local anesthetics.[184] The addition of adjuvant drugs, such as clonidine, in the epidural infusion may enhance postoperative analgesia.[185]

Continuous epidural (caudal) analgesia may be used in the postoperative setting, and the infection rate associated with continuous epidural analgesia is extremely low despite the relatively high colonization rate.[125] In addition, continuous peripheral catheter techniques can be used effectively in pediatric patients. Regional analgesic techniques may be useful in providing analgesia for wound incision (e.g., herniorrhaphy or orchiopexy), thoracotomy, and orthopedic procedures.[186] Local anesthetics may also be administered topically to provide analgesia. Despite a lack of data comparing outcomes for regional analgesia versus systemic opioids in the pediatric population, some evidence suggests that the use of epidural analgesia is associated with improvement in some outcomes such as earlier tracheal extubation, return of gastrointestinal function, and length of hospital stay.[187] Finally, other modalities such as acupuncture may be a potentially useful adjunct for the treatment of pediatric postoperative pain, although further large-scale randomized, controlled clinical trials are needed to define the role of these modalities in the treatment of pediatric postoperative pain.[188]

OBESITY AND OBSTRUCTIVE SLEEP APNEA

Patients with obesity and obstructive sleep apnea (OSA) may be at a more frequent risk for postoperative complications. Obesity and OSA are separate disease states, but some association exists between the two because OSA occurs in a relatively higher percentage of obese than nonobese patients.[189] Epidural analgesia may decrease postoperative complications in obese patients[190]; yet the optimal postoperative analgesic and monitoring regimen for patients with OSA is not clear. Data suggest that sleep is disrupted in the immediate postoperative period and may influence postoperative morbidity and patient-oriented outcomes.

Obesity is defined as a body mass index (BMI) of greater than 30 kg/m^2, with morbid and supermorbid obesity defined as BMI of greater than 35 kg/m^2 and 55 kg/m^2, respectively. The prevalence of obesity has continued to increase over the past decades to epidemic proportions (including children and adolescents) and is similar across different ethnic, educational, and income

groups.[191-194] Although obese patients do not necessarily have OSA, obesity is the most important physical characteristic associated with OSA. Approximately 60% to 90% of OSA patients are obese, and at least 5% of morbidly obese patients have OSA, which is defined as more than five episodes per hour of cessation of airflow for more than 10 seconds despite continued ventilatory effort.[189] Approximately 4% of men and 2% of women (18 million Americans overall) have OSA, and OSA is underdiagnosed in up to 95% of persons.[189] Patients with OSA are generally at higher risk for pulmonary hypertension, cardiomyopathy, systemic hypertension, and possibly myocardial infarction.[195] The pathophysiology of airflow obstruction is related primarily to upper airway pharyngeal collapse, including the retropalatal, retroglossal, and retroepiglottic pharynx, during sleep, especially during rapid eye movement sleep.[189] During these obstructive episodes, OSA patients may exhibit hypoxia, bradyarrhythmias or tachyarrhythmias, myocardial ischemia, abrupt decreases in left ventricular stroke volume and cardiac output, or increases in pulmonary and systemic blood pressure.[195]

Based on our understanding of the pathophysiology of OSA, postoperative pain management can be difficult in this population. Patients with OSA may be at an increased risk for respiratory arrest.[196] Although it is not clear whether OSA will increase the risk of postoperative hypoxemia when compared with other morbidly obese subjects without OSA, morbidly obese subjects (with or without OSA) most likely will experience frequent oxygen desaturation episodes in the postoperative period even with the use of supplemental oxygen.[197] Use of sedative doses of benzodiazepines and opioids may result in frequent hypoxemia and apnea, which may be especially dangerous in OSA patients.[196] Use of nonopioids (e.g., tramadol, dexmedetomidine) or an opioid-sparing technique may limit some of the respiratory-related events postoperatively; this is supported by the fact that the rate of respiratory events per hour were related to postoperative morphine dose.[198] The risk for respiratory depression and arrest may be attenuated by optimizing the use of NSAIDs or nonopioid adjuvants (including clonidine, ketamine, dexmedetomidine) and by completely avoiding benzodiazepines and epidural analgesia with a local anesthetic–based regimen. Epidural and systemic opioids may be associated with sudden postoperative respiratory arrest.[196,199] Furthermore, use of regional analgesic techniques (e.g., thoracic epidural analgesia) may be of benefit in facilitating the recovery of spirometric values in obese patients.[200]

The American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea created guidelines that include recommendations for postoperative analgesia in patients with OSA.[201] Although the consultants acknowledged that the conclusions regarding postoperative analgesic options were based on insufficient literature evaluating the effects of various analgesic techniques, the presence of equivocal literature regarding the use of epidural opioids versus intramuscular or intravenous opioids in reducing respiratory depression, and insufficient literature regarding the addition of a basal infusion to systemic patient-controlled opioids, the consultants nevertheless recommended that regional techniques rather than systemic opioids be used in an attempt to reduce the likelihood of adverse outcomes in patients at increased perioperative risk from OSA.[201] In addition, the consultants recommended the exclusion (versus inclusion) of opioids from neuraxial postoperative analgesia to reduce perioperative risk and the use of NSAIDs to reduce adverse outcomes through their opioid-sparing effect. The consultants were equivocal regarding whether avoiding a basal infusion of opioids in patients with OSA reduces the likelihood of adverse outcomes.[201] Unfortunately, randomized clinical trial data is lacking to provide definitive high-quality evidence-based recommendations for the provision of postoperative analgesia to OSA patients.

INPATIENT PAIN SERVICES

The terms acute pain service (APS) or acute pain medicine (APM) are not synonymous with the terms regional anesthesiology pain service (RAPS) or perioperative pain service (PPS). Each term describes a unique role, and the terminology can be confusing to other physicians in the health care system. APS/APM is a more comprehensive service than a perioperative service. APS/APM addresses all inpatient acute pain issues, including perioperative pain, medical pain, and acute-on-chronic pain, such as occurs with sickle cell disease, pancreatitis, and acute exacerbations of inflammatory bowel disease or other condition requiring medicinal or catheter-based techniques for pain relief. PPS takes care of only perioperative pain patients with the same techniques, and RAPS addresses only those patients with a catheter placed by an anesthesiologist for postoperative pain. Which type of service each hospital provides depends greatly on the local expertise, the local financial resources available, and the patient population. Chronic pain services developed from the needs of patients in hospitals with the less-comprehensive or RAPS/PPS-type of pain service because these services have a very restricted treatment group. As academic regional anesthesiologists have expanded their roles to include that of the perioperative pain physician or the acute pain medicine physician, they have developed services that encompass all inpatient pain concerns, and the role or necessity of the primarily outpatient pain medicine physician (commonly referred to as the chronic pain physician) in the hospital has been reduced.

Although there are several models for the development of APS/APM, the key organizational aspects are similar (Box 98-2). Development and maintenance of APS/APM requires commitment and financial support at the national and local (institutional and departmental) level. In the United States, a dichotomy exists at the national and third-party payer levels between the requests for improved inpatient pain control (along with the introduction of practice guidelines or expanded roles for acute pain services) and the decreased reimbursement for the provision of such services. Because there is a substantial financial burden associated with the establishment of an inpatient pain service, large-volume or larger hospitals may be more likely to have these services and access to more high-tech analgesic techniques such as regional

BOX 98-2 ***Organizational Aspects of an Inpatient Pain Medicine Service***

EDUCATIONAL ACTIVITY

Anesthesiologists
Residency-fellowship teaching (if applicable)
Health insurance carriers
Hospital administrators
Nurses
Patients and families
Pharmacists
Surgeons

ADMINISTRATIVE ACTIVITY

Economic issues
Evaluation of equipment
Human resources: pain service personnel, administrative-secretarial support
Institutional administrative activity
Quality improvement and assurance
Research (if applicable)

NURSING

Continuing education and in-service training
Defining of roles in patient care
Nursing policies and procedures
Pain service nurse (if applicable)
Quality improvement and assurance

DOCUMENTATION

analgesia.[202] Formal inpatient pain services using postoperative pain protocols are more likely to be present in academic/teaching hospitals compared with nonteaching hospitals.[203] Whether inpatient pain services actually improve outcomes is unclear. Two earlier systematic reviews have examined the impact of acute pain services on patient outcomes,[100,204] and although both systematic reviews suggest that the introduction of acute pain services is associated with a decrease in pain scores, the effect of acute pain services on the incidence of analgesic-related side effects (e.g., nausea, vomiting), satisfaction, and overall costs is uncertain. Despite the direct costs (e.g., personnel, equipment, medication) associated with managing an acute pain service, no properly conducted pharmacoeconomic study is available to examine the cost effectiveness of an acute pain service. Use of postoperative epidural analgesia in the context of acute pain services may decrease the cost of patient care through shorter intensive care unit stays and a decreased rate of complications.[10] Nevertheless, a randomized controlled trial comparing an anesthesiologist-led, nurse-based acute pain service group with patient-controlled analgesia versus a control group with systemic boluses of opioid analgesia noted that an acute pain service was likely to be cost effective when the role of the acute pain service was extended to a specific group of major surgical procedures.[205]

A dedicated inpatient pain service allows anesthesiologists to extend their presence in the field of perioperative medicine, although there is no universal agreement on how to provide these services in a financially viable way.[206] This represents one of the numerous challenges that face the development of these services. If that service becomes valuable to the local medical scene, financial support will almost always follow in one way or another. As inpatient acute pain medicine services continue to evolve into comprehensive inpatient pain medicine services, there may be less need for a separation of acute and chronic pain services for inpatient pain care. The elimination of this duplication and the indeterminate roles of service(s) can reduce costs and improve continuity of patient pain care. Despite the costs associated with implementation of a comprehensive inpatient pain service, these services provide a valuable resource at the individual, institutional, and societal levels. With the development of the APS/APM, we now have different training goals for the traditional regional anesthesiology fellowships, including more formal education in chronic pain conditions and management of these conditions while the patient is hospitalized with acute illness. This would involve education on the medical management of these conditions in the short-term, maintenance of the patient's long-term therapies, and knowledge of how these long-term therapies interact with acute pain management.

With skills in regional anesthetic techniques and knowledge of the neurobiology of nociception and the pharmacology of analgesics and local anesthetics, as well as specialty education in the treatment of acute and chronic pain conditions, anesthesiologists are recognized leaders in perioperative pain relief and the development of acute pain services. Provision of inpatient analgesia, along with other services such as critical care medicine and preoperative evaluation, is highly compatible with the emerging identity of anesthesiologists as perioperative physicians and enhances the role of anesthesiologists as valued consultants outside the operating room.

Chapter 99

Cognitive Dysfunction and Other Long-term Complications of Surgery and Anesthesia

LARS S. RASMUSSEN • JAN STYGALL • STANTON P. NEWMAN

Key Points

- The selection, measurement, and analysis of neuropsychological tests will influence findings with postoperative cognitive dysfunction (POCD). Patients' subjective reports after surgery are unrelated to assessed neuropsychological change and appear to be driven by mood. Good evidence exists for POCD after cardiac surgery in which the mechanism is multifactorial but seems to include microembolization. POCD after major noncardiac surgery occurs, although the mechanisms are less clear than after cardiac surgery. Increased age is a risk factor for POCD (see Chapter 80).

Brain function is clearly altered immediately after anesthesia and surgery, as manifested by depressed level of consciousness and impairment of attention, memory, and reaction time. Patients also may experience complete amnesia for several hours after anesthesia despite appearing to be completely awake. Consequently, patients often ask the same questions on a repetitive basis. Because of these issues, patients should be accompanied by an adult during transportation and throughout the first postoperative night whether in a hospital or after outpatient surgery.

When brain function returns to normal after anesthesia is not clear. If all the difficulties were due to the anesthetic, cognitive function should have recovered to a preoperative level of functioning soon after termination of the administration of anesthesia. If the eliminated anesthetics were the sole criteria, inhaled anesthetics and propofol would differ from slowly eliminated hypnotics, such as barbiturates and benzodiazepines. However, anesthetics and their concentrations (dose) are among the many factors of importance for recovery (see also Chapter 30). The duration of recovery of cognition after anesthesia and surgery is multifactorial and depends on the type of anesthesia used, type of surgery, and characteristics of the patient. In some individuals, cognitive recovery is rapid (within a matter of hours), whereas in others brain function may be disturbed for a much longer time. The concept of postoperative disturbance in cognition is not new and has often been referred to as postoperative cognitive dysfunction (POCD). The term is used variably and should be distinguished among the following three types of cognitive deterioration after surgery:

1. Delirium is usually easily recognized, being an acute condition with fluctuating course, characterized by disturbances in attention combined with either a change in level of consciousness or disorganized thinking. The duration is usually a few days, and the degree of severity ranges from mild to severe.
2. Short-term cognitive disturbance may be apparent in the days after surgery. This occurs relatively frequently and may be due to a combination of factors, including surgery and anesthetics. This cognitive disturbance is of short duration and does not persist beyond a few days after surgery. A neuropsychological assessment is an excellent choice, but frequently screening tests such as the Mini–Mental State Examination (MMSE) have been used. Some studies have assessed POCD in the first few hours and days after anesthesia. The results from some of these studies are described in this chapter.
3. What we consider true POCD is a subtle deterioration in cognitive function, lasting for weeks, months, or longer; and neuropsychological testing is needed for verification. It can be considered to be a mild cognitive disorder characterized by impairment of memory, learning difficulties, and reduced ability to concentrate.

All of these different forms of postoperative cognitive disturbance are to be distinguished from dementia. Dementia is a syndrome that is due to disease of the brain, usually of a chronic or progressive nature, in which profound disturbance occurs in multiple higher cortical functions, including memory, thinking, orientation, comprehension, calculation, learning capacity, language, and judgment. Consciousness is not clouded. The impairment of cognitive function is associated with

a deterioration in emotional control, social behavior, or motivation. Dementia is usually diagnosed only if the condition has been present for at least 6 months.

DETECTION OF POSTOPERATIVE COGNITIVE DYSFUNCTION

The incidence of POCD varies widely across studies even though the conduct of surgery and anesthesia may be similar. Besides individual patient differences, methodologic issues such as the choice of test battery, the time of postoperative assessments, and the method of analysis to determine POCD may be the source of differences.

NEUROPSYCHOLOGICAL TESTING IN SURGICAL PATIENTS

Neuropsychological assessment tools are used to objectively measure cognitive function. The tests used in the detection of POCD, unlike many employed in a clinical assessment, must be sensitive to change. The assessment tools should be sensitive to potentially diffuse brain injury; therefore, these measures should form a battery of tests that attempt to cover a range of cognitive domains, such as memory, attention, concentration, and perceptual and motor ability. Because of the time constraints imposed by the surgical environment, the time set aside to conduct these tests is often limited; therefore, the battery of tests by necessity frequently represents a compromise. A review of POCD studies in noncardiac surgery[1] indicated that 70 different neuropsychological assessment tools had been used in conjunction with 9 composite batteries, with between 1 and 13 tests used per study. The domains most often assessed were memory and learning. However, differences in the number of tests used can be problematic, because when more tests are used, dysfunction is more likely to be detected. However, even the definition used to determine whether POCD is present varies. Using a lengthy battery of tests is a problem, because they can cause fatigue in patients. Maintaining patient interest is often achieved by the variety of tests employed, but, in addition, interest can be maintained by alternating paper and pencil, computerized, manual, and verbal tasks.

Early studies investigating POCD often used traditional intelligence tests such as the Wechsler Adult Intelligence Scale (WAIS or WAIS-R) or screening tests such as the MMSE. Although these batteries are highly reliable, they are insensitive to the more subtle changes that may occur postoperatively.[2,3] These batteries have been replaced by many neuropsychological assessment tools designed for repeated assessments, many of which have been computerized to ease administration and improve standardization. Assessments are performed by a range of health care and non–health care professionals. The assessment of brain function requires expertise, particularly in how to present the tests and address patient responses. Ideally, the tests should be administered by the same trained neuropsychologist in the same quiet environment at each testing session.

Timing of Assessments

A very important issue regarding the measurement of POCD is the timing of assessments. The timings of preoperative assessments have varied widely, ranging from within weeks of surgery to 1 day before surgery or even the day of surgery. Patients are frequently anxious about surgery and anesthesia. Although preoperative anxiety is not apparent on neuropsychological tests that have been employed in most POCD studies, whether levels of both anxiety and depression may have an impact on the cognitive tests employed should be assessed.

Cognitive problems are frequently observed and often transitory in patients in the immediate postoperative period. These early assessments may well be detecting a transient disturbance of cognition. The assessments conducted postoperatively may be influenced by general postoperative readjustment, opioids, pain, and fatigue. Assessments conducted later in the recovery period (at least 4 weeks after surgery) are more likely to detect a persistent and clinically important change.

A relevant question is whether the early indications of cognitive disturbance are in any way predictive of longer term difficulties in cognition. Early predischarge assessments may predict longer term decline,[4-6] but the association is neither simple nor clear.

Analysis

Many methods can measure and define dysfunction. Some studies have used a significant difference between postoperative and normative scores[7] and others a cutoff on a screening measure.[8-11] In a third approach, two different surgical and anesthetic groups were compared.[12,13] A fourth approach compared a surgical group and a control group.[14,15] In other studies, a fifth approach analyzed neuropsychological test data as multiple comparisons of variables in the test battery. This approach provides the sensitivity to detect even small differences, but the risk for a type 1 error is high. In addition, this analysis is not well suited to address whether deterioration has occurred, because it is based on group means rather than individual change; no incidence of cognitive decline can be calculated.[11,16]

Many researchers have adopted a sixth method that uses an "individual change" approach in which each participant acts as the control. Here the participant's score postoperatively is compared with the preoperative score. Then a statistically defined criterion is used to rate the participant as having or not having POCD. However, this statistically defined criterion is not uniform over studies; for example, Shaw and associates[17] defined POCD as a decline in performance equal to or more than 1 standard deviation (SD) from the preoperative score in 1 or more neuropsychological tests, Yet, this same decline needed to be present in two or more tests before Treasure and co-workers[18] rated the participant as having POCD. Other investigators have used the same decline of 1 SD but in 1 of 21 tests and 4 of 21,[19] and yet others have defined POCD as being a 20% decline in 20% of tests.[20] The advantage of this binary approach is that it defines and categorizes individual performance into an entity that appears meaningful in a clinical environment and is easily understood. However, these definitions are statistically derived and have no intrinsic meaning or relationship to brain injury. Another disadvantage is that

these methods take into account only deterioration without considering improvement. Because the neuropsychological tests used in studies of the detection of POCD should be sensitive to change, they are amenable to repeated administration. However, if two assessments are conducted with only a short time between them, learning can occur. This may be due to an increased familiarity with the tests or differing strategies employed when completing the assessments. Although many attempts are made to reduce these learning effects, such as use of parallel equivalent forms, it is almost impossible to remove them from repeat testing. Perhaps, one measure of cerebral damage is the inability to learn a task or strategy that is the underlying basis of practice effects. This learning has been apparent in many POCD studies.[9,21] Therefore, the form of analysis used should take into account any learning, or failure to learn, occurring postoperatively.

One such study that took learning into account was that of Williams-Russo and associates,[22] who examined individual change after establishing a clinically important difference score for each test. When studies have employed a control group, the effect of learning can be assessed. The multicenter International Study of Post-Operative Cognitive Dysfunction (ISPOCD) group[23] compared the mean of the neuropsychological test score change obtained from a healthy control group over three assessments to that of a surgical group. The mean of the control group changes was used as an estimation of learning. The mean was subtracted from the surgical participants' change score and the result divided by the SD of the corresponding change in the control group to obtain a Z score for each test. Using a Z score allows the scores for each individual test to be combined to obtain a composite neuropsychological score. The authors also applied a cutoff score to identify POCD, which they defined as when the Z scores on two individual tests or the combined Z score reached 1.96 or more (the higher the score, the more deterioration).

The definition of what defines a control group is sometimes not obvious. Using a control group strengthens a study considerably and allows the influence of variables such as learning to be assessed, yet what constitutes an *appropriate* control group? POCD studies have used various types of control groups, such as healthy volunteers, friends, and relatives of the participants under study; patients with other conditions; and patients with the same condition but not undergoing surgery.[24,25] However, in POCD, no ideal control exists. For example, using healthy volunteers fails to take account of any nonspecific effects of having the condition on cognition. Using patients with different conditions as controls assumes equivalence in cognition and learning between the conditions of the control and that of the groups of interest. When considering participants with the same condition who do not undergo surgery because of either a surgical decision or patient choice, the groups could differ on important clinical factors because the allocation to groups is not random.

LIMITATIONS OF NEUROPSYCHOLOGICAL STUDIES

Patients need to be cognitively able to complete neuropsychological tests at baseline; therefore, only patients without preoperative brain disease have been included in these studies. Also, patients undergoing emergency procedures have not been studied owing to difficulties with obtaining a reliable evaluation preoperatively.

In these studies, especially the long-term follow-up studies, some patients die or are too ill to return to be assessed and, in addition, some choose not to participate in follow-up. In some cases, those who are particularly well and have returned to work may see no purpose in further contact and are lost to follow-up. The attrition is unlikely to be random but may be more influenced by travel distance and inconvenience. Not unexpectedly, attrition rates are less for shorter follow-up.[1] Sicker patients are more likely to be unavailable for follow-up.[25] Attrition is more frequent among those with lower intelligent quotients[5] and lower levels of education.[26] Perhaps the incidence of POCD would be higher or different if all patients had been assessed.

SUBJECTIVE COGNITION AND PROXY RATINGS OF COGNITIVE CHANGE

Although neuropsychological tests are the most frequently used approach to detect POCD, another method sometimes employed is self-report of cognitive changes.[27-30] These types of studies have used measures such as the Cognitive Failures Questionnaire, the Cognitive Behavior Rating Scale, the Cognitive Difficulties Scale, or interviews and have reported subjective cognitive dysfunction after surgery. For example, Khatri and co-workers,[28] using the Cognitive Difficulties Scale, found that 16% of patients rated themselves as having cognitive difficulties 6 weeks after coronary artery bypass graft (CABG) surgery. Also, comparing local anesthesia with general anesthesia, Ward and associates[30] found that a statistically significant impairment of perceived cognitive function using the Cognitive Failures Questionnaire was reported by patients who had undergone general anesthesia but not those who had undergone local anesthesia 3 days previously.

Although studies have been conducted to ascertain the reliability of proxy respondents in relation to quality of life of patients in a range of clinical cohorts,[31] very little research has been conducted regarding cognition. Thornton and associates[32] found that cognitive changes were likely to be noticed by the patient's spouse or a close relative. Another study by Bergh and associates[33] found that a spouse's ratings of the patient's concentration and memory were in agreement with that of the patient. A clear relationship between patients' subjective reports and formally assessed cognition has not been found. Many studies have found a stronger relationship between mood and patient perception of cognitive changes after surgery and anesthesia than between neuropsychological test scores and subjective reports,[28,34-37] with patients who are more anxious and depressed reporting more cognitive problems. This may be due to patients who are emotionally distressed forming a negative information-processing bias, which in turn leads to distorted perceptions of cognitive performance.[28,34,36]

INCIDENCE AND RISK FACTORS FOR POSTOPERATIVE COGNITIVE DYSFUNCTION AFTER CARDIAC SURGERY

The incidence of POCD after cardiac surgery (coronary artery bypass, valve replacement or repair, or both) is 50% to 70% in the first postoperative week, 30% to 50% after 6 weeks, and 20% to 40% at 6 months and 1 year (see also Chapter 67).[38] This variability is, as discussed previously, due in part to the problems of methodology, such as differing neuropsychological tests used, timing of assessments, and definitions of decline. In an attempt to reduce this variability, a consensus meeting developed guidelines for neuropsychological tests conducted to assess cardiac POCD.[39]

Despite variability in incidence, timing, types of tests, and analysis, a general consensus appears to exist that POCD after cardiac surgery does occur in a proportion of patients. The cause is probably multifactorial, although the use of cardiopulmonary bypass (CPB) often has been implicated.

INTERVENTIONS TO REDUCE THE INCIDENCE OF COGNITIVE DECLINE IN CONNECTION WITH CARDIAC SURGERY

Strategies to reduce the incidence of cerebral complications after cardiac surgery are based on perceived problems (see also Chapter 67). Significant risk factors include advanced age (see Chapter 80), untreatable poor left ventricular function, and duration of CPB. Of these, only the last factor is modifiable by either changing the management of CPB and related techniques or avoiding CPB completely.

CPB involves numerous violations of normal physiology. The length of time on bypass has tended to be related to POCD, suggesting that something in the CPB procedure is deleterious to the brain.[40,41] Important intraoperative causative agents are cerebral microemboli, which can be either particulate (e.g., atheroma, fat, platelet aggregates) or air. Microemboli occurring in the cerebral circulation can be detected noninvasively using continuous transcranial Doppler imaging of the middle cerebral artery. In this technique, the number of microemboli is related to the length of time on bypass. Microemboli found in the brains of patients who have died soon after cardiac surgery are related to the length of time on CPB.[42] However, the relationship between POCD in cardiac surgery and microemboli is not always clear, with some studies finding an association[43-45] and others not.[46-48] This relationship is complicated by a range of factors, including the size and final distribution in the brain of the microemboli. This final location of the microemboli is an important factor because they may be lodged in an area not covered by the neuropsychological tests used or in an area less important for cognition. Presumably, solid microemboli are more likely to cause damage than gaseous microemboli, but no clear evidence supports this conclusion.

MANAGEMENT OF CARDIOPULMONARY BYPASS

pH Management

Management of pH during hypothermia can be carried out as pH-stat or α-stat management (see also Chapters 54 and 67).[49] α-Stat management may lead to better neurologic and cognitive outcomes. Stephan and coworkers[50] found marked cerebral hyperemia and an increase in neurologic events 7 days after surgery when using pH-stat management. Although Bashein and colleagues[51] found no difference in neuropsychological test outcome between these two techniques, both Murkin and associates[52] and Patel and colleagues[49] have shown that α-stat is associated with less neuropsychological test result deterioration than that with pH-stat management.

Temperature

Hypothermia can prolong the safe period of circulatory arrest (see also Chapter 54). Hypothermic perfusion has been used routinely for both valve and CABG surgery (see also Chapter 67). Recently, normothermia and normothermic cardioplegia have been used for myocardial protection, but neuroprotection may be compromised. Studies produced conflicting results, with some showing that normothermic perfusion may be potentially harmful[53-55] and others finding no difference.[56-58] Because a small decrease in temperature is neuroprotective, the failure to find an advantage for hypothermia in clinical trials is surprising. However, brain hypothermia may not be guaranteed in all patients and the process of rewarming to normothermia may be harmful. Neurons may be injured by rewarming to 38° C. Perhaps rapid rewarming may force anesthetic and other gases out of solution and thereby produce microemboli. However, Buss and associates[59] found no effect on neuropsychological test outcome of rewarming temperature exceeding 38° C in contrast to lower temperatures. Nathan and colleagues[60] found that hypothermia may be cognitively beneficial.

Temperature regulation in the postoperative period is not clear. Grocott and co-workers[61] examined POCD in relation to temperature in the first 24 hours after surgery. Although they found no association between the area under the curve above 37° C during this period, they did find a direct relationship between POCD at 6 weeks after surgery and the maximum temperature achieved.

Arterial Line Filtration

Arterial line filters, which are an optional addition to the CPB circuit, are designed to prevent extraneous matter in the circuit from entering the patient (see also Chapter 67). Two studies found that the number of microemboli detected in the middle cerebral artery was significantly reduced when an arterial line filter was used.[62,63] Although two earlier studies reported that arterial line filters made no difference to cognitive outcome,[64,65] a further study by Pugsley and co-workers[63] found less POCD in the filter group (46% filter versus 71% nonfilter; $P = .05$) 8 days after surgery and (8% filter versus 27% nonfilter, $P = .03$) at 8 weeks. The two earlier studies conducted their assessments only during the acute in-hospital phase, which may have confounded the results, whereas Pugsley and co-workers[63] were able to demonstrate an even more pronounced effect at 8 weeks.

Pulsatile Versus Nonpulsatile

Although nonpulsatile CPB is the most commonly practiced form of perfusion, pulsatile flow may be more physiologic (see also Chapter 67). A study by Murkin and colleagues[52] found no differences in neuropsychological benefits from pulsatile versus nonpulsatile flow.

Hematocrit

The hematocrit value may be related to outcome after CABG. Habib and associates[66] found that the lowest quintile of hematocrit was related to vital organ dysfunction, morbidity, and 6-year survival in a survey of 5000 consecutive operations. Also, Karkouti and colleagues[67] found a positive association between the risk for perioperative stroke and the lowest operative hematocrit. However, in a study examining cognitive dysfunction, Harrison and associates[68] found no correlation between cognitive outcome and hematocrit.

Blood Glucose Management

The relationship between POCD and hyperglycemia after cardiac surgery is not well defined[69] (see also Chapter 39). However, a study conducted by Puskas and associates[70] of 525 patients undergoing CABG found that hyperglycemia was associated with a decrease in cognitive performance at 6 weeks after surgery in patients without diabetes, whereas hyperglycemia had no effect on cognition in patients with diabetes.

Type of Oxygenator

Oxygenators have undergone considerable development over the years (see also Chapter 67). Early studies compared the two types of oxygenators (bubble versus membrane). Padayachee and colleagues[71] found that membrane oxygenators produced fewer cerebral microemboli detected by transcranial Doppler imaging than bubble oxygenators. Also, two studies suggest that POCD is reduced when membrane oxygenators are used rather than bubble oxygenators.[72,73] The nearly universal use of membrane oxygenators is likely to have a beneficial effect on neuropsychological test outcome.

Avoiding Cardiopulmonary Bypass

The resurgence of off-pump coronary artery bypass (OPCAB) surgery as a common technique for multivessel revascularization has paved the way for research into isolating the role that CPB plays in neurologic and neuropsychological decline after CABG surgery. OPCAB surgery may reduce the number of microemboli and strokes. Three recent meta-analysis studies,[74-76] while showing a trend toward an advantage for OPCAB over conventional CABG for incidence of stroke, failed to find a significant difference.

Studies reporting neuropsychological outcome are equally inconsistent. Poorer cognitive outcome at both 1 and 10 weeks was reported in patients undergoing on-pump surgery compared with OPCAB.[77] A large (N = 281) randomized study also found that neuropsychological performance at 3 months after surgery was better in patients undergoing OPCAB; however, these differences had disappeared by the 12-month[78] and 5-year[79] follow-up assessments. Subjective reports of cognitive difficulties have also been found to be similar at 1 year after surgery.[80] A further study by van Dijk and colleagues in 2004[6] found that early cognitive decline in patients undergoing first-time CABG predicted cognitive outcome after 3 months but suggested that this early cognitive decline was not significantly influenced by the use of CPB.

Management of Atherosclerosis of the Ascending Aorta

Embolization may result from dislodgment of atheromatous material during handling of the aorta—for instance, when cannulation is conducted (see also Chapters 67 and 69). Identification of plaques may therefore be advantageous to change the site of cannulation or carry out a coronary artery bypass as an off-pump procedure. That identification is often based on palpation, but ultrasound is clearly more sensitive. Epiaortic ultrasound to detect atheroma has been found to be associated with a reduction in the incidence of POCD.[81]

PHARMACOLOGIC TECHNIQUES TO PROTECT THE BRAIN IN CARDIAC SURGERY

Putative neuroprotective drugs have had variable results in protecting the brain (Table 99-1). Furthermore, many of the studies were underpowered, making their findings unreliable. The previously reported benefit of lidocaine has subsequently been refuted.

INCIDENCE AND RISK FACTORS FOR POSTOPERATIVE COGNITIVE DYSFUNCTION AFTER NONCARDIAC SURGERY

Whether cognitive function deteriorates postoperatively in noncardiac surgery was examined more than 50 years ago by Bedford in 1955.[82] The findings were based on subjective observations and questioning of relatives or caretakers. Using these techniques he concluded that 7% (18 of 251) of patients older than 65 years of age became "demented" (not in the way it is used earlier) after undergoing general anesthesia (see also Chapter 80). Clearly, a lack of objective verification existed, such as means testing of cognitive function by neuropsychological testing. Subsequently, Simpson and associates[83] reported no significant connection between anesthesia and decreased mental performance in 620 elderly patients.

Early studies of POCD tended to recruit a small number of participants. Therefore, many of these early studies did not have the statistical power to detect POCD. In addition, several investigators examined participants on whom a limited number of neuropsychological tests had been performed. The resultant analysis was often unclear and different across the studies. Nonetheless, the evidence for POCD after noncardiac surgery began to accumulate. For example, Grichnik and co-workers[20] found POCD in 45% of a sample of 29 patients with a mean age of 60 years at 6 to 12 weeks after thoracic or

TABLE 99-1 RANDOMIZED TRIALS OF PHARMACOLOGIC INTERVENTION TO REDUCE COGNITIVE DYSFUNCTION AFTER CARDIAC SURGERY

Authors	Year	Drug	No.	Result
Nussmeier et al[139]	1986	Thiopental	182 complete	Neuropsychological test results showed no difference at 5 days
Roach et al[140]	1999	Propofol	99 complete	No significant difference at days 5-7 or days 50-70
Legault et al[141]	1996	Nimodipine	149 recruited, complete in 65%-69%	No significant difference, at 1 wk, 1 mo, or 6 mo (study terminated early)
Fish et al[142]	1987	Prostacyclin	74 complete	No significant difference at 1 wk or 2 mo
Grieco et al[143]	1996	GM_1 ganglioside	25 complete	No significant difference at 1 wk or at 6 mo
Arrowsmith et al[46]	1998	Remacemide	159 complete	Using incidence, no significant difference; but using Z-change score, significantly less POCD with remacemide
Butterworth et al[144]	1999	Pegorgotein	58 complete	No significant difference at days 5-7 or wk 4-6
Mitchell et al[145]	1999	Lidocaine	42 complete	Significantly less POCD with lidocaine at 10 days (40% versus 75%) and at 10 wk (46% versus 75%)
Wang et al[146]	2002	Lidocaine	88 complete	Significantly less POCD with lidocaine (19% versus 40%) at 9 days
Kong et al[147]	2002	Clomethiazole	219 complete	No significant difference at 4-7 wk
Taggart et al[148]	2003	Lexipafant	135 complete	No significant difference at discharge or 3 mo
Mathew et al[149]	2004	Pexelizumab	800 recruited	No significant difference at day 4 or at day 30
Harmon et al[150]	2004	Aprotinin	35 complete	Significantly less POCD in the aprotinin group: 94% versus 58% at day 4 and at 6 wk 23% versus 55%
Mathew et al[151]	2009	Lidocaine	182 complete at 6 weeks	No significant difference at 6 wk or at 1 yr
Mitchell et al[152]	2009	Lidocaine	118 complete at 10 wk	No significant difference at 10 or 25 wk

vascular surgery (see also Chapters 66 and 69). The definition of POCD was similar to that in earlier studies in cardiac surgery, using a 20% deterioration in 20% of the tests (11 test variables considered) (see also Chapter 67). In a larger study of 98 patients with a mean age of 73 years, Ancelin and associates[19] found deterioration in at least 1 test of 28 in 71% of patients 9 days after surgery and in 56% of patients at 3 months. After knee replacement (see also Chapter 79), POCD was seen in 41% of patients at 1 week and in 18% at 3 months.[84] In a much larger study (228 patients) including a very early assessment in patients older than 64 years of age, POCD was found in 16.8% 1 to 2 days after noncardiac surgery. The definition of POCD was based on deterioration in two of three test variables.[85] Further evidence that POCD exists after noncardiac surgery was provided by Williams-Russo and colleagues,[22] who reported POCD in 5% of 231 patients older than 65 years of age at 6 months after knee replacement (see also Chapter 79). In this study, POCD was defined by a panel agreeing on what constituted a "clinically important deterioration" in each of the applied tests; however, no control group was included to allow a comparison. Unfortunately, these studies usually did not have a control group. In contrast, the ISPOCD study recruited 1218 elderly patients and 176 healthy volunteers.[23] The patients underwent major noncardiac surgery with general anesthesia. POCD was found in 25.8% after 1 week and 9.9% after 3 months. This was significantly more frequent than in the control group, in whom the diagnostic criteria were fulfilled in only 3.4% and 2.8%, respectively. These findings were further supported in a single-center study using the same methodology, in which POCD was found in 41.4% of those older than 60 years of age at discharge and in 12.7% after 3 months.[86]

RISK FACTORS FOR POSTOPERATIVE COGNITIVE DYSFUNCTION AFTER NONCARDIAC SURGERY

In most studies investigating POCD, the mean age of the participants assessed has been approximately 60 years,[1] with many studies specifically selecting participants of an "older" age group (see also Chapter 80). This is in part due to beliefs that cognitive dysfunction would be more likely with "older people." However, age is a significant and independent risk factor for POCD; for example, after 3 months, POCD in the ISPOCD study[23] was seen in 7% of those aged 60 to 69 years in contrast to 14% in those older than 69 years. Also, Ancelin and colleagues[19] found a relationship between increasing age and POCD. However, few studies of POCD have included younger patients. The largest study was conducted by the ISPOCD2 group and included 508 middle-aged patients (40 to 59 years) and 185 control subjects of similar age.[35] POCD was found in 89 of 463 (19.2%) of the patients at 7 days and in 26 of 422 (6.2%) at 3 months; this is compared with 7 of 176 (4.0%) in the controls at 1 week and in 7 of 169 (4.1%) at 3 months. The difference in incidence of cognitive dysfunction between patients and controls was statistically significant ($P = .001$) at 1 week but not at 3 months ($P = .33$). Interestingly, when the surgical participants were compared with a previous group older than 60 years, they found the younger group showed significantly less POCD at both 7 days ($P = .0064$) and 3 months ($P = .026$) after surgery.[35] These findings are similar to those in a recent study by Monk and co-workers[86] that examined 1064 participants undergoing major noncardiac surgery. A comparison was made between 331 patients aged 18 to 39 years, 378 patients aged 40 to 59 years, and 355 patients aged 60 years and older. At discharge, POCD was found

TABLE 99-2 **PROPORTION OF ELDERLY PATIENTS WITH COGNITIVE DYSFUNCTION AFTER MAJOR SURGERY WITH GENERAL ANESTHESIA AT 1 WEEK AND 3 MONTHS POSTOPERATIVELY BY SELECTED PATIENT, SURGICAL, AND ANESTHETIC FACTORS**

	1 Week		3 Months	
Patient, Surgical and Anesthetic Factors	No. Patients	Patients With POCD (%)	No. Patients	Patients With POCD (%)
Age (yr)

in 36.6% of the youngest, 30.4% of the middle aged, and 41.4% of those older than 60 years, with a significant difference among all groups. By 3 months, POCD incidence was similar in the young and middle-aged groups (5.7% and 5.6%, respectively) but a significantly more frequent rate was detected in the older age group (12.7%).

Risk factors for POCD other than age have been identified. Duration of anesthesia, respiratory complications, infectious complications, second operation and a low level of education were important factors in the ISPOCD1 study.[23] Surprisingly, episodes of hypoxemia or hypotension had no statistically significant correlation with POCD. The most important results from the risk factor analyses of this study are shown in Table 99-2. Other investigators have also examined potential risk factors for POCD. Previous cerebrovascular accident has been identified as a significant risk factor for POCD at 3 months.[86] Ancelin and associates[19] found a relationship between postoperative cognitive deterioration and increasing age, low level of education, poor preoperative test performance, depression, and type of anesthesia (general versus epidural). The possible importance of type of anesthesia is discussed later in this chapter.

TYPE OF SURGERY

Minor Surgery

Studies of POCD after minor surgery focused primarily on early outcomes after outpatient surgery. Heath and associates[87] randomized 60 patients 18 to 60 years of age to receive thiopental-based or propofol-based anesthesia. In addition, 30 age-matched control subjects were included. Although significant differences in neuropsychological performance between patients and controls were found at 1 and 2 hours after surgery, this difference had disappeared by 24 hours. The ISPOCD group recruited 372 patients undergoing minor surgery as either an inpatient or outpatient procedure.[88] At 7 days, POCD was found in 22 of 323 (6.8%); in 164 inpatients, 16 (9.8%) had POCD and 5 of 141 (3.5%) outpatients had POCD ($P = .033$), but the group allocation was not randomized (see also Chapter 89). At 3 months the incidence of POCD between the two groups (8.8% for inpatients and 4.5% for outpatients) was not significantly different.

In conclusion, POCD after 1 week seems to be much less common after minor surgery than after major surgery. Several factors may be important in explaining this difference in incidence of POCD, including the obvious difference in surgical trauma, postoperative stress response, postoperative pain, sleep deprivation, need for analgesia, and the possibility for early return to a familiar environment after early discharge. Also, a relationship between the inflammatory response and the extent of recovery after surgery may exist. Hall and colleagues[89] report a relationship between inflammatory response as measured by interleukin (IL)-6 and the extent of functional recovery after hip arthroplasty.

Carotid Endarterectomy

Carotid endarterectomy has been considered a procedure that calls for special attention regarding changes in cognition function (see also Chapter 69).

It is performed in patients with a tight (i.e., narrow) (>70% or >90%) stenosis of the internal carotid artery. Postoperatively, neurologic complications may occur as a result of brain ischemia, embolism, or brain hyperperfusion. Yet, an improvement in brain function could occur

if brain perfusion was corrected or perhaps because the carotid plaque is a source of brain emboli. However, neuropsychological studies conducted in this area have produced inconsistent findings that have been highlighted in two systematic reviews.[90,91] Improvement in cognitive performance after carotid endarterectomy was reported in over 50% of studies, with 43% showing no change or decline.[91]

REGIONAL VERSUS GENERAL ANESTHESIA

If general anesthesia is an important factor leading to the development of POCD, regional anesthesia would reduce its incidence (see also Chapters 56 and 57). In the randomized studies using neuropsychological testing after surgery, no clear picture emerges during the first postoperative week. Significantly better neuropsychological test performance has been reported at examination from the first 6 hours to 4 days with regional anesthesia[12,92,93] but after the first week after surgery, no significant advantage of regional anesthesia has been detected (Table 99-3). Methodologic limitations could be an important confounding factor because in these types of studies blinding of patients and even blinding of examiners may be difficult.

The largest study conducted found no significant difference in POCD between general or regional anesthesia at either 1 week (general anesthesia = 37 of 188 (19.7%), regional anesthesia = 22 of 176 (12.5%), P = .06), or 3 months (general anesthesia = 25 of 175 (14.3%), regional anesthesia = 23 of 165 (13.9%), P = .93) after surgery.[94] Regional anesthesia was unsuccessful in 24 patients allocated to regional anesthesia for whom general anesthesia was therefore necessary (see also Chapter 56). Also, 35 patients allocated to general anesthesia actually received spinal or epidural anesthesia. Not all of these 59 patients

TABLE 99-3 RANDOMIZED STUDIES COMPARING GENERAL AND REGIONAL ANESTHESIA USING NEUROPSYCHOLOGICAL TESTING

Authors	No. Completed	Age	Interval After Surgery	Type of Surgery	Results
O'Dwyer et al[153]	255	Mean 55 yr	6 hr, 24 hr, and 3 days	Hernia repair	No significant difference
Casati et al[154]	30	Median 84 yr	1 and 7 days	Hip fracture repair	No significant difference
Rasmussen et al[94]	340	Median 71 yr	3 mo	Mixed	No significant difference at 3 mo using intention to treat but significant difference at 1 wk 21% versus 13% in favor of regional when using per protocol analysis
Somprakit et al[155]	120	Group 1 = mean 37 yr Group 2 = mean 67 yr	1 and 3 days	Mixed	No significant difference in whole group, but older group had significantly more POCD
Williams-Russo et al[22]	231	Median 69 yr	1 wk and 6 mo	Knee replacement	No difference between groups
Campbell et al[156]	157	Mean 77 yr	24 hr, 2 wk, 3 mo	Cataract	No differences between groups
Haan et al[13]	37	Mean 72 yr	4 days and 3 mo	Urology	No significant difference
Nielson et al[157]	64	Mean 69 yr	3 mo	Knee replacement	Improvement: No difference between groups
Jones et al[158]	129 50 controls	>60 yr	3 mo	Knee or hip replacement	Significant improvement in 2/5 variables in general anesthesia group, no change in regional anesthesia group (P = .03 and .04 between groups)
Chung et al[10]	44	Mean 72 yr	6 hr, 1, 3, and 5 days and 1 mo	Urology	No difference
Asbjørn et al[93]	40	Mean 69 yr	4 days and 3 wk	Prostatectomy	No difference
Ghoneim et al[159]	105	Mean 61 yr	1-7 days and 3 mo	Mixed	No difference
Hughes et al[12]	30	Mean 68 yr	24 hr, 48 hr, and 1 wk	Hip arthroplasty	No difference after 1 week
Chung et al[92]	44	Mean 72 yr	6 hr, 1, 3, and 5 days and 1 mo	Prostate resection	Significantly higher MMSE in regional at 6 hr
Bigler et al[160]	38	79 yr	1 wk and 3 mo	Repair of hip fracture	Improvement in both, with no difference between the two regimens
Riis et al[161]	30	>60 yr	1 wk and 3 mo	Hip replacement: general, epidural or combined	Initial decline from baseline at 4 days and then improved, with no group differences
Karhunen and Jöhn[162]	47	Mean 73 yr	1 wk	Cataract surgery	After 1 wk significantly more deterioration in local anesthesia group in one of two combined scores

completed the study, but when excluded in a per protocol analysis, a significant difference in the incidence of POCD was found between general anesthesia in 33 of 156 (21.2%) versus regional anesthesia in 20 of 158 (12.7%) after 1 week ($P = .04$); however, at 3 months no difference was found.

ETIOLOGIC CONSIDERATIONS

Perhaps POCD is the result of brain cell damage caused by toxic substances or hypoxia. Toxic substances could be drugs such as general anesthetics or analgesics, but also the surgery-induced release of hormones or inflammatory mediators or a combination of these factors. Hypoxia may result from arterial hypoxemia or low perfusion caused by low cardiac output, inappropriate blood flow distribution, thrombosis, or embolism.

DRUGS

Anesthetic central nervous system toxicity may be a possible explanation for POCD (see also Chapter 15). General anesthesia is assumed to be a completely reversible condition. Yet, this conclusion has not been conclusively proved. Exposure of animals to anesthetics has resulted in the detection of several types of changes in the brain. Jevtovic-Todorovic and co-workers[95] demonstrated histologic changes in the brain after exposure to isoflurane, nitrous oxide (N_2O), and midazolam. In developing rat brain, apoptosis was found in thalamic nuclei and the parietal cortex after exposure to isoflurane and this effect was more pronounced if midazolam or N_2O was added.[95] Memory testing using a water maze revealed inferior performance in the anesthetized rats compared with control animals. Also, infant mice showed signs of apoptosis in brain cortex after subcutaneous administration of midazolam or ketamine[96] and after propofol or combinations of ketamine with propofol or thiopental.[97] In adult rat brain cortex, neuronal vacuolization and neuronal degeneration with necrosis were found after N_2O administration. The neuronal vacuolization, however, seemed to be reversible, with no vacuolated neurons after 3 hours of recovery, and the addition of diazepam or isoflurane blocked the neurodegeneration.[98] These findings are interesting but do not provide convincing evidence for induction of persistent neuronal changes after general anesthesia in humans, where N_2O is not used as the only anesthetic.

Apoptosis occurred in human neuroglioma cells that were exposed to isoflurane, and increased levels of amyloid precursor protein were also found.[99] Abnormal processing of amyloid precursor protein with accumulation of β-amyloid protein is a feature of Alzheimer disease, and it is therefore important to determine whether general anesthetics influence the processing of this protein.Another possible effect of anesthetics could be related to long-term changes in brain receptor function. A decrease in cholinergic function has been found in Alzheimer disease, and cholinesterase inhibitors may be beneficial for patients with this condition. In one study, changes in cholinergic binding were found in rat brains after repeated pentobarbital anesthesia given by intraperitoneal injection.[100] Anesthetics cause changes in gene expression in the brain and in the protein synthesis pattern, as detected by comparison of brain tissue protein contents in anesthetized and control animals.[101-103] These findings in animals or cell cultures are difficult to apply to the clinical situation with POCD in humans. Animal studies of anesthetic drug toxicity may be influenced by inadequate oxygenation, ventilation, perfusion, or temperature regulation. In addition, hypoglycemia may occur in infant rodents exposed to general anesthesia. The brain cell damage of anesthesia in this situation may therefore be caused by mechanisms other than drug effects, but these findings have caused much concern in relation to pediatric anesthesia. It is difficult to study central nervous system toxicity consequent to anesthetic exposure. Although large epidemiologic studies have not detected a major long-term effect of anesthesia on cognitive function, such research has important limitations. For example, in a study of 1257 healthy subjects, 946 participants had been previously exposed to at least one general anesthetic with no significant correlation between exposure to anesthesia and performance in cognitive tests.[104] However, as with the collection of any retrospective data, subjects may not recall reliably the type and number of anesthetics they have received or the exact date they received the anesthetic. The importance of age at time of exposure is difficult to ascertain. Better cognitive performance has been found in two studies of cardiac surgery patients receiving inhaled anesthesia compared with propofol during CPB[105,106] (see also Chapter 67). However, the difference was present only within the first postoperative week and no difference was seen at 3 months.[105]Apart from anesthetics, many other drugs are given in connection with surgery. As an example, analgesics may have important effects on cognitive function but have not been related to cognitive decline in elderly surgical patients.[107] In agreement, Johnson and associates[35] found that opioid administration within the 24 hours before the test had no significant influence on performance. Still, other psychoactive medication cannot be excluded as a potential influence on neuropsychological test data obtained in patients during the weeks to months after surgery.

HORMONES

Major surgery causes an endocrine response with release of hypothalamic-pituitary-adrenal (HPA) and sympathetic nervous system hormones. Cognitive impairment can occur with high levels of glucocorticoids.[108,109] Cortisol is toxic to cells in the hippocampus, and this structure plays a critical role in the consolidation of short-term into long-term explicit memory and descending control of the HPA axis. Perhaps repeated episodes of stress cause decreased hippocampal inhibition of the HPA axis and, thus, prolonged hyperactivation.[110] This was studied in 187 patients older than 60 years of age undergoing major noncardiac surgery, and a persistent change in the cortisol secretion pattern was significantly related to POCD at 1 week.[111]

INFLAMMATORY MEDIATORS

Surgery can activate the immune system with release of inflammatory mediators from lymphocytes. Important mediators include cytokines that are able to initiate the activation of other inflammatory mediators and affect brain function either directly or indirectly.[89,112,113] A very pronounced inflammatory response is seen in connection with cardiac surgery using CPB, and significantly higher levels of the cytokines IL-1 and IL-10 in patients with POCD after such procedures.[114] Also, after noncardiac surgery, POCD is associated with increased levels of inflammatory mediators[115,116]; this area is currently a focus of research using animal models.[117,118]

HYPOXIA

Brain hypoxia may lead to irreversible damage depending on the level, duration, and susceptibility. Oxygen (O_2) delivery to the brain depends on blood flow and arterial O_2 concentration, which is primarily related to hemoglobin concentration and arterial O_2 saturation. Brain hypoxia may be caused by a decrease in blood flow or arterial hypoxemia. In connection with anesthesia, inability to initiate ventilation in the patient or unrecognized esophageal intubation may cause profound and long-lasting hypoxemia[119] and subsequently brain damage. Modest perioperative decreases in arterial O_2 saturation are common, but their importance is probably overemphasized when compared with the wide fluctuations in cerebral blood flow and blood hemoglobin level.[120] One possible explanation for this is the ease of measuring arterial O_2 saturation continuously by pulse oximetry. No connection has been shown between modest arterial hypoxemia and postoperative complications, including POCD.[23,121]

BRAIN HYPOPERFUSION

A temporary reduction of cerebral blood flow can cause neurologic or cognitive dysfunction without occlusion of cerebral vessels (see also Chapter 70). Cerebral blood flow is regulated according to brain metabolism and nearly unchanged within wide variations in blood pressure (autoregulation) mediated through changes in diameter of resistance vessels. This autoregulation has a lower limit at approximately a mean arterial blood pressure of 50 mm Hg in healthy adults but is higher in hypertensive subjects.[122] Below this limit, further dilatation of vessels cannot compensate and cerebral blood flow decreases. Measuring cerebral blood flow or brain oxygenation during surgery is complicated. The techniques used include xenon-133, near-infrared spectroscopy, transcranial Doppler imaging (which really measures velocity), and jugular bulb O_2 saturation. All of these techniques are associated with important limitations. Brain perfusion pressure is therefore frequently used to evaluate brain perfusion in clinical practice. During anesthesia, brain metabolism is reduced, and, therefore, a lower brain blood flow may be acceptable. In earlier studies of cardiac surgery, prolonged episodes of hypotension were a risk factor for brain dysfunction,[40,123] but subsequent studies have not been able to confirm this.

THROMBOSIS OR EMBOLISM

Cerebral infarction can be caused by an embolic or a thrombotic occlusion of a cerebral artery, and necrosis of brain tissue, including neurons and glial cells, may result. Thus, tissue architecture is lost and a well-defined infarct can be identified by autopsy or brain imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Cerebral infarcts may cause no symptoms at all, depending on the size and location, but the usual clinical presentation is a stroke. Several risk factors have been identified in studies of stroke in the general population and in relation to surgery. Age is an important factor, and other important risk factors include type of surgery; cardiac disease, especially atrial fibrillation; peripheral vascular disease; previous cerebrovascular attacks; and diabetes[124,125] (see also Chapter 80). The incidence of major cerebral complications presenting as stroke after general surgery varies between 0.2% and 0.7%. Most cerebral infarctions in the perioperative period are caused by emboli. Macroemboli are more than 200 μm in diameter and typically consist of atheromatous material or thrombi. These may arise from the left atrium, left ventricle, or aorta.

Microemboli are less than 200 μm in diameter and, as stated earlier, are common in cardiac surgery (see also Chapter 67). As opposed to macroemboli, they may often consist of air introduced into the venous circulation—for instance, through tubing used in the CPB circuit or arterial lines. In addition, paradoxical embolization may occur through an open foramen ovale from the venous side because of subatmospheric pressure in veins or bone marrow if the surgical field is above heart level and venous structures are noncollapsible, as in procedures such as back surgery, craniotomy in the sitting position, and knee replacement. Microemboli occur in joint replacement surgery (see also Chapter 79). It was specifically assessed in 37 patients in whom cognitive function was studied with a battery of 13 tests at 1 week and at 3 months; POCD was found in 41% and 18%, respectively, but no significant association with microemboli was detected using transcranial Doppler imaging.[84]

GENETIC ASPECTS

Polymorphic genetic variation may explain individual differences in susceptibility to medication, inflammation, trauma, and other harmful factors. Such genetic factors are important for the development of dementia but do not uniquely determine the phenotype.

Apolipoprotein E (ApoE) is a protein that is important for recovery after central nervous system injuries.[126] Important differences exist in the three different isoforms of ApoE—E2, E3, and E4, which are encoded by the alleles *ε2, ε3,* and *ε4* of the *ApoE* gene, respectively. The *ε3* allele is the wild-type and present in 75% of the native European population, whereas *ε2* and *ε4* are less frequent.[127] The *ε4* allele seems to increase the risk for Alzheimer disease, and it is also associated with a poor prognosis after head injury.[128-130] The possible association between the *ε4* allele and POCD after cardiac surgery has been studied, but literature presents conflicting information.[131,132]

The possible relationship between the *ε4* allele and POCD after noncardiac surgery was studied in 976 patients 40 years of age and older; the *ε4* allele was not a risk factor at 1 week ($P = .49$) or 3 months after noncardiac surgery ($P = .28$).[133] POCD is related to the presence of the *ε4* allele in patients undergoing carotid surgery.[134] Other genetic factors could be important in the general surgical population—for instance, individual differences in inflammation and drug metabolism, with polymorphism of the drug metabolism system's cytochrome P-450, are well described. Very slow metabolism of certain drugs could be associated with prolonged recovery, and very fast metabolism could lead to high concentrations of intermediary degradation products.[135] Both situations could result in a disturbance of receptor function, but the relationship, if any, with POCD remains to be established.

CLINICAL SIGNIFICANCE AND LONG-TERM CONSEQUENCES OF POSTOPERATIVE COGNITIVE DYSFUNCTION

The detection of POCD and its likely causes have been discussed. What effect does this dysfunction have on the patient? A frequent report is an elderly patient whose cognitive function has deteriorated profoundly after surgery, especially regarding memory. The relatives describe a loss of function, lack of initiative, and lack of interest in activities that previously meant a lot to the person. In a retired individual, this could be playing cards or doing crossword puzzles. The deterioration may be most noticeable in patients returning to work, when usual tasks may be difficult to carry out in the same manner and at the same speed as before surgery. Such difficulty also is not uncommon in middle-aged or young patients, who also may experience some degree of dysfunction in cognition.

One relevant question is whether POCD in fact results in impairment of function as reflected in activities of daily living. In a study of elderly patients undergoing major noncardiac surgery with general anesthesia, a statistically significant correlation was found between POCD at 3 months and a decline in activities of daily living.[23] Another study of middle-aged patients, by Johnson and associates,[35] found a statistically significant correlation between POCD at 1 week and a decline in instrumental activities of daily living at 1 week reported by relatives at 3 months. Long-term follow-up has revealed a significantly higher mortality in patients with cognitive dysfunction after noncardiac surgery.[86,136] POCD also is associated with earlier retirement and need for social transfer payment.[136] Dementia does not occur frequently after surgery, and whether POCD is a precursor of that condition has not been well studied. Avidan and colleagues[137] found no difference in the rate of cognitive decline according to exposure to surgery and anesthesia in a population undergoing repeated cognitive testing, and age-related cognitive decline may account for some of the changes reported previously. The pronounced variability is also important, and some studies have found no difference in long-term POCD between patients undergoing major surgery (even cardiac) and subjects who had very minor procedures, such as percutaneous angiography.[24,138]

Chapter 100

Postoperative Visual Loss

STEVEN ROTH

Key Points

- Visual loss after anesthesia is a rare but devastating injury that appears more frequently after cardiac, spine, and orthopedic joint surgery.
- Causes of perioperative visual loss include central or branch retinal artery occlusion (RAO), anterior and posterior ischemic optic neuropathy (ION), cortical blindness, and acute glaucoma. Transient visual loss may occur after transurethral resection of the prostate. Retinal vascular occlusion in patients who receive nitrous oxide–containing gas mixtures after a vitrectomy procedure with vitreal gas bubble tamponade is caused by acute expansion of the gas bubble and increased intraocular pressure.
- Signs and symptoms of visual loss in the postoperative period may be subtle and can be incorrectly attributed to the residual effects of anesthetic drugs. Any patient reporting eye pain, an inability to perceive light or motion, complete or partial loss of visual fields, decreased visual acuity, or loss of pupil reactivity must be evaluated immediately by an ophthalmologist.
- The most common cause of perioperative central and branch RAO is compression of the eye. During cardiac surgery, emboli may occlude the retinal arteries.
- Patients who undergo prolonged operative procedures in the prone position with large blood losses are at frequent risk for development of ION. Other factors conferring a more frequent risk during spine surgery include male gender, obesity, the use of a Wilson frame, and intravascular fluids administered perioperatively. Controversy exists with respect to the appropriate arterial blood pressure, hemoglobin, intravascular fluid administration, and use of vasopressors in these patients. The potential risk for ION should be considered in the design of an anesthetic plan. Patients must be informed of the risk for visual loss accompanying lengthy surgical procedures with the patient positioned prone and with anticipated large blood loss. Both anesthesia and surgery personnel, together, should develop a plan in conjunction with the surgeons by which informed consent for this complication may be facilitated.
- Perioperative visual loss in the presence of focal neurologic signs or the loss of accommodation reflexes or abnormal eye movements suggests a diagnosis of cortical blindness. Neurologic consultation should be obtained.

Perioperative visual loss (POVL) is a rare but unexpected and devastating complication. Spine surgery, particularly when fusion is performed, is one of the most common procedures associated with POVL. Hence, a major emphasis of this chapter is on POVL associated with spine surgery. The incidence, suspected risk factors, diagnosis, and treatment of eye injuries leading to visual loss in the perioperative period are discussed. The discussion is confined to visual loss that follows nonocular surgery because eye damage after ocular surgery is well described in the ophthalmology literature (see also Chapter 84). Injuries to the retina and optic nerve and the visual connections to the brain are discussed.

No prospective studies of POVL have been performed. A few retrospective studies and published surveys and case reports provide much of the current knowledge on postoperative visual loss. Two large retrospective studies showed that perioperative ischemic optic neuropathy (ION) is rare, occurring in approximately 1 in 60,000 to 1 in 125,000 anesthetic procedures in the overall surgical population.[1,2]

Spine and cardiac surgery are associated with a more frequent incidence of POVL than other operative procedures. Shen and associates[3] examined the POVL prevalence in the U.S. database, Nationwide Inpatient Sample (NIS), for the eight most commonly performed surgical

procedures, excluding obstetrics and gynecologic surgery, which is the largest patient population studied. The most frequent were spine (3.09 per 10,000, 0.03%) and cardiac surgery (8.64 per 10,000, 0.086%). The yearly rates of POVL in the procedures studied by Shen and colleagues[3] have been decreasing in the 10-year period from 1996 to 2005. Patil and colleagues[4] found an overall rate of 0.094% in spine surgery discharges in the NIS.[4] In previous, smaller case series, Stevens and colleagues[5] found four ION cases in 3450 spine surgeries (0.1%), and two cases in 3300 patients after spine surgery were reported at another hospital (0.06%).[6] Chang and Miller reviewed 14,102 spine surgery procedures in one hospital, identifying four ION cases (0.028%).[7] After cardiac surgery, the incidence may be as frequent as 1.3% in one study[8] but 0.06% and 0.113% in two more recent larger retrospective studies.[9,10]

Myers and associates[11] conducted a retrospective case-control study of 28 patients with visual loss after spine surgery. The American Society of Anesthesiologists (ASA) Postoperative Visual Loss Registry reported on 93 cases of visual loss after spine surgery submitted anonymously to the ASA Closed Claims Study.[12] Nuttall and associates[9] performed a retrospective case-control study of cardiac surgery patients at the Mayo Clinic.[9] The most recent study was a retrospective, case-controlled study of factors involved in perioperative ION in spine surgery, a collaborative effort of 17 U.S. and Canadian medical centers.[13] Each of these studies is described in detail in subsequent sections of this chapter.

RETINAL ISCHEMIA: BRANCH AND CENTRAL RETINAL ARTERY OCCLUSION

Central retinal artery occlusion (CRAO) decreases the blood supply to the entire retina, whereas occlusion of a retinal arterial branch (BRAO) is a localized injury affecting only a portion of the retina. This injury is usually unilateral. Four causes can be distinguished: (1) external compression of the eye, (2) decreased arterial supply to the retina (embolism to the retinal arterial circulation or decreased blood flow from a systemic cause), (3) impaired venous drainage of the retina, and (4) arterial thrombosis from a coagulation disorder.

The most common cause of perioperative retinal arterial occlusion is improper patient positioning with external compression of the eye producing sufficient intraocular pressure (IOP) to stop flow in the central retinal artery (see also Chapter 41). It most commonly occurs during spine surgery performed with the patient in the prone position. Pressure within the orbit also can be increased internally after retrobulbar hemorrhage, which is associated with vascular injuries during sinus or nasal surgery.

Although rare in most surgical procedures, emboli can directly impair blood flow in the central retinal artery (CRA) itself or a branch of it. Paradoxical embolism originating from the operative site and reaching the arterial circulation through a patent foramen ovale has rarely been reported as a cause of perioperative retinal vascular occlusion.[14] Retinal microemboli, however, are common during open heart surgery.[15] Hypotension itself seems to be a rare cause of retinal ischemia. The incidence of retinal ischemia after hypotensive anesthesia was only 3 cases in 27,930 hypotensive anesthetic procedures.[16]

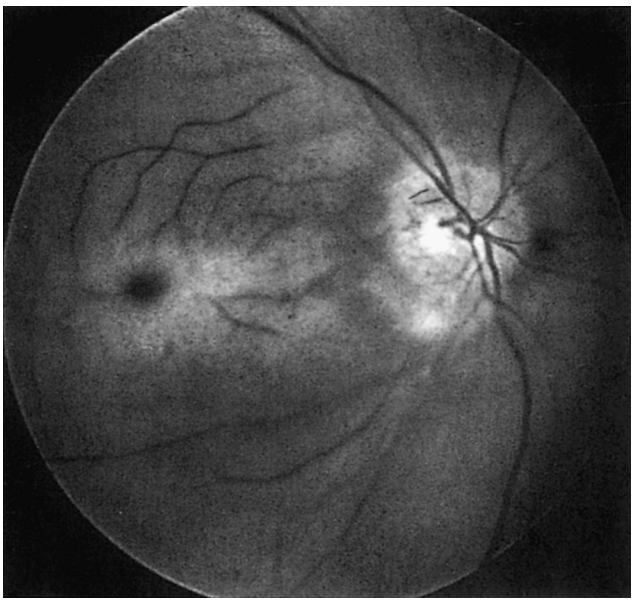

Figure 100-1. Funduscopic appearance of retinal vascular occlusion. Note the pallor of the retina and the cherry-red spot, visible in the fovea near the center of the photograph. The ischemic retina loses its normal transparency, and because the fovea is thinner than the surrounding retina, the underlying choroid is visible as a cherry-red spot. *(From Ryan SJ:* Retina, *ed 2, St. Louis, CV Mosby, 1995.)*

Venous drainage can be impaired after radical neck surgery by jugular vein ligation.[17] In normal volunteers or spine surgery patients positioned prone, IOP increased and head-down position resulted in further increases. Changes were attenuated by head-up positioning.[18,19] The clinical significance of these changes are not clear.

CLINICAL FINDINGS

Painless visual loss and abnormal pupil reactivity occur. Funduscopic examination shows opacification or whitening of the ischemic retina, and narrowing of retinal arterioles may be visible.[20] BRAO is characterized by cholesterol emboli (bright yellowish, glistening), calcific emboli (white, nonglistening), or migrant pale platelet fibrin emboli (dull, dirty white). A cherry-red macula with a white ground-glass appearance of the retina and attenuated arterioles is a "classic" diagnostic sign in CRAO (Fig. 100-1). The red appearance from pallor in the ischemic, overlying retina makes visible the color of the intact, underlying choroidal circulation. However, this sign is not always present; thus, its absence does not rule out retinal artery occlusion (RAO). Differential diagnosis from other causes of visual loss is presented in Table 100-1.

MECHANISMS OF RETINAL ISCHEMIA

Increased extracellular glutamate concentrations during retinal ischemia[21] and attenuation of ischemic injury in vitro and in vivo by glutamate receptor antagonists[22] support a role for excitotoxicity. It is thought that an

*Typical symptoms and signs are listed. Some patients may have varying findings as a result, among other factors, of timing of examination relative to symptom onset.

†Because of a lack of overlying inner retinal cells in the fovea, the intact choroidal circulation is visible as a cherry-red spot.

‡Cholesterol, platelet-fibrin emboli, calcified atheromatous material.

increased intracellular Ca^{2+} concentration as a result of enhanced glutamate release ultimately initiates mechanisms that result in cellular destruction.

Two distinct blood flow patterns follow a period of ischemia. In cats, retinal and choroidal blood flow increased dramatically (hyperemia) immediately after the end of ischemia.[23] Hyperemia is of clinical relevance in reperfusion after a period of ischemia, increasing flow when vessels or the blood-retinal barrier is damaged, and might lead to macular edema.[24] Hypoperfusion is the other extreme. In adult rats, delayed retinal hypoperfusion occurs 1 to 4 hours after the end of a period of ischemia.[25] The mechanism of these changes in blood flow is not clear, although depletion of vasodilators such as adenosine or nitric oxide (NO) may be responsible.

The retinal blood supply is derived from the retinal and choroidal vessels.[26] Therefore, after retinal vascular occlusion, some oxygen (O_2) may still be supplied by diffusion from outer retinal layers by way of the choroid. In monkeys, eyes with CRAO showed little damage in the macular retina after 97 minutes of ischemia. After 240 minutes, damage was profound and irreversible.[27] These studies were conducted by clamping the central retinal artery (CRA) and may not necessarily extrapolate to the perioperative complication of external compression of the eye.[28] Interestingly, the same investigators reported that atherosclerosis did not increase sensitivity to ischemia in monkeys and actually may have "preconditioned" the animals against ischemic insult.

Increased IOP from external compression of the eye is a more severe insult than ligation of the CRA because of the profound simultaneous decreases in both retinal and choroidal blood flow[23] and the differential susceptibility of the inner retinal cells to damage from pressure.[29] Ischemic tolerance time is probably shorter with external compression, as evident in studies of injury in animal models of retinal ischemia[30-33] (Table 100-2).

Central Retinal Artery Occlusion

The cause of perioperative CRAO is usually external compression and sufficiently high IOP to occlude the retinal arterial circulation. Patient characteristics may increase the risk for CRAO. Altered facial anatomy may predispose to damage by the external pressure of anesthesia masks or headrests. In osteogenesis imperfecta, fibrous coats of the eye are thin and immature because of deficiency of collagen fibers, persistent reticulin fibers, and increased mucopolysaccharide ground substance. Sclerae and corneas

TABLE 100-2 ANIMAL STUDIES OF RETINAL ISCHEMIA AND TIME REQUIRED TO PRODUCE INJURY

Author	Animal	Ischemia Method	Ischemia Time
Hayreh et al (1980, 2004)[27,28]	Monkey	Central retinal artery ligation	>100-240 min

Zhu et al (2002)[33]	Mouse (ND4)	Increased intraocular pressure	30, 45, 60 min

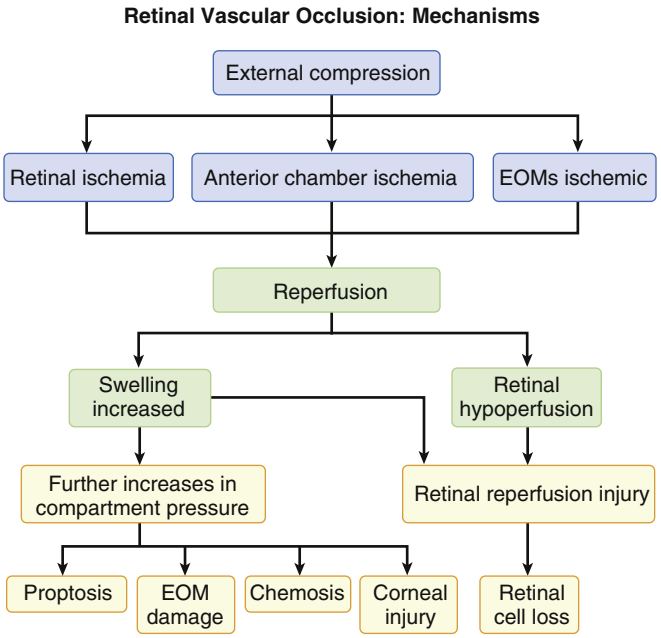

Figure 100-2. Mechanisms of retinal injury after external compression of the eye. *EOM,* Extraocular muscle.

are unusually thin and exophthalmos is common, rendering the eye more vulnerable to damage from external pressure. Those of Asian descent tend to have lower nasal bridges, which may increase the risk for external compression.[34]

Improper positioning of the head with external pressure on the eyes may compress ocular contents and, consequently, occlude retinal blood flow (see also Chapter 41). Most reports of improper positioning involve patients positioned prone for surgery. The horseshoe headrest is of particular concern because of its shape and its narrow opening for the face; improper head position or unintended head movement may place the eye in contact with the headrest. In most of the reports of CRAO in patients positioned prone for surgery, the horseshoe headrest or a similar device (e.g., a rectangular headrest[35]) was used.[34,36] Kumar and colleagues[37] reviewed published case reports of CRAO after spine surgery. Signs and symptoms included unilateral loss of vision, usually with loss of light perception, afferent pupil defect, periorbital or eyelid edema, chemosis, proptosis, ptosis, paresthesias of the supraorbital region, hazy or cloudy cornea, and corneal abrasion. Loss of eye movements, ecchymosis, or other trauma near the eye also was reported. On funduscopic examination, findings included macular or retinal edema, a cherry-red spot, or attenuated retinal vessels. Two reports describing four patients who sustained external compression documented the development of retinal pigmentary alterations, suggesting simultaneous choroidal circulatory ischemia.[38,39] Early orbital computed tomography (CT) or magnetic resonance imaging (MRI) showed proptosis and extraocular muscle swelling, although most cases did not have imaging studies to confirm the diagnosis.[37] Findings were similar to the syndrome of "Saturday night retinopathy" in intoxicated individuals who slept while their eyes were compressed.[40]

Hollenhorst and co-workers,[41] who described unilateral blindness in patients positioned prone for neurosurgery, replicated the human findings in monkeys with 60 minutes of elevated IOP by exerting a pressure of 200 mm Hg on the eye together with hypotension. (Hypotension was not a feature in six of the eight human subjects in their report.) In the monkey, histologic findings were edema of the retina and dilated vascular channels, followed by severe loss of retinal structure and axonal loss in the optic nerve 4 months later, owing to retrograde axonal degeneration after death of retinal ganglion cells.[41]

More recently, Bui and colleagues[42] documented that during acute increases in IOP in the rat, changes in visual function assessed by electroretinography progressed from the inner to the outer retina. In other words, retinal ganglion cells were the most sensitive to raised IOP, showing abnormalities on the electroretinogram at IOPs of 30 to 50 mm Hg; the photoreceptor cells were not affected until IOP was higher.[42] The duration of increased IOP that injures the retina (see Table 100-2) varies depending on rat or mouse strain. Ischemic times were as short as 20 minutes or as long as 30 or 45 minutes.[32,33,43] The mechanisms of injury with increased IOP from external compression are summarized in Figure 100-2.

Proper use of modern head-positioning devices such as square or circular foam headrests with cutouts for the eyes as well as a mirror to view the eyes (i.e., ProneView, Dupaco, Oceanside, Calif.) should prevent ocular compression. However, we reported a case of unilateral RAO in a prone-positioned patient whose head was placed in a square foam headrest and goggles were used to cover the eyes. This practice is hazardous because of the limited amount of space between the headrest and the goggles and the risk for compression of the eye by the goggles. The patient exhibited signs of direct compression of the eye by the goggles, which, ironically, were designed by the manufacturer Dupaco to function as eye protectors.[44]

Ischemic ocular compartment syndrome, more typical in the setting of retrobulbar hemorrhage after nasal sinus surgery, was described in a patient undergoing spine surgery and positioned prone.[45] The patient's head had been positioned on a silicone headrest for surgery that

lasted 8 hours during which he received only 1 L of crystalloids. Postoperatively, he had left ocular pain, no light perception from the eye, facial edema, 4-mm left proptosis, and a tight orbit. Corneal edema was present, with a large abrasion, mid-dilated and fixed pupil, advanced cataract, pale optic nerve, retinal hemorrhages, and complete inability to move the eye. The IOP was 45 mm Hg. MRI showed proptosis, extraocular muscle enlargement, and severe globe tenting. Despite lateral canthotomy to relieve the pressure, vision did not improve. The cause was thought to be related to positioning with possible direct pressure on the eye.

Orbital compartment syndrome can occur from perioperative intraorbital hemorrhage, orbital emphysema, or intraorbital bacitracin ointment during endoscopic sinus surgery.[46] This syndrome is different from cases of ION after spine surgery but may be similar to the early descriptions of ocular compression by Hollenhorst and co-workers.[41] Orbital compartment syndrome is an acute ophthalmologic injury, requiring prompt decompression to relieve the increased IOP.

Head and Neck Surgery

CRAO has occurred after neck and nasal or sinus surgery, although most cases of visual loss in neck dissection are from ION.[47] The incidence of orbital complications after endoscopic sinus surgery is 0.12%.[48] Orbital hemorrhage from blunt trauma during the procedure can result in orbital compartment syndrome with compression of the arterial and venous circulations and in CRAO and optic nerve injury.[49] Indirect damage to the CRA from intraarterial injections of 1% lidocaine with epinephrine has also been described; the mechanism of action is thought to be arterial spasm or embolism.[50]

Branch Retinal Artery Occlusion

BRAO usually leads to permanent ischemic retinal damage with partial visual field loss. Patients may not notice symptoms immediately if the visual field loss is peripheral or if a small scotoma is present. BRAO is primarily the result of emboli, but vasospasm has been reported in a few cases. Most case reports describe embolization of material from intravascular injections and circulating embolic material from the surgical field or cardiopulmonary bypass (CPB) equipment in cardiac surgery.

Microemboli to the retina during CPB have been shown by retinal fluorescein angiography. Occurrence and extent of perfusion defects were related to oxygenator type. When a bubble oxygenator was used, all patients had perfusion defects indicative of microemboli; when a membrane oxygenator was used, retinal perfusion defects were found in only half. Neurologic outcome was not reported.[51] In coronary artery bypass graft (CABG) surgery, multiple calcific emboli in branches of the CRA are not unusual, resulting in visual field deficits of varying size and location. In pigs, mechanisms of air embolism during CPB included nonperfusion, vascular leakage and spasm, red blood cell (RBC) sludging, and hemorrhage. Priming with perfluorocarbons blocked many of these mechanisms.[52]

Case reports have described sudden irreversible blindness with BRAO in patients after the injection of various drugs into the head and neck region. Loss of vision was nearly instantaneous when steroids were injected into the nasal mucosa.[53] In approximately half of cases, crystalline emboli could be seen at fundoscopy, and one incident appeared to be complicated by vasospasm. Other agents, such as superselective injection of carmustine into the internal carotid artery to treat gliomas, or fat injected into the orbit for cosmetic surgery, also have been complicated by visual loss from retinal arterial occlusion.[54] This complication can occur from a neuroradiologic or angiographic or embolism procedure in the head and neck.

Local infiltration anesthesia with lidocaine or bupivacaine in combination with epinephrine (1:100,000 or 1:200,000) for nasal septal surgery can cause partial or total visual field defects postoperatively attributable to BRAO.[50] The cause of BRAO was vasospasm, likely induced by accidental intraarterial retrograde injection of epinephrine or the combination of lidocaine and epinephrine into branches of the external carotid artery.

BRAO was described in a patient in the prone position for spine surgery. After surgery a patent foramen ovale was discovered. The patient likely sustained a paradoxical air, fat, or bone marrow embolization from the operative site in the lumbar spine.[14]

PROGNOSIS

Perioperative RAO results in permanent loss of vision in most cases.

TREATMENT

Currently available methods of treatment are not satisfactory. Treatment with ocular massage to decrease IOP (contraindicated if glaucoma cannot be ruled out) and thereby dislodge an embolus, if present, to more peripheral arterial branches could be instituted.[20] Intravenous acetazolamide can be administered to increase retinal blood flow. Five percent carbon dioxide in O_2 can be given to enhance dilation and increase O_2 delivery from retinal and choroidal vessels.[26] Further treatment may include thrombolysis, although it is contraindicated after certain surgical procedures. Fibrinolysis through a catheter in the ophthalmic artery within 6 to 8 hours after spontaneous CRAO was associated with improved visual outcome. An ongoing multicenter study is testing efficacy. [55] Localized application of hypothermia to the affected eye is a simple technique that has decreased injury in animal studies after ischemia,[56] and probably should be instituted in humans because of its minimal risk.

PREVENTION

Because retinal arterial occlusion in the perioperative period is most often caused by unintended application of external pressure to the eye, steps must be taken to avoid compression of the globe. Pressure on the eye from anesthetic masks is avoidable. If surgery is near the face, the surgeon's arm must not be allowed to rest on the patient's eye. In patients positioned prone for surgery, a foam headrest should be used with the eyes properly placed in the opening of the headrest; the position of the head and

the eyes should be checked intermittently by palpation or visualization. The horseshoe headrest for the prone-positioned patient must be used with great caution, and safer choices are available. For the patient positioned prone for cervical spine surgery, this headrest should not be used because of the likelihood of head movement, leading to compression of the eye. In the setting of cervical spine surgery with the patient prone, the most effective method for preventing head movement is to place the head in pins.

While the patient is prone, intermittent examination of the eyes is advisable approximately every 20 minutes for a change in position and the absence of external compression. If the patient's head does not fit the headrest adequately (e.g., it is too large) or for surgery on the cervical spine, the head could be held with a pin head holder. Some surgeons now routinely place the patient's head in a pin head holder even for lumbar spine surgery, which eliminates opportunity for pressure on the eyes. This use must be weighed against the associated risks. For most procedures in which the patient is prone, I recommend any of the commercially available square foam headrests. The head is positioned straight down in the neutral position. The eyes and nose are then placed in the open portion of the headrest so that they can be easily checked underneath for pressure intermittently. When a transparent head piece is in use on the operating table, a mirror can be positioned underneath to indirectly view the eyes on the headrest. The ProneView is useful because it combines a foam headrest with a mirror immediately below, which enables the eyes to be seen easily during surgery. The use of goggles to cover the eyes is not advised when the head is positioned prone in a conventional square foam headrest.

In nasal and sinus surgery and in neuroradiologic procedures, the most important principles are avoidance of inadvertent injections into, or compromise of, the ocular circulation. After endoscopic sinus surgery, patients should be checked for signs of acutely elevated IOP suggestive of orbital hemorrhage. If present, immediate ophthalmologic consultation should be obtained. Embolization during CPB remains a cause of retinal vascular occlusion. Better means for detecting and preventing this complication are needed.

ISCHEMIC OPTIC NEUROPATHY

ION, primarily manifesting spontaneously without warning signs, is the leading cause of sudden visual loss in patients 50 years of age or older, with an estimated annual incidence of nonarteritic ION in the United States of 2.3 per 100,000.[57] The two types of ION—anterior (AION) and posterior (PION)—can be arteritic or nonarteritic. Arteritic AION, caused by temporal arteritis, responds to steroids. It is a systemic disease, generally occurs in patients 60 years of age or older, and has a female preponderance. Spontaneously occurring ION, unrelated to surgical procedures, is usually caused by AION. The specific mechanism and location of the vascular insult remain unclear.[58] A rodent model for AION has been recently described.[59]

Nonarteritic ION, more common than arteritic, is overwhelmingly the type found perioperatively. It has been reported after a wide variety of surgical procedures, with most after cardiothoracic surgery,[60] instrumented spinal fusion operations,[61] head and neck surgery,[62] orthopedic joint procedures,[3] and surgery on the nose or sinuses.[63] Cases also have been described after vascular surgery, general surgical and urologic procedures (radical prostatectomy), caesarean section and gynecologic surgery, and liposuction. Most perioperative cases are in adults, with some reports in children.

Although many clinical studies of spontaneously occurring AION have been conducted, few concern PION. The lack of controlled studies, the absence of an animal model, and poorly defined pathologic and risk factors limit our understanding of perioperative ION. The largest and best described single series is the ASA Postoperative Visual Loss Registry.[12] Two case-control studies in spine surgery patients[11,13] and two in cardiac surgery have been done.[8,9]

MECHANISM

Simulated ischemia in optic nerve axons in vitro[64] culminates in axonal destruction. When O_2 delivery decreases, adenosine triphosphate is depleted, leading to membrane depolarization, influx of Na^+ and Ca^{2+} through specific voltage-gated channels, and reversal of the Na^+-Ca^{2+} exchange pump.[65] Ca^{2+} overload damages cells from activation of proteolytic and other enzymes. ION may lead to neuronal injury by apoptotic cell death, which may be stimulated in vitro with reduced O_2 delivery.[66]

Disruption of the blood-brain barrier occurs early in AION, and fluorescein angiography shows the dye leakage in the optic nerve head.[67] Dye leakage correlates with the early onset of optic disk edema, seen even before symptoms.[68] The relationship between disruption of the blood-brain barrier and ischemic injury is not known. Earlier studies showed classic blood-brain barrier properties in the optic nerve head[69]; however, more recent immunohistochemical studies of microvessels in the monkey and human optic nerve head suggest a lack of classic blood-brain barrier characteristics in the prelaminar region,[70] which could explain the early edema in the optic nerve head after ischemia.

In vivo cellular mechanisms lead to ischemic injury in the optic nerve. Guy[71] showed that 30-minute occlusion of the carotid artery in rats produced ischemia and a swollen optic nerve within 24 hours. The positive nitrotyrosine immunostaining found in the ischemic optic nerve suggests a possible role for NO and perhaps O_2 free radicals, which would be expected to increase disruption of the blood-brain barrier. Bernstein and associates[59] described a rodent model of AION. After AION induction by a photothrombotic method, circulation to the optic nerve was lost within 30 minutes; edema peaked 1 to 2 days later and resolved by 5 days. A pale, shrunken optic nerve was found, similar to that in limited pathologic studies of human AION.[72] By 37 days after ischemic insult, the percentage of retinal ganglion cells was reduced by approximately 40%. After 6 days, the optic nerve showed axonal swelling and collapse. Permanent changes included septal

thickening and axonal loss, most evident in the center, also similar to that found in the human optic nerve.

Clinical studies of AION with fluorescein angiography showed delayed filling of the prelaminar optic disk in 76% of subjects and was not found in normal eyes. This suggests that delayed filling is the primary process, and it is not caused by disk edema.[58] Hayreh[73] attributed AION to individual variations in blood supply to the optic nerve.[73] This theory is supported not only by anatomic studies but also by the variability of visual loss in patients with AION. The watershed concept—that impaired perfusion and distribution within a posterior ciliary artery predisposes the optic disk to infarction—is disputed. Arnold and Hepler[67] demonstrated that delayed filling of watershed zones was more common in normal eyes than in patients with AION.[67] Thus, reduced perfusion pressure in the region of the paraoptic branches of the short posterior ciliary arteries (PCAs) results in optic disk hypoperfusion, rather than a watershed event.[74] Histopathologic examination in AION showed that the infarction was mainly in the retrolaminar region.[75] This implicates as the source of decreased blood flow the short PCAs directly supplying the optic disk.

Some have suggested that variability in blood pressure or IOP may predispose patients to the development of AION. Nocturnal hypotension in patients treated with antihypertensive agents may expose patients to low-level, albeit repeated, decreases in perfusion to the optic nerve.[76] The importance of IOP fluctuations in the pathogenesis of AION has not been established.[77] Anatomic or physiologic variations in the circulatory supply of the optic nerve may predispose some patients to the development of AION,[78] especially if systemic arterial blood pressure is decreased.

Hayreh[79] reported nocturnal decreases of 25% to 30% in arterial blood pressure in patients with AION.[79] No control group was included, but the decrease was larger than in age-matched normal subjects. Landau and associates[80] compared arterial blood pressure decreases in normal and AION subjects and found no difference, although daytime blood pressures were slightly lower in those with AION. Thus, the role of chronically or intermittently low blood pressures in the pathogenesis of AION remains controversial. AION is also associated with sleep apnea syndrome,[81] but whether the mechanism depends on repeated hypoxia, increased IOP, decreased blood pressure, or altered autoregulation of blood flow in the optic nerve is still unclear.

A small optic disk (known as a small cup-to-disk ratio) may play a role in susceptibility to AION[82] because axons of the optic nerve pass through a narrower opening as they exit the eye and are therefore susceptible to injury in the presence of edema or decreased blood flow. Mechanisms of injury resulting from a crowded disk include mechanical axoplasmic flow obstruction, stiff cribriform plate, and decreased availability of neurotrophic factors to retinal ganglion cells.[58] Tesser and colleagues[72] reported that in a patient with spontaneous AION, axonal loss was in the superior part of the nerve, largely encircling the central retinal artery. The infarct was in the intrascleral portion of the nerve, extending 1.5 mm posteriorly. Perhaps a tight scleral canal contributed to a compartment syndrome in the anterior optic nerve.[72]

The role of systemic diseases such as hypertension and diabetes has been examined (see also Chapter 39). Hypertension was present in 34% to 47% of patients with AION but was significantly different from that in patients without AION only in those 45 to 64 years of age. Increased prevalence of diabetes is present in most studies of AION, but AION has not been consistently associated with stroke and myocardial infarction, cigarette smoking, and elevated cholesterol.[58] Among patients in the Ischemic Optic Neuropathy Decompression Trial (IONDT), 47% had hypertension, 24% had diabetes, 11% had a previous myocardial infarction, and 3% had a stroke.[83] These proportions of patients with vascular risk factors might, however, be similar to those in the general population. For ethical reasons, the IONDT could not include a non-ION control group. Smoking also might be a risk factor for the development of ION, but large numbers of patients have not been reported. AION may be associated with prothrombotic factors, such as deficiencies of protein C, protein S, or factor V Leiden, but reports are conflicting.[84]

PATIENT CHARACTERISTICS

Most of the cases occurring after spine surgery have been PION.[85] A diagnosis of AION occurs more frequently after cardiac surgery. The onset of POVL is typically within the first 24 to 48 hours after surgery and is frequently noted on awakening, although later onset has been described, particularly in sedated patients whose lungs were mechanically ventilated postoperatively.[13] Patients present typically with painless visual loss, afferent pupil defect or nonreactive pupils, complete visual loss, no light perception, or visual field deficits. Color vision is decreased or absent. In AION, altitudinal visual field deficits may be present. Optic disk edema and hemorrhages are seen on symptom onset in AION; in PION, the optic disk appears normal even though the patient reports visual loss. Over a span of weeks to months, optic atrophy develops. The lesion may be unilateral or bilateral, but most post–spine surgery ION cases have bilateral involvement. In ION, orbital MRI is frequently nondiagnostic, although some reports have described changes including enlargement of the nerve from edema or perineural enhancement.[86] More recent MRI techniques may enhance diagnostic capabilities.[87] Visual evoked potential is abnormal, whereas the electroretinogram is unaffected.[88]

Some of the individual case reports should be examined, especially when some patient-specific data are provided. After presentation of this information, the more recent case series will be examined. Case reports in the literature from 1968 to 2002 described 51 patients in whom perioperative AION was diagnosed.[89] Among this group, 59% underwent open heart surgery; 12%, nasal, head, or neck surgery; and 12%, spine surgery. The average age was 53 years, and 72% were male. In many cases, data are missing and variability is seen in the types of data reported. These patients tended to undergo lengthy operations, with an average operative time of 508 minutes. In patients for whom blood pressure was reported, mean arterial pressure averaged 92 mm Hg preoperatively and the lowest mean arterial pressure averaged 65 mm Hg intraoperatively. Preoperative hemoglobin averaged 13.7 g/dL, the lowest

intraoperative value was 8.7 g/dL, and the postoperative hemoglobin concentration was 8.1 g/dL. The patients received considerable amounts of fluid intraoperatively; they averaged 1.4 L of blood replacement, 8.2 L of crystalloid, and 1.0 L of colloid. In 20%, blood loss exceeded 2 L. Coronary artery disease was present in 61%, hypertension in 27%, and diabetes mellitus in 24% of patients. Because of the predominance of CABG, these data may be weighted toward a more frequent prevalence of these disorders in this group.

In 67%, symptoms of visual loss were not evident until more than 24 hours after surgery, either because of delayed onset of the disease or delayed recognition of the symptoms and signs of AION in the perioperative period as a result of mechanical ventilation and sedation postoperatively. Nearly all had disc edema, pallor, or both. Over 60% had an afferent pupil defect or nonreactive pupils. The visual field deficit was altitudinal in 14%, a central scotoma was present in 20%, and in 20% blindness was the initial symptom. Visual loss was bilateral in 55% and unilateral in 45% of patients. Some treatment was attempted in 15 patients, including steroids, aggressive volume replacement, vasopressors, or a combination of these therapies. Treatment did not necessarily result in improvement. Overall, in the 51 patients, 47% had no improvement or a worsening of symptoms, 29% improved, and in 25% the outcome was not described.

Between 1968 and 2002, case reports described 38 patients with perioperative PION. The nature of the surgical procedures in these patients tended to differ from those in the AION reports. In this group, 8% underwent open heart surgery; 24%, nasal, head, or neck surgery; and 39%, spine surgery. The average age was 50 years, and 63% were male. Although AION is rarely reported in children, four patients with PION were 13 years or younger. As with AION, surgery tended to be lengthy, averaging 448 minutes. In patients for whom blood pressure was reported, mean arterial pressure averaged 90 mm Hg preoperatively, with an average lowest mean arterial pressure intraoperatively of 61 mm Hg. Preoperative hemoglobin averaged 12 g/dL, the lowest intraoperative hemoglobin concentration was 8 g/dL, and postoperative values averaged 10 g/dL. These values are similar to those reported in the patients with AION. Hematocrit decreased from 44% to 27% intraoperatively and increased to 29% postoperatively. The patients also received considerable amounts of fluid intraoperatively; they averaged 2.3 L of blood replacement, 8.8 L of crystalloid, and 1.6 L of colloid. In 37% of cases, intraoperative blood loss exceeded 2 L. Coronary artery disease was present in only 8%, hypertension in 32%, and diabetes mellitus in 21%. In contrast to patients with AION, the incidence of coronary artery disease was much lower. The onset of symptoms was typically within 24 hours postoperatively. Blindness was reported in 47%, an altitudinal defect in 8%, and a central scotoma in 26%. Twenty-seven (71%) patients had an afferent pupil defect or nonreactive pupils. A normal optic disk on initial funduscopic examination was evident in 92%. Visual loss was bilateral in 63% and unilateral in 34%. Forty-five percent had no improvement, 29% improved, and for 18% the outcome was not described.

In summary, most patients with AION had undergone open heart surgery. The largest single group of patients with PION had spine fusion surgery. The main differences were a less frequent incidence of coronary artery disease in the group with PION; the occurrence of PION in younger patients; an increase in intraoperative blood replacement, more rapid onset or recognition of visual loss, and a greater likelihood of complete blindness initially in PION cases than in AION cases.

RETROSPECTIVE CASE SERIES

Sadda and associates[90] retrospectively collected 72 reports on cases of ION from two large academic institutions over a 22-year period. In 38 subjects, PION developed spontaneously, and in 28, it developed in the perioperative period. In the remaining 6, the diagnosis was arteritic PION. For the 38 with spontaneous nonarteritic PION, the average age was 68 years; 39% had hypertension, 24% had diabetes, 18% had coronary artery disease, and 32% had a history of cerebrovascular disease. Bilateral involvement occurred in 21%, and 90% had some form of visual field deficit. Only 30% improved, and 35% worsened. Unlike AION, in which a structural difference in the optic nerve, such as a small cup-to-disk ratio, may be found, these authors could identify a structural abnormality in the optic nerve in only 4% of patients with PION. The 14 patients who had spinal surgery tended to be younger and have a lower incidence of coronary artery disease and diabetes, but not hypertension, relative to the other two groups. Unfortunately, intraoperative data were not included, but the postsurgical patients were more likely to have bilateral involvement (54%) and a worse visual outcome at initial examination and later follow-up compared with PION in nonsurgical cases.

Buono and Foroozan[85] reviewed 83 PION cases reported in the literature. In 36, details of clinical features were included; in the other 47, aggregate data had been reported. Approximately 54% followed spine surgery, 13% radical neck dissection, and 33% other surgery. Mean age was 52 years; patients who had spine surgery were younger (mean age, 44 years) than those in the other groups. Approximately two thirds were men. In 75% of cases, visual loss was apparent within 24 hours of surgery. Visual acuity was "counting fingers" or worse in 76%, and 54% of eyes had an initial visual acuity of no light perception. Over 60% of cases were bilateral. In 38% of patients, vision improved, but of 14 with no light perception initially, 12 (85%) had no improvement. Among patients with PION, 65% had one or more of the following: hypertension, diabetes, cigarette use, hypercholesterolemia, coronary artery disease, congestive heart failure, arrhythmia, cerebrovascular disease, or obesity. Mean lowest hemoglobin value was 9.5 g/dL (5.8 to 14.2 g/dL), mean lowest systolic blood pressure was 77 (48 to 120 mm Hg), mean intraoperative blood loss was 3.7 L (0.8 to 16 L), and mean operative duration was 8.7 hours (3.5 to 23 hours).

Spine Surgery

Cheng and colleagues[91] surveyed neurosurgeons in the United States who performed spine surgery, with 24 cases of visual loss reported by 22 surgeons. Mean age was 47

± 15 years. Lumbar spine surgery was the procedure performed most frequently, and mean surgery duration was 4.8 ± 3.5 hours. Mean hematocrit changed from 42 ± 5% to 35 ± 7%. Mean estimated blood loss was 793 ± 1142 mL. In 5 patients, estimated blood loss exceeded 1800 mL; 3 received blood transfusions. Of the 24 patients, 21 were normotensive intraoperatively and 2 had deliberate hypotension; 4 had diabetes mellitus, 1 had peripheral vascular disease, and 1 had diabetes and peripheral vascular disease.

Ho and associates[92] reviewed reported cases of AION and PION in the literature after spine surgery. In the 5 cases of AION and 17 of PION, median ages were 53 and 43 years, respectively. Most of the cases followed lumbar spine fusion surgery. Mean operative time for AION cases was 522 minutes and for PION cases was 456 minutes. For AION, the range of the lowest mean arterial pressure was 62 to 78 mm Hg; for PION, it was 52 to 85 mm Hg. Lowest mean intraoperative hematocrit was 27% in the PION cases. Mean blood loss was 1.7 L and 5 L for AION and PION, respectively. Crystalloid/colloid volumes averaged 6.0/0.8 L and 8.0/2.2 L for AION and PION, respectively. Sixty percent of patients with AION and 27% with PION had diabetes mellitus; coronary artery disease was noted in 20% of patients with AION and in none with PION. Prevalence of hypertension was similar (40% or 53%). Symptoms were reported within 24 hours of surgery in 40% of patients with AION; 59% of patients with PION reported symptoms immediately on awakening and 88% within 24 hours. Visual acuity improved somewhat in 60% of AION and 65% of PION cases.

Data from spine surgery patients in the ASA Postoperative Visual Loss Registry[12] showed striking differences between patients with ION ($n = 83$) and those with CRAO ($n = 10$). The average blood loss in ION patients was 2.0 versus 0.75 L with CRAO. The lowest hematocrit was 26% with ION and 31% with CRAO. With ION, decreases in blood pressure varied widely from preoperative baseline: in 33% of cases, the lowest systolic blood pressures were greater than 90 mm Hg; in 20%, the lowest was 80 mm Hg or less. Approximately 57% of patients had systolic or mean arterial blood pressure 20% to 39% below baseline, and 25% of patients were at 40% to 49% below preoperative baseline. Deliberate hypotension was used in approximately a fourth of the patients. Nearly all cases involved surgery exceeding 6 hours. In the majority of the patients, estimated blood loss was greater than 1 L, the median estimated blood loss was 2 L, and the median lowest hematocrit was 26%. Large-volume fluid resuscitation was typical in these patients, with median crystalloid administration of approximately 10 L. Most of the patients underwent thoracic, lumbar, or lumbar-sacral fusion procedures that were often repeat operations that mostly involved multilevel surgery. Surgical positioning devices for these patients were the Wilson frame (30%), Jackson spinal table (27%), and soft chest rolls (20%). A foam pad was used for head positioning for 57%; 19% had the head positioned in a Mayfield head holder. PION accounted for the majority of the cases, compared with AION. Patients in ASA class 1 or 2 accounted for 64% of cases. The mean age was 50 ± 14 years. Approximately 41% had hypertension, 16% had diabetes mellitus, and 10% had coronary artery disease. The ASA Postoperative Visual Loss Registry does not have a control group of unaffected spine surgery patients for comparison to enable a case-control study of risk factors.

In a retrospective case-control study of 28 patients with visual loss after spine surgery, Myers and colleagues[11] found no difference in the lowest systolic blood pressure or hematocrit in the affected versus unaffected patients, suggesting that hypotension and anemia do not completely explain the occurrence of ION. Approximately 40% of these patients had no risk factors for vascular disease preoperatively; a similar percentage in the two groups had hypertension or were smokers.[11]

An important follow-up study to the ASA Postoperative Visual Loss Registry and a more complete examination of possible risk factors compared to the Myers study was published in 2012. This study was a multicenter case-controlled retrospective examination of the factors involved in perioperative ION in lumbar spine fusion surgery. Affected patients were those in the first publication of the ASA Postoperative Visual Loss Registry. The control patients were randomly selected matched patients derived from 17 academic medical centers in the United States and Canada. The results of the study are summarized in Table 100-3. In this retrospective controlled study, six specific factors were found to confer higher risk for sustaining perioperative ION in the setting of lumbar spine surgery: male gender, obesity, positioning on a Wilson frame, duration of anesthesia, large blood loss, and a relatively low ratio of colloid to crystalloid fluid resuscitation.[13]

Cardiac Surgery

Two retrospective case-control studies of blindness after cardiac surgery have been reported (see also Chapter 67). Shapira and colleagues[8] studied 602 patients at a single institution. Patients underwent CPB under moderate systemic hypothermia (25° C) with pulsatile flow and a membrane oxygenator. Neo-Synephrine was used if perfusion pressure could not be maintained above 50 mm Hg despite a flow index of 2 L/m^2/min, and α-stat was used for pH management. Eight patients (1.2%) had AION. There were no differences in preoperative risk factors for vascular disease between patients with or without visual loss. CPB time was longer in patients with AION (252 versus 164 minutes), and minimum hematocrit was lower (18% versus 21%) compared with unaffected patients. No differences were found in flow indices, perfusion pressures,

TABLE 100-3 **FACTORS INCREASING THE ODDS RATIO OF DEVELOPING PERIOPERATIVE ION IN LUMBAR SPINE FUSION SURGERY**

	Odds Ratio	*P* Value
Male	2.53 (1.35-4.91)	.005
Obesity	2.83 (1.52-5.39)	.001
Wilson frame	4.30 (2.13-8.75)	<.001
Anesthesia duration, per hour	1.39 (1.22-1.58)	<.001
Estimated blood loss, per 1 L	1.34 (1.13-1.61)	.001
Colloid as percent of nonblood replacement, per 5%	0.67 (0.52-0.82)	<.001

and P_{CO_2} levels intraoperatively. Patients with AION had a greater 24-hour postoperative weight gain (18% versus 11%) and required more epinephrine and amrinone postoperatively to maintain hemodynamics than did patients with unaffected vision. Visual symptoms were usually reported between days 1 and 3 postoperatively, soon after removal of mechanical ventilatory support.

Nuttall and colleagues[9] performed a larger retrospective case-control study of approximately 28,000 patients who had cardiac surgery at the Mayo Clinic from 1976 to 1994, with 17 patients with ION (0.06%). By univariate analysis, significant risk factors included lower minimum postoperative hemoglobin, history of clinically severe vascular disease, preoperative angiogram within 48 hours of CPB, longer duration of CPB, RBC transfusions, and any use of non-RBC blood components. Patients with ION underwent longer CPB runs; no differences were found in pre-CPB or post-CPB systemic blood pressures. Nine cases of bilateral ION were reported; disk edema was not found in 5 patients (29%), who may have had PION, not AION. Small cup-to-disk ratio (<0.3) was identified in 5 patients (29%) with ION. A more recent series by Holy and colleagues[93] showed similar results, but their series included other surgical procedures, which complicates interpretation of the specific results with cardiac surgery. Kalyani and colleagues[10] retrospectively reviewed cases of ION after 9701 cardiac surgeries over a 9-year period at a single institution. Specific risk factors could not be determined from the 11 patients (0.11%) with ION.

Trauma

Cullinane and co-workers[94] retrospectively reviewed the medical records of over 18,000 trauma cases at a single institution between 1991 and 1998 (see also Chapter 81). Of these, 350 required massive resuscitation with more than 20 L of fluid during the first 24 hours after admission. Volume resuscitation consisted of 21 to 50 L (mean 33 ± 8 L) in the first 24 hours. ION was found in 2.6% (9 patients). Four patients had bilateral blindness. No information was provided on funduscopic examinations. The mean age was 34 ± 13 years. Patients were acidotic, with serum lactate levels ranging from 2.5 to 17.5 mEq/L. Mean lowest hematocrit was 7.5% to 28% (mean 20 ± 8%); blood products included 9 to 39 units of packed RBCs (mean 22 ± 10 units). All patients had a coagulopathy, and all developed acute respiratory distress syndrome that required increased levels of inspired O_2 and positive end-expiratory pressure (mean level 29 ± 9 cm H_2O). All patients had systemic inflammatory response syndrome, and 66% had compartment syndrome at some location remote from the eye. Mean time until detection of visual loss was 36 days because patients needed prolonged mechanical ventilation and sedation.

BLOOD SUPPLY TO THE OPTIC NERVE

ION affects the anterior portion of the optic nerve in AION or beyond the retrolaminar region behind the eye in PION. The ischemic insult has been theorized to be of vascular origin, but this has not been conclusively shown; whether the defect is on the arterial or venous side has not been resolved. Anatomy of and blood supply to the anterior and posterior optic nerves differ.[73] The pathophysiologic basis of PION is even less well understood than that of AION.

The anterior portion of the optic nerve is proximal to the lamina cribrosa, an elastic, collagenous tissue through which the optic nerve, central retinal artery, and central retinal vein pass as they enter the optic disk. The anterior portion of the optic nerve includes the superficial nerve fiber layer and the prelaminar region. The prelaminar area is a thick tissue that constitutes most of the optic disk volume.[95] The superficial nerve fiber layer, composed of axons extending from the retinal ganglion cells, is anterior to the plane extending across the optic nerve from the peripapillary Bruch membrane. Immediately posterior is the prelaminar region, adjacent to the peripapillary choroid. The laminar region is a transition zone between columns of glial cells and dense connective tissue plates. Astrocytes are predominant in the anterior optic nerve, and oligodendrocytes and microglial cells are more common in the posterior or retrobulbar optic nerve. Neural fibers transit the laminar region through fenestrations. The retrolaminar region is the posterior portion of the optic nerve and consists of meningeal sheaths and myelinated axons. The diameter of the optic nerve is enlarged in this area to approximately 3 mm.

The superficial nerve fiber layer derives its blood supply mainly from arterioles in the retina, although in the temporal regions it may receive blood from the posterior ciliary arteries. The prelaminar region is perfused by centripetal branches of the peripapillary choroid and vessels from the circle of Zinn-Haller (Fig. 100-3), which are not found in every eye.[73] Whether the region has a choroid-derived source of blood is controversial. The laminar region is supplied by centripetal branches from the short posterior ciliary arteries or by the circle of Zinn-Haller, but the short posterior ciliary arteries are the primary inputs. Longitudinal anastomoses of capillaries can be seen in the prelaminar and laminar regions and may provide some circulation, although their functional importance is not clearly known.

The retrolaminar, posterior portion of the optic nerve, which is affected in PION (Fig. 100-4), is perfused by two main vascular supplies. The peripheral centripetal vascular system is the major supply and is found in all optic nerves. It is formed by recurrent branches of the peripapillary choroid and the circle of Zinn-Haller. Pial branches of the central retinal artery and other orbital arteries, the ophthalmic artery, and the posterior ciliary arteries also contribute. Branches of the pial vasculature run in the septa of the nerve. The axial centrifugal vascular system is formed by small branches from the intraneural part of the central retinal artery and is not present in every eye; thus, differences in blood supply in the posterior optic nerve may render some individuals more susceptible to PION.[96]

CONTROL OF BLOOD FLOW

Studies of autoregulation of blood flow in the optic nerve head have yielded conflicting results because measurement techniques are limited. Blood flow in the optic nerve head is autoregulated within a range of perfusion

pressures similar to those in the brain of monkeys and sheep. In a small sample of atherosclerotic monkeys, however, autoregulation was defective.[97] This study did not directly measure blood flow; rather, it measured glucose consumption, and the sample size was small. Other evidence of autoregulation is seen in the posterior portion of the optic nerve. In cats, blood flow in the optic nerve measured directly by autoradiography remained constant in the prelaminar, laminar, and postlaminar nerve across a range of systemic mean arterial blood pressure values from 40 to more than 200 mm Hg.[98]

In a study in 13 healthy volunteers, blood flow in the optic nerve head measured by laser Doppler flowmetry was constant between ocular perfusion pressures of 56 to 80 mm Hg[99]; in another, flow was preserved at extremely high IOP that resulted in a minimal perfusion pressure of 22 mm Hg.[100] Other investigators found that flow was preserved in the optic nerve head until ocular pressure reached levels of 40 mm Hg. However, 2 of 10 healthy young volunteers in the study failed to demonstrate autoregulation.[78] Using color Doppler imaging in humans, another group showed that flow velocity in the posterior ciliary arteries decreased at extremely high IOP. These findings seem to support the theory that "watershed" areas in the distribution of the posterior ciliary arteries predispose some patients, including otherwise healthy ones with no known vascular disease, to damage to the anterior portion of the optic nerve when perfusion pressure is decreased, either after systemic blood pressure decreases or IOP is elevated. At present, however, no clinical technique can reliably detect such patients.

HISTOLOGIC FINDINGS

Few reports have been published on the histopathologic examination of the optic nerve in ION. Of three PION cases evaluated after surgical procedures, all of the patients showed infarcts in the intraorbital portion of the optic nerve, but results were not consistent. Two patients had lesions in the central axial portion with peripheral axonal sparing; the other had the opposite pattern in one eye and complete axonal loss in the other.[85] Despite a larger autopsy series in AION, the location of the infarct has not been documented. Tesser and colleagues[72] showed that in a patient with spontaneous AION the axonal loss was in the superior part of the nerve, largely encircling the central retinal artery. The infarct was in the intrascleral portion of the nerve, extending 1.5 mm posteriorly.

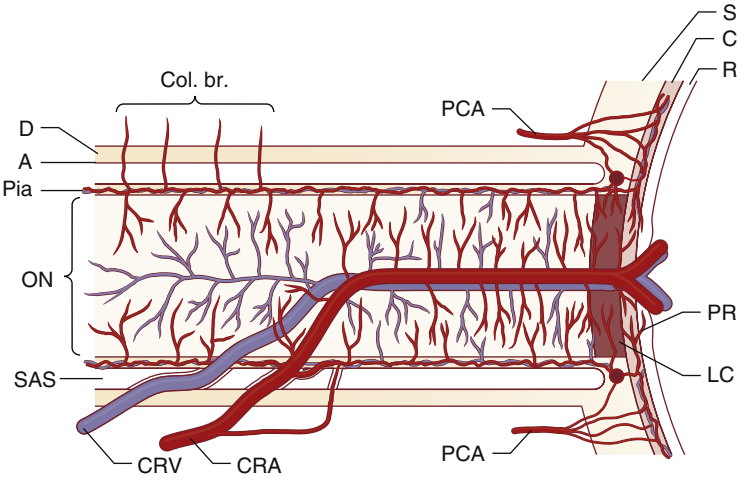

Figure 100-4. The blood supply to the optic nerve. The anterior portion of the optic nerve is located to the left, whereas the posterior portion (closer to the brain) is on the right. The anterior portion of the nerve derives its blood supply from the posterior ciliary arteries (*PCA*) and the choroid (*C*), whereas the posterior optic nerve derives its blood supply from penetrating pial arteries (collateral branches [*Col. br.*]) and branches of the central retinal artery (*CRA*). *A,* Arachnoid; *CRV,* central retinal vein; *D,* dura; *LC,* long ciliary artery; *ON,* optic nerve; *PR,* short posterior ciliary artery; *R,* retina; *S,* sclera; *SAS,* subarachnoid space. *(From Hayreh SS: Ischemic optic neuropathy, University of Iowa, Department of Ophthalmology.* <http://www.medicine.uiowa.edu/eye/AION-part2.> *Accessed August 8, 2014)*

POSSIBLE PATHOGENIC FACTORS

Factors in perioperative ION via retrospective case-control studies are long surgery; hypotension; blood loss; anemia or hemodilution; altered venous hemodynamics; flow of cerebrospinal fluid in the optic nerve (including the influence of patient positioning and perioperative fluid resuscitation); abnormal autoregulation in the optic nerve; anatomic variants in blood supply to the optic nerve; male gender; small cup-to-disk ratio; the use of vasopressors; the presence of systemic vascular risk factors, including hypertension, diabetes, atherosclerosis, hyperlipidemia, obesity, and smoking history; prone positioning; lengthy surgery for spinal fusion; the nature of the intravascular fluid resuscitation during surgery; and other preexisting systemic abnormalities, such as sleep apnea syndrome and hypercoagulability.

Some of these factors are often present in an individual patient in an unpredictable fashion. In most cases, hypotension, anemia, and intravascular fluid resuscitation have occurred. Many of the patients with ION after spine surgery were relatively healthy preoperatively. Hypotension, blood loss, lengthy surgery, and large intravascular fluid administration occur frequently in many patients undergoing complex spine surgery.[11,85,90-92] Perhaps a combination of these factors, together with abnormal autoregulation in the posterior optic nerve, prothrombotic tendencies, and other patient-specific factors, are responsible for ION.

CURRENT KNOWLEDGE AND CONTROVERSIES

Because of limited data, risk factors for ION have not yet been well defined. However, a number of potential factors warrant discussion. Myers and associates[11] showed that length of surgery and estimated blood loss were higher in patients with postoperative blindness after spine surgery than in unaffected patients. This has also been found by the Postoperative Visual Loss (POVL) Study Group.[13] Therefore, patients undergoing anticipated long-duration surgery with large blood loss are recognized to be at higher risk.[101] Staging of spinal fusion procedures, particularly those for anterior and posterior surgery, may be advisable A discussion between the surgeon and anesthesia provider should occur for appropriate cases. Revision spinal fusion procedures are common, and these operations may be longer in duration and involve larger blood losses.

Intraoperative hypotension has been cited as a risk factor by a number of authors of case reports,[102,103] but because it is not always present, and some degree of hypotension frequently occurs in anesthetized patients, hypotension itself might not be responsible.[8,104-106] In the survey by Cheng and colleagues[91] of 24 cases of visual loss after spine surgery, deliberate hypotension was used in only 2 cases.[91] In a retrospective case-control study of patients undergoing spinal fusion, Myers and colleagues[11] showed that levels of hypotension and anemia were equivalent in patients in whom ION developed after spinal surgery and in those in whom it did not. In the ASA Postoperative Visual Loss Registry, which contains the largest series of visual loss after spine surgery, a wide variation was observed in blood pressure decreases intraoperatively among the patients with ION; in 33% of cases, the lowest systolic blood pressures were more than 90 mm Hg, and in 20% the lowest were 80 mm Hg or less. Approximately 57% of patients had systolic or mean arterial blood pressure 20% to 39% below baseline, and in 25% of patients it was 40% to 49% below preoperative baseline. Deliberate hypotension was used in 27% of the patients.[12] Patil and colleagues[4] reported a higher odds ratio for ION in patients who sustained hypotension. However, the study results are weakened by a number of factors. Among them are that this study used the Nationwide Inpatient Sample (NIS). None of the diagnostic coding can be confirmed, and the timing (perioperative period or not) and the degree of hypotension are not specified and cannot be determined using the NIS.[3,107] The POVL Study Group did not find an involvement of hypotension in the case-control study.[13] The same result was reported by Holy and colleagues.[93] Similarly, in the retrospective case-control study by Shapira and associates[8] of 602 patients who underwent open heart surgery at one institution during a 2-year period, the lowest perfusion pressure intraoperatively was no different between affected and normal patients. The larger case-control study by Nuttall and co-workers[9] did not report the blood pressures during CPB, but no differences were observed in prebypass or postbypass blood pressures between patients with ION and unaffected patients. In open heart surgery, hypothermia during CPB and other systemic alterations such as systemic inflammatory syndrome might play a role in the development of ION but these mechanisms have not been studied.

Hypotension can potentially lead to decreases in perfusion pressure in the optic nerve and to ischemic injury because of either anatomic variation in the circulation or abnormal autoregulation and an inability to adequately compensate for decreased perfusion pressure. The degree of hypotension that is potentially dangerous is difficult to quantitate because of the lack of data in the literature.[101]

Blood loss may be considerable in reports of perioperative ION. It is apparent that, on average, patients sustained considerable blood loss and had a decreased hemoglobin concentration intraoperatively. Clinical blood transfusion practice in surgical patients, based on ASA practice guidelines,[108] suggests that transfusion is not generally required for hemoglobin values higher than 8.0 g/dL. The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists, which reviewed the available evidence base for these practices in cardiac surgery in particular, has issued a recent, similar clinical practice guideline.[109]

Some authors suggest that allowing hemoglobin to decrease, as is common in anesthesia practice, may be putting patients at increased risk for ION[110]; however, whether practice should be changed in surgical procedures such as spine or heart surgery—or in any operative procedure—remains controversial. Four retrospective case-control studies examined whether decreased hemoglobin or hematocrit relates to the occurrence of ION. In patients undergoing spine surgery, Myers and associates[11] determined that the lowest levels of hematocrit did not

differ between patients sustaining ION and those who were not affected; similarly the POVL Study Group found that decreased hemoglobin did not increase the odds ratio for developing ION.[13] Holy and colleagues[93] had similar findings but in a mixed population of patients. In patients undergoing cardiac surgery, Nuttall and co-workers[9] found a somewhat different result. The presence of a lower minimum postoperative hemoglobin was associated weakly with ION (odds ratio, 1.9; $P < .047$). Looked at another way, 13 of 17 patients with ION in their study had a minimum postoperative hemoglobin value less than 8.5 g/dL, versus 14 of 34 control patients with this level. The type of ION sustained by the patients was not specified, and the study had numerous statistical comparisons and a small sample size. Because spine and open heart surgery patients are different, it is doubtful that the results can be extrapolated to types of surgery other than cardiac. Although visual loss after cardiac surgery is a rare but dreaded complication, the possibility of a relationship among blood loss, hemoglobin value, and visual loss was not a consideration in the clinical practice guideline for blood transfusion in cardiac surgery.[109]

In uncontrolled hemorrhage in which blood volume is not maintained, decreased O_2 delivery to the optic nerve could result in either AION or PION.[111] Just how low or for how long the hemoglobin concentration must decrease to lead to this complication is not known (see also Chapter 61). However, the presence of recurrent and profound hemorrhage has been described in many reports. The argument that blood loss in the presence of maintained intravascular volume (hemodilution) is harmful seems less scientifically grounded. It has been shown experimentally in miniature pigs that blood flow in the optic nerve head, as measured by laser Doppler imaging, was maintained during isovolumic hemodilution with a 30% decrease in hematocrit. Moreover, O_2 tension at the vitreal surface increased 15%.[112] Also, Lee and associates[113] demonstrated that extreme decreases in hematocrit (15%) and mean arterial pressure (50 mm Hg) in adult pigs resulted in significant reductions in blood flow to the optic nerve. But no histologic or optic nerve function was studied, and the pig brain and eye circulation significantly differ from that of humans.[113] Hemodilution in cats resulted in a nonsignificant decrease in choroidal O_2 delivery[114] and an increase in preretinal O_2 tension.[115] Healthy volunteers tolerated very deep levels of hemodilution (hemoglobin 50 g/L) without any disturbance in systemic O_2 delivery.[116] The multicenter prospective randomized trial conducted by Hebert and co-workers[117] provided data justifying clinical use of a liberal transfusion strategy (lower hematocrit) in critically ill patients. AION and PION occur in massive intravascular fluid replacement. Many reports include patients who were in the prone position, raising the possibility that positioning itself contributes to altered venous hemodynamics within the optic nerve. The patient's head should be level with or above the heart, when possible, and in a neutral position during spine surgery performed with the patient in the prone position. Several studies found that IOP increased in the prone position and was influenced by the position of the operating room table. However, there has been no correlation between IOP changes and visual outcome or visual function.[18] Cheng and colleagues[19] found that in anesthetized patients, IOP increased significantly on initial prone positioning relative to supine (27 ± 2 versus 13 ± 1 mm Hg). After 5 hours in the prone position, IOP remained increased at 40 ± 2 mm Hg. None of the 20 patients in the study experienced visual loss. The largest increases in IOP were evident near the time patients were awakening. Although these data suggest that ocular perfusion pressure may decline even during maintenance of normotension, some experimental design issues must be considered in interpreting these results. The main issue is that the largest increases in IOP were evident near the time of awakening from anesthesia. Accordingly, IOP could have increased because of light anesthesia. Moreover, the study did not include a supine group to control for the effects of fluid administration on IOP. Such control is important because prone positioning itself may not explain the large increases in IOP. These results are valuable as well as of concern, but further studies are needed to fully evaluate their significance.

External pressure on the eye is a potential concern when a patient is positioned prone for surgery. Many cases of ION have occurred when pressure could not have been placed on the eye. Such cases include patients in pin head holders[118] and those in whom the head was turned with the affected eye placed upward.[119] But ION would not occur without retinal damage in a situation in which external compression was applied (see earlier discussion). Although we demonstrated that high IOP decreased retinal and choroidal blood flows in cats,[23] Geijer and Bill[120] specifically measured the impact of graded increases in IOP on blood flow in the retina and optic nerve in monkeys. When IOP was elevated such that perfusion pressure was decreased to levels above 40 cm H_2O, small effects on retinal blood flow and in the prelaminar portion of the optic nerve were noted. When perfusion pressure was less than 40 cm H_2O, retinal and prelaminar flows were proportional to the perfusion pressure. At very high IOP, blood flow stopped in the retina and the prelaminar area but flow in the retrolaminar region increased. High IOP results in a redistribution of blood flow that favors the retrolaminar portion of the optic nerve. Therefore, an increase in IOP would not produce an isolated ION without also causing retinal damage. Further support is that sustained increases in IOP significantly decreased both retinal and choroidal blood flow, and even small increases in IOP damaged the retinal ganglion cells, which are sensitive to pressure alterations.[23,42]

The theory that massive intravascular fluid resuscitation could be a pathogenic factor in perioperative ION remains speculative, but it does have some merit. Fluid resuscitation is a necessity during lengthy, complex spine surgery associated with substantial blood and fluid losses at the operative site.[104,105] Conceivably, fluid administration could result in increased IOP, accumulation of fluid in the optic nerve, or both. Because the central retinal vein exits out of the optic nerve, an internal compartment syndrome may occur in the optic nerve. Alternatively, fluid accumulation in the vicinity of the lamina cribrosa may compress axons as they transit this region. In the report by Cullinane and associates,[94] trauma patients who were acidotic received massive blood replacement and

most had abdominal compartment syndrome. Analysis of these patients is complicated because of the presence of numerous systemic alterations. Sullivan and associates[121] described a retrospective series of 13 burn patients with 25% or greater body surface area burns and massive fluid resuscitation. IOP was elevated more than 30 mm Hg in 4 patients at 48 hours after admission, all of whom received more than 27 L of intravenous fluid. Eye findings and vision diagnoses were not described. Large-volume fluid replacement is generally seen in many case reports of ION.[89] Patients in the ASA Postoperative Visual Loss Registry received on average 9.7 L of crystalloid intraoperatively,[12] and increased postoperative weight gain was identified in a case-control study of visual loss after heart surgery,[8] suggesting, although not proving, that fluid replacement may play a role. The finding of the POVL Study Group was that the odds ratio for developing ION was increased as the percent colloid of nonblood replacement decreased.[13] It is possible that the use of colloids may decrease edema in the optic nerve during surgery, particularly when the patient is placed prone for surgery. However, at present, such edema has not yet been demonstrated. In healthy volunteer subjects, placement in the prone position led to an increase in diameter of the optic nerve.[122] This could be due to venous hypertension. New MRI methods may enable the study of edema and venous hemodynamics in the optic nerve in the near future. Animal models also may provide a means to study these perioperative factors.

Further support of an idea that increases in venous pressure within the optic nerve are potentially deleterious can be seen in reports of ION after head and neck surgery in which the internal jugular veins were ligated.[17,62,123] However, there are venous drainage bypass pathways from the head and neck when the internal jugular veins are ligated. Although the relationship to fluid therapy is not clear, Myers and colleagues,[11] the POVL Study Group,[13] and Patil and co-workers[4] found that longer surgery was associated with ION. However, cases of ION have been found after widely varying operative times.[12]

Cases of ION have been reported after radical robotic-assisted prostatectomy (see also Chapter 87). This surgical procedure is notable for placement of the patient in steep head-down tilt and increases in intraabdominal pressure because of laparoscopy.[124] Some have speculated that facial edema indicates a risk for ION after spine surgery.[125] However, in clinical practice, facial edema is often seen after spinal fusion in many patients in whom ION does not develop, and, therefore, its relevance remains unclear and facial edema as a risk factor is unproved.

Killer and co-workers[126] sampled cerebrospinal fluid (CSF) from the subarachnoid space of the optic nerve and the lumbar region in patients with idiopathic intracranial hypertension undergoing optic nerve sheath fenestration. The authors compared content of albumin, immunoglobulin G, β-trace protein, and brain-derived protein lipocalin-like prostaglandin D-synthase. MRI and CT cisternography were performed. From differences in the ratios of the CSF proteins in the optic nerve versus the CSF proteins in the lumbar region, and the results of cisternography, they concluded that CSF flow was compartmentalized in the optic nerve under these pathologic conditions. The implication of this conclusion is that relatively high CSF pressures in the intraorbital optic nerve can result in compression. Because CSF pressure may increase with fluid resuscitation, this may explain optic nerve compression. However, this theory has not been tested.

Although various theories concerning the role of intraoperative fluids in perioperative ION have been postulated, including extravasation from the central retinal vein, influence of directional CSF flow in the optic nerve, and changes in intracranial pressure, among others, none of these has been examined in either animal or human studies. MRI of the orbit in humans with ION has provided no evidence for any of these theories.[127] No study has shown any relationship among periorbital edema, IOP, and ION. Fluid administration could be a pathogenic factor in ION, especially in patients positioned prone or undergoing cardiac surgery, but the mechanisms involved, as well as the amounts and nature of fluid required, remain undefined.

Anatomic variation in the circulation of the optic nerve may potentially predispose patients to the development of ION. The location of potential watershed zones in the anterior and posterior circulation and the presence of disturbed autoregulation, even in normal patients,[78] are of concern but at present cannot be predicted clinically. Few human studies have been conducted on the relationship between perfusion pressure and changes in blood flow in the optic nerve. Human studies generally show preserved blood flow at clinically used or even lower ranges of perfusion pressure, but these studies have focused primarily on the anterior portion of the optic nerve.[99] In the studies that used laser Doppler flowmetry, depth of penetration of the measuring device is critical. Measurements might have been closer to the retinal blood vessels than the optic nerve head, and these do not measure optic nerve circulation. It is not currently feasible to measure blood flow in the human retrolaminar optic nerve. In animal studies, blood flow is preserved in various layers of the optic nerve, including the retrolaminar area, at a mean arterial blood pressure as low as 40 mm Hg.[98]

Hayreh and associates[128] theorized that AION is related to excessive secretion of vasoconstrictors, which in turn could lower optic nerve perfusion to dangerously low levels. However, the theory was based on the development of AION in patients who sustained massive hemorrhage. Vasopressors are used to maintain blood pressure in circumstances such as after cardiac surgery and in cases in which vasomotor tone is decreased. Shapira and co-workers[8] showed an association between prolonged use of epinephrine or long bypass time and ION in patients undergoing open heart surgery. Lee and Lam[106] reported a case of ION in a patient after lumbar spine fusion during which a phenylephrine (Neo-Synephrine) infusion was used to maintain blood pressure. They later presented a series of four case reports of ION in critically ill patients with significant systemic illness who required prolonged use of vasopressors and inotropic agents to maintain blood pressure and cardiac output.[129] However, α-adrenergic receptors are not located in the optic nerve and the blood-brain barrier prevents entry of systemically administered agents, except possibly in the prelaminar zone of the nerve. Therefore, a role of vasopressor use in

ION remains unclear and no clear guidance with respect to risk for ION can be provided at this time.

A medical history of hypertension, diabetes, and coronary artery or cerebrovascular disease has been cited in case reports but is not present in all patients in whom ION has developed. Moreover, hypertension and coronary artery disease are nearly always found in patients undergoing CABG but ION develops in few of these patients. No case-control data have shown an association of these factors with the development of ION in spine surgery patients, including those studies of Myers, Holy, and the POVL Study Group.[11,13,93] Case series show that many patients with perioperative PION have few vascular disease risk factors.[90] In a prospective study of nonsurgical patients, ION was not associated with the presence of carotid artery disease.[130] Although a basis for the notion that perioperative ION is related to atherosclerosis is that the optic nerve vasculature would respond abnormally to changes in perfusion pressure (i.e., demonstrate disturbed autoregulation), this association has not been studied in humans, and animal data are inconclusive.[97]

AION has been described in patients who used erectile dysfunction drugs. Cause and effect has been debated,[131] but because of the possible increased risk and unknown impact on events in the perioperative period, it seems sensible to discontinue use of these agents 1 or 2 days before surgical procedures.

Because the sphenoidal sinus and ethmoidal cells are close to the orbit and optic nerve and the bone is fragile, surgery on the nose and paranasal sinuses poses a special risk for ocular damage. Retrobulbar hemorrhage may follow surgical damage to the fragile lateral wall of ethmoidal cells, the lamina papyracea. Blindness has occasionally been reported after endoscopic sinus surgery[132] as a result of direct surgical damage to the optic nerve, but indirect damage by compression from retrobulbar hematoma leading to ION is more commonly reported. Paresis of eye muscles (mostly the medial rectus muscle), including ptosis, is often seen; an ocular compartment syndrome may be present, necessitating immediate surgical decompression to preserve vision.[133] The outcome is poor; in only one case was blindness temporary,[132] whereas all other reported cases of retrobulbar hematoma resulted in permanent blindness. The anesthesiologist should maintain a high degree of vigilance for possible retrobulbar hemorrhage, so that, if it occurs, rapid surgical decompression can be accomplished.

In summary, the pathogenesis of perioperative ION is incompletely understood. Multiple factors that could contribute are frequently present in patients undergoing open heart surgery, spine surgery, or head and neck operations. A patient may have anatomic variation and abnormal autoregulation in the optic nerve, but these anomalies are currently undetectable in the preoperative period. Preexisting as well as intraoperative factors may interact in an unpredictable fashion and lead to ION. Clinicians should be aware of the higher risk for visual loss with prolonged spine surgery with the patient positioned prone and in which large blood loss is anticipated. The risk is heightened also in these circumstances in men, obese individuals, and those positioned for surgery on a Wilson frame and when the percent colloid of total nonblood fluid resuscitation was lower (see also Chapter 61). Although concern exists regarding factors such as arterial blood pressure and intravascular fluid resuscitation during lengthy spine surgery, the mechanisms leading to ION in the perioperative period are not well understood.

PROGNOSIS, TREATMENT, AND PREVENTION

No proved treatment exists for ION. A few cases of treating perioperative ION have been reported. Williams and co-workers[110] reviewed the attempted treatments. Acetazolamide decreases IOP and may improve flow to the optic nerve head and retina.[134] Diuretics such as mannitol or furosemide reduce edema. In the acute phase, corticosteroids may reduce axonal swelling, but in the postoperative period they increase the risk for wound infection. Because steroids are of unproved benefit, their use must be carefully weighed. Increasing ocular perfusion pressure or hemoglobin concentration may be appropriate when ION is found in conjunction with significant decreases in blood pressure and hemoglobin concentration. Maintaining the patient in a head-up position if increased ocular venous pressure is suspected may be advantageous, but its use must be balanced against decreased arterial supply with the head-up position. Clearly, if a patient has visual loss from ocular compartment syndrome, immediate decompression (lateral canthotomy) is indicated (see also Chapter 84).

In their review of perioperative PION reports in the literature, Buono and Foroozan[85] summarized the lack of proof that treatment altered the course of PION. In a few anecdotal case reports, increasing blood pressure or hemoglobin, or applying hyperbaric O_2, improved visual outcome.[89] The use of neuroprotective agents or drugs that lower IOP, valuable in theory, has never been shown to result in improvement.[135] Stevens and associates,[136] who compiled a report of ION in patients after spine surgery, had apparent improvement of vision in two patients when anemia and hypotension were corrected. One patient demonstrated partial improvement that subsequently regressed, and one patient showed more clear signs of improvement. However, as Buono and Foroozan[85] mentioned, it is difficult to ascertain if improvement came from treatment, because some patients recover vision spontaneously after PION.

Prevention strategies depend on the status of the patient's optic nerve circulation, which is not known preoperatively and cannot be monitored intraoperatively. Some general recommendations could be made for spine surgery, but whether any of these can prevent ION remains unknown at this time.

The head should be positioned neutral relative to the back, and head-down positioning is discouraged. Although intraoperative blood pressure management has not been shown to affect the risk for developing ION, arterial blood pressure probably should be maintained close to baseline. Of course, judgment and discussion are necessary when surgeons request a decrease in blood pressure as a means of decreasing arterial bleeding and blood loss. In cardiac surgery, special considerations exist regarding the optimal

systemic perfusion pressures to be maintained during CPB. In addition, it is evident that arterial blood pressure management is only one part of the care of the anesthetized patient, considering, of course, the entire patient and not the optic nerve alone. Increasingly, anesthesiologists are encountering patients whose hypertension is controlled with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers, often together with β-adrenergic blockers or calcium channel blockers. These patients frequently become hypotensive intraoperatively.[137] In this common situation during which arterial blood pressure declines intraoperatively, particularly during spine surgery, vasopressors may be required. Patients may be refractory to ephedrine and Neo-Synephrine and require vasopressin to maintain blood pressure.[137] Systemic risks exist for increasing blood pressure with vasoactive agents or by infusion of intravenous fluids, such as decreased renal, liver, and intestinal perfusion, congestive heart failure, and myocardial ischemia. These risks are important considerations in decisions regarding the appropriate range for blood pressure and fluid resuscitation requirements.[138]

Whether hematocrit should be maintained at or near its baseline value is controversial (see also Chapter 61). However, simultaneous deliberate hypotension and hemodilution to a hematocrit of less than 25% should be done with caution. Whereas contemporary practice is to conserve blood by initially replacing lost blood with fluids, the effect of such hemodilution will often be a large fluid resuscitation, in some instances further amplifying an already high intravascular volume resuscitation, particularly in repeat operations for spine fusion, which typically involves large fluid and blood requirements. A relatively "dry" fluid strategy has been tested in abdominal surgery, but its use is controversial and has risks and outcomes have not been widely tested in any other surgery.[139] Either earlier blood replacement or greater use of colloids may potentially decrease the volume of infused crystalloids, although the impact of this practice on the occurrence of visual loss is not known. Here the results of the POVL Study Group provide some guidance; it seems advisable to use some colloid during large fluid resuscitation when patients are positioned prone for surgery. Withholding fluids is inadvisable because of many other risks, including multiple organ failure.[138]

Increasingly, neurosurgeons have been using minimally invasive surgical techniques toward lumbar spine surgery and fusion. These methods reduce the amount of blood loss and fluid requirements, but cases of ION have arisen under these circumstances as well.[140] Another strategy not under the direct control of the anesthesia provider is to consider staging of complex spine procedures. However, in some instances the anesthesiologist may be able to persuade a surgeon to follow a less ambitious surgical plan. This decision requires an assessment of the associated risks for multiple surgeries (infection, spinal instability) but may significantly shorten the duration of each procedure. Another strategy is to advocate for patients by regular preoperative conferencing with surgeons. Anticipating high blood loss and other risks may enhance perioperative planning and care in spine surgery patients (R. Caplan, Seattle, Wash, personal communication).

In the seventh edition of *Miller's Anesthesia*, Box 90-1 summarized the conclusions of a 2006 ASA Task Force regarding perioperative blindness associated with spine surgery. In 2012, another ASA Task Force published an update regarding perioperative visual loss primarily associated with spine surgery (Box 100-1). While major changes were not made, analysis of the literature was updated and the recommendations were more detailed. For example, the 2006 Summary had 7 bullet points. In contrast, the 2012 Summary of Advisory Statements has 22 bullet points subdivided into Preoperative, Intraoperative, Staging of Surgical Procedures, and Postoperative Management.

The 2006 Task Force concluded that high-risk patients who have surgery that is prolonged in duration and/or have large blood loss have an increased risk of perioperative visual loss. Yet perioperative visual loss was not related to blood loss per se, hemoglobin levels, or the use of crystalloids. Positioning of the head level or above the body was a risk factor.

The 2012 Task Force reviewed the additional literature. They concluded that newer findings and the literature do not justify major changes in the 2006 recommendations. However, more details were provided in the 2012 advisory statements. Box 100-1 lists the 2012 Task Force Summary of Advisory Statements (Appendix 1).

Whether patients should be warned about the possibility of ION during the process of informed consent, especially those undergoing apparently higher risk operations such as CABG and complex instrumented spinal fusion surgery, is controversial. The Task Force recommended considering informing high-risk patients, that is, those undergoing prolonged spine fusion surgery with large anticipated blood loss, about this risk.[141] This is difficult to accomplish in the often few rushed minutes of a preanesthetic interview on the day of surgery, typical of modern anesthetic practice in the United States. Accordingly, anesthesiologists may wish to consider requesting that the surgeon discuss the possible complication at an earlier, more relaxed preoperative visit.

CORTICAL BLINDNESS

Complete cortical blindness is bilateral visual loss with an absence of optokinetic nystagmus and of the lid reflex response to threat. The pupillary response, eye motility, retina, and optic nerve are normal. Complete blindness implies damage to both the left and right occipital cortex, whereas a more localized injury produces homonymous hemianopia.

Total blindness from bilateral occipital infarction is rare. Because the visual pathway travels through the parietotemporal lobes, a perioperative cerebrovascular accident affecting the internal carotid, or middle, basilar, or posterior cerebral arteries is the more common cause of cortical blindness. Yet because of collateral circulation, the degree of visual damage is difficult to predict.[142] Approximately 80% of cases of cortical blindness postoperatively have followed cardiac or other thoracic surgery. Depending on the sensitivity of the neuropsychological testing, these patients frequently show evidence of postoperative neurologic sequelae.[143]

BOX 100-1 *American Society of Anesthesiologists 2012 Task Force Summary of Advisory Statements*

I. Preoperative Considerations

- At this time there were no identifiable preoperative patient characteristics that predispose patients to perioperative posterior ischemic optic neuropathy (ION).
- There is no evidence that an ophthalmic or neuro-ophthalmic evaluation would be useful in identifying patients at risk for perioperative visual loss.
- The risk of perioperative ION may be increased in patients who undergo prolonged procedures, have substantial blood loss, or both.
- Prolonged procedures, substantial blood loss, or both are associated with a small, unpredictable risk of perioperative visual loss.
- Because the frequency of visual loss after spine surgery of short duration is infrequent, the decision to inform patients who are *not* anticipated to be "high risk" for visual loss should be determined on a case-by-case basis.

II. Intraoperative Management

Blood Pressure Management

- Arterial blood pressure should be monitored continually in high-risk patients.
- The use of deliberate hypotensive techniques during spine surgery can be associated with the development of perioperative visual loss. Therefore the use of deliberate hypotension for these patients should be determined on a case-by-case basis.
- Central venous pressure monitoring should be considered in high-risk patients. Colloids should be used along with crystalloids to maintain intravascular volume in patients who have substantial blood loss.

Management of Anemia

- Hemoglobin or hematocrit values should be monitored periodically during surgery in high-risk patients who experience substantial blood loss. A transfusion threshold that would eliminate the risk of perioperative visual loss related to anemia cannot be established at this time.

Use of Vasopressors

- There is insufficient evidence to provide guidance for the use of α-adrenergic agonists in high-risk patients during spine surgery.

Patient Positioning

- The Task Force believes that there is no pathophysiologic mechanism by which facial edema can cause perioperative ION. There is no evidence that ocular compression causes isolated perioperative anterior ION or posterior ION. However, direct pressure on the eye should be avoided to prevent central retinal artery occlusion (CRAO).
- The high-risk patient should be positioned so that the head is level with or higher than the heart when possible.

III. Staging of Surgical Procedures

- Although the use of staged spine surgery procedures in high-risk patients may entail additional costs and patient risks (e.g., infection, thromboembolism, or neurologic injury), it also may decrease these risks and the risk of perioperative visual loss in some patients.

IV. Postoperative Management

- The consensus of the Task Force is that a high-risk patient's vision should be assessed when the patient becomes alert.
- If there is concern regarding potential visual loss, an urgent ophthalmologic consultation should be obtained to determine its cause.
- There is no role for antiplatelet drugs, steroids, or intraocular pressure-decreasing drugs in the treatment of perioperative ION.

From Practice advisory for perioperative visual loss associated with spine surgery: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Visual Loss <https://www.asahq.org/For-Members/Practice-Management/Practice-Parameters.aspx>. (Accessed 09.09.14)

Initially, total cortical blindness is usually accompanied by signs of stroke in the parietooccipital region. The patient may experience agnosia, an inability to interpret sensory stimuli. Often, vision improves over time, with incomplete lesions in the visual field combined with visual disorientation. Pupillary reflexes are preserved and most of the visual field is restored within days, but impairment in spatial perception and in the relationship between sizes and distances may remain. Visual attention may be restricted, and images formed on all parts of the retina may not be visualized at one time.

The incidence of cortical blindness was 10 in 808 CABG surgeries in one hospital, with brain scans in 5 patients showing occipital infarcts.[144] In a retrospective series of 700 CABG surgeries and valve replacements by a single surgeon, 2 patients had unilateral occipital cortical infarcts.[145] Shaw and colleagues[146] prospectively studied 312 patients who had undergone CABG and found a 5% incidence of cortical blindness.[146] At least 50% of the patients had associated neurologic deficits. In another study, the onset of visual deficits followed a time course similar to that of neurologic damage.[147] Among the largest studies of neurologic dysfunction after cardiac surgery is that of Roach and co-workers.[148] In a prospective study of 2108 patients who had CABG at one of 24 hospitals, the incidence of neurologic complications was 6%. The specific incidence of eye complications was not reported. Results of subsequent studies are similar and have been reviewed by Newman and associates.[149] Associated factors included age, unstable angina, diabetes, prior stroke or transient ischemic attack, previous CABG surgery, and history of vascular or pulmonary disease. The incidence of visual disorders was not reported in any of these studies.

In case reports of cortical blindness, 55% of cases were reported after CABG surgery and 23% after other thoracovascular operations.[150] Cases have been reported in children. Hypotension was found in 45% and anemia or hemodilution in 23%. Over half the patients had coronary artery disease, but cortical blindness was found in patients with a wide range of systemic disorders, including congenital heart disease, liver failure, postpartum pulmonary embolism, and hypercholesterolemia. Unfortunately, the time of onset of symptoms was not reported in approximately half the cases. For the remaining 50%, onset was within the first postoperative day. As would be expected, fundoscopy was normal in nearly all patients when reported, except one, in whom AION was combined with cortical blindness. Visual defects were bilateral in all but one, who had a lesion near the lateral geniculate nucleus. The incidence of other objective neurologic findings was 38%. Confusion was present in 25% of patients. Visual outcome improved in 65% of cases.

MECHANISM AND PATHOPHYSIOLOGY

Cortical blindness can result from global ischemia, cardiac arrest, hypoxemia, intracranial hypertension and exsanguinating hemorrhage, focal ischemia, vascular occlusion, thrombosis, intracranial hemorrhage, vasospasm, and emboli. If blood and O_2 deprivation persists long enough, the cellular energy supply ceases and a series of biochemical events are initiated that ultimately lead to cell death. The pathways responsible for neuronal injury in the cerebral cortex have been reviewed extensively.[151]

CABG is the most common operation associated with cortical blindness, but the pathophysiology of cortical blindness after CABG surgery remains incompletely understood. The major source of brain and visual damage is believed to be embolism from the surgical field, such as fat and atheroma or microemboli of lipid and fibrin-platelet aggregates.[152] A high incidence of emboli in the retinal circulation of patients undergoing CABG has been documented.[153] Patients with aortic atherosclerosis appear to be at particular risk.[148] Cerebral edema also may be responsible for cortical blindness, but a study of MRI of the brain soon after CABG showed cortical swelling within 20 to 40 minutes that was not found on follow-up 1 to 3 weeks later, thus questioning its pathogenic role.[154] Edema may somehow contribute to the vague visual disturbances found in up to 25% of patients after CABG.[155] Another suspected factor is transient decreases in blood flow to border zones of perfusion between the middle and posterior cerebral arteries, especially in patients with preexistent cerebrovascular disease.[156]

PROGNOSIS, TREATMENT, AND PREVENTION

Visual recovery from cortical blindness may be prolonged, but previously healthy patients are likely to show a considerable degree of recovery. Therefore, when cortical blindness is accompanied by focal neurologic signs, treatment should be directed toward preventing progression of stroke. The optimal strategy to prevent neurologic injury during cardiac surgery remains controversial. Several different techniques have been advocated to decrease intraoperative manipulation of the aorta and embolization.[157] Adequate removal of air and particulate matter from the heart during valvular operations may decrease the risk for embolism. In patients younger than 70 years of age without evidence of cerebrovascular disease, an arterial line filter during CPB significantly reduced the number of microemboli detectable by transcranial Doppler ultrasonography. The frequency of subtle neuropsychological and neurologic changes (including nystagmus) was also reduced. No visual defects were found in the study patients.[158] Maintenance of adequate systemic perfusion pressure may prevent episodes of hypoperfusion in patients with cerebrovascular disease, but no controlled studies have associated visual loss and perfusion pressure in open heart surgery. The development of better transcranial Doppler techniques may enhance detection of embolic events. As yet, no proved neuroprotective agents whose use is feasible in these patients are available. Nonbypass heart surgery would be expected to avoid, but not eliminate, many embolic complications.[158]

ACUTE GLAUCOMA

Acute angle-closure glaucoma is a well-known disease that has been described rarely after general anesthesia. It usually occurs spontaneously and is more common in women and the elderly. Genetic predisposition, a shallow anterior chamber, and increased thickness of the lens are frequently found. The peak age for acute glaucoma is between 55 and 65 years.[159] Three case series in surgical patients have been reported. Gartner and Billet[160] described acute angle-closure glaucoma in 4 of 3437 patients (0.1%) undergoing general or spinal anesthesia.[160] Subsequently, Wang and colleagues[161] reported 5 cases in 25,000 surgical patients (0.02%). The highest incidence was found by Fazio and co-workers[162] after reviewing the records of 913 patients who had general or spinal anesthesia. Nine cases were detected, two of which were bilateral (1%). In these studies, no association was made between acute glaucoma and an anesthetic technique or drug.

Acute angle closure results in glaucomatous damage to the optic nerve and occurs when the passage of aqueous humor from the posterior to the anterior chamber is obstructed by apposition of the iris to the anterior surface of the lens. The pupil is mid-dilated, with an associated pupillary block. The diagnosis should be suspected in a patient with a painful red eye and cloudy or blurred vision, possibly accompanied by headache, nausea, and vomiting. This condition is often bilateral. It is distinguished from corneal abrasion, which also produces pain but without the papillary signs, increased IOP, subjective visual loss, and headache.[2] Symptoms may not appear for hours to days after a surgical procedure. Acute glaucoma is an emergency, and ophthalmologic consultation should be obtained immediately. Patients are treated with β-adrenergic antagonists, α-adrenergic agonists, carbonic anhydrase inhibitors, cholinergic agonists, and corticosteroids. Systemic analgesic agents are given as needed. A peripheral iridectomy should be performed later to create a permanent opening between the anterior and posterior chambers.[160]

VISUAL CHANGES AFTER TRANSURETHRAL RESECTION OF THE PROSTATE

Visual changes after transurethral resection of the prostate (TURP) have been recognized for over 50 years (see also Chapter 72).[163] Changes appear alone or as part of a syndrome after excessive absorption of irrigating fluid (usually 1.5% glycine) with subsequent hyponatremia, cerebral edema, seizures, coma, and cardiac failure from excessive intravascular fluid administration.[164] Although use of TURP is declining because of economic and regulatory constraints and noninvasive alternatives,[165] complications still occur. Absorption of the irrigant is the major source of nonsurgical complications. Determinants of the amount of irrigant absorbed include the duration of the resection, the extent of the opening of the prostatic venous sinuses, the hydrostatic pressure of the irrigation

fluid, and venous pressure at the "irrigant-blood interface."[166] Hamilton-Stewart and Barlow[167] disputed the effect of operative time; they found that a longer resection time did not increase absorption. The veins and capsule of a smaller prostate may be exposed earlier in the resection, so greater absorption during a quick resection leads to the same amount of irrigant absorption as slower absorption during a long resection.[167] Nonetheless, significant quantities of irrigant may be absorbed even if the surgeon believes that no venous sinuses are open, and the operator thus cannot predict or estimate the amount absorbed.

SIGNS AND SYMPTOMS

Visual deficits may occur during the resection, several hours after, or, rarely, on the second postoperative day as the patient awakens from a TURP-related coma.[168] The range of signs and symptoms is wide, from complete loss of light perception to more subtle defects. The first complaint may be visual halos and a blue visual hue. Dilated pupils that are nonreactive to light, a normal IOP, normal extraocular muscle movement, and normal fundus examination without papilledema are the objective findings.[169] Visual changes may resolve over a few hours or persist for up to 80 hours. Permanent visual loss has not been reported.

MECHANISMS OF VISUAL DYSFUNCTION

Proposed mechanisms of the visual changes include cerebral edema,[170] glycine toxicity involving the retina and cerebral cortex,[169] ammonia toxicity,[171] and increased IOP.[172] Glycine, the smallest amino acid, enters cells primarily through a carrier-mediated process, but its rate of transport is relatively slow. It easily crosses the blood-brain barrier, and it depresses the spontaneous and evoked activity of retinal neurons and hyperpolarizes cells through blockade of chloride channels.[173] The highest glycine concentration is in the amacrine cells, inner plexiform, and ganglion cell layers of the retina.[174] Because of a profound effect on oscillatory potentials of the electroretinogram, the predominant site of action may be amacrine cells,[175] although other inner retinal cells are probably involved. Glycine altered visual evoked potentials in dogs and in humans, thus suggesting an effect on the optic nerve. The threshold for visual symptoms is a plasma glycine concentration over 4000 μmol/L.[176]

Hyponatremia and hypo-osmolality during TURP produce occipital cortical edema, but such an association has not been confirmed. Segmental vascular disease in the blood supply to the occipital cortex may have placed that portion of the brain at risk for swelling.[164] Ocular hypertension causes enlarged blind spots and paracentral scotoma. In the presence of water overload, it seemed logical that an increase in IOP is part of the TURP syndrome. Yet in a prospective study of 22 patients who had TURP, Peters and colleagues[172] found no change in IOP in the patients with visual changes.[172] Such changes after TURP are transient and often associated with TURP syndrome. The most important means of prevention is to maintain intense vigilance to avoid excessive absorption of irrigating solution.

VISUAL LOSS AFTER VITRECTOMY AND VITREAL GAS BUBBLE TAMPONADE

Patients who have undergone vitrectomy with perfluorocarbon gas tamponade (C^3Fl^8) are at risk for gas bubble expansion and loss of vision from acutely increased IOP. Patients anesthetized for a subsequent surgical procedure with gas mixtures containing nitrous oxide (N_2O) after vitrectomy sustained retinal vascular occlusion from acute gas bubble expansion. N_2O anesthesia affects the size of the intraocular gas bubble. Wolf and co-workers[177] demonstrated that N_2O and O_2 resulted in a more than threefold increase in SFl^6 gas bubble volume, in contrast to a 50% increase with air ventilation and 35% increase with O_2 ventilation alone. Perfluorocarbon gas remains in the eye for at least 28 days. Visual loss has been reported with N_2O anesthesia administered as long as 41 days after vitrectomy and gas bubble tamponade. Therefore, patients should wear a warning tag to alert the anesthesiologist to the presence of the gas bubble in the vitreous, and N_2O should not be used in patients who have had recent vitrectomy and gas bubble tamponade.[178,179]

CONCLUSION

Visual loss can result in the perioperative period from retinal arterial occlusion, ION, cortical blindness, or acute glaucoma. Visual loss after TURP is transient; visual loss in patients anesthetized with N_2O after a vitrectomy and placement of a gas bubble tamponade may be permanent. The most serious injuries that are likely to result in blindness are retinal arterial occlusion and ION. Even if unintended pressure on the eye is avoided, these complications may still occur, particularly after spine, cardiac, or orthopedic surgery (see also Chapters 68 and 79). The risk factors for ION in particular remain incompletely explained.

Chapter 101

Critical Care Anesthesiology

LINDA L. LIU • MICHAEL A. GROPPER

Key Points

- With an anticipated shortage of critical care physicians, many different staffing models of intensive care units (ICUs) have been proposed, including the use of nonphysician providers, multidisciplinary care teams, and telemedicine.
- Evidence-based medicine now suggests that for the management of sepsis, large doses of corticosteroids are no longer recommended. Moderate glucose control may be safer than tight glucose control, and activated protein C does not reduce mortality from sepsis.
- Patients with acute lung injury or acute respiratory distress syndrome should be mechanically ventilated with tidal volumes of 6 mL/kg of ideal body weight and traditional positive end-expiratory pressure (PEEP) values of 5 to 12 cm water (H_2O). Other maneuvers that increase the partial alveolar pressure of oxygen/fraction of inspired oxygen concentration (PaO_2/FiO_2) ratio, such as recruitment maneuvers and inhaled nitric oxide, have not been shown to reduce mortality.
- Without liver transplantation, mortality from acute liver failure is high and primarily the result of multisystem organ failure, sepsis, and cerebral edema.
- Reduced mortality among patients in the ICU with acute renal failure is associated with earlier institution of dialysis and higher filtration volumes as opposed to the type of dialysis (intermittent hemodialysis versus continuous renal replacement therapy).
- Early mobilization decreases hospital mortality, decreases lengths of ICU and hospital stay, increases ventilator-free days, and leads to a shorter duration of delirium.
- Proposals to prevent ventilator-associated pneumonia include maintenance of gastric pH with sucralfate, positioning the head of the bed at 30 degrees, and subglottic aspiration of secretions.
- A comprehensive approach to the insertion of central venous catheters, including ultrasound guidance, maximum sterile barrier precautions, and antibiotic-coated catheters, can reduce the rate of catheter-related bloodstream infections.

The practice of critical care medicine, which originated in the 1940s with anesthesiologists providing life support to patients with poliomyelitis, has undergone revolutionary changes. The development of new equipment, procedures, and medications has enabled intensivists to treat critically ill patients and support them through increasingly invasive procedures. In the past decade, another revolution has taken place, the introduction of evidence-based medicine into intensive care unit (ICU) practice. In this chapter, the models of ICU staffing, including studies examining the value of intensivist staffing are discussed. Then a review of how intensivist staffing might lead to improved outcomes, specifically through the implementation of evidence-based practices, is presented. Particular attention is paid to the implementation and cost-effectiveness of new clinical practices. Finally, the management of some common diagnoses that are encountered while caring for critically ill patients is reviewed.

INTENSIVE CARE UNIT ORGANIZATION

With an aging population and increasing availability of medical technology, ICUs have become a critical component of modern hospital care. An estimated 0.5% to 1% of the U.S. gross domestic product is spent on critical care,[1] and patients 65 years of age and older make up over 50% of all ICU admissions.[2] Considering the magnitude of this expense, extensive research has focused on how the most cost-effective care can be delivered. Although ICUs started as open wards where any physician could admit patients, they have become increasingly managed.

Most ICUs now have a designated medical director who is responsible for the overall management of patient care and policies.

ROLE OF THE MEDICAL DIRECTOR

Each ICU should have a physician who is board certified or board eligible in critical care medicine to function as medical director.[3] The role of the medical director is to ensure the quality and safety of patient care in the ICU. Responsibilities often include patient triage decisions, education of house staff members, development of clinical protocols, and improvement of performance. Anesthesiologists frequently serve as medical directors, primarily of surgical ICUs. As hospital-based physicians, anesthesiologists are particularly well placed to appreciate the issues that affect patient care and the efficient flow of patients from surgical units through the ICUs. In 1994, the Society of Critical Care Medicine described the seven organizational duties of an ICU administrator[4]:

1. Triage of admissions and discharges
2. Development of treatment protocols or guidelines
3. Collection of data
4. Involvement in unit budget approval
5. Updating of equipment and unit practices
6. Promotion of efficient use of material and personnel resources
7. Responsibility for coordination and dissemination of continuing education of hospital- and ICU-based personnel

Because of the increasing importance of the medical director and the time commitment required, the hospital should provide salary support to allow an adequate investment of time in the position.

STAFFING

In 2003, Congress asked the Health Resources and Services Administration (HRSA) to examine the adequacy of the critical care workforce. HRSA maintains physician workforce supply and demand models that can assess the adequacy of supply for many physician specialties. Working with the American College of Chest Physicians and other consultants, the HRSA concluded that if current trends continue, then the growing supply of intensivists will be insufficient to provide the optimal level of care to future populations through 2020.[5] These projections are based on conservative estimates that intensivists will continue to direct the care of only one third of critically ill patients. If mandates by the Leapfrog Group are enacted and the proportion of patients in the ICU whose care is directed by an intensivist were to increase to two thirds, then the large potential growth in utilization of intensivist services represents a shortage of 1500 critical care providers.[6]

Anesthesiologists in Critical Care Medicine

Although anesthesiologists originated critical care medicine, they represent a shrinking percentage of critical care physicians. In a survey performed between 1996 and 1999, the Committee on Manpower for the Pulmonary and Critical Care Societies (COMPACCS) found that anesthesiologists accounted for only 6.1% of all intensivists in the workforce,[6] although they are particularly well trained to manage critically ill patients and do so on a regular basis in the surgical department. This trend comes at a time when the need for intensivists is increasing. The most recent data available show that there were 49 Anesthesiology Critical Care Medicine fellowship programs with 83 fellows in training for the 2010-2011 academic year,[7] compared with 417 fellows in 122 Pulmonary Disease and Critical Care Medicine programs.

The reason for the decreasing representation of anesthesiologists in critical care is multifactorial. Reimbursement for critical care services is generally less than that for surgical anesthesia services. Subspecialty training in critical care medicine for anesthesiologists creates a unique situation in which additional subspecialty training results in lower compensation. In Europe, where such a payment discrepancy between the surgical unit and the ICU does not exist, anesthesiologists provide the majority of critical care services.[8] In Australia and New Zealand, critical care training has become a separate specialty with its own residency. The College of Intensive Care Medicine took over in 2010 with the goal of developing a single training program for the specialty and to supervise all intensive care trainees.[9]

The American Board of Anesthesiology and American Society of Anesthesiologists have begun to address the diminishing role of anesthesiologists in critical care medicine. Proposed changes include an increasing component of training in critical care medicine during anesthesia residency. Programs for "experimental residencies" are also available that concurrently offer training for anesthesia and critical care in a blended residency and fellowship.

Physicians

For general and subspecialty patient populations, most studies suggest that an intensivist should provide care to critically ill patients. For example, Pronovost and associates[10] studied whether the organizational characteristics of ICUs could influence outcomes in patients undergoing surgery for an abdominal aortic aneurysm. They analyzed almost 3000 patients who underwent aneurysm repair in the state of Maryland and found that in risk-adjusted patients, not having daily ICU rounds by an intensivist was associated with a threefold increase in mortality. In addition to increased mortality, the patients not seen by an intensivist also had an increased risk for cardiac arrest, renal failure, septicemia, platelet transfusion, and reintubation.

In a large meta-analysis examining physician staffing and outcomes of critically ill patients, Pronovost and colleagues[8] compared low-intensity ICU staffing consisting of no or elective intensivist consultation with high-intensity staffing consisting of mandatory intensivist consultation or a closed ICU. This study found that the relative risk for hospital mortality was reduced by 29% and the relative risk for ICU mortality was reduced by 39% with high-intensity staffing. This and other studies have led to significant consumer and regulatory pressure mandating that intensivists staff all ICUs.

The Leapfrog Group (www.leapfroggroup.org) was established by the Business Roundtable, which consists of

the chief executive officers of several large corporations. These corporations purchase health insurance for more than 34 million health care consumers and therefore have considerable influence on health policy. One of the first recommendations by this group was that trained intensivists should staff ICUs. Although this recommendation has a strong evidence base, the other Leapfrog recommendations are not as strongly supported.[11] In addition to the factors discussed earlier, these pressures will create a significant demand for trained intensivists.

Considerable debate has occurred regarding whether intensivists should be continually present in ICUs even overnight. Prior studies have primarily evaluated academic ICUs with house staff, whereas many ICUs are in community hospitals and lack any overnight physician presence.[2] Introduction of an additional night shift to provide mandatory as opposed to on-demand 24-hour critical care specialist coverage has not been shown to affect long-term survival of patients in medical ICUs.[12] Wallace and associates studied a retrospective multicenter cohort of over 65,000 patients. They linked a survey of ICU staffing practices with patient outcomes and then used multivariate models to assess for relationships between nighttime intensivist staffing and in-hospital mortality among patients in the ICU.[13] They found that nighttime intensivist staffing improved mortality when added to low-intensity daytime staffing, but nighttime intensivists did not reduce mortality in ICUs with high-intensity daytime staffing. Kerlin and associates obtained similar results.[14] They conducted a randomized trial of nighttime intensivists staffing at an academic medical ICU with high-intensity daytime staffing and nighttime resident coverage and reported no improvement in patient outcomes. These results suggest that increasing ICU coverage to 24 hours a day, 7 days a week may not be the most reasonable nor economical decision for all hospitals.

Advanced Health Care Practitioners

The use of nonphysician providers, such as nurse practitioners (NPs) and physician assistants (PAs), under the supervision of attending physicians to augment or replace intensivists has become very popular, especially with the institution of resident duty hour limitations. These staffing models appear to be a safe and effective alternative to the traditional house staff-based team in a high-acuity, adult ICU.[15] Nonphysician providers are also a more consistent presence than house staff members who rotate through the unit for short blocks of time. This consistency can allow for improved communication and culture as team members become familiar with one another.[16] Currently, survey data suggest that PAs provide care in approximately 25% of adult ICUs in academic U.S. hospitals, and NPs provide care in more than 50%.[17]

Multidisciplinary Care Teams

One approach to lowering ICU mortality and improving quality is to optimize the organization of ICU services. The multidisciplinary model approach is to complement intensivist staffing with nurses, respiratory therapists, clinical pharmacists, and other staff members who can provide critical care as a team. The Society of Critical Care Medicine and the American Association of Critical Care Nurses have endorsed this approach.[18,19] In a retrospective cohort study, Kim and associates showed that when stratifying by intensivist physician staffing, the lowest odds of death were in ICUs with high-intensity physician staffing and multidisciplinary care teams (odds ratio [OR] 0.78; 95% confidence interval [CI] 0.68 to 0.89, $P < 0.001$), followed by ICUs with low-intensity physician staffing and multidisciplinary care teams (OR 0.88; 95% CI 0.79 to 0.97, $P = 0.01$), compared with low-intensity physician staffing.[20]

Nursing. The exact number of nurses needed to produce the best patient outcomes is not known. Although most studies show a trend toward lower nurse staffing and adverse ICU patient outcomes (i.e., mortality, infection, pressure ulcers), the studies have mostly been observational in design and therefore unable to demonstrate a causal relationship of nurse staffing on patient outcomes.[21,22] Many factors may affect patient outcomes, and nurse staffing is only one potential contributor.[23] Some hospitals prefer flexible scheduling, meaning ICU nurses are scheduled on the basis of anticipated workload in the unit at the start of the shift. This structure is financially good for the hospital by matching staff to workload demands, but it may provide uncertainty for the nursing staff.

Pharmacists. Pharmacists have become integral members of the ICU team as a result of contributions to medication safety, improved patient outcomes, reduced drug costs, and house staff education.[24] In a survey conducted among 1034 ICUs in the United States, clinical pharmacists provided care and attended rounds in 62% of the units.[25] Their presence has been shown to reduce mortality in patients with thromboembolic or infarction-related events[26] and in patients with nosocomial-acquired infections, community-acquired infections, and sepsis.[27] Their most important benefit is the potential to decrease adverse drug events. Leape and associates showed that the presence of a pharmacist on rounds was associated with a decrease in the rate of adverse drug events (ADE) from 10.4 per 1000 patient days (95% CI 7 to 14) to 3.5 per 1000 patient days (95% CI 1 to 5, $P < 0.001$).[28]

Respiratory Therapists. Respiratory therapists often assume important clinical roles with respect to ventilator management. Their involvement improves compliance with weaning protocols and decreases the duration of mechanical ventilation.[29,30] Other hospitals are using their care in innovative ways. Arroliga and colleagues found that the introduction of an intervention that included respiratory therapists performing oral care for patients who were mechanically ventilated reduced the rate of ventilator-associated pneumonia (VAP) from 4.3 per 1000 ventilator days to 1.2 per 1000 ventilator days.[31]

Telemedicine

Despite evidence supporting intensivist staffing of ICUs, the numbers of intensivists from all areas of training are inadequate to meet this mandate. Ewart and colleagues estimated that less than 15% of ICUs continue to have

dedicated intensivist coverage.[32] Recognition of this shortage has led to innovations such as the *eICU*, for which a small number of intensivists can monitor and consult on a large number of ICU beds from remote locations. Indeed, telemedicine is stated to meet the requirements of the Leapfrog Group, and it is an attractive alternative. Consolidating expensive and scarce resources could optimize critical care, especially to rural or community ICUs, by concentrating staff expertise. As of 2008, remote intensivists monitored almost 5000 eICU beds.[33]

The first hospital to adopt telemedicine occurred in 2000. In 2004, this facility published its results, showing a 25% reduction in ICU mortality (from 8.6% to 6.3%) and a 14% reduction in ICU length of stay (LOS) (from 5.6 to 4.8 days).[34] Most recently, in a system in which only residents were on call, Lilly and colleagues showed that implementation of a tele-ICU system decreased hospital mortality rate from 13.6% to 11.8% and decreased hospital LOS from 13.3 to 9.8 days.[35] They also found that this model resulted in improved adherence to critical care best practices. Conflicting results, no reduction in mortality, hospital LOS, or cost, were reported in another study of 4000 patients across two community hospitals, but this study was limited by a large number of clinicians who only allowed restricted participation of the tele-ICU model.[36] The physicians in the Lilly study seemed to work more proactively and were involved in the care of a greater proportion of the patients.

Overall, the available data suggest that eICUs can have the most impact and improve outcomes in ICUs that initially begin with a deficit in intensivist coverage or have a need to supplement current coverage levels, have high severity-adjusted mortality and LOS rates, are remotely located where the safe transfer of high-acuity patients may not be possible, and are part of an organizational structure that supports the presence of tele-ICU intensivists.[37] The role of eICUs in the delivery of critical care services continues to evolve. In systems with institutional buy-in, the eICU can be one way to help bridge the supply-demand gap of critical care physicians, but it remains unclear whether or how remote monitoring will be reimbursed.

QUALITY MEASUREMENT IN CRITICAL CARE

QUALITY OF EVIDENCE

To determine the value of a clinical intervention, evaluating the quality of the study on which it is based is important. A number of groups have developed criteria with which evidence can be graded. The Oxford Centre for Evidence-Based Medicine has strict criteria for grading the level of evidence. These criteria are described in Table 101-1. After the evidence level has been determined, specific practices can be graded by using the described criteria (see Table 101-1). Only through rigorous clinical experimentation can a determination be made as to which practices will improve the outcomes of critically ill patients. Equally important is an analysis of the cost-effectiveness of these interventions. Implementation may require fiscal and personnel expenditure, and it is the role of the medical director to convince hospital administrators of the cost-effectiveness of new interventions. Figure 101-1 describes the cost-effectiveness relationship for a theoretic treatment.

TABLE 101-1 LEVELS OF EVIDENCE

Level	Description
1a	Systematic review of randomized, controlled trials (with homogeneity)
1b	Individual randomized, controlled trial with a narrow confidence interval
1c	All-or-none trial*
2a	Systematic review of cohort studies (with homogeneity)
2b	Individual cohort study (including low-quality randomized, controlled trials)
2c	Outcomes research
3a	Systematic review (with homogeneity) of case-control studies
3b	Individual case-control study
4	Case series (and poor-quality cohort and case-control studies)
5	Expert opinion without explicit critical appraisal or based on physiology, bench research, or "first principles"

Modified from data provided by the Centre for Evidence-Based Medicine, Oxford, UK. Available at <http://www.cebm.net/index.aspx?o=1025.> (Accessed 15.07.12.)

*Met when all patients died before the treatment became available but some now survive on it, or when some patients died before the treatment became available but none now die on it.

Care of critically ill patients has been revolutionized by technology and drug development, but an equally important contribution has come with the application of evidence-based medicine to critical care practice. Although critical care initially focused on attempting to restore homeostasis, recognition that normal physiologic functioning is not always the most desirable therapeutic target is increasing. An important example of this principle is found in the management of patients with acute respiratory distress syndrome (ARDS). When patients with ARDS are mechanically ventilated with larger tidal volumes (12 mL/kg ideal body weight), they improve their oxygenation ratio.[38] However, these patients have significantly higher mortality rates than those who are mechanically ventilated with smaller tidal volumes (6 mL/kg ideal body weight). This example and others illustrate the need for randomized, prospective trials of new and existing therapies.

IMPLEMENTATION OF EVIDENCE-BASED PRACTICE

Application of evidence-based practice resulting in protocols to standardize patient care has been shown to improve the efficiency of care and reduce resource use.[39] Hospitals must customize the protocols to fit their practices, but protocols should not be used in place of good clinical judgment. They should be used as a complementary tool, and physicians should be able to justify departures from the protocol. These departures should be used to further refine the protocol to ensure that it is not viewed as a static entity but rather as an evolving guideline. For protocols to be effective, the hospital must be willing to invest the resources necessary for implementation.

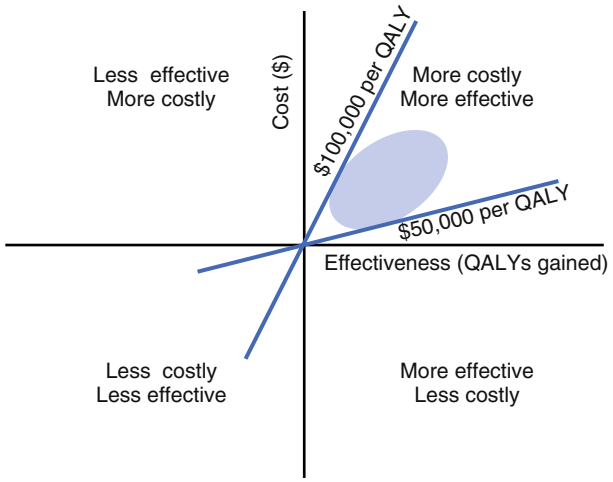

Figure 101-1. Graphic display of the cost-effectiveness of a theoretic treatment that adds additional cost but is effective in extending quality-adjusted life. A quality-adjusted life-year (QALY) is a year of life gained for which the quality of life is judged to be acceptable. The lines represent cost per QALY. Cost per QALY depends on the patient population that receives the intervention. For example, patients with a low severity of illness receiving activated protein C have a much higher cost per QALY than do those with a higher severity of illness.

Key personnel such as physicians, respiratory therapists, and nursing staff should be enlisted so that the entire patient care team helps define the standards on which the protocol is based.

Perhaps the most difficult task in the application of evidence-based practice is determining whether a given patient with a particular clinical scenario will benefit from that practice. Are there pathophysiologic differences in a particular patient's illness that may lead to a diminished treatment response? Are there important differences in systems or provider compliance that may diminish the safety or efficacy of the treatment? Does a patient have comorbid conditions that would lead to exclusion from a clinical trial? Despite these limitations, when applied to large populations of patients, practice protocols usually decrease mortality and reduce costs.

MANAGEMENT OF CRITICALLY ILL PATIENTS

The following sections examine the care of patients with some common diagnoses in critical care: sepsis, ARDS, hepatic failure, and renal failure. Many management plans have data supporting the use of protocol-based therapy. Others are introductory management ideas that may lead to integration into future protocols but are discussed here because of their importance in critical care.

SEPSIS AND MULTISYSTEM ORGAN FAILURE

Sepsis is the leading cause of death in critically ill patients in the United States and develops in 750,000 people annually.[1] The economic costs of sepsis are large, with annual expenditures totaling nearly $17 billion.[1] The high mortality rate and economic costs have led to considerable interest in the development of effective therapies for sepsis. As with other areas of medicine, adoption plus integration of new treatment strategies into routine clinical practice has been slow. After many years of unsuccessful clinical trials, randomized controlled trials have begun to show efficacy. The following therapies—cortisol replacement, glucose control, and activated protein C—have been intensively studied.

Cortisol Replacement

With the recognition that severe sepsis represents a state of overwhelming inflammation, corticosteroids were among the first therapies tested in randomized trials of patients with sepsis. At large doses and with short courses, the studies showed a negative effect.[40,41] Annane and associates proposed a different hypothesis in 2002.[42] Prompted by studies showing significantly improved time to withdrawal of vasopressor therapy in patients with sepsis who received small doses of hydrocortisone over a longer period (>5 days),[43,44] they administered low-dose steroids for 7 days. Their results showed that among patients who did not appropriately respond to the corticotropin test, 63% in the placebo group versus 53% in the corticosteroid group died ($P = 0.02$). Vasopressor therapy was withdrawn in 40% of patients in the placebo group, as opposed to 57% in the corticosteroid group ($P = 0.001$).

Despite this initial positive data, the administration of steroids to patients with sepsis remained controversial. A large randomized trial recapitulating the study of Annane and coworkers has been completed and documents the lack of efficacy of even low-dose steroids and the association of increased infections with steroid administration. The Corticosteroid Therapy of Septic Shock (CORTICUS) study was carried out to assess whether low-dose corticosteroids improve survival in patients with septic shock and sepsis.[45] A total of 499 patients were enrolled over a period of 3 years from 52 European ICUs. Patients received a tapering steroid regimen over an 11-day period but no mineralocorticoids. The results refuted Annane's initial study. The 28-day mortality rate in patients receiving low-dose steroids was not significantly improved from that in the placebo group (34% versus 31%, $P = 0.57$). In summary, although low-dose steroids with mineralocorticoids initially appeared to be beneficial, the results have not been reproducible in a large multicentered randomized study. Large doses of corticosteroids should not be used in patients with severe sepsis.

One issue raised by these investigations was the role of etomidate in causing adrenal suppression. Patients who received etomidate to facilitate endotracheal intubation had worse outcomes, thus leading to suggestions that etomidate not be used. Chan and associates conducted a meta-analysis with five studies assessing mortality and seven studies assessing adrenal insufficiency associated with etomidate use in patients with severe sepsis and septic shock.[46] They found an increased pooled relative risk for mortality of 1.20 (95% CI 1.02 to 1.42) and an increased pooled relative risk (RR) for adrenal insufficiency of 1.33 (95% CI 1.22 to 1.46). Although the data are not conclusive, the literature suggests that perhaps etomidate should not be the first choice for use in patients with sepsis.

Glycemic Control in the Critically Ill

Critically ill patients admitted to the ICU with severe injury or infection, such as burns, trauma, or sepsis, commonly enter into a hypermetabolic state (see also Chapter 39). This state is associated with enhanced peripheral glucose uptake and use,[47] hyperlactatemia,[48] increased glucose production,[49] depressed glycogenesis,[50] and insulin resistance.[49] Glucose intolerance develops after uptake of glucose in skeletal muscle, adipose tissue, and liver, and the heart becomes saturated,[51] and hyperglycemia occurs because of defective suppression of gluconeogenesis and a resistance to the peripheral action of insulin. These mechanisms all work to generate a hyperglycemic state to satisfy an obligatory requirement for glucose as an energy substrate. The intensity of the metabolic response peaks several days after the initial insult and then diminishes as the patient recovers.[48] However, a prolonged hyperglycemic response may occur in patients who continue to have tissue hypoperfusion or persistent infection, which then predisposes them to progressive metabolic derangements and multisystem organ failure.

Traditionally, hyperglycemia, secondary to sepsis, was viewed as a beneficial response because it promoted cellular glucose uptake when cells were energy deprived. A glucose concentration of 160 to 200 mg/dL was commonly recommended and believed to maximize cellular glucose uptake without causing hyperosmolarity.[52] However, neutrophil function is impaired in patients with hyperglycemia because of decreased bacterial phagocytosis,[53] and many studies report the negative effects of high blood sugar. Hyperglycemia in diabetic patients is associated with an increased rate of postoperative infections,[54] and decreased long-term outcomes after myocardial infarction.[55] Hyperglycemia is also associated with a poorer prognosis after stroke or head injury[56] (see also Chapter 70).

Van den Berghe and coworkers[57] hypothesized that even mild hyperglycemia (i.e., blood glucose levels between 110 and 200 mg/dL) could be harmful by predisposing critically ill patients to increased morbidity and mortality. They performed a prospective, controlled study involving 1548 patients in the surgical ICU who were randomized to receive intensive insulin therapy (i.e., blood glucose maintained between 80 and 110 mg/dL) or conventional treatment (i.e., blood glucose maintained between 180 and 200 mg/dL). In patients who remained in the ICU for longer than 5 days, intensive insulin therapy reduced the mortality rate from 20.2% with conventional therapy to 10% with intensive therapy ($P = 0.005$). The group receiving intensive insulin therapy also had a lower incidence of bloodstream infections (4.2% versus 7.8%, $P = 0.003$), renal failure requiring dialysis (4.8% versus 8.2%, $P = 0.007$) and critical illness polyneuropathy (28.7% versus 51.9%, $P = 0.001$). Patients in the intensive insulin group were also less likely to require prolonged mechanical ventilation and intensive care. The results of this trial made a persuasive argument for tighter glucose control, at least in patients in the surgical ICU.

Opponents of the use of strict glycemic control in critically ill patients argued that the risks of hypoglycemia should be seriously considered and that the therapeutic effect of insulin rather than glycemic control leads to the beneficial outcomes. Insulin has multiple effects, including the inhibition of tumor necrosis factor alpha (TNF-α),[58] which triggers procoagulant activity and fibrin deposition and inhibits macrophage inhibitory factor, thereby contributing to endotoxemia and toxic shock.[59] To determine whether it was insulin effect or glycemic control, van den Berghe and colleagues[60] used multivariate analysis to reanalyze their previous data. It appeared that decreasing blood glucose levels rather than the actual amount of insulin given was more closely correlated with the beneficial reductions in mortality, polyneuropathy, and bloodstream infections. Instead of the glucose level, the dose of insulin correlates with the incidence of renal failure. Investigators thought that this difference might be the result of the direct effect of insulin on the kidney or the need for less exogenous insulin in patients with renal failure because insulin is cleared through the kidney. Finney and associates[61] in a prospective, observational study provided additional evidence that glycemic control, rather than insulin administration, provided the benefit. They examined the effects of glucose control in 523 patients admitted to a single surgical ICU. In this trial the primary determinant of a bad outcome was hyperglycemia rather than hypoinsulinemia, and a lower mortality rate was associated with glycemic control rather than a protective effect of insulin administration. Increased insulin dosing resulted in an increased mortality rate across all ranges of glycemia. With regression analysis, their data also suggest that keeping blood glucose below 145 mg/dL may provide a survival benefit similar to that achieved with the tighter range of 80 to 110 mg/dL.

A major criticism of the original van den Berghe study was that it was performed on relatively homogeneous surgical populations. The same group then published a follow-up study examining tight glucose control in 1200 patients in medical ICUs.[62] The results showed reduced morbidity defined as a reduction in newly acquired renal injury, earlier weaning from mechanical ventilation, and earlier discharge from the ICU and the hospital but no difference in mortality. With subgroup analysis, they were able to determine a mortality benefit from tight glucose control if the patient was admitted to the ICU for 3 days or longer (43% versus 52.5%, $P = 0.009$). From the study design, it is unclear whether intensive insulin therapy for less than 3 days causes harm or perhaps the benefit from intensive insulin therapy requires time to be realized.

Since then, several multicentered randomized controlled studies have examined the risk-benefit ratio of tight glucose control.[63-65] Two studies (Volume Substitution and Insulin Therapy in Severe Sepsis [VISEP] and Glucontrol) were stopped early because of a high rate of hypoglycemia (17% versus 4.1%, $P < 0.001$, and 8.7% versus 2.7%, $P < 0.001$, respectively). The Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation (NICE-SUGAR) trial, the most recent and largest of the studies, involved 42 ICUs and enrolled 6000 patients. The investigators reported no difference between the two groups in terms of days in the ICU, days on mechanical ventilation, and days requiring renal replacement therapy. Disturbingly, they found an increased incidence of hypoglycemia

in the tight glucose control arm (6.8% versus 0.5%, $P < 0.001$) and a higher 28-day mortality (22.3% versus 20.8%, $P = 0.02$).[65] Finally, a detailed analysis of the NICE-SUGAR database showed a dose-response relationship for harm, dependent on the degree of hypoglycemia.[66] Based on the current studies, it appears that tight glycemic control, and even routine normalization of plasma glucose,[67] may not be the right goal. The optimal glucose target may not be the same for all patients and all clinical scenarios; it may be more a function of the rate of glucose change as opposed to a static number.

Activated Protein C

Patients with severe sepsis have systemic inflammation resulting in coagulation abnormalities that range from subtle elevations in plasma D-dimer levels to clinically evident disseminated intravascular coagulation.[68,69] Recognition that sepsis can cause microthrombosis and that patients with sepsis have low circulating levels of activated protein C (APC) led to the investigation of APC as a specific therapy for sepsis.[70] APC is a naturally occurring anticoagulant that inactivates factors Va and VIIIa and prevents the generation of thrombin,[71] which is capable of stimulating multiple inflammatory pathways. Additional effects of APC include a permissive effect on thrombolysis that allows clearance of systemic microthrombi.[69] APC also decreases the expression of tissue factor and can bind selectins, which activate neutrophils on the endothelial surface.[72] Recent data suggest that APC levels can predict the outcome from multisystem organ failure, regardless of the inciting event.[73]

Recombinant human APC (Xigris) was developed by Eli Lilly for use in the treatment of severe sepsis.[72] In a publication of the Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) study of 1690 patients with severe sepsis randomized to receive APC or placebo, the mortality rate was 30.8% in the placebo group and 24.7% in the APC group ($P = 0.005$). Intravenous infusion of APC at 24 μg/kg/hr for 96 hours was associated with a 6.1% absolute reduction in the risk for death. The trial was stopped early for efficacy, but subsequent subgroup analysis suggested that the mortality benefit was limited to patients with increased illness severity (i.e., Acute Physiology and Chronic Health Evaluation [APACHE] score of >24). The most important adverse effect was serious bleeding (3.5% versus 2%, $P = 0.06$), as would be expected because of its anticoagulant effect. The U.S. Food and Drug Administration (FDA) approved the release of the drug based on only this study, but limited its use to patients with a high risk of death and requested additional trials involving patients with lower APACHE II scores. The trial enrolling patients with lower APACHE scores (ADministration of DRotrecogin alfa [activated] in Early stage Severe Sepsis) [ADDRESS] trial) was terminated early for futility by the data and safety monitoring committee.[74]

A new randomized, placebo-controlled trial of APC (PROWESS-SHOCK) was undertaken to hopefully provide the definitive answer.[75] In this trial, 1697 patients with infection, systemic inflammation, and shock were recruited from 208 sites in Europe, North and South America, Australia, New Zealand and India. They were randomized to receive a 96-hour infusion of APC or placebo. The primary endpoint, 28-day mortality, was equal between the two groups. (26.4% in APC group versus 24.2% in control group, RR 1.09, 95% CI 0.92 to 1.28, $P = 0.31$). Eli Lilly voluntarily withdrew APC from the market late in 2011 because of these study results.

ACUTE RESPIRATORY FAILURE

ICUs were first developed to manage patients with acute respiratory failure as a result of poliomyelitis. Since then, management of patients with acute respiratory failure has been revolutionized by the development of modern mechanical ventilators. Ashbaugh and associates first reported ARDS in 1967.[76] They described 12 patients with acute respiratory distress, cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse bilateral infiltrates on chest radiography. Because this initial definition lacked specific criteria that could be used to identify patients for research, the American-European Consensus Conference Committee recommended new definitions in 1994.[77]

Although critical for providing a framework for the ARDS network (ARDSnet) and other studies, it was recognized that the American-European consensus definitions had significant limitations as a result of the variability in the PaO_2/FiO_2 ratio with ventilator settings, poor reliability of chest radiographic criteria, and difficulties distinguishing hydrostatic edema. Therefore, a new consensus conference was convened to update the definitions, and the Berlin Definition of ARDS was formed.[78] Table 101-2 compares the two lists of criteria used to define acute lung injury (ALI) and ARDS.

Treatment of ALI or ARDS is primarily supportive and consists of mechanical ventilation, which allows time for treatment of the underlying cause of the lung injury and for natural healing.[79] Until recently, most studies of ALI or ARDS reported a mortality rate of 40% to 60%, with death attributed to sepsis or multiorgan failure rather than the primary respiratory causes.[80,81]

Several clinical trials have addressed one of the hallmarks of ALI or ARDS—decreased lung compliance. The National Institutes of Health (NIH) ARDSnet reported the definitive study on protective mechanical ventilation in 2000.[38] In this prospective study of patients with ALI, the mortality rate was reduced from 40% in patients receiving tidal volume ventilation of 12 mL/kg to 31% in those receiving 6 mL/kg. The low–tidal volume group also had more ventilator-free and organ failure–free days than did the higher–tidal volume group. Several reasons have been postulated for the discrepancy between this study and the previous inconclusive studies. First, the NIH study may have been better able to show a difference because it used lower tidal volumes than used in the other studies. Second, the NIH study allowed treatment of respiratory acidosis with high respiratory rates or with sodium bicarbonate. Treatment of respiratory acidosis may have prevented deleterious effects. Third, the NIH study enrolled 861 patients, which was by far the largest study and increased the statistical power to find a positive effect of low–tidal volume ventilation.[82]

In a second study using the same patient database, Eisner and associates[83] did not find any evidence that the

efficacy of the low–tidal volume strategy varied according to the clinical cause of ARDS. Although the mortality rate was highest (43%) in patients with sepsis, intermediate (36%) in patients with pneumonia and aspiration pneumonitis, and lowest (11%) in patients with trauma, no evidence of differential efficacy of low–tidal volume ventilation was found in different groups with ALI or ARDS. The investigators concluded that the recommendations for low–tidal volume ventilation should be applied to all patients with ALI or ARDS, regardless of the inciting cause.

Important advances in the ventilatory management of patients with ALI or ARDS have led to improvements in the care of patients in the ICU. With the impressive 9% absolute reduction in mortality demonstrated by the ARDSnet trial, low–tidal volume mechanical ventilation should be considered the standard of care for patients with ALI or ARDS unless a more efficacious strategy is demonstrated. Figure 101-2 shows the protocol used at the University of California, San Francisco, for mechanical ventilation of patients with ALI or ARDS. An unanswered question remains regarding whether patients without ARDS should be managed with a lung-protective strategy. A recent meta-analysis showed that in patients without lung injury, low tidal volume was associated with less progression to lung injury and lower mortality.[84]

Nontraditional Ventilatory Interventions

In addition to low tidal volume, other therapies have been used for the care of patients with ALI. Most have tried to improve the ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching and hypoxemia that result from ALI. The following sections discuss data associated with high PEEP, recruitment maneuvers, prone positioning, inhaled nitric oxide (iNO), neuromuscular blocking agents, and early tracheostomy.

High Positive End-Expiratory Pressure. The use of PEEP has been proposed as a mechanism to minimize cyclical alveolar collapse and shear injury (atelectrauma). Brower and coworkers (Assessment of Low–Tidal Volume and increased End-Expiratory Volume to Obviate Lung Injury [ALVEOLI] trial) randomly assigned 549 patients with ARDS to receive low–tidal volume ventilation with either lower or higher PEEP levels.[85] They found similar rates of death before hospital discharge whether lower or higher PEEP was used (24.9% versus 27.5%, respectively, $P < 0.001$). These results were confirmed by a recent meta-analysis that combined data from three trials including more than 2000 patients to examine the effects of higher versus lower PEEP. Treatment with higher versus lower levels of PEEP was not associated with improved hospital survival.[86] For now, the recommendations are to use traditional PEEP values of 5 to 12 cm H_2O.

Lung Recruitment Maneuvers. Gravity-dependent atelectasis is invariably observed in patients with ARDS. The atelectatic lung areas lead to intrapulmonary shunting, $\dot{V}/\dot{Q}$ mismatching, and regional differences in compliance. Recruitment maneuvers, which involve periods of sustained increased airway pressure, have been proposed to re-expand atelectatic alveoli and avoid atelectrauma.[87] These maneuvers must be performed with caution because venous return may significantly decrease, thereby leading to hypotension, and alveolar ventilation may decrease, thereby resulting in hypercapnia and respiratory acidosis. Other clinically significant events can include pneumothorax, arrhythmias, and bacterial translocation. The optimal pressure, duration, and frequency of recruitment maneuvers have not been defined. In the ARDSnet ALVEOLI trial, patients randomized to the PEEP group also received recruitment maneuvers with airway pressures of 35 to 40 cm H_2O for 30 seconds to assess the effect on oxygenation.[85] After the first 80 patients, recruitment maneuvers had only a modest effect on oxygenation and were not continued for the remainder of the study. At this time, routine use of recruitment maneuvers cannot be recommended because they have been shown to increase oxygenation only transiently without improving mortality.

Prone Positioning. Because atelectasis and $\dot{V}/\dot{Q}$ mismatching appear to be dependent on gravity, one assumption is that turning a patient from the supine to the prone

TABLE 101-2 COMPARISON OF THE AMERICAN-EUROPEAN CONSENSUS CONFERENCE AND BERLIN DEFINITION OF ACUTE RESPIRATORY DISTRESS SYNDROME

	AECC Definition[77]	Berlin Definition[78]
Timing	Acute onset	Onset is within 1 week of a known clinical insult or new or worsening respiratory symptoms.
Oxygenation	**ALI**: PaO_2/FiO_2 ≤300 mm Hg **ARDS**: PaO_2/FiO_2 ≤200 mm Hg	**Mild**: 200 mm Hg; PaO_2/FiO_2 ≤300 mm Hg with PEEP or CPAP ≥5 cm H_2O **Moderate**: 100 mm Hg; PaO_2/FiO_2 ≤200 mm Hg with PEEP ≥5 cm H_2O **Severe**: PaO_2/FiO_2 ≤100 mm Hg with PEEP ≥5 cm H_2O
Chest radiograph	Bilateral infiltrates	Bilateral opacities are not fully explained by effusions, lobar or lung collapse, or nodules.
Edema	PAWP ≤18 mm Hg when measured or no clinical evidence of left atrial hypertension	Respiratory failure is not fully explained by cardiac failure or fluid overload.
Risk factor	Not included in definition	If no risk factor for lung injury is identified, then objective assessment such as echocardiography to exclude hydrostatic edema is needed.

AECC, American-European Consensus Conference; *ALI,* acute lung injury; *ARDS,* acute respiratory distress syndrome; *FiO_2,* fraction of inspired oxygen; *PaO_2,* partial arterial pressure of oxygen; *PAWP,* pulmonary artery wedge pressure; *PEEP,* positive end-expiratory pressure.

ARDSnet
NIH NHLBI ARDS Clinical Trials Network
Mechanical Ventilation Protocol Summary
UCSF Division of Critical Care Medicine

INCLUSION CRITERIA Acute onset of:
1. $PaO_2/FiO_2 \leq 300$ (corrected for altitude).
2. Bilateral (patchy, diffuse or homogeneous) infiltrates consistent with pulmonary edema.
3. No clinical evidence of left atrial hypertension.

PART I: Ventilator setup and adjustment
1. Calculate ideal body weight (IBW):
   Male = 50 + 2.3 (height [inches] − 60)
   Female = 45.5 + 2.3 (height [inches] − 50)
2. Select Assist Control Mode.
3. Set initial TV to 8 mL/kg IBW.
4. Reduce TV by 1 mL/kg at intervals ≤ 2 hours until TV = 6 mL/kg.
5. Set initial rate to approximate baseline $\dot{V}_E$ (not >35 bpm).
6. Adjust TV and RR to achieve pH and plateau pressure goals below.
7. Set inspiratory flow rate above patient demand (usually >80 L/min).

PART II: Weaning

Definition of weaning tolerance
1. RR ≤ 35 (may exceed 35 for ≤5 minutes) and:
2. $SpO_2 \geq 88\%$ (<15 minutes at <88% may be tolerated) and
3. Respiratory distress is absent (<2 of the following)
Pulse > 120% of usual rate for >5 minutes; marked use of accessory muscles; abdominal paradox, diaphoresis; marked complaints of dyspnea.

A. Conduct a CPAP Trial daily when:
1. $FiO_2 \leq 0.40$ and PEEP ≤ 8.
2. PEEP and $FiO_2 \leq$ values of previous day.
3. Patient has acceptable spontaneous breathing efforts. (May decrease vent rate by 50% for 5 minutes to detect effort.)
4. Systolic BP ≥ 90 mm Hg without vasopressor support.

CONDUCTING THE TRIAL:
Set CPAP = 5 cm H_2O, $FiO_2 = 0.50$
If RR ≤ 35 for 5 min: advance to Pressure Support Weaning below.
If RR > 35 in <5 min: may repeat trial after appropriate intervention (e.g., suction, analgesia, anxiolysis).
If CPAP trial not tolerated: return to previous A/C settings.

B. Pressure support (ps) weaning procedure
1. Set PEEP = 5 and $FiO_2 = 0.50$.
2. Set initial PS based on RR during CPAP trial:
   a. If CPAP RR < 25: set PS = 5 cm H_2O and go to step 3d.
   b. If CPAP RR = 25 to 35: set PS = 20 cm H_2O then reduce by 5 cm H_2O at ≤ 5-min intervals until RR = 26 to 35, then go to step 3a.
   c. If initial PS not tolerated: return to previous A/C settings.
3. REDUCING PS (No reductions made after 1700 hr.)
   a. Reduce PS by 5 cm H_2O q1-3h, then go to step 3d.
   b. If PS ≥ 10 cm H_2O not tolerated, return to previous A/C settings. (Reinitiate last tolerated PS level next AM and go to step 3a.)
   c. If PS = 5 cm H_2O not tolerated, return to PS = 10 cm H_2O. If tolerated, 5 or 10 cm H_2O may be used overnight with further attempts at weaning the next morning.
   d. If PS = 5 cm H_2O tolerated for ≥2 hr, assess for ability to sustain unassisted breathing below.
