Chapter 70

Anesthesia for Neurologic Surgery

JOHN C. DRUMMOND • PIYUSH M. PATEL • BRIAN P. LEMKUIL

Key Points

- For the purposes of planning a strategy for controlling intracranial pressure (ICP), the clinician should consider the four subcompartments of the intracranial space: cells, interstitial and intracellular fluid, cerebrospinal fluid (CSF), and blood.
- The clinician should make a preoperative assessment of the probable intracranial compliance reserve as the basis for selection of appropriate anesthetic drugs and techniques.
- The venous side of the cerebral circulation is a largely passive compartment that is often the cause of increased ICP, or "tightness," of the surgical field but is commonly overlooked by clinicians.
- Cerebral perfusion pressure (CPP) should be supported at or near waking normal levels in patients with recent cerebral injuries (e.g., traumatic brain injury [TBI], subarachnoid hemorrhage [SAH]), and spinal cord injury because of low resting cerebral blood flow and impaired autoregulation.
- When neurosurgical procedures are performed in the sitting position, blood pressure should be corrected to the level of the external auditory meatus, and mean arterial pressure (MAP) should be maintained at 60 mm Hg in normotensive adults.
- The minimal standard of care for monitoring to detect venous air embolism (VAE) in at-risk situations includes the precordial Doppler and end-tidal carbon dioxide analysis.
- Despite encouraging preclinical data, therapeutic mild hypothermia cannot currently be advocated in the care of head-injured patients in the intensive care unit (ICU) or during the operative management of patients with intracranial aneurysms because of negative human trial results for those patient groups.
- The most important consideration in the anesthetic management of patients undergoing clipping or coiling after acute SAH is the prevention of paroxysmal hypertension with its attendant risk of aneurysm rerupture. Nonetheless, adequate perfusion pressure is needed if temporary clips are used during management of cerebral vasospasm.
- Although induced hypotension is rarely used electively in aneurysm surgery, the clinician must be ready to reduce blood pressure immediately and accurately in the event of aneurysm rupture.
- Tracheal intubation of a head-injured patient with an undefined cervical spine injury can be accomplished using rapid-sequence induction with manual in-line stabilization (the occiput held rigidly to the backboard), with only a very small risk of injury to the spinal cord.
- CPP (CPP = MAP – ICP) should be supported at 60 mm Hg in the first 48 to 72 hours after TBI in adults.
- Hypocapnia has the potential to cause cerebral ischemia, particularly in a recently injured brain and in a brain beneath retractors; it should be used only when absolutely necessary for the control of critically increased or uncertain ICP.

This chapter provides guidelines for the management of common situations in neurosurgical anesthesia. Issues that arise in connection with a wide variety of neurosurgical procedures—those constituting a checklist that the practitioner should review before undertaking anesthesia for any neurosurgical procedure—are reviewed first, followed by procedure-specific discussions. This chapter assumes familiarity with the cerebral physiology and effects of anesthetics as described in Chapter 17, and with neurologic monitoring as described in Chapter 49. Carotid endarterectomy and carotid angioplasty and stenting are discussed in Chapter 69.

RECURRENT ISSUES IN NEUROANESTHESIA

Several basic elements of neurosurgical and neuroanesthetic management are recurrent and, in the absence of an established understanding between surgeon and anesthesiologist, should be discussed and agreed upon at the outset of every neurosurgical procedure (Box 70-1). The list varies by procedure and may include the intended surgical position and requisite positioning aids; intentions with respect to the use of steroids, osmotic agents/diuretics, anticonvulsants, and antibiotics; the surgeon's perception of the "tightness" of the intracranial space and the remaining intracranial compliance reserve; appropriate objectives for the management of blood pressure, carbon dioxide tension, and body temperature; anticipated blood loss; the intended use of neurophysiologic monitoring (which may impose constraints on the use of anesthetics or muscle relaxants, or both); and, sometimes, the perceived risk of air embolization. The considerations driving the decisions made about these issues are presented in this section. One additional recurrent issue, brain protection, is discussed briefly in the section on aneurysms and arteriovenous malformations (AVMs) and in detail in Chapter 17.

CONTROL OF INTRACRANIAL PRESSURE AND BRAIN RELAXATION

The necessity of preventing increases in intracranial pressure (ICP) or reducing ICP that is already increased is recurrent in neuroanesthesia. When the cranium is closed, the physician's objectives are to maintain adequate cerebral perfusion pressure (CPP) (CPP = mean arterial pressure [MAP] – ICP) and prevent the herniation of brain tissue between intracranial compartments or through the foramen magnum (Fig. 70-1).[1] When the cranium is open, the issue may be to provide relaxation of the intracranial contents to facilitate surgical access or, in extreme circumstances, reverse ongoing brain herniation through craniotomy. The principles that apply are similar whether the cranium is open or closed.

The various clinical indicators of increased ICP include headache (particularly headache that awakens the patient at night), nausea and vomiting, blurred vision, somnolence, and papilledema. Computed tomography (CT) findings suggestive of either increased ICP or reduced intracranial compliance reserve include midline shift, obliteration of the basal cisterns, loss of sulci, ventricular effacement (or enlarged ventricles in the event of hydrocephalus or ventricular trapping), and edema. Edema appears on a CT scan as a region of hypodensity. The basal cisterns appear on CT as a black (fluid) halo around the upper end of the brainstem (Fig. 70-2). They include the interpeduncular cistern, which lies between the two cerebral peduncles, the quadrigeminal cistern, which overlies

the four colliculi, and the ambient cisterns, which lie lateral to the cerebral peduncles.

Figure 70-3 presents the pressure-volume relationship of the intracranial space. The plateau phase occurring at low volumes reveals that the intracranial space is not a completely closed one, and that there is some compensatory latitude. Compensation is accomplished principally by the translocation of cerebrospinal fluid (CSF) and venous blood to the spinal CSF space and the extracranial veins, respectively. Ultimately, when the compensatory potential is exhausted, even tiny increments in volume of the intracranial contents can result in substantial increases in ICP. These increases have the potential to result in either herniation of brain tissue from one compartment to another (or into the surgical field) (see Fig. 70-1), with resultant mechanical injury to brain tissue, or in reduction of perfusion pressure, leading to ischemic injury.

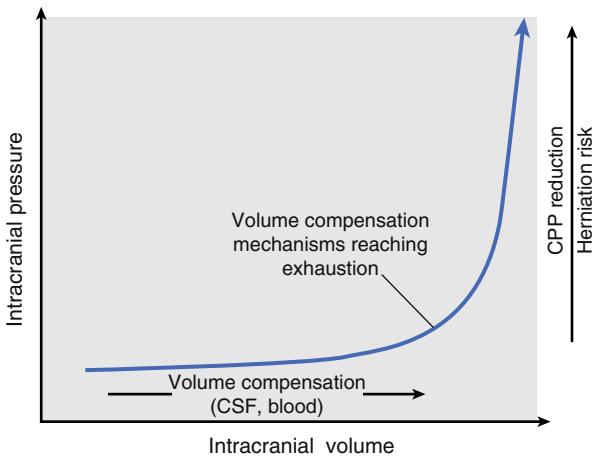

Figure 70-3. The intracranial pressure–volume relationship. The horizontal portion of the curve indicates that there is initially some latitude for compensation in the face of an expanding intracranial lesion. That compensation is accomplished largely by displacement of cerebrospinal fluid (CSF) and venous blood from intracranial to extracranial spaces. Once the compensatory latitudes are exhausted, small-volume increments result in large increases in intracranial pressure with the associated hazards of herniation or of decreased cerebral perfusion pressure (CPP), resulting in ischemia.

Several variables can interact to cause or aggravate intracranial hypertension (Fig. 70-4). For clinicians faced with the problem of managing increased ICP, the objective is, broadly speaking, to reduce the volume of the intracranial contents. For mnemonic purposes, the clinician can divide the intracranial space into four subcompartments (Table 70-1): cells (including neurons, glia, tumors, and extravasated collections of blood), fluid (intracellular and extracellular), CSF, and blood.

1. *The cellular compartment.* This compartment is largely the province of the surgeon. However, it may be the anesthesiologist's responsibility to pose a well-placed diagnostic question. When the brain is bulging into the surgical field at the conclusion of evacuation of an extradural hematoma, the clinician should ask whether a subdural or extradural hematoma is present on the contralateral side that warrants either immediate burr holes or immediate postprocedure radiologic evaluation.
2. *The CSF compartment.* There is no pharmacologic manipulation of the CSF space with a time course and magnitude that is relevant to the neurosurgical operating room. The only practical means of manipulating the size of this compartment is by drainage. A tight surgical field can sometimes be improved by passage of a brain needle by the surgeon into a lateral ventricle to drain CSF. Lumbar CSF drainage can be used to improve surgical exposure in situations with no substantial hazard of uncal or transforamen magnum herniation.

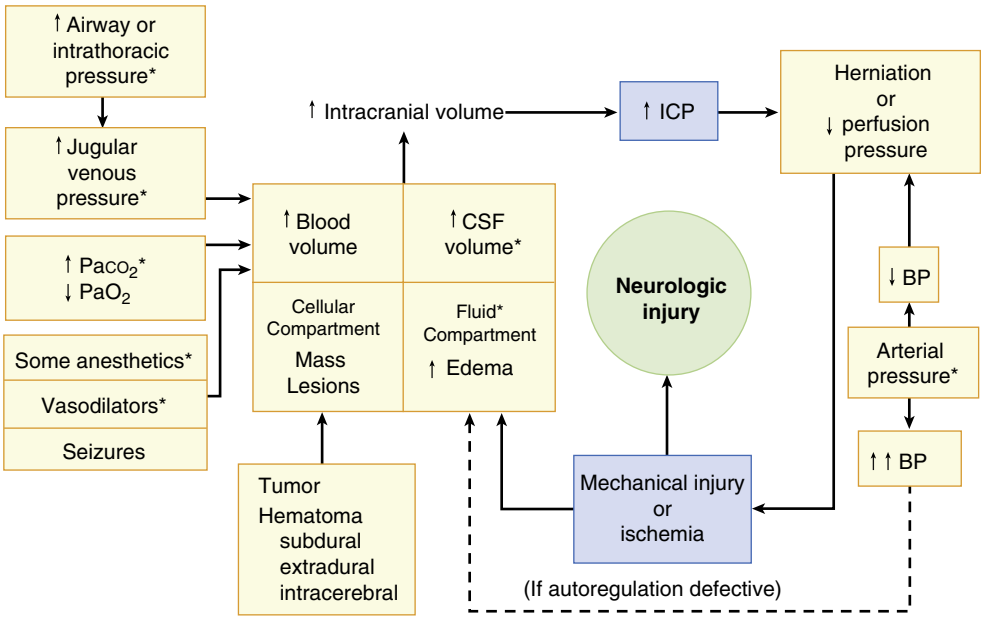

Figure 70-4. The pathophysiology of intracranial hypertension. The figure depicts the manner in which increases in the volumes of any or all of the four intracranial compartments, blood, cerebrospinal fluid (CSF), fluid (interstitial or intracellular), and cells, result in intracranial pressure (ICP) increases and eventual neurologic damage. The elements that are most readily under the control of the anesthesiologist are indicated with asterisks (*). (Control of CSF volume requires the presence of a ventriculostomy catheter.) *BP,* Blood pressure.

3. *The fluid compartment.* This compartment can be addressed with steroids and osmotic/diuretic agents. The use of these agents is discussed later.
4. *The blood compartment.* This compartment receives the anesthesiologist's greatest attention because it is the most amenable to rapid alteration. The blood compartment should be viewed as having two separate components: venous and arterial.

With respect to the blood compartment, the venous side of the circulation should initially be considered. It is largely a passive compartment and often overlooked. Despite this passivity, engorgement of this compartment is a common cause of increased ICP or poor conditions in the surgical field (Fig. 70-5). A head-up posture to ensure good venous drainage is the standard in neurosurgical anesthesia and critical care. Obstruction of cerebral venous drainage by extremes of head position or circumferential pressure (cervical collars, endotracheal tube ties) should be avoided. Anything that causes increased intrathoracic pressure can also result in obstruction of cerebral venous drainage. Relevant phenomena include kinking or partial obstruction of endotracheal tubes, tension pneumothorax, coughing or straining against the endotracheal tube, or gas trapping as a result of bronchospasm. Neuromuscular blockade (see Chapter 34) is usually induced during craniotomies unless a contraindication is present. Such a blockade would prevent a sudden cough that can cause a dramatic herniation of cerebral structures through the craniotomy.

Thereafter, the arterial side of the circulation should be considered. Attention to the effect of anesthetic drugs and techniques on cerebral blood flow (CBF) (see Chapter 17) is an established part of neuroanesthesia because, in general, increases in CBF are associated with increases in cerebral blood volume (CBV).[2-4] The notable exception to this rule occurs in the context of cerebral ischemia caused by hypotension or vessel occlusion, at which times CBV may increase as the cerebral vasculature dilates in response to a sudden reduction in CBF. However, the relationship generally applies, and attention to the control of CBF is relevant in situations in which intracranial volume compensation mechanisms are exhausted or ICP is already increased. The general approach is to select anesthetics and to control physiologic variables in a manner that avoids unnecessary increases in CBF. The variables that influence CBF are listed in Box 70-2 and are discussed in Chapter 17.

TABLE 70-1 INTRACRANIAL COMPARTMENTS AND TECHNIQUES FOR MANIPULATION OF THEIR VOLUME

Compartment	Volume Control Methods
1. Cells (including neurons, glia, tumors, and extravasated blood)	Surgical removal
2. Fluid (intracellular and extracellular)	Diuretics Steroids (principally tumors)
3. CSF	Drainage
4. Blood	
Arterial side	Decrease cerebral blood flow
Venous side	Improve cerebral venous drainage

SELECTION OF ANESTHETICS

The question of which anesthetics are appropriate, especially in the context of unstable ICP, arises frequently. Chapter 17 provides relevant information in detail, and only broad generalizations are described.

In general, intravenous anesthetic, analgesic, and sedative drugs are associated with parallel reductions in CBF and cerebral metabolic rate (CMR) and consequently will not have adverse effects on ICP. Ketamine, given in large doses to patients with a generally normal level of consciousness before anesthesia, is the exception. Autoregulation and carbon dioxide (CO_2) responsiveness is generally preserved during the administration of intravenous anesthetics (see Chapter 17).

By contrast, all of the volatile anesthetics can be, depending on physiologic and pharmacologic circumstances, dose-dependent cerebral vasodilators. The order of vasodilating potency is approximately halothane → enflurane → desflurane → isoflurane → sevoflurane. As noted in Chapter 17, the CBF differences among desflurane, isoflurane,

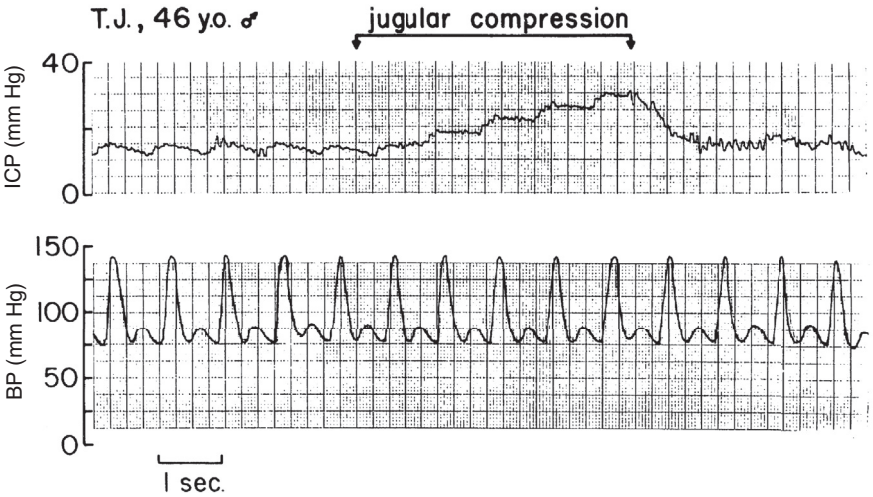

Figure 70-5. The effect of cerebral venous outflow obstruction on intracranial pressure (ICP) in a patient with an intracerebral hematoma. Bilateral jugular compression was applied briefly to verify the function of a newly placed ventriculostomy. The ICP response illustrates the importance of maintaining unobstructed cerebral venous drainage.

and sevoflurane are most likely not clinically significant. The net CBF effect of a volatile anesthetic depends on the interaction of several factors: the concentration of the anesthetic, the extent of previous CMR depression, simultaneous blood pressure changes acting in conjunction with previous or anesthetic-induced autoregulation abnormalities, and simultaneous changes in partial pressure of carbon dioxide in the arterial blood ($Paco_2$) acting in conjunction with any disease-related impairment in CO_2 responsiveness.

Nitrous oxide (N_2O) can also be a cerebral vasodilator. The CBF effect of N_2O is greatest when it is administered as a sole anesthetic; least when it is administered against a background of narcotics, propofol, or benzodiazepines; and intermediate when it is administered in conjunction with volatile anesthetics (see Chapter 17).

Despite the vasodilatory potential of both N_2O and volatile anesthetics, experience dictates that the latter, usually in concentrations less than the minimum alveolar concentration (MAC), when administered as components of a balanced anesthetic technique in combination with opioids, can be used in most elective and many emergency neurosurgical procedures. However, there are infrequent exceptions. Because both N_2O and volatile anesthetics can be vasodilators in some circumstances, when the compensatory latitude of the intracranial space has been exhausted and physiology is abnormal, omitting them on a just-in-case basis may be prudent. In a somnolent, vomiting patient with papilledema, a large tumor mass, and compressed basal cisterns; or in a traumatic brain injury (TBI) victim with an expanding mass lesion or obliterated cisterns and sulci on CT, a predominantly intravenous technique should be used until the cranium and dura are open and the effect of the anesthetic technique can be assessed by direct observation of the surgical field. Although inhaled anesthetics are entirely acceptable components of most anesthetics for neurosurgery, in circumstances in which ICP is persistently increased or the surgical field is persistently "tight," N_2O and volatile anesthetics[5,6] should be replaced by intravenous anesthetics.

See Regulation of Cerebral Blood Flow and Effects of Anesthetics on Cerebral Blood Flow and Cerebral Metabolic Rate in Chapter 17 for detailed discussion.

Older neuromuscular blockers (D-tubocurarine, metocurine, mivacurium, atracurium) can release histamine and should be given in small, divided doses. Although succinylcholine can increase ICP, the increases are small and transient. Moreover, the increases can be blocked by a preceding dose of metocurine 0.03 mg/kg (and probably other nondepolarizer neuromuscular blocking drugs) and, in at least some instances, are not evident in patients with common emergency neurosurgical conditions (TBI, subarachnoid hemorrhage [SAH]).[7,8] Succinylcholine in conjunction with proper management of the airway and MAP can be used when rapid endotracheal intubation is needed.

From the material just presented and from the discussion of cerebral physiology in Chapter 17, a systematic clinical approach should easily follow. A schema for approaching the problem of an acute increase in ICP or acute deterioration in conditions in the surgical field is presented in Box 70-3.

If the problem has not resolved satisfactorily after following the approach in Box 70-3, Box 70-4 presents options for resolution. CSF drainage was discussed

BOX 70-3 ***High Intracranial Pressure ("Tight Brain") Checklist***

1. Are the relevant pressures controlled?
   a. Jugular venous pressure
      i. Extreme head rotation or neck flexion?
      ii. Direct jugular compression?
      iii. Head-up posture?
   b. Airway pressure
      i. Airway obstruction?
      ii. Bronchospasm?
      iii. Straining, coughing; adequately relaxed?
      iv. Pneumothorax?
      v. Excessive PEEP or APR ventilation?
   c. Partial pressure of CO_2 and O_2 ($Paco_2$, PaO_2)
   d. Arterial pressure
2. Is the metabolic rate controlled?
   a. Pain/arousal?
   b. Seizures?
   c. Febrile?
3. Are any potential vasodilators in use?
   a. N_2O, volatile agents, nitroprusside, calcium channel blockers?
4. Are there any unrecognized mass lesions?
   a. Hematoma
   b. Air ± N_2O
   c. CSF (clamped ventricular drain)

APR, Airway pressure release; *CSF,* cerebrospinal fluid; *PEEP,* positive end-expiratory pressure.

BOX 70-4 ***Methods for Rapid Reduction of Intracranial Pressure and Brain Volume (After Review of the Checklist in Box 70-3)***

- Further reduction of $Paco_2$ (to not <23-25 mm Hg)
- CSF drainage (ventriculostomy, brain needle)
- Diuresis (usually mannitol)
- CMR suppression (barbiturates, propofol)
- MAP reduction (if dysautoregulation)
- Surgical control (i.e., lobectomy or removal of bone flap)

earlier. Hyperosmolar solutions are frequently used (see the subsequent section "Osmotherapy and Diuretics"). Barbiturates have long been the most widely used drugs for inducing reduction in CMR, with the objective of causing a coupled reduction in CBF and CBV. Propofol has gained popularity for this application. However, although the use of barbiturates is supported by intensive care unit (ICU) experience, demonstrating efficacy in ICP control[9] (if not outcome), no such experience has been accumulated for propofol. Furthermore, a frequently fatal syndrome of metabolic acidosis and rhabdomyolysis has been recognized in patients who have received prolonged propofol infusions in the ICU setting.[10,11]

MANAGEMENT OF $Paco_2$

The anesthesiologist and the surgeon should agree on the objectives with respect to $Paco_2$. Induction of hypocapnia was once a routine part of the management of intracranial neurosurgical procedures. The rationale is principally that the concomitant reduction in CBF (see Chapter 17, Fig. 17-7) and CBV will result in a reduction in ICP, or "brain relaxation." The rationale is valid.[12] However, two considerations should influence the clinician's use of hyperventilation. First, the vasoconstrictive effect of hypocapnia can cause ischemia in certain situations. Second, the CBF-lowering and ICP-lowering effect is not sustained.[13]

Hypocapnia-Induced Cerebral Ischemia

A normal brain is unlikely to be damaged by the typical clinical use of hyperventilation. However, this may not be the case in certain pathologic conditions.

Normal Brain. Current data[14-18] indicate that in normal subjects, ischemia will not occur at a $Paco_2$ greater than 20 mm Hg. However, in one investigation,[17] electroencephalogram (EEG) abnormalities and paresthesia occurred in volunteers hyperventilating to $Paco_2$ values less than 20 mm Hg, and these effects were reversed by hyperbaric oxygenation, suggesting that they may truly have been caused by ischemia. Accordingly, given that a $Paco_2$ of less than 20 to 25 mm Hg offers very little additional benefit in terms of improvement in intracranial compliance, acute reduction of $Paco_2$ should be no more than 22 to 25 mm Hg in previously normocapnic persons.

Injured Brain. Preventing herniation, maintaining ICP less than 20 mm Hg, minimizing retractor pressure, and facilitating surgical access remain priorities that may justify hypocapnia. Yet hyperventilation is potentially deleterious and should not be overused. Hyperventilation can result in ischemia,[19-29] especially when baseline CBF is low,[30] as is commonly the case in the first 24 hours after injury.[31-37] An increased frequency of brain regions with very low CBF has been demonstrated in head-injured patients who were acutely hyperventilated.[19,28,29] In addition, low levels of jugular venous oxygen saturation ($SjvO_2$) can be increased and lactate levels in the jugular venous effluent can be decreased by reducing the degree of hyperventilation.[21,30,38]

The deleterious effect of hyperventilation is difficult to prove. Muizelaar and colleagues[22] performed a study that included a near normocapnic group in which $Paco_2$ was maintained at approximately 35 mm Hg, and a hypocapnic group in which $Paco_2$ was maintained in the vicinity of 25 mm Hg. Outcomes at 3 and 6 months after injury were not different. However, in a subset of patients with the best initial motor scores, outcome was better in the normocapnic group. These patients with good motor scores probably represented a subgroup in which the severity of injury was such that, although they needed tracheal intubation, their clinical condition may have been such that hyperventilation was not necessarily required for control of ICP and who therefore had little to gain from hyperventilation. Thus "prophylactic" hyperventilation seemed inadvisable. That conclusion has been extrapolated far beyond the circumstances of relatively mild TBI.

Hyperventilation should not be an automatic component of every "neuroanesthetic." There should be an indication for its institution (usually increased or uncertain ICP or the need to improve conditions in the surgical field, or both). Hyperventilation has the potential to cause an adverse effect and should be withdrawn as the indication for it subsides. The concern regarding the hazards of hypocapnia, which evolved in the context of TBI, has influenced all of neurosurgery. In particular, it is now widely avoided in the management of SAH because of the low CBF state that is known to occur.[39] In addition, brain tissue beneath retractors can have a similarly reduced CBF.[24,40] However, hyperventilation, used as briefly as possible, is still very much a component of "rescue therapy," when herniation is imminent or in progress, or when conditions in the surgical field are too difficult to allow surgery to proceed.

Duration of Hypocapnia-Induced Reduction in Cerebral Blood Flow

The effect of hypocapnia on CBF is not sustained. Figure 70-6 is a nonquantitative representation of changes in CBF and CSF pH occurring in association with a sustained period of hyperventilation. With the onset of hyperventilation, the pH of both CSF and the brain's extracellular fluid space increases, and CBF decreases abruptly. However, the cerebral alkalosis is not sustained. By alterations in function of the enzyme carbonic anhydrase, the concentration of bicarbonate in CSF and the brain's extracellular fluid space is reduced, and in a time course of 8 to 12 hours, the pH of these compartments returns to normal.[41] Simultaneously, CBF returns toward normal levels.[41,42] The implications are twofold. First, patients should be hyperventilated for only as long as a reduction in brain volume is required. Prolonged but unnecessary hyperventilation can lead to a circumstance wherein subsequent clinical events call for additional maneuvers to reduce the volume of the intracranial contents and incremental hyperventilation is not feasible. If, after adaptation, $Paco_2$ is already in the 23 to 25 mm Hg range, additional hyperventilation may risk pulmonary barotrauma. Second, in a patient who has been hyperventilated for a sustained period (e.g., 2 days in an ICU setting), restoration of $Paco_2$ from values in the vicinity of 25 mm Hg to typical normal

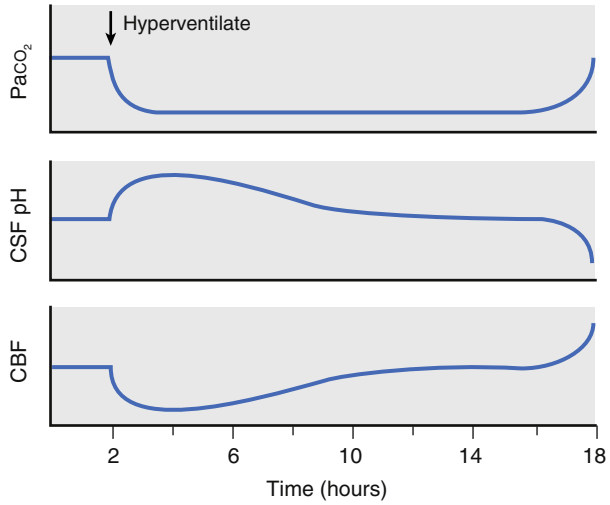

Figure 70-6. Partial pressure of carbon dioxide in the arterial blood ($Paco_2$), cerebral blood flow (CBF), and cerebrospinal fluid (CSF) pH changes with prolonged hyperventilation. Although the decreased arterial $Paco_2$ (and the systemic alkalosis) persists for the duration of the period of hyperventilation, the pH of the brain and CBF return toward normal over 8 to 12 hours.

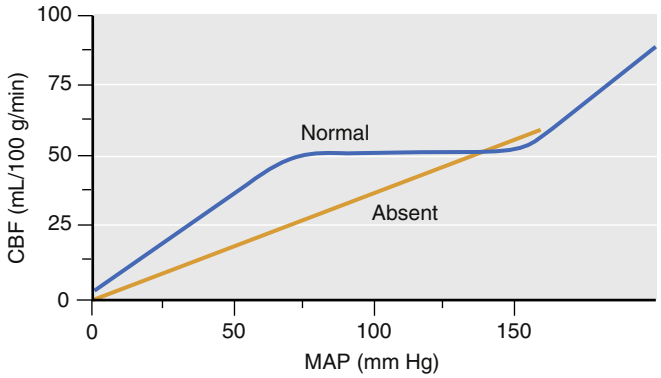

Figure 70-7. Normal and absent autoregulation curves. The "absent" curve indicates a pressure-passive condition in which cerebral blood flow (CBF) varies in proportion to cerebral perfusion pressure (CPP). This curve is drawn to indicate subnormal CBF values during normotension, as have been shown to occur immediately after head injury[21] and subarachnoid hemorrhage.[39] The potential for modest hypotension to cause ischemia is apparent. *MAP,* Mean arterial pressure.

values (e.g., 40 mm Hg) should ideally be accomplished slowly. A sudden increase in $Paco_2$ from 25 to 40 mm Hg in a patient who has been chronically hyperventilated will have the same physiologic effect that a rapid change from 40 to 55 mm Hg would have in a previously normocapnic patient.

If hypocapnia has been required as an adjunct to brain relaxation during craniotomy, $Paco_2$ should also be allowed to increase once the retractors are removed (if dural closure requirements permit) to minimize the residual intracranial pneumatocele (see the section on Pneumocephalus).

MANAGEMENT OF ARTERIAL BLOOD PRESSURE

Acceptable arterial blood pressure limits should similarly be agreed on at the beginning of a neurosurgical procedure. One of the prominent themes of contemporary neurosurgery is that CPP should be maintained at normal or even high-normal levels after acute central nervous system insults and during most intracranial neurosurgical procedures. This concept has evolved from the growing appreciation that CBF is frequently very low in some brain regions after acute neurologic insults, in particular TBI and SAH. Two additional factors should be considered. The first is that the autoregulatory response to decreasing blood pressure may not be intact throughout the brain. Figure 70-7 depicts the ischemic hazard that attends the circumstance of a low resting CBF and absent autoregulation even at blood pressure levels considered safe when autoregulation is intact. In addition, maintenance of arterial pressure is also relevant to brain compressed under retractors[24] because the effective perfusion pressure is lowered by increased local tissue pressure.

Although the only supportive data are anecdotal, we nonetheless believe that an aggressive attitude toward arterial blood pressure support should also be given to patients who have sustained a recent spinal cord injury, to a spinal cord that is under compression or at risk for compression or vascular compromise because of a disease process (most commonly cervical spinal stenosis with or without ossification of the posterior longitudinal ligament) or an intended surgical procedure, and to those patients undergoing surgery involving retraction of the spinal cord. We believe that arterial blood pressure during anesthesia in these patients should be maintained as closely as possible to, and certainly within, 10% of average awake values.

STEROIDS

The administration of steroids for the purpose of reducing or limiting the formation of edema has a well-established place in neurosurgery. The efficacy of steroids in reducing the edema and increased blood-brain barrier (BBB) permeability associated with tumors (and only tumors) is well confirmed.[43-46] Although the time course of this effect is relatively rapid, it is too slow for the management of acute intraoperative events. However, administration beginning 48 hours before an elective surgical procedure has the potential to reduce edema formation and improve the clinical condition by the time of craniotomy.[43,47,48] Although clinical improvement occurs within 24 hours,[47] a reduction in ICP may not occur for 48 to 72 hours after the initiation of therapy.[47] Steroids somehow improve the viscoelastic properties of the intracranial space before a reduction in edema occurs, although the mechanism remains undefined.[48] The practice of administering steroids to patients with TBI has been abandoned as a result of controlled trials that demonstrated either no benefit or deleterious effects.[49]

OSMOTHERAPY AND DIURETICS

Hyperosmolar agents and diuretics are used widely in neurosurgery and neurocritical care to reduce the volume of the brain's intracellular and extracellular fluid

compartments. Both osmotic and loop diuretics have been used. Although loop diuretics can be effective,[50] hyperosmolar agents are more widely used.

Mannitol

Mannitol is used most commonly intraoperatively because of its long history of rapid and effective reduction of brain volume. The doses vary from 0.25 g/kg to 100 g "for all comers"; 1.0 g/kg is the most common dose. However, a systematic study in TBI demonstrated that an equivalent initial ICP-reducing effect can be achieved with 0.25 g/kg, although that effect cannot be as sustained as when larger doses are used.[51] Others use doses greater than 1.0 g/kg.[52] Mannitol should be administered by infusion (e.g., over 10 to 15 minutes). Sudden exposure of the cerebral circulation to extreme hyperosmolarity can have a vasodilatory effect, which can produce brain engorgement and increased ICP, both of which do not occur with slower administration.

Mannitol enters the brain and, over a reasonably short time course, appears in the CSF space.[53] The possibility that the mannitol that gains access to the parenchyma aggravates swelling has resulted in varying degrees of reluctance among clinicians to administer mannitol.[54] Most clinicians nonetheless find it to be a mainstay of ICP management. Is it only effective when some degree of BBB integrity is preserved in a significant portion of the brain? Clinicians respond to this concern by making empirical use of this agent; that is, if it is effective in reducing ICP or improving conditions in the surgical field, repeated doses are administered. The use of hyperosmolar agents is theoretically limited by an upper acceptable osmolarity limit of approximately 320 mOsm/L (although the data supporting the validity of that limit is "soft"[55]). However, in life-threatening situations, the use is frequently empirical, and incremental doses (e.g., 12.5 g of mannitol) are administered until a clinical response is no longer observed.

Hypertonic Saline

In the critical care environment (see Chapter 105), the use of hypertonic saline (HTS) in place of mannitol is increasing.[56] Although the initial ICP effects of equiosmolar doses of mannitol and HTS are very similar,[57-60] HTS may have some advantages in the ICU, where repeated administration makes the adverse effects (e.g., diuresis, renal injury) more likely to have clinical significance. In addition, there are anecdotal reports of HTS being effective in patients who were refractory to mannitol.[61,62] Although there is enthusiasm for HTS,[61,63,64] supporting data are limited.[65] Furthermore, because of the variations in HTS concentrations (3%, 7.5%, 15%, 23.4%) and osmolar loads in the various studies, it is difficult to make specific recommendations.

Diuretic Combinations

The combination of a loop diuretic (usually furosemide) and an osmotic diuretic is sometimes used. The superficial rationale is that mannitol establishes an osmotic gradient that draws fluid out of brain parenchyma and that the furosemide, by hastening excretion of water from the intravascular space, facilitates the maintenance of that gradient. A second mechanism may add additional justification for the practice of combining the two diuretics. Neurons and glia have homeostatic mechanisms to ensure regulation of cell volume. Neurons and glia that shrink in response to an increased osmolarity in the external environment recover their volume rapidly as a consequence of the accumulation of so-called *idiogenic osmoles*, which serve to minimize the gradient between the internal and external environments. One of those idiogenic osmoles is chloride. Loop diuretics inhibit the chloride channel through which this ion must pass and thereby retard the normal volume-restoring mechanism.[66,67] These diuretic combinations may cause hypovolemia and electrolyte disturbances.

The normal volume regulatory mechanisms of neurons and glia may also be relevant to the phenomenon of rebound swelling. Rebound is commonly attributed to the prior use of mannitol and assumed to be a function of the accumulation of mannitol in cerebral tissue. Although possible, the rebound may in fact be hypertonic rebound rather than mannitol rebound. After a sustained period of hyperosmolarity of any etiology, rebound swelling of neurons and glia (which have accumulated idiogenic osmoles) may occur in the event that systemic osmolarity decreases rapidly toward normal levels. Rebound cerebral swelling can certainly occur after an episode of extreme increase in blood glucose concentration. The use of HTS rather than mannitol will not obviate this phenomenon.

ANTICONVULSANTS

The general principle is that any acute irritation of the cortical surface has the potential to result in seizures. This includes acute neurologic events such as TBI and SAH.[68,69] Cortical incisions and brain surface irritation by retractors may similarly be potential foci. Given the relatively benign nature of contemporary anticonvulsants (e.g., levetiracetam), routine administration to patients undergoing most supratentorial craniotomies, as well as to patients who have sustained a significant recent TBI[68] or a SAH, seems appropriate in the absence of a contraindication. There is no necessity for rapid administration because the intention is to prevent seizures during the postoperative period.

POSITIONING

The intended surgical position and the necessary positioning aids should be agreed upon at the outset. The commonly used positions and positioning aids and supports are listed in Box 70-5 (see Chapter 41).

General Considerations

The prolonged duration of many neurosurgical procedures should be taken into account in all positions. Pressure points should be identified and padded carefully. Pressure and traction on nerves must be avoided. Given the high risk of thromboembolic complications in neurosurgical patients, precautions including support hose and sequential compression devices are warranted. For cranial procedures, some component of head-up posturing (e.g., 15 to 20 degrees) is used to ensure optimal venous drainage.

BOX 70-5 ***Common Neurosurgical Positions and Positioning Aids***

Positions

- Supine
- Lateral (park bench)
- Semi-lateral (Jannetta)
- Prone
- Sitting

Positioning Aids/Supports

- Pin ("Mayfield") head holder
- Radiolucent pin head holder
- Horseshoe head rest
- Foam head support (e.g., Voss, O.S.I., Prone-View)
- Vacuum mattress ("bean bag")
- Wilson-type frame
- Andrews ("hinder binder")-type frame
- Relton-Hall (four-poster) frame

The conspicuous exception occurs with evacuation of a chronic subdural hemorrhage, after which patients are usually nursed flat to discourage reaccumulation of fluid. Patients are occasionally also maintained flat after CSF shunting to avoid overly rapid collapse of the ventricles.

Supine

The supine position is used with the head neutral or rotated for frontal, temporal, or parietal access. Extremes of head rotation can obstruct the jugular venous drainage, and a shoulder roll can attenuate this problem. The head is usually in a neutral position for bifrontal craniotomies and transsphenoidal approaches to the pituitary. The head-up posture is best accomplished by adjusting the operating table to a chaise longue (lawn chair) position (flexion, pillows under the knees, slight reverse Trendelenburg). This orientation, in addition to promoting cerebral venous drainage, decreases back strain.

Semilateral

The semilateral position, also known as the Jannetta position, named after the neurosurgeon who popularized its use for microvascular decompression of the fifth cranial nerve, is used for retromastoid access. It is achieved by lateral tilting of the table 10 to 20 degrees combined with a generous shoulder roll. Again, extreme head rotation, sufficient to cause compression of the contralateral jugular vein by the chin, should be avoided.

Lateral

The lateral position can be used for access to the posterior parietal and occipital lobes and the lateral posterior fossa including tumors at the cerebellopontine angle and aneurysms of the vertebral and basilar arteries. An axillary roll is important for preventing brachial plexus injury.

Prone

The prone position is used for spinal cord, occipital lobe, craniosynostosis, and posterior fossa procedures. The prone position has also been aptly referred to as the *Concorde position*, because for cervical spine and posterior fossa procedures, the final position commonly entails neck flexion, reverse Trendelenburg, and elevation of the legs. This orientation serves to bring the surgical field to a horizontal position. There should be a plan for detaching and reattaching monitors in an orderly manner to prevent an excessive monitoring "window." Awake tracheal intubation and prone positioning may be warranted in patients with an unstable cervical spine in whom an unchanged neurologic status should be confirmed before induction of anesthesia in the final surgical position. This approach is also sometimes performed in obese patients.

The head can be secured in a pin head holder (applied before the turn) or positioned on a disposable foam head rest or, less frequently, a horseshoe head rest. A complication of the prone position, which requires constant attention, is retinal ischemia and blindness caused by orbital compression causing central retinal vessel occlusion. It must be intermittently confirmed (i.e., every 15 minutes) and after any surgery-related head or neck movement that pressure has not come to bear on the eye. However, not all postoperative vision loss (POVL) is a result of direct orbital compression (see Chapter 100). Ischemic optic neuropathy actually appears to be a more frequent cause of POVL than pressure-causing occlusion of central retinal vessels. The cause-and-effect relationships associated with ischemic optic neuropathy are uncertain, but low arterial pressure, low hematocrit level, lengthy surgical procedures, and large intravascular volume fluid administration are statistically associated with the phenomenon.[70] POVL is discussed extensively in Chapter 100.

Direct pressure can also result in various degrees of pressure necrosis of the forehead, maxillae, and chin, especially with prolonged spinal procedures. Pressure should be distributed as evenly as possible over facial structures. Other pressure points to check include the axillae, breasts, iliac crests, femoral canals, genitalia, knees, and heels. When the arms are placed in the "stick 'em up" position, traction on the brachial plexus must be avoided. That can usually be accomplished by not exceeding a "90-90" position (arms abducted not >90 degrees; elbows extended not >90 degrees) with care taken to ensure that the elbow is anterior to the shoulder to prevent wrapping of the brachial plexus around the head of the humerus. An antisialagogue (e.g., glycopyrrolate) and an adhesive (e.g., benzoin) may help reduce loosening of the tape used to secure the endotracheal tube.

An objective during prone positioning, especially for lumbar spine surgery, is the avoidance of compression of the inferior vena cava. Impairment of vena cava return diverts blood to the epidural plexus and increases the potential for bleeding during spinal surgery. Minimizing vena cava pressure is an objective of all spinal surgery frames and is accomplished effectively by the Wilson, Andrews, and Jackson variants. However, this does introduce a risk of air embolism,[71,72] although severe clinical occurrences have been very infrequent.[73]

There should be attention to preventing injury to the tongue in the prone position. With both cervical and posterior fossa procedures, it is frequently necessary to flex the neck substantially to facilitate surgical access. This reduces the anterior-posterior dimension of the oropharynx, and compression ischemia of the base of the tongue (as well as the soft palate and posterior wall of

the pharynx) can occur in the presence of foreign bodies (endotracheal tube, esophageal stethoscope, oral airway). The consequence can be macroglossia, caused by accumulation of edema after reperfusion of the ischemic tissue causing airway obstruction of rapid onset after extubation (discussed later). Accordingly, placing unnecessary paraphernalia in the oral cavity and pharynx should be avoided. Omitting the oral airway entirely is unwise because the tongue may then protrude between and be trapped by the teeth as progressive swelling of facial structures occurs during a prolonged prone procedure. A rolled gauze bite block prevents this problem without adding bulk to the oropharynx.

Sitting

There have been several reviews of large experiences with the sitting position.[74-78] All concluded that the sitting position can be used with acceptable rates of morbidity and mortality. However, these reports were prepared by groups that perform 50 to 100 or more of these procedures per year, and the hazards of the sitting position may be more frequent for teams who have fewer occasions to use it. The sitting position can be avoided by using one of its alternatives (prone, semilateral, lateral). However, this position will continue to be used because even surgeons who are inclined to use alternative positions may opt for it when access to midline structures (e.g., the quadrigeminal plate, the floor of the fourth ventricle, the pontomedullary junction, and the vermis) is required. Nonetheless, alternative positions for posterior fossa surgery are available and should be considered when contraindications to the sitting position exist.

Achieving the Sitting Position. The properly positioned patient is more commonly in a modified recumbent position as shown in Figure 70-8 rather than truly sitting. The legs should be kept as high as possible (usually with pillows under the knees) to promote venous return. Ideally, the head holder should be attached to the back portion of the table (see Fig. 70-8, *A*) rather than to the portions under thighs or legs[79] (see Fig. 70-8, *B*). This permits lowering of the head and closed chest massage if necessary, without the necessity of first taking the patient out of the head holder.

When procedures are performed in the sitting position, the clinician should think in terms of measuring and maintaining perfusion pressure at the level of the surgical field. This is best accomplished by referencing transducers to the level of the external auditory canal. If a manual blood pressure cuff on the arm is used, a correction* to allow for the hydrostatic difference between the arm and the operative field should be applied.

A series of hazards are associated with the sitting position. Circulatory instability, macroglossia, and quadriplegia are discussed in this section. Pneumocephalus is discussed in its own section. Venous air embolism (VAE) and paradoxical air embolism (PAE) are discussed in Venous Air Embolism. Several of these hazards are also relevant when cervical spine and posterior fossa procedures are performed in nonsitting positions but occur with greater frequency in the sitting position.

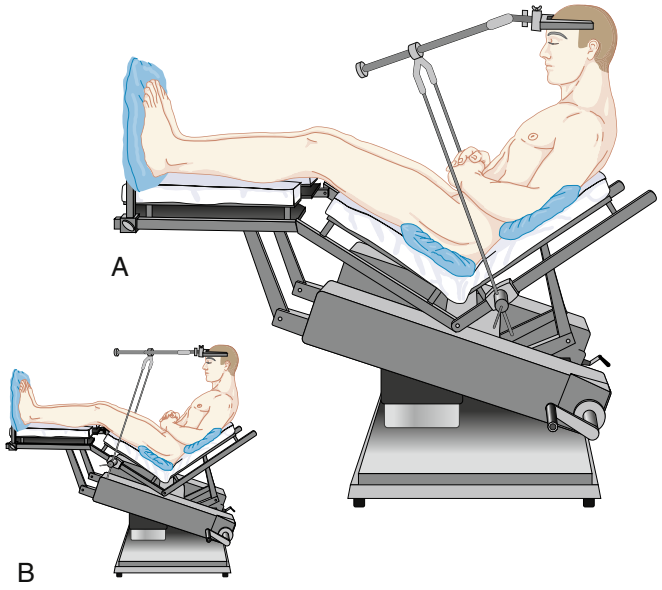

Figure 70-8. The sitting position. The patient is typically semirecumbent rather than sitting. **A,** The head-holder support is correctly positioned so that the head can be lowered without the necessity to first detach the head holder. **B,** This configuration, with the support attached to the thigh portion of the table, should be avoided. *(From Martin JT:* Positioning in anesthesia and surgery, *Philadelphia, 1988, Saunders, with permission.)*

Cardiovascular Effects of the Sitting Position. Hypotension should be avoided. Prepositioning hydration; compressive stockings; and slow, incremental adjustment of table position are appropriate. Intravenous vasopressor administration may be required in some patients. However, in most healthy subjects the hemodynamic changes are of a nonthreatening magnitude. In a study of healthy anesthetized adult subjects ages 22 to 64 years old, Marshall[80] observed relatively modest changes. Mean arterial blood pressure was relatively unaffected, whereas wedge pressure, stroke volume, and cardiac index decreased—the latter by approximately 15%—although there was some variation with the anesthetics used. The combination of an unchanged MAP (which in general requires the use of a light, high sympathetic tone anesthetic) and a reduced cardiac index implies that systemic vascular resistance (SVR) increased. Their calculations and the observations of other investigators[81] reveal significant increases in SVR. For patients in whom an abrupt increase in SVR may be poorly tolerated, the sitting position may represent a physiologic threat and alternative positions should be considered. A pulmonary artery catheter may be warranted only when there is clinical or historical evidence of antecedent coronary artery or valvular heart disease.

During procedures performed in the sitting position, MAP should be transduced at or corrected to head level to provide a meaningful index of CPP. Specifically, CPP (MAP – Estimated ICP) should be maintained at a minimum value of 60 mm Hg in healthy patients in whom it is reasonable to assume a normal cerebral vasculature.

*A column of blood 32 cm high exerts a pressure of 25 mm Hg.

The safe lower limit should be raised for elderly patients, for those with hypertension or known cerebral vascular disease, or for those with degenerative disease of the cervical spine or cervical spinal stenosis who may be at risk for decreased spinal cord perfusion, and in the event that substantial or sustained retractor pressure must be applied to brain or spinal cord tissue.

Macroglossia. There have been sporadic reports of upper airway obstruction after posterior fossa procedures in which swelling of pharyngeal structures, including the soft palate, posterior pharyngeal wall, and base of the tongue, has been observed.[46,82] These episodes have been attributed to edema formation at the time of reperfusion after trauma or prolonged ischemia, occurring as the result of foreign bodies (usually oral airways) causing pressure on these structures in the circumstances of lengthy procedures with sustained neck flexion (which is usually required to improve access to posterior structures). It is customary to maintain at least two fingerbreadths between the chin/mandible and the sternum/clavicle to prevent excessive reduction of the anterior-posterior diameter of the oropharynx. In addition, it is our practice to position patients with the oral airway in place and then, once the final head position is achieved, withdraw it and replace it with a gauze roll between the teeth. Consideration of the macroglossia phenomenon may also be relevant as clinicians contemplate the use of transesophageal echocardiography (TEE) in the neurosurgery suite. The centers that routinely use TEE in neurosurgery mostly use pediatric diameter probes to avoid trauma to pharyngeal and perilaryngeal structures.

Quadriplegia. The sitting position has been implicated as a cause of rare instances of unexplained postoperative quadriplegia. It has been hypothesized[83] that the neck flexion that is a common concomitant of the seated position may result in stretching or compression of the cervical spinal cord. This possibility may represent a relative contraindication to the use of this position in patients with significant degenerative disease of the cervical spine, especially when there is evidence of associated cerebral vascular disease. The arterial blood pressure management implications are mentioned in the preceding section on cardiovascular effects. It may also represent a justification for somatosensory evoked response monitoring during the positioning phase of a sitting procedure for patients perceived to be at high risk. (Also see Chapter 49.)

PNEUMOCEPHALUS

The issue of pneumocephalus arises most often in connection with posterior fossa craniotomies performed with a head-up posture.[84,85] During these procedures, air may enter the supratentorial space, much as air enters an inverted pop bottle. Depending on the relationship of the brainstem and temporal lobes to the incisura, the pressure in the air collection may or may not be able to equilibrate with atmospheric pressure. This phenomenon has relevance to the use of N_2O because any N_2O that enters a trapped gas space augments the volume of that space. In those (probably uncommon) intraoperative circumstances where there is, in fact, a completely closed intracranial gas space, the use of N_2O may result in an effect comparable with that of an expanding mass lesion. We do not view N_2O as absolutely contraindicated because, before dural closure, intracranial gas is probably only rarely trapped. Nonetheless, attention to this possibility is important when one is presented with the problem of an increasingly "tight" brain during a posterior fossa craniotomy.[86,87]

Figure 70-9. Postoperative computed tomographic scan demonstrating a large pneumocephalus after a subfrontal approach to a suprasellar glioma. Immediately postoperatively, the patient was confused and agitated, and he complained of a severe headache.

During a posterior fossa procedure done in a head-up posture, when surgical closure has reached a stage such that the intracranial space has been completely sealed from the atmosphere, N_2O should be omitted because of the possibility of contributing to a tension pneumocephalus. Note that the use of N_2O up to the point of dural closure may actually represent a clinical advantage[88] because the gas pocket can be expected to shrink more rapidly because of the presence of N_2O (because N_2O diffuses much more quickly than nitrogen). Tension pneumocephalus is often naively viewed as exclusively a function of the use of N_2O. However, tension pneumocephalus can most certainly occur as a complication of intracranial neurosurgery entirely *unrelated* to the use of N_2O.[89] It is one of the causes of delayed awakening or nonawakening after both posterior fossa and supratentorial procedures (Fig. 70-9).[89,90] It occurs because air enters the cranium when the patient is in a head-up position at a time when the volume of the intracranial contents has been reduced because of some combination of hypocapnia, good venous drainage, osmotic diuresis, and CSF loss from the operative field. When the cranium is closed and the patient is returned to the near supine position, CSF,

venous blood volume, and extracellular fluid return or reaccumulate and the air pocket becomes an unyielding mass lesion (because of the very slow diffusion of nitrogen). It may cause delayed recovery of consciousness or severe headache. Among supratentorial craniotomies, the largest residual air spaces occur after frontal skull base procedures in which energetic brain relaxation measures are used to facilitate subfrontal access (see Fig. 70-9). At the end of these procedures, typically done in a supine/brow-up position, the intracranial dead space cannot be filled with normal saline as is commonly done with smaller craniotomy defects, and there may be a large residual pneumatocele. We doubt that the possible occurrence of this phenomenon represents a contraindication to N_2O. However, withdrawal of N_2O may be appropriate at the time of scalp closure. The diagnosis of pneumocephalus is established by a brow-up lateral radiography or, more commonly, a CT scan. The treatment is a twist-drill hole followed by needle puncture of the dura.

Residual intracranial air should be considered at the time of repeat anesthesia, both neurosurgical and nonneurosurgical. Air frequently remains evident on CT scan for more than 7 days after a craniotomy.[91] Pneumocephalus can also develop de novo in the postoperative period in patients who have a residual dural defect and a communication between the nasal sinuses and the intracranial space.[92]

VENOUS AIR EMBOLISM

The rate of occurrence of VAE varies according to the procedure, the intraoperative position, and the detection method used. During posterior fossa procedures performed in the sitting position, VAE is detectable by precordial Doppler in approximately 40% of patients and by TEE in as much as 76%.[93-96] The incidence of VAE during posterior fossa procedures performed in nonsitting positions is much less (12% using precordial Doppler in the report of Black and colleagues[76]), and it is probable but unproven that the average volume of air entrained per event is also smaller. The rate of VAE is apparently lower with cervical laminectomy (25% using TEE in the sitting position versus 76% for posterior fossa procedures[95]). Although VAE is principally a hazard of posterior fossa and upper cervical spine procedures, especially when they are performed in the sitting position, it can occur with supratentorial procedures. The most common situations involve tumors, most often parasagittal or falcine meningiomas, that encroach on the posterior half of the sagittal sinus (Fig. 70-10) and craniosynostosis procedures, typically performed in children.[97,98] Pin sites can also serve as VAE access sites. Accordingly, pin head holders should be removed after the patient has been taken out of significant degrees of the head-up positioning. Spontaneous ventilation (with the attendant intermittent negative intrathoracic pressure) will increase the risk of air entrainment. A 6% incidence of Doppler-detectable VAE was reported in a recent series of deep-brain stimulator placement procedures performed in spontaneously breathing patients.[99]

The common sources of critical VAE are the major cerebral venous sinuses, in particular the transverse, the sigmoid, and the posterior half of the sagittal sinus, all of which may be noncollapsible because of their dural attachments. Air entry may also occur via emissary veins, particularly from suboccipital musculature, via the diploic space of the skull (which can be violated by both the craniotomy and pin fixation) and the cervical epidural veins. It is believed (but not confirmed by systematic study) that the VAE risk associated with cervical laminectomy is more likely when the exposure requires dissection of suboccipital muscle with the potential to open emissary veins to the atmosphere at their point of entry into occipital bone. There is also anecdotal evidence[100] that air under pressure in the ventricles or subdural space can occasionally enter the venous system, perhaps along the normal egress route of the CSF.

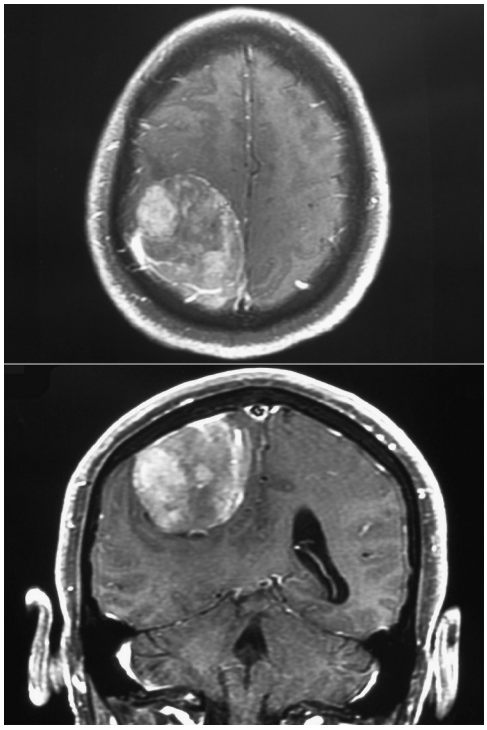

Figure 70-10. Axial *(top)* and coronal *(bottom)* magnetic resonance images of a parasagittal meningioma. Resection of meningiomas arising from the dural reflection overlying the sagittal sinus or from the dura of the adjacent convexity or falx often entails a risk of venous air embolism because of the proximity of the sagittal sinus (the triangular structure at the superior end of the interhemispheric fissure in the bottom panel).

Detection of Venous Air Embolism

The monitors used for the detection of VAE should provide (1) a high level of sensitivity, (2) a high level of specificity, (3) a rapid response, (4) a quantitative measure of the VAE event, and (5) an indication of the course of recovery from the VAE event. The combination of a precordial Doppler and expired CO_2 monitoring meets these criteria and is the current standard of care. Doppler placement in a left or right parasternal location between the second and third or third and fourth ribs has a very high detection rate for gas embolization,[101] and when good heart tones are heard, maneuvers to confirm adequate placement appear to be unnecessary. The TEE is

more sensitive than the precordial Doppler (Fig. 70-11) to VAE[102] and offers the advantage of also identifying right-to-left shunting of air. However, its safety during prolonged use (especially with pronounced neck flexion) is not well established. Expired nitrogen analysis is theoretically attractive. However, the expired nitrogen concentrations involved in anything less than catastrophic VAE are very small and push the available instrumentation to the limits of its sensitivity.[103]

Figure 70-12 presents the physiologic and monitor response to an air embolic event, and Box 70-6 offers an appropriate management response to such an event.

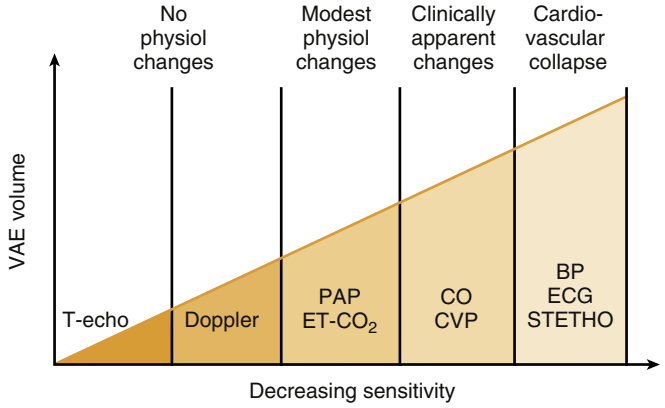

Figure 70-11. The relative sensitivity of various monitoring techniques to the occurrence of venous air embolism. *BP*, Blood pressure; *CO*, cardiac output; *CVP*, central venous pressure; *ECG*, electrocardiogram; *ET-CO_2*, end-tidal carbon dioxide; *PAP*, pulmonary artery pressure; *Stetho*, esophageal stethoscope; *T-echo*, transesophageal echo.

Which Patients Should Have a Right Heart Catheter?

Essentially, all patients who undergo sitting posterior fossa procedures should have a right heart catheter placed. Although life-threatening, VAE is relatively uncommon, a catheter that permits immediate evacuation of an air-filled heart is occasionally the sine qua non for resuscitation. The latitudes are much wider with the nonsitting positions, and it is frequently appropriate, after a documented discussion with the surgeon, to omit the right heart catheter. The perceived risks of VAE associated with the intended procedure, and the patient's physiologic reserve are the variables that contribute to the decision. Microvascular decompression of the fifth cranial nerve for tic douloureux or the seventh cranial nerve for hemifacial spasm are examples of procedures

BOX 70-6 ***Management of an Acute Air Embolic Event***

1. Prevent further air entry
   - Notify surgeon (flood or pack surgical field)
   - Jugular compression
   - Lower the head
2. Treat the intravascular air
   - Aspirate right heart catheter
   - Discontinue N_2O
   - Fio_2: 1.0
   - Pressors, inotropes
   - Chest compression

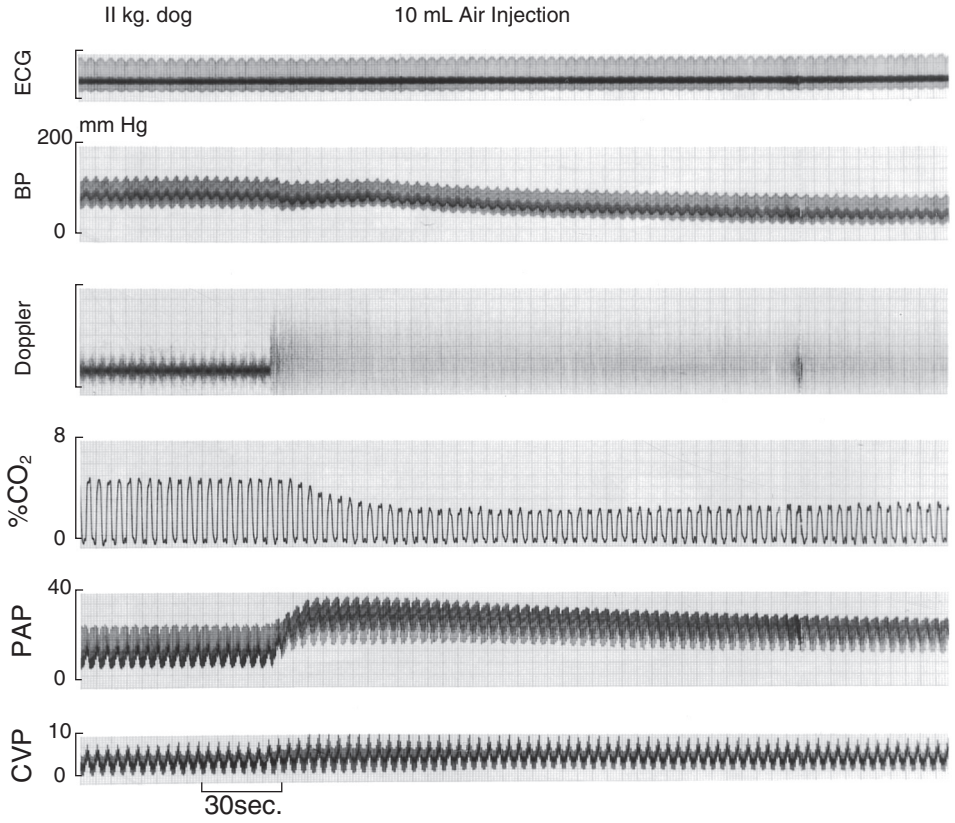

Figure 70-12. The responses of the electrocardiogram (ECG), arterial pressure, pulmonary artery pressure (PAP), pan-tidal CO_2 concentration, a precordial Doppler and central venous pressure (CVP) to the intravenous administration of 10 mL of air over 30 seconds to an 11-kg dog.

for which the right heart catheter is usually omitted. The essentially horizontal semilateral position and the very limited retromastoid craniectomy that is required have resulted (at our institution) in a very low incidence of Doppler-detectable VAE. One should know the local surgical practices, particularly with respect to the degree of head-up posture, before becoming casual about omitting the right atrial catheter. With regard to the Jannetta procedure, the necessary retromastoid craniectomy is performed in the angle between the transverse and sigmoid sinuses, and venous sinusoids and emissary veins in the suboccipital bone are common. If this procedure is performed with any degree of head-up posturing, the risk of VAE may still be substantial.

Which Vein Should Be Used for Right Heart Access?

Although some surgeons may ask that neck veins not be used, a skillfully placed jugular catheter is usually acceptable. In a very limited number of patients, high ICP may make the head-down posture undesirable. In others, unfavorable anatomy with an increased likelihood of a difficult cannulation and hematoma formation may also encourage the use of alternate access sites.

Positioning the Right Heart Catheter

The investigation of Bunegin and colleagues suggested that a multi-orificed catheter should be located with the tip 2 cm below the superior vena caval–atrial junction and a single orificed catheter with the tip 3 cm above the superior vena caval–atrial junction.[104] Although these small distinctions in location may be relevant for optimal recovery of small volumes of air when cardiac output is well maintained, for the recovery of massive volumes of air in the face of cardiovascular collapse, anywhere in the right atrium should suffice. Confirmation of right heart placement can be accomplished by (1) radiography or (2) intravascular electrocardiography (ECG).[105] Although there is no literature to support the practice, with catheter access via the right internal jugular vein, a measured placement to the level of the second or third right intercostal space should suffice when the catheter passes readily. The intravascular electrocardiography technique makes use of the fact that an ECG "electrode" placed in the middle of the right atrium will initially "see" an increasing positivity as the developing P-wave vector approaches it (Fig. 70-13), and then an increasing negativity as the wave of atrial depolarization passes and moves away from it. The resultant biphasic P wave is characteristic of an intraatrial electrode position. The technique requires that the CVP catheter become an exploring ECG electrode. This is accomplished by filling the catheter with an electrolyte solution (bicarbonate is best) and attaching an ECG lead (the leg lead if lead II is selected) to the hub of the CVP catheter. Commercial CVP kits with an ECG adapter are available. The ECG configurations that will be observed at various intravascular locations are shown in Figure 70-13. To minimize the microshock hazard, a battery-operated ECG unit is preferable, and any unnecessary electrical apparatus should be detached from the patient during catheter placement.

Paradoxical Air Embolism

The possibility of the passage of air across the interatrial septum via a patent foramen ovale (PFO), which is known to be present in approximately 25% of adults, is a concern.[106] The risk is major cerebral and coronary morbidity. However, the precise definition of the morbidity that can actually be attributed to PAE is not clear. Although the minimal pressure required to open a probe patent foramen ovale is not known with certainty, the necessary gradient may be as much as 5 mm Hg. In a clinical investigation, Mammoto and colleagues observed that PAE occurred only in the context of major air embolic events, suggesting that significant increases in right heart pressures are an important predisposing factor of the occurrence of PAE.[107] Several clinical investigations have examined factors that influence the right atrial pressure (RAP) to left atrial pressure (LAP) gradient. The use of PEEP increases the incidence of a positive RAP to pulmonary wedge pressure gradient[108] and generous fluid administration (e.g., 2800 mL/patient versus 1220 mL/control patient[109]) reduces it. As a result, the use of positive end-expiratory pressure

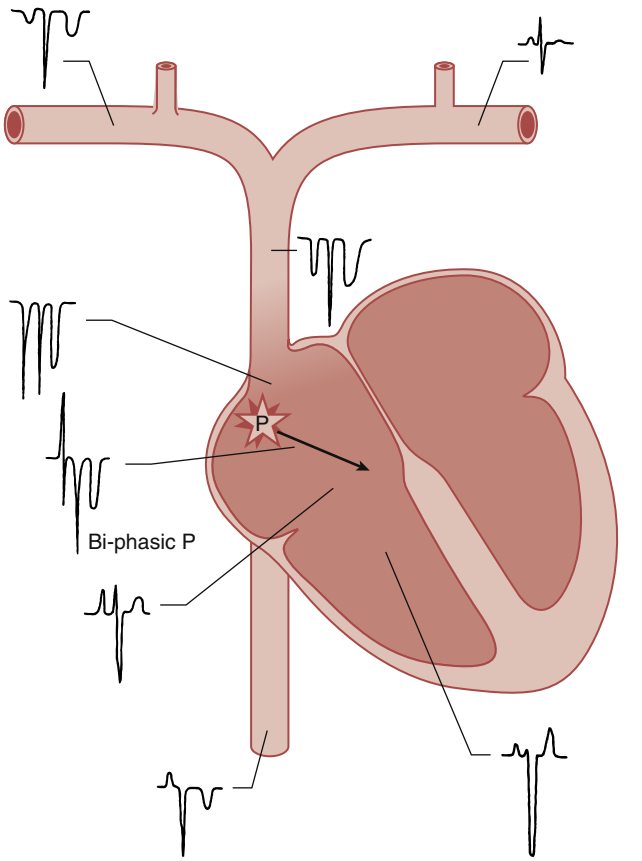

Figure 70-13. Electrocardiogram (ECG) configurations observed at various locations when a central venous catheter is used as an intravascular ECG electrode. The configurations in the figure will be observed when Lead II is monitored and the positive electrode (the leg electrode) is connected to the catheter. *P* indicates the sinoatrial node. The *black arrow* indicates the P-wave vector. Note the equi-biphasic P wave when the catheter tip is in the mid–right atrial position.[105]

(PEEP), which was once advocated as a means of preventing air entrainment, was abandoned. Subsequently, the practice of more generous fluid administration for patients undergoing posterior fossa procedures evolved. However, even when mean LAP exceeds mean RAP, PAE can still occur because transient reversal of the interatrial pressure gradient can occur during each cardiac cycle.[110]

Some centers have advocated performing bubble studies preoperatively with either precordial ECG[96] or transcranial Doppler (TCD)[111] or prepositioning using TEE[112] to identify patients with a PFO with a view to using alternatives to the sitting position in this subpopulation.[95,113] Some centers thereafter advocate the use TEE to identify paradoxical embolization intraoperatively[95,114] (see Chapter 46). However, none of these practices has become a community-wide standard of care.[78] Furthermore, because the morbid events attributable to PAE have been relatively infrequent, surgeons who are convinced that the sitting position is optimal for a given procedure[78] are loath to be dissuaded from using it on the basis of what may seem like the very minor possibility of an injury to the patient occurring by this mechanism.

Transpulmonary Passage of Air

Air can sometimes traverse the pulmonary vascular bed to reach the systemic circulation.[115-117] Transpulmonary passage is more likely to occur when large volumes of air are presented to the pulmonary vascular filter.[118,119] In addition, pulmonary vasodilators, including volatile anesthetics, may decrease the threshold for transpulmonary passage.[118-120] The magnitude of differences among anesthetics does not appear to mandate any related "tailoring" of anesthetic techniques. However, N_2O should be discontinued promptly after even apparently minor VAE events because of the possibility that air may reach the left-sided circulation either via a PFO or the pulmonary vascular bed.

Box 70-6 presents an approach for responding to an acute VAE event. It includes raising venous pressure by direct compression of the jugular veins. PEEP and the Valsalva maneuver were once advocated. However, both PEEP[108] and the release of a Valsalva maneuver increase the risk of PAE, and the relative superiority of jugular venous compression in raising cerebral venous pressures has been confirmed.[121,122] Furthermore, the impairment of systemic venous return caused by the sudden application of substantial PEEP may be undesirable in the face of the cardiovascular dysfunction already caused by the VAE event.

It has been recommended that a patient who has sustained a hemodynamically significant VAE should be placed in a lateral position with the right side up. The rationale is that air will remain in the right atrium, where it will not contribute to an air lock in the right ventricle and where it will remain amenable to recovery via a right atrial catheter. The first difficulty is that this repositioning is all but impossible with a patient in a pin head holder. In addition, the only systematic attempt to examine the efficacy of this maneuver, albeit performed in dogs, failed to identify any hemodynamic benefit.[123]

BOX 70-7 ***Relative Indications for Intraarterial Pressure Monitoring***

- Elevated intracranial pressure
- Ischemia or incipient ischemia of neural tissue
  - Recent subarachnoid hemorrhage
  - Recent head injury
  - Recent spinal cord injury
  - Intended or possible temporary vessel occlusion
- Circulatory instability
  - Trauma
  - Spinal cord injury (spinal shock)
  - Sitting position
  - Possible barbiturate coma
- Possibility of induced hypotension
- Possibility of induced hypertension
- Anticipated or potential major blood loss
  - Aneurysm clipping
  - Arteriovenous malformations
  - Vascular tumors
  - Tumors involving or adjacent to major venous sinuses
  - Craniofacial reconstruction
  - Extensive craniosynostosis procedures
- Anticipated light anesthesia without paralysis
- Brainstem manipulation, compression, dissection
- Anticipated cranial nerve (CN) manipulation (especially CN V)
- Advantageous for postoperative intensive care
  - Hypervolemic therapy
  - Head injury
  - Diabetes insipidus
- Incidental cardiac disease

Nitrous Oxide

Nitrous oxide diffuses into air bubbles trapped in the vascular tree and, accordingly, N_2O should be eliminated after a clinical VAE event to avoid aggravating the cardiovascular impact. As noted earlier, the PAE phenomenon adds an additional reason for eliminating N_2O *after* the occurrence of VAE. When major VAE occurs, no matter how the RAP-LAP gradient was manipulated before the event, RAP increases abruptly with respect to LAP,[124] and major VAE results in an acutely increased risk of PAE in patients with a PFO.[107] Should N_2O be used in patients at risk for VAE? Some clinicians may decide that it is the "path of least resistance" to simply avoid it and to avoid having to worry about the considerations it creates. However, N_2O can be used with the knowledge that it neither increases the incidence of VAE[125] nor aggravates the hemodynamic response to VAE provided that it is eliminated when VAE occurs.[126]

MONITORING

Neurologic monitoring techniques are discussed in Chapter 49. Invasive monitoring is frequently appropriate in neurosurgery. Some of the numerous indications for an arterial catheter are listed in Box 70-7.

Patients with increased ICP may be intolerant of the vascular engorgement associated with sudden hypertension occurring as a consequence of light anesthesia. Surgical relief of increased ICP may be associated with sudden hypotension as brainstem compression is relieved.

Beat-by-beat arterial pressure monitoring also serves as an important depth of anesthesia monitoring and as a neurologic injury early warning system. Much of the brain is insensate. As a consequence, the intracranial portion of many neurosurgical procedures is not very stimulating and, to achieve circulatory stability, relatively light anesthesia is often necessary. There should be constant attention to the possibility of sudden arousal (most often associated with cranial nerve traction or irritation). This is especially important when paralysis is precluded by the use of electromyographic recording from facial muscles to monitor cranial nerve integrity. Blood pressure responses may reveal imminent arousal; they may also serve to warn a surgeon of excessive or unrecognized irritation, traction, or compression of neurologic tissue. These occur most often with posterior fossa procedures involving brainstem or cranial nerves, and abrupt changes should be reported to the surgeon immediately.

The use of right heart catheters for air retrieval is discussed in the section Venous Air Embolism. In the absence of VAE risk and in the presence of good peripheral venous access, we rarely place right heart catheters for neurosurgical procedures. Antecedent cardiac disease may justify a pulmonary arterial catheter. The use of the precordial Doppler is also described in the section Venous Air Embolism.

INTRAVENOUS FLUID MANAGEMENT

The general principles of fluid management for neurosurgical anesthesia are (1) maintain normovolemia and (2) avoid reduction of serum osmolarity. The first principle is a derivative of the concept presented in the section "Management of Arterial Blood Pressure," which is that it is generally ideal to maintain a normal MAP in patients undergoing most neurosurgical procedures and neurosurgical critical care. Maintaining normovolemia is simply one element of maintaining a normal MAP. The second principle is a derivative of the observation that lowering serum osmolarity results in edema of both normal and abnormal brain.[127,128] Administering fluids that provide free water (i.e., fluids that do not have sufficient nonglucose solutes to render them iso-osmolar with respect to blood) lowers serum osmolarity if the amount of free water administered is in excess of that required to maintain ongoing free water loss. Normal saline and lactated Ringer solution are the fluids most often used intraoperatively. At 308 mOsm/L, normal saline is slightly hyperosmolar with respect to plasma (295 mOsm/L). It has the disadvantage that large volumes can cause hyperchloremic metabolic acidosis.[129] The physiologic significance of this acidosis, which involves the extracellular but not the intracellular fluid space, is unclear. At a minimum, it has the potential to confuse the diagnostic picture when acidosis is present. As a result, many clinicians use predominately lactated Ringer solution. Although lactated Ringer solution (273 mOsm/L) is in theory not ideal for replacement of blood and third space loss or insensible losses, it serves as an entirely reasonable compromise for meeting both needs simultaneously and is very suitable in most instances. It is a hypo-osmolar fluid, and in a healthy experimental animal, it is possible to reduce serum osmolarity and produce cerebral edema with a large volume of lactated Ringer solution.[128] In the setting of large-volume fluid administration (e.g., significant blood loss, multiple trauma), it is the authors' practice to alternate, liter by liter, lactated Ringer solution, and normal saline.

The crystalloid versus colloid discussion is a recurrent one. It arises most commonly in the context of the patient with TBI. Although there are numerous fervent beliefs regarding this issue, there has in fact been only a single demonstration that the reduction of colloid oncotic pressure (COP) in the absence of a change of osmolarity can actually contribute to an augmentation of cerebral edema in the setting of experimental head injury.[130] The transcapillary membrane pressure gradients that can be produced by reduction of COP are in fact very small by comparison of those created by changes in serum osmolarity. Nonetheless, it appears that those small gradients, probably in the setting of an experimental BBB injury of intermediate severity, have the potential to augment edema. A fluid administration pattern should be selected that, in addition to maintaining normal serum osmolarity, prevents substantial reductions in COP. For the majority of elective craniotomies, which entail only modest fluid administration, this does not require the administration of colloid solutions. However, in situations requiring substantial volume administration (e.g., multiple trauma, aneurysm rupture, cerebral venous sinus laceration, filling pressure support during barbiturate coma), a combination of isotonic crystalloid and colloid may be appropriate.

Which Colloid Solutions Should Be Used?

Colloid administration has created increasing concern about not only its efficacy but its safety (as discussed in Chapter 61). Based on empirical local experience, we view albumin to be a reasonable choice. However, there are conflicting opinions and cross-currents in the literature (especially noted in Chapter 61). An analysis of the subset of patients in the SAFE (Saline versus Albumin Fluid Evaluation) trial with severe TBI (Glasgow Coma Scale [GCS] score, 3 to 8) revealed increased mortality among those who received albumin.[131] However, there are several reasons to be suspicious of that conclusion. First, SAFE trial patients were not originally randomized on the basis of TBI characteristics and, by chance, there were imbalances in TBI-related characteristics that appear to have placed the albumin group at greater risk.[132] Second, the 4% albumin solution used was hypo-osmolar (274 mOsm/L) and might have been expected to aggravate edema.[133] Furthermore, there is no compelling physiologic explanation for an albumin-specific hazard. The formation of cerebral edema that is more difficult to clear is an inevitable suspicion.[134] However, if valid, that should be a class effect relevant to all colloids (including fresh frozen plasma and starches) rather than being albumin specific. Furthermore, albumin has been used in TBI by others with no evidence of adverse effects.[135,136] In addition, in contrast to alleged adverse effects in the context of TBI are suspected beneficial effects in two other cerebral injury conditions, SAH and stroke, both of which are the subject of ongoing phase III clinical trials.[137,138] At best, the existing literature may justify consideration of limiting albumin volumes in patients

with severe head injury. The indications and concerns for colloids, and especially albumin administration, have been recently expressed (see Chapter 61).

The various starch-containing solutions should be used cautiously in neurosurgery because, in addition to a dilutional reduction of coagulation factors, they interfere directly with both platelets and the factor VIII complex.[139] The coagulation effects are proportional to the average molecular weight and the hydroxyethyl group substitution ratio of the starch preparation (also see Chapters 61 and 62). There have been several reported instances of bleeding in neurosurgical patients that were attributed to hetastarch administration. However, all of those have involved circumstances in which the manufacturer's recommended dosage limit was exceeded[140] or in which the starch was administered up to the recommended limit on successive days, probably resulting in an accumulation effect.[141] The latitudes are wider with the more recently available small molecule/lower substitution ratio preparations. These preparations have a record of safety when used in the operating room in general[142] and have been administered uneventfully to patients with severe TBI.[143] The decision about whether to use these products is frequently a matter of local bias. Although hetastarch solutions can be used in neuroanesthesia, the clinician should respect the manufacturers' recommended dose restrictions and should use additional restraint in situations where there are other reasons for impairment of the coagulation mechanism. Recent concern about adverse effects on renal function in patients who have received starches in critical care situations have made some reluctant to use these compounds in any setting. The dextran-containing solutions are generally avoided because of their effects on platelet function.

There is longstanding interest in the use of hypertonic fluids for the resuscitation of polytrauma victims in general, and of patients with TBI in particular. However, there has yet to be a scientifically convincing demonstration of improvement in outcome in either group in association with hypertonic solutions.[144]

GLUCOSE MANAGEMENT

There is a widespread notion that increased plasma glucose aggravates a cerebral ischemic insult. This may be true for an acute ischemic event in a previously normal brain, but that should not be extrapolated to the idea that all "neuro patients" should be submitted to very tight glycemic control. The potential benefits of a lower plasma glucose concentration in the event of an acute ischemic episode (which have not been well confirmed in humans) should be outweighed by the very clear demonstrations that the injured brain (e.g., TBI, SAH) becomes "hypoglycemic" and suffers metabolic distress at plasma glucose levels that are satisfactory for normal brain.[145-148] This may be because injury can produce a state of hyperglycolysis.[146,149] Although severe hyperglycemia should be treated to reduce infection rates, patients with acute injuries (e.g., TBI, SAH) should not be submitted to very tight control. As one reviewer said, "extra sweetness [is] required"[150] by the injured brain. The authors' intraoperative intervention threshold is 250 mg/dL, the objective being to reduce plasma glucose to less than 200/dL. A recently published guideline recommends an ICU objective of less than 180 mg/dL in patients with cerebral injuries but cautions that plasma glucose not be allowed to decrease to less than 100 mg/dL.[151] The NICE-Sugar study's control group range of 140 to 180 mg/dL[152] is probably also a reasonable target. However, control should only be undertaken when processes to prevent hypoglycemia are firmly in place, and the lower the targets, the more comprehensive the hypoglycemia prevention processes must be (see Chapter 39).

HYPOTHERMIA

The effects of hypothermia on cerebral physiology and its potential cerebral protective mechanisms are presented in Chapter 17. There have been numerous laboratory demonstrations on the efficacy of mild hypothermia (32° C to 34° C) in reducing the neurologic injury occurring after standardized cerebral and spinal cord ischemic insults. On that basis, the use of induced hypothermia in the management of cerebral vascular procedures, in particular aneurysms and sometimes AVMs, became widespread. However, an international multicenter trial of mild hypothermia in 1001 relatively good-grade patients undergoing aneurysm surgery revealed no improvement in neurologic outcome.[153] The routine use of intraoperative hypothermia will probably diminish.

Because ischemia is recognized to make a postinsult contribution to neuronal injury after TBI,[21,154] hypothermia was also studied in laboratory models of TBI.[155] It was effective and resulted in a prospective multicenter trial in which hypothermia (33°C) was induced within 8 hours of injury and was maintained for 48 hours. No outcome benefit was evident.[156] Post hoc subgroup analysis indicated that patients younger than 45 years old who arrived at the tertiary care facility with a temperature less than 35°C who were randomly assigned to the cooling limb of the trial did have an improved outcome. A second trial in which more rapid induction of hypothermia was accomplished (35°C by 2.6 hours, 33°C by 4.4 hours) was undertaken. However, the results were similarly negative.[157]

Based on a lack of demonstrated efficacy in humans, routine use of hypothermia in neurosurgery cannot be advocated in a standard text such as "Anesthesia." The decision to use it, usually in the context of aneurysm surgery, is local. The authors continue to use mild hypothermia selectively, most commonly in patients perceived to be at an especially high risk of intraoperative ischemia. If hypothermia is used, cardiac dysrhythmia and coagulation dysfunction can occur if body temperatures become too low. Patients should be rewarmed adequately before emergence to avoid shivering and hypertension.

By contrast with clinical neurosurgery, the use of hypothermia after cardiac arrest is now practiced widely. Two multicenter trials demonstrated improved neurologic outcome among survivors of witnessed cardiac arrest cooled to 32° C to 34° C within 4 hours and maintained at that temperature for 12 to 24 hours.[158,159] Widespread clinical application has been advocated by an international task force.[160]

Although mild hypothermia is perceived to convey the hazard of coagulation dysfunction and dysrhythmia, neither has been evident in elective neurosurgery in the temperature ranges typically used (32° C to 34° C).

The issue of where body temperature should be recorded to best reflect brain temperature has been addressed.[161] It appears that esophageal, tympanic membrane, pulmonary arterial, and jugular bulb temperature are all very similar and provide a reasonable reflection of deep brain temperature, whereas bladder temperature does not. During craniotomies, superficial layers of cortex may be substantially cooler than deep brain and central temperatures.

EMERGENCE FROM ANESTHESIA

Most practitioners of neuroanesthesia feel that there is a premium on a "smooth" emergence: one free of coughing, straining, and arterial hypertension. The avoidance of arterial hypertension is desired because arterial hypertension can contribute to intracranial bleeding and increased edema formation.[162-167] In the face of a poorly autoregulating cerebral vasculature, hypertension also has the potential, through vascular engorgement, to contribute to an increase in ICP. Much of the concern with coughing and straining has a similar basis. The sudden increases in intrathoracic pressure are transmitted to both arteries and veins, producing transient increases in both cerebral arterial and venous pressure, with the same potential consequences: edema formation, bleeding, and elevation of ICP. Coughing is a specific concern with certain individual procedures. In the circumstances of transsphenoidal pituitary surgery in which a surgeon has opened, and subsequently taken pains to close, the arachnoid membrane to prevent CSF leakage, there is a belief that coughing has the potential to disrupt this closure because of the sudden and substantial increases in CSF pressure. Opening a pathway from the intracranial space to the nasal cavity conveys a substantial risk of postoperative meningitis. In other procedures, notably those that have violated the floor of the anterior fossa, air can be driven into the cranium and, in the event of a flap-valve mechanism, cause a tension pneumocephalus. This latter event can only happen when coughing occurs after the endotracheal tube has been removed.

There is a paucity of systematically obtained clinical data to give a perspective to the actual magnitude of the risks associated with emergences that are not considered smooth. Two retrospective studies have revealed that increased postoperative arterial blood pressure was associated with intracerebral bleeding after craniotomy.[166,167] However, whether hypertension occurring at emergence causes postoperative intracerebral bleeding is not clear. Also, the relationship between hypertensive transients at emergence and edema formation is unconfirmed. In anesthetized animals, sudden and very substantial increases in arterial pressure can result in a breach of the BBB with extravasation of tracers.[163] However, there are no data to confirm that the pressure transients associated with the typical coughing episode or typical emergence hypertensive transient are in fact associated with increased edema formation. Nonetheless, it seems reasonable to take measures, to the extent that these measures do not themselves add potential patient morbidity, to prevent these occurrences.

A common method for the management of systemic hypertension during the last stages of a craniotomy is the expectant and/or reactive administration of lidocaine and vasoactive agents, most commonly labetalol and esmolol.[168] Other drugs, including hydralazine, enalapril, and diltiazem, have been used to good effect. Administration of dexmedetomidine during the procedure also reduces the hypertensive response to emergence[169] and hypertension in the postanesthesia care unit.[170]

There are also many approaches to the prevention of coughing and straining. The authors have several biases. We encourage trainees to include in their anesthetic technique "as much narcotic as is consistent with spontaneous ventilation at the conclusion of the procedure." That practice is based on the same physiologic effect that justifies the administration of codeine and related compounds as antitussive medication (i.e., the depression of airway reflexes by narcotics). We also have the bias that patients emerge more rapidly and smoothly when the last inhaled anesthetic to be withdrawn is nitrous oxide and that clinicians should seek to avoid the "neither here nor there" phase of anesthesia that occurs in patients who are stimulated in the face of residual exhaled concentrations of volatile anesthetic on the order of 0.2 to 0.3 MAC. A common practice among neuroanesthetists near the conclusion of a craniotomy is the relatively early discontinuation of the volatile anesthetic with supplementation, if necessary, of residual nitrous oxide with propofol by either bolus increments or infusion at rates in the range of 12.5 to 25 μg/kg/hr.

An additional principle relevant to the emergence from neurosurgical procedures is that emergence should be timed to coincide not with the final suture but rather with the conclusion of the application of the head dressing. Many a good anesthetic for neurosurgery has been spoiled by severe coughing and straining that occurs in association with endotracheal tube motion during the application of the head dressing. Another nuance of our practice has been to withhold administration of neuromuscular antagonists, such as neostigmine, as long as possible as a "hedge" against misjudgment while lightening a patient in the later stages of the procedure. The administration of lidocaine is another apparently effective technique for reducing airway responsiveness and the likelihood of coughing/straining as the depth of anesthesia is reduced in anticipation of emergence. We commonly administer 1.5 mg/kg of intravenous lidocaine just before the head movement associated with applying the dressing.

Because of the premium placed on minimizing coughing and straining and hypertension, there may be a temptation to extubate from the trachea before complete recovery of consciousness. This may be acceptable in some circumstances. However, it should be undertaken with caution when the circumstances of the surgical procedure make it possible that neurologic events have occurred that will delay recovery of consciousness, or when there may be less cranial nerve dysfunction. In these circumstances, it would, in general, be best to wait until the likelihood of the patient's recovery of consciousness is confirmed or until patient cooperation and airway reflexes are likely to have recovered.

SPECIFIC PROCEDURES

Many of the considerations relevant to individual neurosurgical procedures are generic ones that have already been presented in the preceding section on Recurrent Issues. The descriptions that follow will highlight only procedure-specific issues (Box 70-8).

SUPRATENTORIAL TUMORS

Craniotomies for excision or biopsy, or both, of supratentorial tumors are among the most common neurosurgical procedures. Gliomas and meningiomas are among the most frequent tumors. The relevant preoperative considerations include the patient's ICP status and the location and size of the tumor. Location and size of the tumor give the anesthesiologist an indication of the surgical position, the potential for blood loss, and will sometimes reveal a risk of air embolism. The VAE risk is infrequent for the majority of supratentorial tumors. However, lesions (usually convexity meningiomas) that encroach upon the sagittal sinus may convey a substantial risk of VAE. Full VAE precautions, including a right atrial catheter, are usually reserved for only the supratentorial tumors that lie near the posterior half of the superior sagittal sinus.

Excision of craniopharyngiomas and pituitary tumors with suprasellar extension may entail dissection in and around the hypothalamus (see Fig. 70-17). Irritation of the hypothalamus can elicit sympathetic responses including hypertension. Damage to the hypothalamus can result in a spectrum of physiologic disturbances, notably water balance. Diabetes insipidus is the most likely, although the cerebral salt-wasting syndrome can potentially occur. The latter has been very infrequent. The various disturbances of water balance typically have a delayed onset, beginning 12 to 24 hours postoperatively, rather than in the operating room. Postoperative temperature homeostasis may also be disturbed.

Patients who undergo a craniotomy involving a subfrontal approach sometimes manifest a disturbance of consciousness in the immediate postoperative period. Retraction and irritation of the inferior surfaces of the frontal lobes can result in a patient who is lethargic and does not awaken "cleanly" and may exhibit either delayed emergence or some degree of disinhibition, or both. Patients exhibiting this phenomenon are sometimes referred to as "frontal lobey." The phenomenon is more likely to be evident when there has been bilateral subfrontal retraction than when it occurs only unilaterally. The anesthetic implication is that the clinician should be more inclined to confirm return of consciousness before extubating the patient rather than to extubate expectantly. A further implication taken by these authors (though not confirmed by any systematic study) is that a less liberal use of fixed anesthetics (narcotics, propofol infusions) may be appropriate when there is to be bilateral subfrontal retraction. This is based on the rationale that low residual concentrations of these anesthetics that are compatible with reasonable recovery of consciousness in the majority of patients may be less well tolerated in this population. Subfrontal approaches are most commonly used in patients with olfactory groove meningiomas and patients with suprasellar tumors including craniopharyngiomas and pituitary tumors with suprasellar extension.

BOX 70-8 *Specific Procedures*

- Supratentorial tumors
- Aneurysms and arteriovenous malformations
- Traumatic brain injury
- Posterior fossa procedures
- Transsphenoidal surgery
- Awake craniotomy/seizure surgery
- Stereotactic procedures
- Neuroendoscopic procedures
- Neuroradiologic procedures
- Cerebrospinal fluid shunting procedures
- Pediatric neurosurgery
- Spinal surgery

Preoperative Preparation

Patients with a significant tumor-related mass effect, especially if there is tumor-related edema, should receive preoperative steroids. If the patient is not receiving steroids, it is the anesthesiologist's responsibility to find out why. A 48-hour course is ideal (see the previous discussion of steroids), although 24 hours is sufficient for a clinical effect to be evident. Dexamethasone is the most commonly used agent. A regimen such as 10 mg intravenously or orally followed by 10 mg every 6 hours is typical. Because of the concern about producing CO_2 retention in a patient whose intracranial compliance is already abnormal, patients with any substantial mass effect are usually not premedicated outside of the operating room with anything beyond full-dose reassurance (see Chapter 38).

Monitoring

Institutional practices vary; however, we almost invariably place arterial catheters for craniotomies under general anesthesia. Preinduction placement may be appropriate in patients with severe mass effect and little residual compensatory latitude. At a minimum, we achieve intraarterial monitoring before pin placement. It is the period of induction and pinning during which hypertension, with its attendant risks in a patient with impaired compliance and autoregulation, is most likely to occur. Arterial lines also facilitate careful management of blood pressure during emergence. Procedures with a substantial blood loss potential (e.g., tumors encroaching on the sagittal sinus, large vascular tumors) may also justify central venous catheters when peripheral venous access is limited. If not already present for other indications, is ICP monitoring ever warranted for intraoperative management? In our opinion, the answer is no. We have sufficient understanding of the potential impact of anesthetics and techniques that we should be able to manage induction of anesthesia blindly. Once the cranium is open, observation of conditions in the surgical field provides equivalent information (see also Chapter 49.)

Management of Anesthesia

The principles governing the choice of anesthetic drugs are presented in the previous section Control of Intracranial Pressure and Brain Relaxation.

ANEURYSMS AND ARTERIOVENOUS MALFORMATIONS

Contemporary management of intracranial aneurysms calls for early intervention after SAH, ideally within 24 hours and certainly within 48 hours.[171] That intervention may entail either operative clipping or an endovascular approach.[171] The latter is discussed in the subsequent section Interventional Neuroradiology (see Chapter 90).

Early intervention was originally undertaken only in patients in the better neurologic grades—that is, grades I-III and perhaps IV of the World Federation of Neurosurgeons classification (Table 70-2) or grades I-III of the Hunt-Hess classification (Table 70-3)—but is now recommended for the majority of patients.[171] If early intervention is not feasible and a surgical approach is intended, surgery is usually delayed for 10 to 14 days to be safely beyond the period of maximal vasospasm risk (i.e., days 4 to 10 post-SAH).

The rationale for early intervention is several-fold. The sooner the aneurysm is clipped or obliterated, the less the likelihood of rebleeding (and rebleeding is the principal cause of death for patients hospitalized after SAH[172]). Second, the management of the ischemia caused by vasospasm involves volume loading and induced hypertension. Early occlusion of the aneurysm eliminates the risk of rebleeding associated with this therapy. Prior surgical practices entailed maintaining the patient on bed rest until approximately day 14 when the period of spasm risk had passed. Early aneurysm clipping reduces the period of hospitalization and reduces the incidence of the medical complications (i.e., deep vein thrombosis, atelectasis, pneumonia) associated with a lengthy period of enforced bed rest.

Early intervention makes the surgeon's task more difficult. The brain in the early post-SAH period is likely to be more edematous than after a 2-week delay. Furthermore, some degree of hydrocephalus is very common after blood contaminates the subarachnoid space. In fact, 10% or more of SAH victims eventually require permanent CSF diversion.[171] Early intervention may also somewhat enhance the risk of intraoperative aneurysmal rupture because of the lesser period of time for a clot to organize over the site of the initial bleed. All of this places a substantial premium on techniques designed to reduce the volume of the intracranial contents (see Control of Intracranial Pressure and Brain Relaxation earlier in this chapter) to facilitate exposure and minimize retraction pressures.

TABLE 70-2 WORLD FEDERATION OF NEUROSURGEONS SUBARACHNOID HEMORRHAGE SCALE

WFNS Grade	GCS Score	Motor Deficit
I	15	Absent
II	14-13	Absent
III	14-13	Present
IV	12-7	Present or absent
V	6-3	Present or absent

WFNS, World Federation of Neurosurgeons; *GCS*, Glasgow Coma Scale.

TABLE 70-3 HUNT-HESS CLASSIFICATION OF NEUROLOGIC STATUS AFTER SUBARACHNOID HEMORRHAGE

Category	Criteria*
Grade I	Asymptomatic, or minimal headache and slight nuchal rigidity
Grade II	Moderate to severe headache, nuchal rigidity, no deficit other than cranial nerve palsy
Grade III	Drowsiness, confusion, or mild focal deficit
Grade IV	Stupor, moderate to severe hemiparesis, possibly early decerebrate rigidity and vegetative disturbances
Grade V	Deep coma, decerebrate rigidity, moribund appearance

* Serious systemic disease, such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography, results in placement of the patient in the next less favorable category.

Preoperative Evaluation

Many patients scheduled for intracranial aneurysm clipping will come directly from the ICU, and elements of their management while there may influence their immediate preoperative status.

Intravenous Fluid Management. Some patients develop the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) after SAH and are appropriately managed with fluid restriction. However, hyponatremia after SAH is likely to be the result of the cerebral salt-wasting syndrome that probably occurs as a result of the release of a natriuretic peptide by the brain.[173,174] Cerebral salt-wasting syndrome is characterized by the triad of hyponatremia, volume contraction, and high urine sodium concentrations (>50 mmol/L), and its occurrence is correlated with the occurrence of symptomatic vasospasm.[175] The distinction between cerebral salt-wasting syndrome and SIADH is important. SIADH, which is characterized by normovolemia or mild hypervolemia, is treated by volume restriction. Cerebral salt-wasting syndrome is associated with a contracted intravascular volume. Fluid restriction and further volume contraction may be especially deleterious in the post-SAH patient and should be avoided.[176-178] Although the clinical distinction between these two causes of hyponatremia (SIADH and cerebral salt-wasting syndrome) may be difficult, management of both is relatively simple: administration of isotonic fluids using intravascular normovolemia as the end point (see also Chapter 59).

Vasospasm. The anesthesiologist should determine whether vasospasm has occurred and what, if any, therapies for it have been undertaken. Vasospasm is thought to be caused by the breakdown products of the hemoglobin that has accumulated around the vessels of the circle of Willis after SAH. A specific mechanism/mediator has

not been identified. Calcium channels are thought to be involved, and there is also suspicion that the nitric oxide and endothelin systems may be contributory.[178,179]

When there is a clinical suspicion of vasospasm (typically because of a change in sensorium or new neurologic deficit), surgery is usually deferred and TCD, angiography, or other imaging is performed. Confirmed vasospasm is commonly treated with the "Triple H" therapy described subsequently and sometimes by balloon angioplasty or intraarterial vasodilators.[180]

For patients proceeding to surgery, hypotension should be avoided[171] and CPP should usually be maintained intraoperatively at values near the waking normal range. The association of hypotension with poor outcome,[181] and the potential for hypotension to cause or aggravate cerebral ischemia in the patient with some degree of vasospasm is now recognized.[182-184] This concern should extend even to patients classified as World Federation of Neurosurgeons grade I who may have regions of cerebral ischemia[39] that are subclinical when the patient is normotensive.

In the ICU (see also Chapter 105), the regimens used to treat vasospasm usually involve some combination of hypervolemia, hemodilution, and hypertension. The science behind hypervolemic-hypertensive therapy is soft and the efficacy of neither Triple H therapy nor volume expansion in isolation has been proved by prospective study.[185-187] The relative importance of the rheologic and blood pressure effects is undefined, although there is evidence for the relevance of blood pressure elevation in isolation.[187-190] Phenylephrine and dopamine are the most commonly used pressors; exact pressor choice should be primarily governed by systemic cardiovascular considerations. The end point for pressor administration varies. Most commonly, the objective is an increase in MAP of approximately 20 to 30 mm Hg above baseline systolic pressure. However, it has been reported that augmentation of cardiac output with dobutamine, without simultaneous MAP increase, augments CBF in vasospastic territories.[187] It is also believed that the hematocrit should be reduced to the low 30s, but this should not be a primary clinical objective. Commonly, hematocrit reduction occurs secondarily as a result of attempts to produce hypervolemia as a part of the effort to increase blood pressure.

Calcium-Channel Blockers. Calcium-channel blockers are an established part of the management of SAH. Administration of nimodipine decreases the incidence of morbidity caused by cerebral ischemia after SAH,[191] although it was not associated with any reduction in the incidence of vasospasm as detected by angiography.[192] Patients presenting to the operating room after SAH should already be receiving nimodipine. Because nimodipine must be administered orally in North America, nicardipine has been evaluated as an intravenous alternative. The multicenter nicardipine trial[193,194] revealed a reduced incidence of symptomatic vasospasm but no improvement in outcome. As a consequence, nimodipine remains the standard. Calcium-channel blockers (i.e., verapamil, nicardipine, nimodipine[195-198]) are also used intraarterially as a primary treatment for medically-refractory vasospasm. Milrinone and papaverine are similarly administered. [197,199]

Other Pharmacologic Therapies. Several other agents/drug classes have been considered for the prevention of vasospasm and delayed ischemic deficits. None of them is approaching the status of standard therapy. A recent study of the endothelin antagonist clazosentan revealed improved mortality without improvement in the outcome of survivors. After several small trials suggested a beneficial effect of magnesium, a recent larger randomized, placebo-controlled trial reported no improvement in outcome among patients in whom magnesium was initiated within 4 days of SAH.[200] Several small trials have examined the post-SAH administration of statins. Meta-analysis revealed only nonsignificant trends toward reduced incidence of delayed cerebral ischemia and death.[201] Although some centers have already implemented statin therapy as part of the local routine, widespread adoption will probably have to await the completion of larger trials. Recently (January 2013), the phosphodiesterase inhibitor cilostazol, administered orally post clipping, was reported to reduce vasospasm and delayed cerebral infarctions substantially.[202] That trial was nonblinded, and cilostazol is a platelet inhibitor as well as a vasodilator. Although the results were promising, verification of both safety and efficacy will probably be required before wide application.

Antifibrinolytics. Antifibrinolytics have been administered in an attempt to reduce the incidence of rebleeding. Although they accomplish this end, long courses do so at the cost of an increased incidence of ischemic symptoms and hydrocephalus, with an overall adverse effect on outcome. However, early, brief courses of antifibrinolytics continued until the aneurysm is secured may have a net favorable effect on outcome.[171]

Subarachnoid Hemorrhage–Associated Myocardial Dysfunction. SAH can result in a largely reversible, "stunning"-like myocardial injury. The severity of the dysfunction correlates best with the severity of the neurologic injury[203] and is sometimes sufficient to require pressor support.[204] The mechanism is uncertain but is thought to be catecholamine mediated.[205] Troponin elevation occurs commonly, though typically reaching levels less than the diagnostic threshold for myocardial infarction.[206] Peak troponin levels correlate with the severity of both neurologic injury and echocardiographic myocardial dysfunction.[204,207]

ECG abnormalities are common after SAH[200] (see also Chapter 47). In addition to the classic canyon T waves (Fig. 70-14), nonspecific T-wave changes, Q-T prolongation, ST-segment depression, and U waves have been described. There is typically no relationship between the ECG changes and echocardiographic myocardial dysfunction.[206] ECG abnormalities do not herald evolving or impending cardiac disease.[208] Accordingly, when ventricular function is adequate and ECG patterns other than those that are typical of myocardial ischemia are observed, no specific interventions or modifications of patient management are warranted, other than attention to the possibility of dysrhythmias. In particular, an increased Q-T interval (>550 msec) occurs frequently after SAH, especially in patients with more severe SAH,[207]

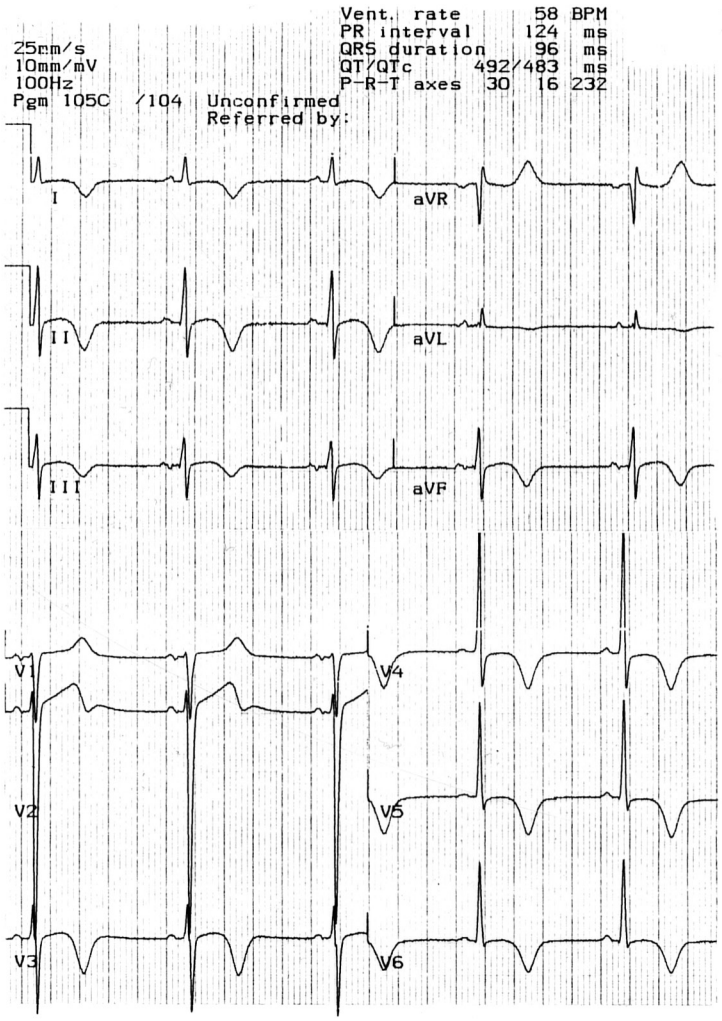

Figure 70-14. Electrocardiogram abnormalities associated with subarachnoid hemorrhage. The canyon T waves that may be seen after subarachnoid hemorrhage are evident.

and has been associated with an increased incidence of malignant ventricular rhythms including torsades de pointes.[209]

Anesthetic Technique

Important considerations include the following:

1. Absolute avoidance of acute hypertension with its attendant risk of rerupture.
2. Achievement of intraoperative brain relaxation to facilitate surgical access to the aneurysm.
3. Maintenance of a high-normal MAP to prevent critical reduction of CBF in recently insulted and now marginally perfused areas of brain, or in regions critically dependent on collateral pathways.
4. Preparedness to perform precise manipulations of MAP as the surgeon attempts to clip the aneurysm or to control bleeding from a ruptured aneurysm or during periods of temporary vascular occlusion.

Monitoring

An arterial line is invariably appropriate. A central venous catheter may be appropriate if peripheral access is inadequate (see also Chapter 49).

Anesthetic Selection. Any technique that permits proper control of MAP is acceptable. However, in the face of increased ICP or a tight surgical field, an inhaled anesthetic technique may be less suitable. The prevention of paroxysmal hypertension is the only absolute requirement in patients undergoing aneurysm clipping. Rebleeding kills[172] and the poorly organized clot over the aneurysms of patients undergoing early post-SAH clipping makes them particularly prone to rebleeding. A rebleed at induction is frequently fatal. The escaping arterial blood is more likely to penetrate brain substance because it cannot dissect through the CSF space (filled with clot), and the ICP increase is extreme because of the poor compliance of the intracranial space (swollen brain, hydrocephalus).

Induced Hypotension. The routine use of induced hypotension has essentially vanished (see previous section Management of Arterial Blood Pressure). Nonetheless, the anesthesiologist should be prepared to reduce blood pressure immediately and precisely if called upon to do so. Preparation must occur before the episode of bleeding. We prepare a sodium nitroprusside infusion before induction. It is placed in line at a Y-injection port at the hub of an intravenous catheter. A carrier drip flows steadily such

that any change in nitroprusside infusion rate is reflected as rapidly as possible in the central compartment. There are theoretical pros and cons for various hypotensive agents. However, the choice should ultimately be made on the basis of which regimen, in the hands of the individual practitioner, results in the most precise control of MAP. There are rare occasions when the anesthesiologist is asked to control MAP in the range of 40 to 50 mm Hg, in the face of active arterial bleeding. This can be extremely difficult in a patient who is hypovolemic at the beginning of the bleeding episode. It is our practice to maintain normovolemia.

Induced Hypertension. Relative hypertension may be requested during periods of temporary arterial occlusion (see the later section Temporary Clipping) to augment collateral CBF. In addition, after clipping of the aneurysm, some surgeons will puncture the dome of the aneurysm to confirm adequate clip placement and may request transient elevation of the systolic pressure to 150 mm Hg. Phenylephrine is suitable in either instance.

Hypocapnia. Hypocapnia has traditionally been used as an adjunct to brain relaxation. However, the practice has been questioned on the basis of the concern that it will aggravate ischemia (see the earlier section Management of $Paco_2$). It is now generally avoided unless ICP/brain relaxation circumstances demand it.

Lumbar Cerebrospinal Fluid Drainage. Cerebrospinal fluid drainage has been used to facilitate exposure. However, its use appears to be diminishing because surgeons have appreciated that the same brain relaxing effect can be achieved by release of CSF from the basal cisterns. If a lumbar CSF drain is placed, it is appropriate to avoid excessive loss of CSF. A sudden reduction in the transmural pressure gradient across the dome of the aneurysm (by sudden reduction of ICP consequent upon substantial CSF drainage) should be avoided because of the theoretical concern that this decompression might encourage rebleeding. Having verified the patency of the drainage system, it is usual to leave it closed until the surgeon is opening the dura. The drain is then opened and allowed to drain freely to floor level. Drainage should be discontinued promptly after final withdrawal of the retractors to allow CSF to reaccumulate and to thereby reduce the size of the potential pneumocephalus. The drain is usually removed immediately postoperatively.

Mannitol. Some surgeons use mannitol relatively aggressively (e.g., 2 g/kg). In part, it is used to facilitate exposure and reduce retractor pressures, but there is evidence that it may have additional benefits. Specifically, there are data derived in both animals and man that indicate that mannitol may have a CBF-enhancing effect in regions of moderate CBF reduction.[210-213] The mechanism is not defined. Reduction of interstitial tissue pressure around capillaries and/or an alteration of blood rheology have been proposed as contributors. Typically, mannitol is administered in a dose of 1 g/kg just before dural opening. Surgeons who believe in its CBF-enhancing effect may request a second 1 g/kg approximately 15 minutes before an anticipated temporary occlusion.

Temporary Clipping. Many surgeons limit inflow to an aneurysm during application of the permanent clip by placing a temporary clip proximally on the feeding vessel. It is occasionally necessary to trap the aneurysm (i.e., to temporarily occlude the vessel on both sides of the aneurysm) to complete the dissection of the neck and apply the clip. This is more common with larger aneurysms. With giant aneurysms in the vicinity of the carotid siphon, the inferior occlusion may be performed at the level of the internal carotid artery via a separate incision in the neck. A clinical survey by Samson and colleagues of the neurologic outcome after temporary occlusion in normothermic, normotensive adults revealed that occlusions of fewer than 14 minutes were invariably tolerated. The likelihood of an ischemic injury increased with longer occlusions and reached 100% with occlusions in excess of 31 minutes.[214] In another institution, the threshold for ischemic injury was 20 minutes of occlusion.[215] An informal 7-minute rule is sometimes applied to individual periods of temporary occlusion. Typically, MAP should be sustained at high-normal levels during periods of occlusion to facilitate collateral CBF.

Brain Protection. We do not select anesthetic drugs on the basis of putative brain-protective effects. Maintenance of MAP to ensure collateral flow and perfusion under retractors, efficient brain relaxation to facilitate surgical access and reduce retractor pressures, limitation of the duration of episodes of temporary occlusion, and perhaps mild hypothermia are the important brain protection techniques. Specific anesthetic drugs have been promoted as brain protectants (see the discussion in Chapter 17). Propofol and etomidate are au courant. However, there have been no convincing laboratory demonstrations that propofol provides any greater tolerance to a standardized ischemic insult than does anesthesia with a volatile anesthetic. Attempts to demonstrate protection by etomidate in an animal model of focal ischemia actually demonstrated an adverse effect of etomidate.[216] Furthermore, a clinical investigation during aneurysm clipping revealed decreases in brain tissue PO_2 in association with administration of etomidate, which contrasted with the brain PO_2 increases that occurred with the introduction of desflurane. During subsequent temporary vessel occlusion, tissue pH decreased alarmingly in patients receiving etomidate and was unchanged with desflurane.[217] Etomidate probably should not be used because of a lack of sufficient data regarding its efficacy. With respect to the volatile anesthetics, attempts in the laboratory to confirm the once proclaimed protective efficacy of isoflurane have demonstrated that there are no differences among the various volatile anesthetics in terms of their influence on outcome after focal or global ischemia in the laboratory.[216,218-220] Nor has there been any demonstration of greater protective efficacy with concentrations of volatile anesthetics sufficient to cause EEG suppression as opposed to more modest (e.g., 1.0 MAC) levels.[220,221] Nonetheless, these animal investigations suggest that a standardized experimental ischemic insult is better

tolerated, relative to the awake state, by animals receiving a volatile anesthetic.[219,220,222] In addition, data derived in animals also suggest that there may also be a relative protective advantage to an anesthetic that includes a volatile anesthetic compared with a strict N_2O-narcotic technique.[220,222] The magnitude of the differences among anesthetics and the absence of proof of relevance in patients precludes advocacy of a particular anesthetic regimen in a standard text. The important anesthetic objectives are precise hemodynamic control and timely wake-up, and those two constraints should dictate the choice of the anesthetic regimen for the majority of aneurysm procedures. Among anesthetics, it is only the barbiturates for which additional protective efficacy has been demonstrated convincingly (see Chapter 17). Because of their potentially adverse effects on hemodynamics and wake-up, they are not ideal for routine use. They should probably be reserved for situations in which a prolonged vessel occlusion is unavoidable, and in that circumstance, it would be ideal that the ischemic hazard be first confirmed by observation of the EEG response to a temporary occlusion.[223]

The patient with or at substantial risk for vasospasm probably benefits from a minimum hemoglobin greater than that which is commonly accepted in stable ICU patients (i.e., >7 g/dL). The best available information suggests a minimal hemoglobin value of 9 g/dL.[190,224]

Hypothermia. As noted in the section Hypothermia, a prospective trial of mild hypothermia in patients undergoing aneurysm surgery revealed no improvement in neurologic outcome.[153] Nonetheless, some neurosurgical teams that were already using mild hypothermia (32° C to 34° C) are continuing its use for procedures in which temporary vessel occlusion may occur. The institutions that use the lower temperatures are those in which the team is willing to accept a delay in emergence from anesthesia to achieve sufficient rewarming to avoid the extreme hypertension that can occur when a patient is awakened at low body temperatures.

Neurophysiologic Monitoring. Evoked responses and EEG have been used for monitoring,[223,225] although neither technique has been used widely. EEG monitoring can be used as a guide to management during the period of flow interruption or to guide the administration of CMR-reducing anesthetic agents given before occlusion.[223] At some institutions, the surgeon places an electrode strip over the region of cortex at risk during the intended occlusion. However, the more commonly used skin surface frontal-mastoid derivation is probably sufficient to reveal a major ischemic event. In most circumstances, if occlusion is deemed necessary, a temporary occlusion is performed and the EEG is observed. If the EEG shows significant slowing, the common practice is to release the clip, raise the MAP, and proceed with as brief as possible a period of occlusion or intermittent episodes of temporary occlusion. If the necessity for a sustained period of occlusion seems likely, it may be appropriate to administer barbiturates (discussed earlier) to produce burst suppression. These events are very infrequent (see also Chapter 49).

Intraoperative Angiography. Intraoperative angiography is an increasingly common component of the management of intracranial aneurysms. It does not have substantial implications for the anesthesiologist. However, any apparatus around the patient's head must be organized to allow C-arm access without snagging airway and monitoring equipment.

Special Considerations for Specific Aneurysms

The most common procedures are performed for aneurysms arising in or close to the circle of Willis. The vessels of origin may be the anterior communicating artery; the middle cerebral artery; the anterior cerebral artery; the ophthalmic artery; the tip of the basilar artery; the posterior communicating artery; and, less frequently, the posterior cerebral artery. These procedures are relatively similar for the anesthesiologist and typically require a supine position with the head turned slightly away from the operative side.

Ophthalmic Artery Aneurysms. Access to the origin of the ophthalmic artery, which is the first intradural branch of the carotid artery, is made difficult by the anterior clinoid process and the optic nerve. As a result, these aneurysms frequently require temporary vascular occlusion**.** The surgeon commonly first exposes the carotid artery in the neck. When the surgeon reaches the stage of seeking definitive access to the neck of the aneurysm, he or she will occlude first the carotid artery in the neck and then the intracranial portion of the carotid artery immediately proximal to the origin of the posterior communicating artery. A catheter is placed in the excluded segment and put to suction. Blood loss, which is usually minimal, should be monitored.

Vertebrobasilar Aneurysms. These procedures are typically performed in the lateral position. The exposure may involve a combined middle and posterior fossa approach, with some attendant, although minor, risk of venous air embolism. Cortical or skin surface EEG monitoring is of less relevance with vertebral-basilar aneurysms. Auditory and or somatosensory evoked responses have been used.[226] As with any other procedure involving the potential for mechanical or vascular injury to the brainstem, cardiovascular responses should be monitored and sudden changes in response to surgical manipulation should prompt immediate notification to the surgeon. Spontaneous ventilation may be appropriate for procedures involving surgical manipulation of the vertebral arteries, the vertebrobasilar junction, and the middle portion of the basilar artery. Apnea, gasping, or other sudden changes in ventilatory pattern during manipulation of the vasculature provide important, though somewhat nonspecific, warning of compromise of the vascular supply of the brainstem.[227] Now largely supplanted by endovascular approaches, management of these aneurysms sometimes requires cardiopulmonary bypass and deep hypothermic circulatory arrest.[228]

Vein of Galen Aneurysms. These "aneurysms" are congenital dural arteriovenous fistulas, usually treated in the neonate using endovascular methods, and share considerations relevant to AVMs. These include anticipation of

the possibility of the cerebral dysautoregulation phenomenon and are considered subsequently.

Arteriovenous Malformations

For the majority of intracranial AVMs, the general considerations are similar to those appropriate to aneurysm surgery: avoidance of acute hypertension and the capability to accurately manipulate arterial blood pressure in the event of bleeding. A problem specific to AVMs is the phenomenon of perfusion pressure breakthrough, or cerebral dysautoregulation.[229,230] It is characterized by an often sudden engorgement and swelling of the brain, sometimes with a relentless cauliflowerlike protrusion from the cranium. It tends to occur in the advanced stages of lengthy procedures on large AVMs, or it may be the cause of otherwise unexplained postoperative swelling and hemorrhage. The phenomenon is not entirely understood. An AVM provides a high-volume, low-resistance pathway that chronically diverts blood from adjacent and therefore marginally perfused vascular territories. Perhaps these tissues have long been maximally vasodilated and are incapable of vasoconstricting when exposed to a higher-pressure head after acute obliteration of the AVM. Although this explanation superficially fits the clinical occurrence, experimental data are not entirely consistent with this mechanism.[229-232] At least some component of the hyperemia is not passive, and neurogenic or paracrine mechanisms may be involved.

Anesthetic Technique. The management constraints are essentially the same as those relevant to aneurysm surgery, although the risk of intraoperative rupture is much less. Institutional practices will vary. We do not use induced hypotension unless it is necessitated by bleeding. We reason that the effects on the surrounding brain of devascularizing the AVM would be best appreciated if the devascularization occurs at normal pressures. If refractory brain swelling occurs, tight blood pressure control is essential, and reducing MAP may be of use to control swelling. The latter is based on the notion that CBF through the involved area is pressure-passive and will decrease as MAP is reduced. With severe episodes of swelling, we have used (in addition to hypotension, which we use cautiously because of the associated ischemia risk) hypocapnia, hypothermia, and barbiturates. The latter three techniques probably serve to reduce the bulk of only normal brain tissue, hypocapnia via a direct effect on CBF and barbiturates and hypothermia via the coupled effects of reduction of CMR on CBF. Induced hypothermia is also an adjunct to minimizing the barbiturate doses. In all of neurosurgery, we seek to prevent postoperative hypertension; however, in AVM surgery this should be accomplished with the greatest care because of the concern that the dysautoregulating brain adjacent to the resected AVM will develop edema or hemorrhage if hypertension occurs.

HEAD INJURY

Intubating the Trachea of a Head-Injured Patient

The anesthesiologist's first interface with the patient who has sustained a TBI may come as a result of a request for assistance with airway management. Patients with GCS scores of 7 to 8 (Table 70-4) or less require intubation and controlled ventilation for ICP or airway control, or both. Patients with less severe TBI may also require intubation because of trauma-related cardiopulmonary dysfunction or, when uncooperative, to facilitate diagnostic procedures. The anesthesiologist, in choosing the intubation technique, may encounter a number of conflicting constraints (Box 70-9). These include: (1) elevated ICP; (2) a full stomach; (3) uncertain cervical spine status; (4) uncertain airway status (e.g., presence of blood, possible laryngeal-tracheal injury, possible skull base fracture); (5) an uncertain volume status; (6) an uncooperative or combative patient; and (7) hypoxemia. There is no correct technique, and the best approach is determined by the relative weight of these various factors along with the degree of urgency. The anesthesiologist must not be distracted by placing an excessive initial emphasis on ICP. The anesthesiologist needs to keep sight of the ABCs of resuscitation: securing the airway, guaranteeing gas exchange, and stabilizing the circulation are higher initial priorities than ICP. Do not risk losing the airway or causing severe hypotension for the sake of preventing coughing on the tube or brief hypertension with intubation.

BOX 70-9 ***Factors That May Be Relevant During Intubation of the Head-Injured Patient***

- Full stomach
- Uncertain cervical spine stability
- Uncertain airway
  - Blood
  - Airway injury (larynx, crico-arytenoid cartilage)
  - Skull-base fracture
- Uncertain volume status
- Uncooperative/combative
- Hypoxemia
- Increased intracranial pressure

The Cervical Spine

The possibility of causing or aggravating an injury to the cervical spine is a relevant concern. Approximately 2% of blunt trauma victims who reach a hospital and 8% to 10% of TBI victims with GCS scores less than 8 have a fracture of the cervical spine.[233,234] Those incidences suggest that a hypnotic-relaxant-direct laryngoscopy approach for all patients with a closed head injury might convey a measurable risk of injuring the cervical cord. Nonetheless, although the literature contains contradictions, several published series have concluded that rapid-sequence induction does not convey significant risk of neurologic injury.[235-238] However, it is possible that the incidence of intubation-related neurologic injury is underreported. An informal survey reported by Criswell and associates[239] indicated that there have been more such events than one can infer from the published literature.[240,241] Nonetheless, the literature argues that we will "get away with it" most of the time, and the majority of patients with TBI requiring airway control are intubated using a hypnotic-relaxant-direct laryngoscopy sequence. It is the (probably minority) opinion of these authors that the possibility of devastating spinal cord injury exists, probably most so with injuries in the atlanto-occipital region, which are also difficult to identify radiologically, and that the anesthesiologist should identify circumstances in which time latitudes allow more detailed examination or radiologic evaluation. When there is any uncertainty regarding the airway or the cervical spine, direct laryngoscopy (with vigorous atlanto-occipital extension) should probably be avoided when the exigencies of the situation do not require an immediate rapid-sequence induction. The nasal route can be considered if the clinical context warrants, bearing in mind that risk of infection may be increased with skull base fracture and CSF leak. The anesthesiologist should use discretion (e.g., in the presence of an obvious facial smash, the nasal route should be avoided) and be sensitive to unusual resistance in passing the endotracheal tube.

When a hypnotic-relaxant sequence is used (and the exigencies of airway control will frequently demand it), the standard approach includes the use of cricoid pressure and in-line axial stabilization. In-line traction was once favored but has been supplanted by stabilization because of the perceived risk of over distraction and cord injury in the event of gross instability. The largest of the clinical series that concluded that oral intubation with anesthesia and relaxation is reasonable[235] used in-line stabilization with the patient's occiput held firmly on the backboard, limiting the amount of "sniff" that was feasible (Fig. 70-15). There is no question that in-line stabilization, properly performed, makes laryngoscopy somewhat more difficult; however, it serves to decrease the amount of atlanto-occipital extension necessary to achieve visualization of the glottis.[242] This is probably because performing the laryngoscopy against the assistant's counterpressure results in greater compression of the soft tissue structures of the tongue and floor of the mouth. Some recommend leaving the back half of the cervical collar in place during laryngoscopy (see Fig. 70-15) because it functions as a strut between the shoulder and the occiput and serves to further limit atlanto-occipital extension.

Figure 70-15. Intubating the acute trauma patient with an uncertain cervical spine. A hypnotic and a relaxant have been administered. One assistant maintains in-line axial stabilization with the occiput held firmly to the backboard; a second applies cricoid pressure. The posterior portion of the cervical collar remains in place to limit atlanto-axial extension. *(Reproduced with permission from Stene JD: Anesthesia for the critically ill trauma patient. In Siegel JH, editor:* Trauma: emergency surgery and critical care, *Melbourne, 1987, Churchill Livingstone, pp 843-862.)*

In a resuscitation situation, before initiating a hypnotic-relaxant sequence, the anesthesiologist should confirm the availability of cricothyrotomy equipment and of someone to make immediate, skilled use of it if necessary. The recently injured brain is very intolerant of hypoxia and hypotension.[243] It is inevitable that there is sometimes failed tracheal intubation. In the extensive experience of the Cowley Shock-Trauma Center in Baltimore, the cricothyrotomy/tracheostomy rate is 0.3%.[244] As is the case in many other situations, the laryngeal mask may be a very useful device for temporizing in the face of a failed intubation and may also provide access for intubation as an alternative to cricothyrotomy.

As noted in Chapter 17, although succinylcholine can cause ICP increases, these increments are small and probably do not occur in patients with serious cerebral injuries.[8] Accordingly, succinylcholine should not be viewed as contraindicated in the TBI victim. If there is an urgent need to secure the airway (to guarantee oxygenation and control CO_2 tension), and if succinylcholine is in other respects the appropriate drug to achieve that end, it should be used.

What should the anesthesiologist do with the patient whose cervical spine has not been cleared? That situation should arise with decreasing frequency. The once standard "three views" (with their inherent difficulties and substantial false-negative rates) have been supplanted by CT scanners that allow rapid, thin-slice evaluation, with sagittal reconstruction. A large meta-analysis concluded that "modern multislice helical CT alone is sufficient to rule out traumatic, unstable cervical spine injuries."[245] However, some remain concerned that CT may fail to identify ligamentous injuries that would be evident on magnetic resonance imaging (MRI).[246] With respect to a conscious patient who has not yet undergone complete radiologic evaluation, several clinical surveys have

confirmed that patients who are alert, nonintoxicated, and free of significant distracting injuries invariably have pain, midline tenderness, limitation of voluntary movement, or neurologic signs[247-249] if they have a cervical spine fracture. Despite the frequency with which an anesthesiologist may encounter patients still wearing their cervical collars because their necks have not yet been cleared, no special precautions appear warranted in the asymptomatic, alert patient.

Anesthetic Technique

Choice of Anesthetic Drugs. Craniotomies are most commonly performed for the evacuation of subdural, epidural, or intracerebral hematomas. The anesthetic approach is similar for all three techniques. The guiding principles have been discussed in the section Control of Intracranial Pressure and Brain Relaxation. In general, anesthetics that are known to be cerebral vasoconstrictors are preferable to those that have the potential to dilate the cerebral circulation. All of the intravenous anesthetics, except perhaps ketamine, cause some cerebral vasoconstriction and are reasonable choices, provided they are consistent with hemodynamic stability. All of the inhaled anesthetics (N_2O and all of the volatile anesthetics) have some cerebral vasodilatory effect. Although their administration frequently is consistent with acceptable ICP levels and appropriate conditions in the surgical field, when the ICP is out of control (or unknown), or the surgical field is tight, eliminating the inhaled anesthetics in favor of fixed agents is appropriate. For patients who are likely to remain tracheally intubated postoperatively, an anesthetic based primarily on a narcotic, such as fentanyl, and a muscle relaxant usually serves well. Any muscle relaxant is acceptable with the proviso that those that can release histamine (now rarely used) should be titrated in small increments. When immediate tracheal extubation is a possibility (e.g., the patient with an acute epidural hematoma who had a lucid interval before witnessed deterioration), the technique should be modified after the opening of the cranium. Introduction of inhaled anesthetics or the use of shorter-acting intravenous agents can be undertaken as guided by observation of the surgical field. If N_2O is contemplated at any time, the anesthesiologist must remember the possibility, in the setting of missile injury or compound skull fracture, of intracranial air.

Monitoring. The anesthesiologist should appreciate that the priority is to open the cranium as rapidly as possible.[250] After achieving intravenous access, the risks and benefits of delaying craniotomy for line placement should be considered carefully. An arterial line, often placed after induction in urgent situations, is appropriate for essentially all acute trauma craniotomies. Peripheral venous access is sufficient in the majority of situations. Sudden hypotension after dural opening with high ICP can occur as brainstem compression is relieved.[251] Appropriate intravascular volume resuscitation should mitigate this occurrence. Infrequently, the management of a depressed skull fracture over the sagittal sinus justifies a precordial Doppler and, subject to the surgeon's assessment of VAE risk, a right heart catheter.

Arterial Blood Pressure Management. The concept that the injured brain is extremely vulnerable to what would otherwise be a minor insult (e.g., modest hypotension, moderate hypoxia), has been well confirmed in the laboratory.[252,253] Although clinically the cause-effect relationships are not absolutely confirmed, several surveys demonstrate the association of otherwise minor degrees of hypotension and hypoxia with poor outcome in both adult[243,254-259] and pediatric patients with TBI.[260] This vulnerability to hypotension probably arises because many patients have brain regions with precariously low CBF in the first 2 to 3 days after TBI[21,31,36,261,262] and autoregulation is frequently defective.[35,263,264] The characteristic behavior of CBF after TBI is an initially low CBF followed by a gradual increase over 48 to 72 hours to normal, or sometimes even slightly hyperemic, levels.* There is considerable evidence that low postinsult CBF values correlate with a poor eventual outcome,† and a large percentage of patients who die after TBI have pathologic changes consistent with ischemia.[154] These observations have resulted in a general emphasis among neurosurgeons, neurointensivists, and anesthesiologists on aggressive support of arterial blood pressure in the patient with TBI.

What constitutes an appropriate arterial blood pressure? Systematic studies, in particular those conducted at the University of Edinburgh, revealed that indices of the adequacy of cerebral perfusion derived from $SjvO_2$ and TCD data begin to deteriorate below a mean CPP (CPP = MAP – ICP) of 70 mm Hg,[255,269,270] and many centers adopted 70 mm Hg as the CPP target. A clinical investigation by Robertson and colleagues comparing the ICU management of patients with TBI at CPPs of 70 and 50 mm Hg demonstrated that, although indices of cerebral well-being were improved by the former, there was no outcome advantage, apparently because of the cardiopulmonary morbidity associated with achieving a sustained CPP of 70 mm Hg.[271] As a result, many groups and authorities have adopted 60 mm Hg as the minimal CPP management objective.[265,272-275] The Brain Trauma Foundation's most recent recommendations, however, give clinicians wide latitude in offering a recommendation of CPP targets "within the range of 50 to 70 mm Hg" in adults.[68] Age-related CPP targets of 40 to 50 mm Hg have been recommended for children.[276,277]

"Maintain CPP at 60 mm Hg in the first 2 to 3 days after TBI" is probably reasonable general advice. However, clinicians may encounter other views, including the argument that a "one-size-fits-all" approach inevitably denies the heterogeneity of pathophysiology among patients with TBI. It is certainly true that not all patients with TBI have low CBF and not all have absent autoregulation. Although an initially low post-injury CBF is probably the most common clinical occurrence, hyperemia does occur.[33,37,266,278,279] It tends to occur in patients with mass lesions rather than contusions, although even those patients have an immediate post-injury period of low CBF, with delayed hyperemia peaking at 24 hours or later.[32,33,266,267,279] Hyperemia may also be more common in children.[280] (Also see Chapter 93.) There is evidence

*References 21, 31, 35, 36, 261, 265, 266.

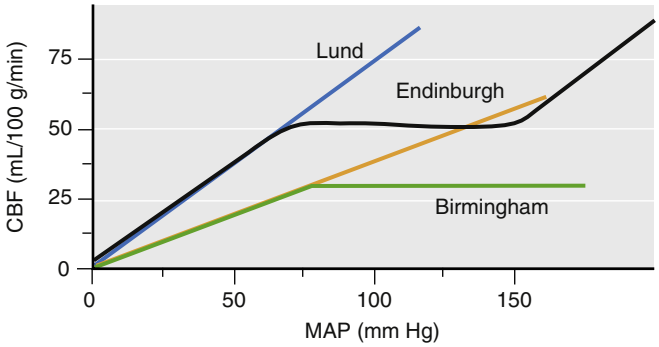

Figure 70-16. The relationship of cerebral blood flow (CBF) to blood pressure after head injury. There are three cerebral perfusion pressure (CPP) management strategies (see text) driven by differing beliefs about common pathophysiologic derangements. The most commonly held strategy is Edinburgh (so named for the institution of the original proponents); it emphasizes low postinjury CBF, impaired autoregulation, and the necessity to support CPP (mean arterial pressure [MAP] – intracranial pressure [ICP]) to 60 to 70 mm Hg. The Lund concept emphasizes the contribution of hyperemia to the occurrence of elevated ICP. That approach uses antihypertensive agents to reduce blood pressure while maintaining CPP greater than 50 mm Hg.[292] That CPP target has increased, in the most recent iteration, to 60 to 70 mm Hg, with allowance for occasional reduction to 50 mm Hg.[294] An approach emanating from the University of Alabama, identified as *Birmingham*, entails pharmacologically induced hypertension. That approach is based on the belief that autoregulation is largely intact and that hypertension will result in cerebral vasoconstriction with concomitantly reduced cerebral blood volume and ICP.[299,300]

that not all patients with TBI benefit from increases in CPP. Patients with TBI and impaired autoregulation, low baseline flows, increased ICP, and low initial GCS score are most likely to benefit.[281-284] Accordingly, "targeted" therapy has been advocated.[285-291] However, techniques to discriminate the various flow states (serial CBF measurement, TCD, $SjvO_2$) are not universally available. Some institutions, which have the necessary data analysis capacity, take another approach to targeted therapy. They identify a nominal "optimal CPP" by examining the changes in ICP that occur in response to variations in MAP. The range of MAPs in which the smallest $\Delta ICP/\Delta MAP$ occurs is taken to be the range within which autoregulation functions most efficiently and is the target range for that individual patient.[286,287] This approach is not feasible in most ICUs. As a result, and despite the theoretic attractiveness of targeted therapy, the CPP of 60 as an objective is more common.

There are at least two alternative approaches to blood pressure management in patients with TBI (Fig. 70-16). The Lund concept is based on the premises that arterial blood pressure causes hydrostatically driven edema accumulation, and that edema formation can be further aggravated by subnormal COP and crystalloid administration.[292-294] As originally described, the Lund approach in part entailed relative dehydration (furosemide, crystalloid restriction), albumin administration to maintain a normal COP, and the administration of metoprolol and clonidine to lower blood pressure to a CPP target of 50 to 55 mm Hg. At its inception, the approach was controversial because it ran counter to the perceptions of many clinicians of the importance of maintaining a CPP of 70 mm Hg and because of the later demonstration that a negative fluid balance in patients with TBI is deleterious.[257] Over time (and in parallel with a relaxation the higher CPP targets by others[68,265,272,273]), the Lund proponents have modified their approach. Normovolemia is now the clinical objective, and CPP is 60 to 70 mm Hg in most patients. The latter has made the approach somewhat less controversial. However, CPP may be reduced to 50 to 60 mm Hg when ICP is not well controlled,[135] and that element remains controversial.[295] Although the proponents of the Lund approach assert improvements in outcome, those reports invariably entail either no control group or comparisons with nonconcurrent controls.[136,296-298] The approach has not been adopted in North America.

The second approach, promoted by neurosurgeons at the University of Alabama at Birmingham (sometimes called the "Rosner concept" after its chief proponent), is that induced hypertension can be used as an adjunct to ICP control.[21,299,300] The underlying concept is that autoregulation is at least partially preserved after TBI and that an increased MAP results in autoregulation-mediated vasoconstriction with a concomitant reduction in CBV and, therefore, ICP. These investigators reported a very satisfactory local experience,[300] but others have reported that induced hypertension was either ineffective or deleterious as a means of reducing increased ICP.[12,301] The Rosner approach now appears to have few advocates.

What should the anesthesiologist managing the patient with TBI do in the face of these various approaches? Perfusion pressure support of varying degrees is a theme that is common to of all of them, and the careful support of CPP at or just above the 60-mm Hg range is probably the most reasonable general approach. When establishing normovolemia alone does not accomplish that objective, phenylephrine, norepinephrine, and dopamine have all been used. With that CPP recommendation offered, it must be acknowledged that convictions vary and anesthesiologists should come to an understanding with the local traumatologists and neurosurgeons as to CPP targets.

Hyperventilation. The use of hypocapnia has been reviewed in detail in the section Management of $Paco_2$. The effectiveness of acute hypocapnia in reducing ICP is well confirmed.[12] But there is substantial evidence that hyperventilation is potentially deleterious[21,22,27-29,302] and should not be overused. That evidence suggests that hyperventilation and the concomitant vasoconstriction can result in ischemia,[19,27-30] especially when baseline CBF is low,[30] as is likely to be the case in the first 48 to 72 hours after head injury.[21,31,36,37] The expert panel convened by the Brain Trauma Foundation specified that prophylactic hyperventilation is "not recommended," and that "hyperventilation should be avoided during the first 24 hours after injury when CBF is often critically reduced."[68] The available information argues that hyperventilation should be used selectively rather than routinely in the management of patients with TBI. Maintaining ICP less than 20 mm Hg, preventing or reversing herniation, minimizing retractor pressure, and facilitating surgical access are still important objectives in the

management of the patient with TBI, and to the extent that these objectives cannot be accomplished by other means, hyperventilation may still be appropriate. Once again, the anesthesiologist should agree on management variables with the surgical team at the outset of all procedures.

Intravenous Fluid Management. Intravenous fluid management of the patient with TBI was addressed earlier in the section Intravenous Fluid Management. The important principles are that fluids should be chosen invariably to prevent reduction of serum osmolarity and should probably be chosen to prevent profound reduction of colloid oncotic pressure—that is, in the circumstances of a large-volume resuscitation (arbitrarily, greater than half a circulating volume), using a mix of colloids and crystalloids is probably appropriate. The clinical objective should be the maintenance of intravascular normovolemia, in part as an adjunct to MAP and CPP support. A chronic negative fluid balance, as can occur with the combination of modest fluid restriction and liberal use of osmotic diuretics, has been shown to be deleterious and should be avoided.[257] The severely injured brain can liberate sufficient thromboplastin into the circulation to result in a consumptive coagulopathy.[303-305] Appropriate laboratory tests and replacement should be performed. The clinician may also find a serum osmolarity determination early in the course of anesthetic management useful in appreciating the cumulative effects of prior administration of mannitol or HTS. The use of hypertonic solutions and the relevant attributes of colloid solutions were discussed in the section Intravenous Fluid Management. Because of the ischemia that can be a component of TBI, the minimal acceptable hemoglobin level should probably be more than that accepted in stable critical care patients (i.e., 7 g/dL). There is relatively little information to provide guidance (also see Chapters 61 and 105). However, one investigation, which presented observations of $PbtO_2$, suggested 9 g/dL as a hazard threshold in patients with TBI.[224]

Monitoring

Jugular Venous Oxygen Saturation. $SjvO_2$ monitoring has been used to guide the management of patients with TBI.* The underlying concept is that a marginal or inadequate CBF results in an increasing oxygen extraction, a widening arteriovenous content difference, and reduction of $SjvO_2$. Normal subjects have $SjvO_2$ values between 60% and 75%. An $SjvO_2$ less than 50% for 5 minutes is commonly accepted as constituting jugular desaturation. There have been numerous reports of low $SjvO_2$ values improving with interventions including reducing hyperventilation, increasing MAP, or inducing hypervolemia. $SjvO_2$ measurement makes an assessment of global oxygen extraction. It might be expected to have limited sensitivity to focal events, and instances in which focal inadequacy of perfusion was not reflected by low $SjvO_2$ have been reported.[27-29,37] An additional limitation inherent to the unilateral placement of the catheter is the observation by Stocchetti and colleagues,[308] who observed that there was an average side-to-side difference between simultaneous jugular bulb saturations of 5.3 ± 5% and that side-to-side differences in hemoglobin saturation of up to 15% were common.[308]

Despite the reported successes with $SjvO_2$ monitoring,[38,309,310] we do not believe that the method is sufficiently well defined to justify advocating widespread intraoperative application. In the ICU, it appears to be potentially useful as a trend monitor that may serve to identify the level of CPP or hyperventilation below which cerebral perfusion begins to be compromised, with the proviso that there is a significant potential for false-negative results.[27-29,37] The technique also has a potential use beyond warning of inadequate perfusion. High $SjvO_2$ values may serve to identify the patient with elevated ICP in whom hyperemia is an important contributing factor and in whom aggressive attempts to decrease CBF (i.e., hyperventilation, barbiturates) may be beneficial.

Brain Tissue PO_2. Brain tissue PO_2 ($PbtO_2$) has been used to guide the management of both TBI and SAH, and there have been limited reports of improvement in outcomes thereby.[301-315] A $PbtO_2$ equal to or more than 20 to 25 mm Hg is viewed as normal, and values equal to or less than 10 to 15 mm Hg are assumed to convey a substantial risk of hypoxic injury. One investigation reported that 29% of patients with TBI with GCS scores equal to or less than 8 have brain regions with $PbtO_2$ equal to or less than10 mm Hg despite meeting CPP and ICP targets of equal to or more than 60 mm Hg or less than 25 mm Hg, respectively.[274] This would seem to encourage the use of these monitors. However, $PbtO_2$ monitors suffer from the inverse of the problem that prevails with $SjvO_2$ monitoring: they provide very focal information about the oxygenation status of only small regions of brain surrounding the tip. If they are placed remotely from focal injuries to provide a global measure of oxygenation, they may not see adverse events in at-risk but salvageable perilesional tissue.[316] They may similarly fail to be a useful therapeutic guide if they are within irredeemably injured brain. The use of $PbtO_2$ monitoring is neither standardized nor widespread.

Intracranial Pressure Monitoring for Nonneurologic Surgery in the Brain-Injured Patient. In the ideal situation, neurosurgical consultation is readily available and, appropriately, the anesthesiologist rarely has to make the decision for surgery. It may, however, be necessary for the anesthesiologist to participate in this decision. The relevant variables include:

1. *The level of consciousness.* If there has been a loss of consciousness at any time (or amnesia for the event in the absence of witnesses) or if the GCS score is less than 15, a CT scan should be obtained. If the CT scan reveals compressed basal cisterns (indicative of an exhaustion of supratentorial compensatory latitudes), midline shift, or effaced ventricles, and probably any intracranial lesion (e.g., contusion, small subdural), an ICP monitor should be considered for surgery, with general anesthesia performed within at least 48 hours after TBI. Excessive comfort should not be taken

*References 27-30, 38, 255, 270, 271, 306, 307.

from a good GCS score. Patients with good scores can talk and deteriorate or talk and die after a TBI associated with loss of consciousness. Delayed deterioration has been observed as much as 4 days after the initial injury.[317,318] Patients with lesions, usually contusions, in the frontal and frontotemporal region, and especially those with medial temporal lesions, are most at risk for this phenomenon. Modest expansion of lesions in this location (i.e., close to the uncus and the incisura where herniation occurs) can result in herniation even at relatively low ICPs (e.g., ≈20 mm Hg). At our institution, neurosurgeons would recommend avoiding an anesthetic in these patients and would certainly advise ICP monitoring if lengthy general anesthesia were unavoidable.

2. *Time since injury*. The longer the patient has had to declare his or her clinical course, the less pressing is the need for ICP monitoring. Delayed deterioration has been observed for as much as 48 hours,[317] and 4.5 days in separate investigations,[318] and a patient with a demonstrable CT lesion and a GCS score less than 15 is a candidate for a monitor during this time frame.
3. *Nature and duration of the intended procedure*. The risks of an untoward ICP event are inevitably greater in a 6-hour spine instrumentation in the prone position than in a 20-minute debridement and suturing of an arm laceration.

Hypothermia

There is clearly an ischemic component to the pathophysiology of TBI, and mild induced hypothermia has been shown to be highly protective in experimental cerebral ischemia. On that basis, the study of hypothermia after experimental TBI was undertaken, and improvements in outcome were demonstrated.[155] Several local, prospective trials of hypothermia after TBI were performed.[319-322] Because those trials appeared to indicate good patient tolerance of sustained mild hypothermia (32° C to 34° C) and improvement in ICP and outcome, a multicenter trial was performed. That trial, which required induction of hypothermia within 8 hours of injury, revealed no overall benefit.[156] Because of concern that 8 hours was not sufficiently rapid, a second trial, which achieved the target temperature in 2.5 hours, was performed. It too was negative for benefits.[157] As a result, there is no established role for hypothermia in TBI management as of this writing. However, interest and investigation appears likely to continue. Post hoc analysis of the two trials just cited revealed improved outcome in patients with intracerebral hematoma who were randomized to hypothermia.[323] A multicenter trial of hypothermia to treat increased ICP after TBI is underway in Europe.[324] (Also see the section Hypothermia.)

POSTERIOR FOSSA PROCEDURES

Most of the topics relevant to posterior fossa procedures (Table 70-5) have been discussed in the section Recurrent Issues. These include the sitting position and its cardiovascular effects and complications (quadriplegia, macroglossia), pneumocephalus, and VAE and PAE. The use of the sitting position to facilitate surgery in the posterior fossa increases the likelihood of all of these phenomena, though they are relevant to nonsitting positions as well. This section reviews the cardiovascular events associated with direct stimulation of the brainstem and their possible implications for postoperative management.

TABLE 70-5 CONSIDERATIONS RELEVANT TO POSTERIOR FOSSA PROCEDURES AND THE LOCATION OF THE RELATED DISCUSSION IN THIS CHAPTER

Consideration	Chapter Section, Subsection
Hemodynamic effects of the sitting position	Positioning, Sitting
Venous air embolism	Venous Air Embolism
Paradoxical air embolism	Venous Air Embolism
Hemodynamic effects of brainstem and cranial nerve manipulation	Posterior Fossa Procedures
Macroglossia	Positioning, Sitting
Pneumocephalus	Pneumocephalus
Quadriplegia	Positioning, Sitting

Brainstem Stimulation

Irritation of the lower portion of the pons and the upper medulla and of the extra-axial portion of the fifth cranial nerve can result in a number of cardiovascular responses. The former two areas are most often stimulated during procedures on the floor of the fourth ventricle and the last during surgery at or near the cerebellopontine angle (e.g., acoustic neuromas, microvascular decompression of fifth [tic douloureux], seventh [hemifacial spasm], or ninth [glossopharyngeal neuralgia] cranial nerves). The responses may include bradycardia and hypotension, tachycardia and hypertension, or bradycardia and hypertension, and ventricular dysrhythmias.[325] Meticulous attention to the ECG and a directly transduced arterial pressure during manipulation in this region are necessary to provide the surgeon with immediate warning of the risk of damage to the adjacent cranial nerve nuclei and respiratory centers. Pharmacologic treatment of the dysrhythmias that occur may serve to attenuate the very warning signs that should be sought.

Irritation and injury of posterior fossa structures that may have occurred during surgery should be taken into account in planning extubation and postoperative care. In particular, procedures involving dissection on the floor of the fourth ventricle entail the possibility of injury to cranial nerve nuclei or postoperative swelling in that region, or both. Cranial nerve dysfunction, particularly of nerves IX, X, and XII, can result in loss of control and patency of the upper airway, and swelling of the brainstem can result in impairment of both cranial nerve function and respiratory drive. The posterior fossa is a relatively small space, and its compensatory latitudes are even more limited than those of the supratentorial space. Relatively little swelling can result in disorders of consciousness, respiratory drive, and cardiomotor function. There should be an interaction between the anesthesiologist and the surgeon in making decisions about whether

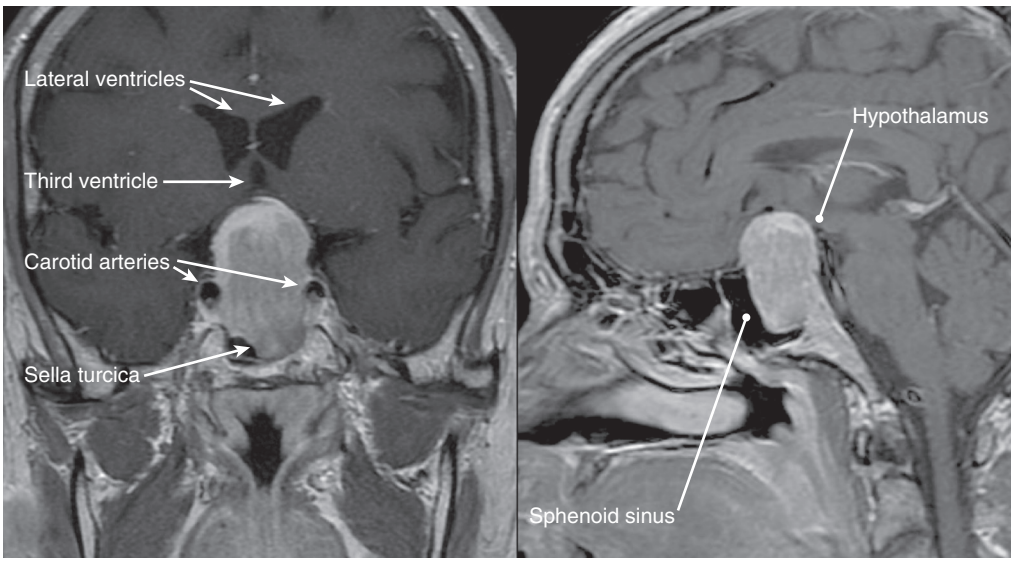

Figure 70-17. Pituitary tumor with suprasellar extension. The *left panel* shows the proximity of the tumor to the carotid arteries (which lie within the cavernous sinuses) and the potential for distortion of the ventricular system. The optic chiasm (not seen) lies above the sella in the path of the upwardly expanding tumor. The *right panel* shows that tumors that lie above the sella (including craniopharyngiomas, which arise in this location) abut and can invade the hypothalamus. The more radio-dense (whiter) cap over the superior and anatomic right lateral aspects of the tumor mass is a normal pituitary gland.

extubation is appropriate and where postoperative observation should occur (i.e., ICU or non-ICU).

Spontaneous ventilation was once advocated for procedures that entailed a risk of damage to the respiratory centers. Spontaneous ventilation is now rarely used because the proximity of the cardiomotor areas to the respiratory centers should permit cardiovascular signs to serve as an indicator of impending injury to the latter. It is our opinion that respiratory pattern is more likely to be a relevant monitor when the threat to the brainstem is the result of vessel occlusion (as might occur with accidental interruption of perforating vessels during vertebrobasilar aneurysm surgery[326]) than when it is because of direct mechanical damage caused by retraction of or dissection in the brainstem.

Various electrophysiologic monitoring techniques may be used during posterior fossa surgery. These include somatosensory evoked responses, brainstem auditory evoked responses, and electromyographic monitoring of the facial nerve. The last requires that the patient not be paralyzed or have a constant state of incomplete paralysis. Somatosensory evoked response monitoring imposes some constraints with respect to the selection of anesthetics. These are discussed in Chapter 49.

Balloon Compression of the Trigeminal Ganglion

This is another situation in which a dysrhythmia may occur. The procedure attempts to produce a neuropraxia of the fifth cranial nerve by the rapid inflation of a Fogarty-type balloon within Meckel's cave.[327,328] The balloon is introduced percutaneously through the cheek and beneath the maxilla. The procedure is best accomplished with a general anesthetic because both the entry of the needle into Meckel's cave and the balloon compression (lasting several minutes) are intensely stimulating. A relatively profound, although transient, bradycardia occurs and is sought as confirmation of adequate compression. External pacemaker pads have been advocated but in our experience are unnecessary.

TRANSSPHENOIDAL SURGERY

The transsphenoidal approach to the sella turcica is used for the excision of tumors that lie within the sella or its environs (Fig. 70-17). The majority of these lesions are tumors arising from the pituitary gland, and the most common of these are prolactin-secreting microadenomas and nonsecreting macroadenomas. Patients with the former are usually women who present with secondary amenorrhea or galactorrhea, or both. The nonsecreting adenomas tend to manifest with mass effects (headache, visual disturbance, hypopituitarism) and are typically larger at the time of diagnosis. Patients may also present with hypopituitary states as a result of dysfunction of the normal gland caused by compression by the tumor mass. There are three other less common pituitary tumors: growth hormone–secreting lesions, which result in acromegaly; adrenocorticotropic hormone (ACTH)-secreting tumors, which cause Cushing disease; and a very rare thyroid-stimulating hormone–secreting lesion, which results in hyperthyroidism. A detailed review of the perioperative management of this group of patients is available.[329]

Preoperative Evaluation

The important preoperative considerations relate to the patient's endocrine and visual status. In general, as a pituitary lesion expands and compresses the pituitary tissue, normal glandular function is compromised. Hormonal function is lost in the following sequence: first, gonadotrophins; second, growth hormone; third, ACTH; and fourth and last, thyroid-stimulating hormone. A decrease in

ACTH secretion results in a hypoadrenal state. Attention to this is critical because an Addisonian crisis can ensue, especially under the stress of surgery. Profound hypocortisolism, with associated hyponatremia, should be corrected preoperatively. Deficiency in thyroid function is uncommon. However, if significant hypothyroidism is present, it should be corrected preoperatively because hypothyroid patients have a diminished tolerance to the cardiovascular depressant effects of anesthetics. Attention to other manifestations of pituitary hypersecretion is also important. Hypertension, diabetes, and central obesity are common concomitants of ACTH-secreting adenomas (Cushing disease). Patients with advanced acromegaly can develop an enlarged tongue and a narrowed glottis, and the airway should be evaluated accordingly. The dermis is thickened and vascular cannulation can be more difficult. Hypertension and a cardiomyopathy may also occur. (See also Chapter 38.)

Monitoring

Many practitioners place an arterial catheter, and this facilitates monitoring of blood pressure as the nasal mucosa is injected with epinephrine containing local anesthetic solutions. Access for blood sampling is also a useful adjunct to postoperative care if diabetes insipidus develops. Blood loss is usually modest. However, the cavernous sinuses, through which the carotid arteries pass (see Fig. 70-17), form the lateral boundary of the sella and may be entered during the resection of large tumors. Entry into these structures can lead to catastrophic blood loss. In addition, in some patients there is an extensive venous sinus connecting the two cavernous sinuses that may cover the entire dural lining of the sella, rendering a transsphenoidal approach hazardous. It has, on occasion, actually precluded this approach to the pituitary gland.

Anesthetic Technique

The latitudes are broad with respect to choice of agent, although tumors with suprasellar extension (see Fig. 70-17) can occasionally cause hydrocephalus and add increased ICP constraints to the anesthetic technique. The procedure is performed in the supine position, usually with some degree of head-up posture to avoid venous engorgement. A pharyngeal pack prevents the accumulation of blood in the stomach (which causes vomiting) or in the glottis (which contributes to coughing at extubation). A RAE-type tube secured to the lower jaw at the corner of the mouth opposite the surgeon's dominant hand (e.g., the left corner of mouth for a right-handed surgeon) is suitable. A small esophageal stethoscope and temperature probe can lie with the endotracheal tube. Covering the entire bundle with a towel drape (a plastic sheet with an adhesive edge) placed just below the lower lip, so that it hangs from the lower jaw like a veil, protects it from contact with the preparation solutions.

The procedure is commonly performed with a C-arm image intensifier (lateral views), and the head and arms are relatively inaccessible once the patient is draped. It is appropriate to establish the nerve stimulator at a lower extremity site. The surgical approach is via the nasal cavity, usually through an incision made under the upper lip or via the nares. During the approach, the mucosal surfaces within the nose are infiltrated with a local anesthetic and epinephrine solution, and the patient should be observed for the occurrence of dysrhythmias.

Surgical preferences for CO_2 management vary. In some instances, hypocapnia is requested to reduce brain volume and minimize the degree to which the arachnoid bulges into the sella. One of the important surgical considerations is the avoidance, when possible, of opening the arachnoid membrane leading to leakage of CSF. Postoperative CSF leaks can be persistent and are associated with a considerable risk of meningitis. By contrast, when there is suprasellar extension of a tumor, a normal CO_2 level helps deliver the lesion into the sella for excision.[330] As an alternative method to accomplish this, some surgeons have resorted to "pumping" of saline into the lumbar CSF space.[331]

A smooth emergence (see the section Emergence from Anesthesia) from anesthesia is desirable, especially if the CSF space has been opened (and resealed with fibrin glue or by packing the sphenoid sinus with fat or muscle). Repeated intense Valsalva maneuvers, as with coughing or vomiting, may contribute to the reopening of a CSF leak and worsen the risk of subsequent meningitis. The airway should be cleared of debris including formed clots. In situations in which there is concern that a persistent CSF leak may occur, the surgeon may place a lumbar CSF drain to maintain CSF decompression in the early postoperative period.

Diabetes Insipidus

The antidiuretic hormone is synthesized in the supraoptic nuclei of the hypothalamus and is transported down the supraoptic-hypophyseal tract to the posterior lobe of the pituitary gland. This portion of the pituitary gland is frequently spared during transsphenoidal tumor excisions. Even when it is excised, water homeostasis commonly normalizes, presumably because the ADH is released from the cut end of the tract. When the pituitary stalk is transected, and sometimes even when the posterior lobe of the pituitary gland is left intact, transient diabetes insipidus may occur. Diabetes insipidus very rarely arises intraoperatively; it usually occurs 4 to 12 hours postoperatively. The clinical picture is one of polyuria in association with a rising serum osmolality. The diagnosis is made by comparison of the osmolalities of urine and serum. Hypo-osmolar urine in the face of an elevated and rising serum osmolality strongly supports the diagnosis. In the presence of bona fide diabetes insipidus, urine-specific gravity is low (i.e., ≤1.002), though this analysis is now rarely performed.

When the diagnosis of diabetes insipidus is established, the following fluid management regimen is appropriate: hourly maintenance of fluids plus two thirds of the previous hour's urine output. (An acceptable alternative is the previous hour's urine output – 50 mL + maintenance.) The choice of fluid is dictated by the patient's electrolyte levels. In general, the patient is losing fluid that is hypo-osmolar and relatively low in sodium. Half-normal saline and 5% dextrose in water are commonly used as replacement fluids. Beware of hyperglycemia when large volumes of 5% dextrose in water are used. An unacceptable fluid regimen that has been used calls for maintenance

fluids plus the previous hour's urine output. This has the potential to put the anesthesiologist and the patient in a "chase your tail" situation. Should the patient become iatrogenically fluid–overloaded, this regimen precludes his or her returning to isovolemia, and where the maintenance fluid allowance is generous, it guarantees that the patient will become increasingly hypervolemic. If the hourly requirement exceeds 350 to 400 mL, desmopressin acetate is often administered.

AWAKE CRANIOTOMY AND SEIZURE SURGERY

Awake craniotomies are performed when tumors or epileptic foci lie close to cortical areas required for either speech or motor function, or to mesial-temporal structures critical to short-term memory. Many patients have so-called temporal lobe epilepsy. There is commonly a structural lesion visible on MRI. Sometimes there is a history of remote trauma.

Presurgical Evaluation

Before the resection, most patients have undergone a Wada test or video-telemetry, or both.[332] More recently, functional testing using MRI or positron emission tomography, or both, has also been introduced to the presurgical evaluation. The Wada test involves selectively anesthetizing the cerebral hemispheres, usually by injection of amobarbital (Amytal) sodium into the carotid artery to localize the hemisphere that controls speech or to confirm that there is bilateral representation for short-term memory, or both. Speech is an issue when the posterolateral portions of the temporal lobe are involved, and memory is the concern when the involvement is mesial.

Anesthesia for Electroencephalogram Electrode Placement

Video-telemetry is performed to permit localization of the seizure focus that is responsible for the clinically problematic events. This usually requires prior placement of either subdural strip electrodes (via burr holes) or a subdural electrode grid (requiring a craniotomy). Electrodes are sometimes placed deep into the parenchyma, usually within the temporal lobe (placed stereotactically via burr holes), or they are positioned to look at the inferior surfaces of the temporal lobe. The latter is commonly accomplished with so-called foramen ovale electrodes. These electrodes are placed using a needle similar to an epidural needle. The point of entry is approximately 2 cm lateral to the angle of the mouth. The needle is passed through soft tissue, under the temporal process of the zygomatic bone and medial to the ramus of the mandible, up to the base of the skull in the vicinity of the foramen ovale. Typically, this procedure is performed as a MAC, although small doses of anesthetics, most often propofol, are usually required at the time of stimulation by the needle of the periosteum at the base of the skull. After placement of the relevant electrodes, the patient's seizure medication is discontinued and the patient remains in an observation unit with EEG and behavior recorded continuously. In this manner, the EEG events associated with the clinically significant seizure events and their anatomic origin can be identified.

Preanesthetic Evaluation and Preparation

At the preoperative interview, the patient should be educated about the nature and duration of the procedure and the limitations on patient movement. A description of both the aura and the seizures to facilitate recognition of impending events should be obtained, and it should be ascertained whether the patient is subject to having grand mal convulsions. If intraoperative electrocorticography to identify seizure foci is intended, it is common to discontinue or reduce by half the anticonvulsants according to the perceived risk of uncontrolled seizures. Premedicants with an anticonvulsant effect (e.g., benzodiazepines) should not be used because they may interfere with intraoperative EEG localization (see also Chapter 38).

Anesthetic Technique

The objectives of the anesthetic technique are as follows:

1. To minimize patient discomfort associated with the potentially painful portions of the procedure and with the prolonged restriction of movement.
2. To ensure patient responsiveness and compliance during the phases of the procedure that require assessment of speech, memory, or motor/sensory responses to cortical stimulation.
3. To select anesthetic techniques that produce minimal inhibition of spontaneous seizure activity.

There are probably many ways of providing sedation that are consistent with the objectives just cited. The techniques used range from minimal sedation approaches, through deep sedation during which intermittent unresponsiveness is achieved with spontaneous ventilation and an unprotected airway, to asleep-awake-asleep techniques with intermittent airway management with a laryngeal mask airway (LMA) or endotracheal tube, sometimes with positive-pressure ventilation. From the outset, the anesthesiologist should appreciate that the essential element of an anesthetic for an awake craniotomy is the local anesthetic technique. Sedation cannot compensate for inadequate anesthesia of the scalp, as is accomplished by nerve blocks (Fig. 70-18), and pin site infiltration. Although the anesthesiologist can contribute enormously to the patient's comfort and tolerance of the painful components of the procedure and the prolonged immobilization, the anesthesiologist must not get trapped into thinking that it is his or her responsibility to provide a general anesthetic equivalent in a spontaneously breathing patient with an unprotected and all but inaccessible airway.

For sedation, there are many options. Many clinicians (including the authors) use principally propofol,[333,334] sometimes supplemented with infusion of remifentanil (e.g., 0.02 to 0.05 μg/kg/min) or dexmedetomidine (e.g., 0.2 μg/kg/hr). Other combinations, including propofol with either fentanyl or remifentanil and dexmedetomidine with or without remifentanil, are reasonable.[335-337] Great care should be taken in administering additional sedative drugs, especially narcotics whose respiratory depressant effects will be synergistic with propofol. This is especially relevant in the presence of pin fixation, which severely restricts the anesthesiologist's capacity to intervene quickly in the event of excessive respiratory depression or loss of patency of the airway. Propofol

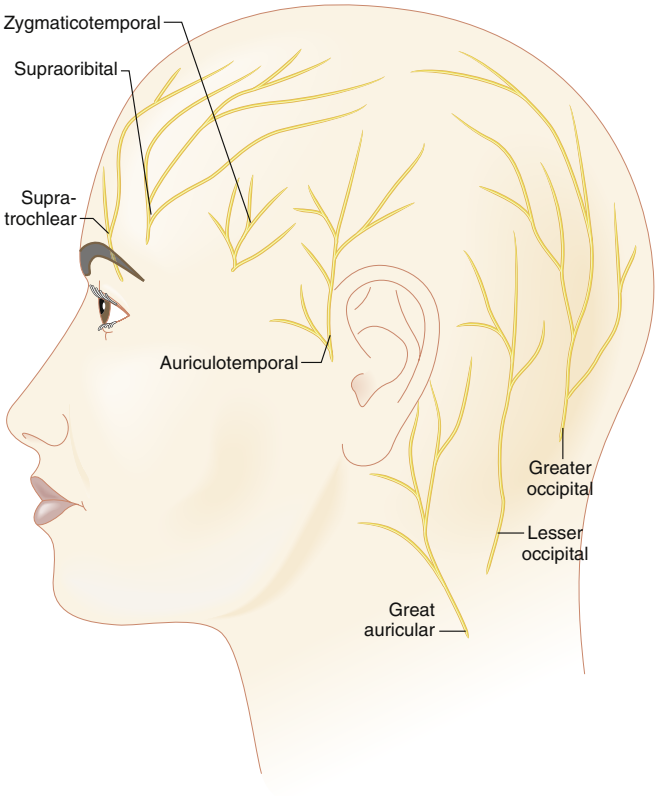

Figure 70-18. The cutaneous nerves of the scalp.

should be discontinued at least 15 minutes before EEG recording. Despite prompt awakening, propofol leaves a residual EEG footprint characterized by high-frequency, high-amplitude beta activity that can obscure the abnormal activity that is being sought in the cortical surface EEG.[333] The use of dexmedetomidine, which in addition to sedation and anxiolysis provides some analgesia with minimal respiratory depression, is increasing.[337-341] Satisfactory conditions for functional testing, including brain stimulation for speech mapping and electrocorticography, have been reported with dexmedetomidine infusions ongoing at rates between 0.1 and 0.5 μg/kg/hr during the testing.[337,339,342,343] The occurrence of delays in achieving satisfactory patient responsiveness has also been reported,[340,344] and using only relatively modest infusion rates (i.e., 0.1-0.2 μg/kg/hr) during neurocognitive testing appears advisable.[342] Administration of antiemetics (ondansetron or dexamethasone, or both) should probably be routine, especially if narcotics are administered.

Various groups have reported the use of the LMA with either spontaneous or controlled ventilation during the craniotomy, with cessation of sedative administration and LMA removal once the brain surface is exposed.[338-340,342,345,346] It is obvious that many approaches can be effective, but it should be noted, for the most part, that the LMA techniques have been used in patients who were *not* in pin fixation of the head. An awake-asleep-awake technique using insertion, removal, and replacement of an endotracheal tube has been reported, but a customized tube that allows installation of local anesthetic in the glottis and trachea was used.[347]

Routine, noninvasive monitors are almost always sufficient. Reliable capnography, to provide breath-by-breath confirmation of airway patency and respiratory drive, is essential if deep sedation is intended for any portion of the procedure. These procedures are often lengthy. Attention to the details of patient comfort (warming blankets, a sheepskin, room temperature) improve patient tolerance.

The uncomfortable phases of the procedure are pin head holder placement (not all groups use a pin head holder) and the craniotomy. Many patients also find manipulation of the dura, in particular traction on subtemporal dura, painful. The actual manipulation of supratentorial brain parenchyma is painless. The volume of local anesthetic used to infiltrate pin sites and perform the scalp nerve blocks can be substantial. It is appropriate for the anesthesiologist to keep track of, and provide advice about, the doses of local anesthetics used.

The anesthesiologist should participate actively at the time of head positioning. The more sniff that can be achieved before the final lockdown of the head holder, the wider the latitudes will be for sedating the patient, while maintaining spontaneous ventilation and a patent airway. During positioning of the patient, there should also be attention to the need to maintain visual access to the face. A clear line of sight to the face is necessary to present the patient with images to name as part of speech testing and to identify the occurrence of facial motor responses during mapping of the motor strip.

In general, after the dural opening is complete, for seizure-related resections, cortical surface EEG recording is performed to locate the seizure focus. If no seizure activity is observed, provocative maneuvers may be requested.[348] Methohexital in a dose of approximately 0.3 mg/kg is generally safe and effective. Etomidate, approximately 0.05 to 0.1 mg/kg, has also been used. Localization of seizure focus can also be accomplished during light general anesthesia (e.g., N_2O /fentanyl/low-dose isoflurane). During general anesthesia, alfentanil, in a bolus dose of 30 to 50 μg/kg[349,350]; etomidate in doses of 0.2 to 0.3 mg/kg[351,352]; and remifentanil, as a bolus of 2.5 μg/kg[353] have been reported to be effective in activating seizure foci. Hyperventilation may also help activate seizure foci.[354]

After localization by EEG (or initially in nonseizure-related resections), functional testing is performed by electrical stimulation of the cortical surface with observation for motor, sensory, or speech interruption effects. During cortical stimulation, the anesthesiologist should be prepared to treat grand mal convulsions. Seizures usually stop with cessation of stimulus or with irrigation of the cortex with cold saline. When they are not self-limited, pharmacologic intervention (e.g., with propofol in increments of 0.5 to 1.0 mg/kg), may be warranted. However, propofol should be withheld briefly until it is clear that the seizure is not going to terminate spontaneously because it may interfere with subsequent EEG localization for some time.[333]

STEREOTACTIC PROCEDURES

Stereotactically-guided procedures are performed for numerous indications including biopsy of small, deep-seated lesions and placement of deep brain stimulation electrodes. The latter are placed most commonly for the

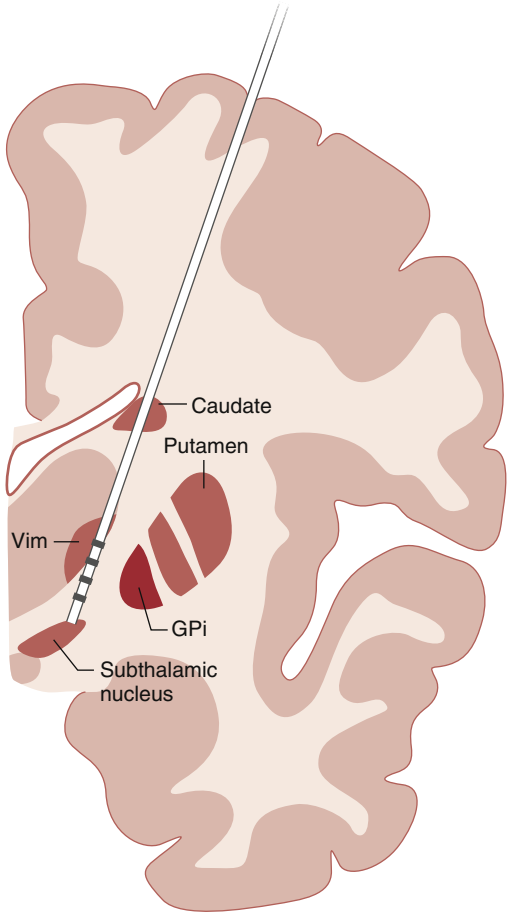

Figure 70-19. Deep-brain stimulation electrode target sites. The most commonly targeted nuclei for the treatment of movement disorders are the subthalamic nucleus, the ventral intermediate nucleus of thalamus (Vim), and the internal segment of globus pallidus (GPi).

treatment of movement disorders (Parkinson disease, essential tremor, and dystonias)[355] and sometimes for a variety of other conditions (Tourette disorder, obsessive-compulsive disorder, and depression). Procedures related to movement disorders most often target the subthalamic nucleus, the internal segment of the globus pallidus, or the ventral intermediate nucleus of the thalamus (Fig. 70-19).[355] The mechanism of the beneficial effect of deep brain stimulation is not well understood. A prominent theory is that the abnormal motor patterns are caused by synchronized oscillations in neural circuits involving several basal ganglia nuclei, as well as the cortex, and that high-frequency stimulation of any of several points along the pathway can interfere with the oscillation.[356]

Preoperative evaluation should include ensuring that the coagulation process is intact and that the patient is not taking platelet-inhibiting agents (including herbal medications). There should be careful explanation of the procedure, its likely duration, and the necessary restraints on patient movement.

Several constraints will confront the anesthesiologist including:

1. *Airway access*. Commonly, the stereotactic frame, of which there are many variations, is placed using local anesthetic and the patient undergoes an imaging study before being brought to the operating room. In some instances, the frame will prevent mask application and ventilation, laryngoscopy, and neck extension. If a general anesthetic is to be used, an awake intubation occasionally may be required. The frame is often anchored to the operating room table. If sedation is to be used, the anesthesiologist should have certain knowledge of how to remove the device rapidly in an urgent situation (including knowledge of the whereabouts of the requisite key or spanner device).
2. *The effect of anesthetics on microelectrode recordings and symptoms*. Localization of deep brain stimulation electrodes typically involves the combination of stereotaxis with fine tuning by identification of the electrophysiologic footprint specific to the targeted nucleus (e.g., the subthalamic nucleus, globus pallidus interna). The sedative agents used must not interfere with that signature. The nature and duration of the effects of anesthetics (which probably vary from nucleus to nucleus) have not been systematically defined. Some surgeons and electrophysiologists may request, on a just-in-case basis, that no sedative agent whatsoever be given. That is likely to be unnecessarily restrictive. Comprehensive reviews are available.[357-359] In short, benzodiazepines probably have the greatest potential to interfere and, for the time being, are best avoided. Propofol has been reported to cause severe dyskinesias in patients with movement disorders,[360] but has nonetheless been used quite frequently. At a minimum, a substantial interval between propofol administration and recording should be planned. Dexmedetomidine in low doses has been used quite widely without reports of interference with signals.[361] Remifentanil, in part because of its rapid clearance, is probably also a reasonable choice, although it too has been reported to suppress Parkinsonian tremor.[362]
   The cessation of the patient's symptoms upon stimulation, without the occurrence of unacceptable side effects, is also an important end point for determining the adequacy of deep brain stimulation position and stimulus parameters. The symptoms must not be suppressed by the sedative agents. This can occur with propofol.[363] Satisfactory electrophysiologic recordings and preservation of the tremor have been reported in Parkinsonian patients who received dexmedetomidine in a dose sufficient to maintain a lethargic response to normal speech.[337,361,364]
   An additional issue that arises in some patients with movement disorders is the problem of obtaining high-quality radiologic images in the presence of a persistent tremor. Sedation immediately preceding the stereotactic placement may be inevitable. Propofol has been used, but the window between propofol administration and subsequent recording should be as long as possible.
3. *Intracerebral hematoma and prevention of hypertension*. Intracerebral hematoma is a serious, potential intraoperative complication of stereotactic procedures. Prevention and prompt treatment of hypertension are among the anesthesiologist's important objectives.

The concern is that, in the face of multiple needle passes through the brain, hypertension will precipitate development of an intracerebral hematoma. In the event of a substantial hematoma, an urgent craniotomy may be required, and the anesthesiologist should be prepared from the outset for this eventuality.

As noted in the section Venous Air Embolism, because of spontaneous ventilation, there is some hazard of VAE during deep brain stimulation placement.[99]

NEUROENDOSCOPIC PROCEDURES

Excision of some intraventricular lesions (e.g., colloid cysts, fenestration of the lamina terminalis or the floor of the third ventricle for treatment of hydrocephalus) can be accomplished endoscopically. Access is usually achieved through burr holes placed over the frontal or occipital horns of the lateral ventricle. The important anesthetic consideration relates to the irrigation fluid (which should be warmed) used to maintain clear visualization, just as is done in orthopedic arthroscopy procedures. Obstruction to the effluent limb produces rapid increases in ICP that are commonly associated with sudden changes in vital signs**.** An increase in blood pressure and decrease in heart rate (a Cushing-type response) is classic, but the heart rate component is less reliable. Cardiovascular changes may also, but less predictably, represent mechanical irritation of intracranial (e.g., hypothalamic) structures. The surgeon should be notified immediately of any sudden hemodynamic changes. The decision of whether intra-arterial monitoring is warranted should be made with the surgeon.

NEURORADIOLOGIC PROCEDURES

A wide variety of interventional procedures are performed for the evaluation and treatment of intracranial and extracranial disease. These include attempts to obliterate aneurysms, devascularize tumors and AVMs, and occlude arteriovenous fistulas. An extensive review is available[365] (see also Chapter 90).

Tumors and Arteriovenous Malformations

Hyperventilation may be appropriate in an attempt to divert flow away from normal brain and toward a lesion that is intended to receive the occlusive device or material. When the interventionalist is attempting to place glue in high-flow lesions (e.g., AVMs, fistulas), the anesthesiologist may be asked to reduce systemic blood pressure to prevent glue passage into the draining veins or systemic venous system. The choice of hypotensive agent depends on the anesthetist's experience and systemic cardiovascular considerations. Adenosine, which produces temporary flow cessation, is almost certainly the most effective means of accomplishing this objective.[366]

Intracranial Aneurysms

The International Subarachnoid Aneurysm Trial and subsequent meta-analysis have confirmed the broad applicability of endovascular treatment of aneurysms,[367,368] and the majority of aneurysms are currently managed by those approaches. Nonetheless, a substantial number of patients continue to undergo operative clipping,[369] primarily those with wide-necked aneurysms, diseased or occluded proximal vessels, and otherwise complex anatomy.

Many aneurysm-related procedures, in particular those involving the treatment of vasospasm by selective intraarterial installation of vasodilators (papaverine, calcium-channel blockers) or more commonly by balloon dilatation, can be accomplished without the involvement of an anesthesiologist. The duration of a procedure, individual patient factors, and sometimes the necessity for precise physiologic control may result in requests for monitored anesthesia care or general anesthesia. A chin-tucked position (to remove the bones of the face from the line of the anteroposterior radiograph source) and absolute immobility are commonly needed by the radiologist and, as a result, when the anesthesiologist's assistance is requested, it is often because a general anesthetic is perceived to be necessary. In addition, anesthesiologists may become involved during the resuscitation stage in the event of vascular rupture or of the migration of an intravascular device to an incorrect location. In the event of rupture, the interventionist may request blood pressure reduction while the coil packing of the aneurysm is completed hastily. In addition, immediate reversal of heparinization is required. When detachable devices, such as coils and balloons (the latter now used infrequently), are misplaced and ischemia ensues, fluid loading and pressor administration may be requested to improve collateral CBF while the device is retrieved. A dedicated arterial line is usually warranted. This may or may not be available via a port in the interventionist's vascular access sheath.

CEREBROSPINAL FLUID SHUNTING PROCEDURES

Cerebrospinal fluid shunts are inserted for the relief of a variety of hydrocephalic states and pseudotumor cerebri. Hydrocephalus can be communicating or noncommunicating. In a noncommunicating hydrocephalus, CSF egress from the ventricular system is obstructed. This can occur as a result of blood or infection in the ventricular system or tumors in or adjacent to the ventricular system. In communicating hydrocephalus, the CSF escapes from the ventricular system but is not absorbed by the arachnoid villi. This occurs most commonly secondary to infection or blood in the CSF space. Some degree of communicating hydrocephalus is particularly common after SAH.

Placement of a ventriculoperitoneal shunt is the most common procedure. Usually a catheter is inserted via a burr hole into the frontal horn of the lateral ventricle on the nondominant (usually the right) side. A reservoir is placed subcutaneously adjacent to the burr hole and the drainage limb passes via a subcutaneous tunnel to a point near the epigastrium, where it is inserted into the peritoneal space via a very small laparotomy. A moderate degree of muscle relaxation may be helpful. A distended stomach can result in an inadvertent gastrostomy. Sometimes, most commonly in pediatric patients, there may be an obstruction at more than one level in the

ventricular system and a so-called double-barreled shunt becomes appropriate. In this instance, there are two proximal ends, usually one in a lateral ventricle and one in the fourth ventricle. This latter procedure is usually performed in the prone position, whereas the majority of ventriculoperitoneal shunts are done supine.

Occasionally, when there is a communicating hydrocephalus, a lumboperitoneal shunt is inserted. The patient is placed in a lateral position and a catheter is put in the lumbar CSF space via a Tuohy-type needle. The catheter is tunneled subcutaneously around to the anterior abdominal wall and inserted into the peritoneal space via a small laparotomy.

Anesthetic Management

Invasive monitoring is generally not required. The anesthetic technique should be chosen to avoid further increases in ICP. Moderate hyperventilation ($Paco_2$ 25 to 30 mm Hg) is customary. Because these procedures are not performed in the context of acute injury states, there is less concern about adverse effects of hypocapnia. The target $Paco_2$ should be agreed upon at the outset with the surgeon. The procedure is usually performed in the supine position, with the table turned 90 degrees. Blood pressure may decrease abruptly when the ventricle is first cannulated (as brainstem pressure is relieved). Infrequently, brief pressor support is required. Burrowing the subcutaneous tunnel can produce a sudden painful stimulus. There is only minor postoperative discomfort. Unlike the majority of neurosurgical patients, shunt patients are often nursed flat after their procedures in an attempt to prevent an excessively rapid collapse of the ventricular system. Empirically, there is a small incidence of subdural hematoma after shunting, and the tearing of bridging veins at the time of rapid brain shrinkage is a suspected cause.

Pediatric Ventriculoperitoneal Shunts

Shunts are probably more commonly performed in children than in adults. Common indications are hydrocephalus occurring in association with meningomyelocele, neonatal intraventricular hemorrhage, and posterior fossa tumors. Although one can never be casual about the management of these patients, open fontanelles seem to provide some margin for error in younger patients and, in addition, palpation of the fontanelles provides on-line trend monitoring of ICP. Despite its theoretic considerations, inhaled inductions using volatile anesthetics are empirically well tolerated, even in children with closed fontanelles. We would avoid the inhaled induction technique in a child who was already stuporous. When an intravenous line is available, a propofol-relaxant induction sequence is preferable. For children in whom cannulation of a peripheral vein cannot be accomplished readily, an inhaled induction with sevoflurane is a common approach, with initiation of controlled ventilation, by bag and mask, as rapidly as possible. After establishing controlled ventilation, an ideal course at this point is to establish an intravenous line and administer a muscle relaxant and perhaps an induction agent, and then intubate the trachea in these optimal circumstances. Anesthesia is most commonly maintained thereafter with 60% to 70% N_2O, mechanical hyperventilation, and volatile agent as required. For children older than 6 months of age who are not stuporous at the outset, we commonly administer 2 to 3 μg/kg of fentanyl in the belief that this procedure is not entirely pain-free postoperatively, and that a smoother emergence can be accomplished with a narcotic background (see also Chapter 93).

PEDIATRIC NEUROSURGERY

Table 70-6 identifies common pediatric procedures and their anesthetic considerations. The most frequent procedures are probably the placement and revision of CSF shunts (discussed in the preceding section). The majority of pediatric tumors occur in the posterior fossa. Most are near the midline and many are associated with hydrocephalus. For pediatric posterior fossa procedures, VAE risk, monitoring, and treatment are similar for adults and children and have been previously discussed. A Doppler is invariably indicated and right heart catheters are generally placed when procedures are done in the sitting position. Craniosynostosis procedures have the potential for substantial blood loss that is roughly proportional to the number of sutures involved. There is a significant VAE risk that justifies the use of a precordial Doppler.[97] Children with neuraxial tumors can present for emergent palliative radiotherapy and may have acutely increased ICP or impending herniation. Intractable pain combined with analgesic tolerance, steroid use causing centripetal obesity, and the side effects of other chemotherapeutic agents may be complicating factors (see also Chapter 93).

SPINAL SURGERY

Table 70-7 summarizes the many issues that may arise in the context of spinal cord or spinal column procedures undertaken by neurosurgeons.

Surgery on the spinal column is reviewed in detail in Chapter 79. The relevant electrophysiologic monitoring techniques are described in Chapter 49. Prone positioning has previously been discussed and postoperative visual loss is discussed in Chapter 100.

The physiology of the spinal cord is, in general, similar to that of the brain: CO_2 responsiveness, BBB, autoregulation, high metabolic rate and blood flow (though somewhat less than the brain), and substantial ischemic vulnerability of gray matter. However, measures to reduce spinal cord swelling, analogous to ICP reduction maneuvers, are rarely used. The anesthesiologist should be attentive to situations in which there is significant compression of the spinal cord. This arises most often in the setting of cervical spinal stenosis and should be assumed to be present with fracture dislocation of the spinal column. For these patients, we place arterial catheters and support blood pressure carefully. We believe that in these settings, and in patients with recent spinal cord injury, blood pressure should be maintained near to waking normal levels. Blood pressure support is less important when the issue is nerve root rather than spinal cord compression. The presence of spinal stenosis and chronic cord compression is frequently, but not invariably, associated with lower extremity hyperreflexia and ankle clonus. Awake

TABLE 70-6 PEDIATRIC NEUROSURGICAL DISORDERS AND THEIR ANESTHETIC CONSIDERATIONS

Age Group	Lesion	Pathogenesis	Anesthetic Considerations
Neonates	Intraventricular hemorrhage	Subependymal vascular rupture	Associated problems of prematurity
	Depressed skull fracture	Forceps injury	Associated cerebral edema
	Meningocele	Out-pouching of meninges through skull defect	Large size creates airway management difficulty Prone or lateral position Repair may increase ICP Variable blood loss
	Encephalocele	Out-pouching of meninges and brain through skull	As above
	Meningomyelocele	Protrusion of meninges and nerve roots through spina bifida	Prone or lateral position Respiratory restriction after covering large defects
Infants	Hydrocephalus	Varied	Increased ICP
	Arnold-Chiari malformation	Posterior fossa contents compressed in foramen magnum	Brainstem compression with neck flexion ± Hydrocephalus/Increased ICP; ± Meningomyelocele; Postoperative respiratory depression
	Craniosynostosis	Premature fusion of cranial sutures	Open or endoscopic procedure Substantial blood loss Air embolism Supine or prone
	Craniofacial dysostosis	Developmental abnormality	Lengthy procedures Substantial blood loss Brain retraction Air embolism Endotracheal tube damage
	Vascular malformations	Varied	Congestive heart failure Large blood loss Induced hypotension
	Subdural hematoma	Trauma	Associated injuries
Older pediatrics	Posterior fossa tumors	Ependymoma Astrocytoma Medulloblastoma Teratoma Brainstem glioma	Hydrocephalus Increased ICP Prone or sitting position Air embolism Brainstem compression Postoperative cranial nerve dysfunction or brainstem swelling or compression

ICP, Intracranial pressure.

TABLE 70-7 ANESTHETIC CONSIDERATIONS AND POSITION REQUIREMENTS ASSOCIATED WITH VARIOUS SPINAL SURGICAL PROCEDURES

Spinal Segment and Surgical Condition	Problems and Considerations	Positions Used and Comments
Cervical region: Spinal stenosis, trauma, rheumatoid arthritis, degenerative disk disease	Maintain neutral neck position to avoid cord compression	Supine/anterior approach for most discectomies Posterior approach (prone or sitting) for laminectomy and pedicle screws
	Maintain perfusion pressure near waking normal levels	If existing cord compression, recent cord injury, or if cord retraction is required
	Hypotension (spinal shock)	Occurs with complete cervical cord injury
	Postoperative respiratory insufficiency	Occurs with cervical cord injury
	Air embolism	With sitting laminectomies
Anterior cervical discectomy	Retractor compression of airway	Supine
	Postoperative swelling/airway compression	Traction may be required for graft insertion
	Postoperative cranial nerve dysfunction	ETT cuff deflation/reinflation after retractor placement
Cervical instability	Awake intubation	Prone or supine
	Awake positioning	
	Manual in-line stabilization for intubation (if awake intubation is not feasible)	

TABLE 70-7 ANESTHETIC CONSIDERATIONS AND POSITION REQUIREMENTS ASSOCIATED WITH VARIOUS SPINAL SURGICAL PROCEDURES—cont'd

Spinal Segment and Surgical Condition	Problems and Considerations	Positions Used and Comments
Thoracolumbar region: degenerative disease, spinal stenosis, trauma	Major position change	Prone, lateral, or knee-chest
	Awake intubation and position	If unstable, post trauma and/or major position change required
	Blood loss	Especially with redos, instrumentations, and spinal stenosis; risk of occult aorto- iliac or major venous injury
	Air embolism	Infrequent
	POVL	Etiology unclear; associated with long prone procedures, low hematocrit, large EBL, and hypotension; patient variables may contribute (see Chapter 100)
Vertebral metastasis	Large blood loss	Prone or anterolateral/retroperitoneal Lung separation for lesions above L1
Spinal cord tumors	Maintain perfusion pressure during retraction	Prone
Procedures with major neurologic risk	Wake-up test (now rare)	Rehearse with patient
	Somatosensory evoked responses	Anesthetic agent restrictions
	Motor evoked responses	Anesthetic/relaxant restrictions
	Pedicle screw EMG	Relaxant restriction

EMG, Electromyogram; *ETT,* endotracheal tube; *POVL,* postoperative vision loss.

intubation may be warranted when there is instability of the cervical spinal column and in some instances of severe cervical spinal stenosis in which it is perceived that minor degrees of flexion or extension, or both, might critically aggravate spinal cord compression. Preintubation discussion and agreement with the surgeon is appropriate.

Chapter 71

Anesthesia for Bariatric Surgery

DAVID M. ECKMANN

Acknowledgment: The editors and the publisher would like to thank Dr. Ashish C. Sinha, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- In the United States, more than 200 million people are overweight or obese. Worldwide, more people are obese than are malnourished. Obesity is becoming the largest single preventable cause of death and represents a cause of major morbidity and mortality.
- Metabolic syndrome includes abdominal obesity, decreased high-density lipoprotein, increased insulin, glucose in tolerance, and hypertension and is present in approximately 50 million people in the United States alone.
- The greatest risk factor for sleep apnea is obesity, including increased oral and pharyngeal tissue. This condition makes ventilation through a mask, tracheal intubation, and even extubation more challenging.
- Choices for medical management of obesity are limited and not usually successful alone. Changes in behaviors are important for success.
- Surgery for obesity is recommended at a body mass index (BMI) of 40 kg/m^2 or BMI greater than 30 kg/m^2 when comorbidities such as hypertension, diabetes, and hypercholesterolemia are expected to improve with weight loss secondary to surgical therapy. In clinical trials, long-term survival is better in surgically treated groups as compared with medically managed patients.
- Preoperative evaluation should focus on cardiopulmonary issues and securing an airway, along with other concerns such as diabetes, hypertension, and obstructive sleep apnea (see also Chapter 38).
- Selection of anesthetic drugs should be based on lipid solubility and increased incidence of lingering respiratory depression effects.
- Preparation and positioning (see Chapter 41) are keys to successful airway management. Preoperative pressure support ventilation should be used adjunctively if possible.
- Intraoperative ventilation is assisted by complete paralysis, moderate positive end-expiratory pressure, tidal volumes based on ideal body weight, and recruitment maneuvers as needed.
- Common serious postoperative complications are deep vein thrombosis and surgical staple line issues.
- Obese patients presenting for non–weight loss surgery benefit from anesthetic approaches similar to those used for bariatric surgery.

OBESITY AS A DISEASE

Obesity is one of the great epidemics of the twenty-first century.[1] Worldwide, obesity was considered a rarity until the middle of the previous century,[2] but now 1.6 billion overweight individuals and more than 400 million obese people live on the planet, including a significant proportion of the adult population in the United States.[3-5] Current estimates are that more than 78 million Americans, or 35.7% of the U.S. adult population,[6] are overweight or obese. Obesity and its associated health concerns are now major causes of morbidity and mortality resulting in an enormous impact on health care spending. More than 300,000 deaths per year in the United States and approximately $147 billion[7,8] in annual health care spending are attributable to obesity, thus placing this condition second only to smoking as a preventable cause of death.[7]

Obesity can be defined as a disease because it is a physiologic dysfunction of the human organism with environmental, genetic, and endocrinologic etiologies.[7] Obesity most frequently develops when food caloric intake exceeds energy expenditure over a long period of

time. Factors influencing obesity involve either energy intake or energy expenditure, and they are influenced by genetic, behavioral, cultural, and socioeconomic factors.[9] For example, some syndromes are associated with obesity, including leptin deficiency, Prader-Willi syndrome, and Lawrence-Moon-Biedl syndrome.[4] Metabolic factors can influence energy regulation, including hormones, peptides, nutrients, uncoupling proteins, and neural regulatory substances emanating from gut, liver, brain, and fat cells, but most of these factors are not well understood.

The body mass index (BMI) is the most widely applied classification tool used to assess individual weight status.[10] The BMI is specifically defined as the patient's weight, measured in kilograms, divided by the square of the patient's height, measured in meters, to yield a measurement bearing units of kilograms per square meter (kg/m^2). Figure 71-1 shows a family of iso-BMI curves for BMI ranging from 13 to 50 and mapped on axes for height (in both inches and centimeters) and weight (in both pounds and kilograms). By using this system, patients are classified according to BMI, and the associated risk of developing health problems is shown in Table 71-1. Patients are considered overweight if they have a BMI between 25 and 29.9 kg/m^2, and they are classified as obese with a BMI between 30 and 49.9 kg/m^2. The obese classification is further subdivided into class 1 (BMI range, 30 to 34.9 kg/m^2), class 2 (35 to 39.9 kg/m^2), and class 3 (40 to 49.9 kg/m^2). Patients with a BMI of 50 kg/m^2 or greater are classified as superobese. As BMI increases beyond normal weight, the risk of developing serious health problems rises greatly and can be correlated with the individual's waist circumference (Table 71-2). Malnourishment and malnutrition are commonly offered as explanations for the finding that underweight patients are also at increased risk for developing illnesses.

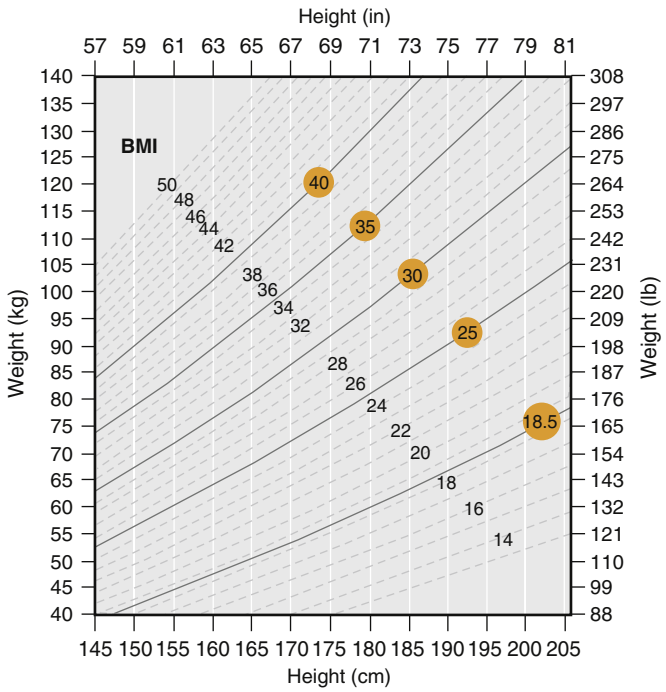

Figure 71-1. A family of iso–body mass index (iso-BMI) curves for BMI ranging from 13 to 50 and mapped on axes for height (in both centimeters and inches) and weight (in both kilograms and pounds).

Certain specific diseases are commonly associated with obesity, and obesity is often accompanied by multiple, and not single, comorbid states.[9] These disorders frequently include insulin resistance, type 2 diabetes mellitus, obstructive sleep apnea (OSA), asthma, chronic obstructive pulmonary disease, hypoventilation, cardiovascular disease, hypertension, certain malignant diseases, and osteoarthritis.[1,11-21] Virtually every organ system can be included in the extended list of health risks associated with having an abnormally elevated BMI. A listing of the most common specific disease states along with their obesity-associated risk is detailed in Table 71-3. As a result, obesity is also associated with early death.[10,22] Of the health risks included in Table 71-3, metabolic syndrome and OSA merit additional attention because they pose special concerns for the anesthetic care of obese patients.

METABOLIC SYNDROME

The clustering of a group of defined metabolic and physical abnormalities is now referred to as *metabolic syndrome*.[23] Patients with metabolic syndrome commonly have abdominal obesity, reduced levels of high-density lipoprotein (HDL), hyperinsulinemia, glucose intolerance, hypertension, and other characteristic features,[17] as listed in Box 71-1. Specific criteria for diagnosing metabolic syndrome are included in Table 71-4. The diagnosis requires that at least three of the following be present: abdominal obesity, elevated fasting glucose, hypertension, low HDL, and hypertriglyceridemia.[24] Weight gain with visceral obesity is a major predictor of metabolic syndrome. The clinical approach uses waist circumference, rather than BMI, to define the adipose mass

TABLE 71-1 LEVELS OF RISK ASSOCIATED WITH INCREASING BODY MASS INDEX

Classification	BMI (kg/m^2)	Risk of Developing Health Problems
Underweight	<18.5	Increased
Normal weight	18.5-24.9	Least
Overweight	25.0-29.9	Increased
Obese		
Class 1	30.0-34.9	High
Class 2	35.0-39.9	Very high
Class 3	40.0-49.9	Extremely high
Superobese	≥50	Exceedingly high

BMI, Body mass index.

TABLE 71-2 WAIST CIRCUMFERENCE AND RISK

	BMI (kg/m^2)		
Waist Circumference	Normal Weight	Overweight	Obese Class 1
<102 cm (♂) <88 cm (♀)	Least risk	Increased risk	High risk
≥102 cm (♂) ≥88 cm (♀)	Increased risk	High risk	Very high risk

♂, Male; ♀, female; *BMI,* body mass index.

component contributing to metabolic syndrome because BMI has been shown to be a relatively insensitive indicator of the risk for obesity-associated metabolic and cardiovascular diseases. Waist circumference, but not BMI, reflects abdominal subcutaneous adipose tissue as well as abdominal visceral adipose tissue and is therefore a better index of central, or truncal, fat mass.

In the United States, approximately 50 million people have metabolic syndrome, thus giving it an age-adjusted prevalence of almost 24%. Of these patients, more than 83% meet the criterion of abdominal obesity. The incidence of metabolic syndrome increases with age, with more than 40% of the U.S. population affected with obesity by the age of 60 years.[23] Men are affected more commonly than women, and Hispanics and South Asians appear to be particularly susceptible. Its frequency is lower in African American men than in whites. Metabolic syndrome may result from use of some commonly prescribed drugs, including corticosteroid, antidepressant, and antipsychotic agents. Protease inhibitors used to treat human immunodeficiency virus (HIV) infection can induce metabolic syndrome secondary to insulin resistance.

Patients with metabolic syndrome have an increased risk for cardiovascular disease events and are at increased risk for all causes of mortality. Metabolic syndrome increases the risk of type 2 diabetes, which itself is an important risk factor for atherosclerotic disease and may be considered a coronary heart disease equivalent.[16,23] Metabolic syndrome is also associated with many other conditions, such as polycystic ovary syndrome, nonalcoholic fatty liver disease, gallstones, sleep disturbances, sexual impotence, and some forms of cancer. This syndrome has considerable overlap with obesity for comorbid states, as detailed in Table 71-3. In multiple trials involving nearly 1900 patients, morbidly obese individuals had much greater weight loss following bariatric surgery than after nonsurgical therapy, with amelioration of most of the diseases associated with morbid obesity in a year's time.[25] Metabolic syndrome is resolved by bariatric surgery in more than 95% of patients who achieve the expected weight loss.[26] This finding makes it clear that bariatric surgery is a metabolic intervention and not simply a weight management procedure.[27]

TABLE 71-3 HEALTH RISKS ASSOCIATED WITH INCREASING BODY MASS INDEX

Metabolic syndrome	30% of middle-aged people in developed countries have features of metabolic syndrome
Type 2 diabetes	90% of type 2 diabetic patients have a BMI of >23 kg/m^2
HTN	5× risk in obesity 66% of HTN is linked to excess weight 85% of HTN is associated with a BMI >25 kg/m^2
CAD and stroke	3.6× risk of CAD for each unit change in BMI Dyslipidemia progressively develops as BMI increases from 21 kg/m^2 with rise in small-particle low-density lipoprotein 70% of obese women with HTN have left ventricular hypertrophy Obesity is a contributing factor to cardiac failure in >10% of patients Overweight or obesity plus HTN is associated with increased risk of ischemic stroke
Respiratory effects (e.g., OSA)	Neck circumference of >43 cm in men and >40.5 cm in women is associated with OSA, daytime somnolence, and development of pulmonary HTN
Cancers	10% of all cancer deaths among nonsmokers are related to obesity (30% of endometrial cancers)
Reproductive function	6% of primary infertility in women is attributable to obesity Impotence and infertility are frequently associated with obesity in men
OA	Frequent association in older adults with increasing body weight; risk of disability attributable to OA is equal to heart disease and greater than any other medical disorder of older patients
Liver and gallbladder disease	Overweight and obesity are associated with nonalcoholic fatty liver disease and NASH; 40% of patients with NASH are obese; 20% have dyslipidemia 3× risk of gallbladder disease in women with a BMI of >32 kg/m^2; 7× risk if BMI >45 kg/m^2

BMI, Body mass index; *CAD,* coronary artery disease; *HTN,* hypertension; *NASH,* nonalcoholic steatohepatitis; *OA,* osteoarthritis; *OSA,* obstructive sleep apnea.

BOX 71-1 ***Features Associated With Metabolic Syndrome***

Abdominal obesity
Atherogenic dyslipidemia (↑ TGs, ↓ HDL cholesterol, ↑ ApoB, ↑ small LDL particles)
Elevated blood pressure
Insulin resistance ± glucose intolerance
Proinflammatory state (↑ hs-CRP)
Prothombotic state (↑ PAI-1, ↓ FIB)
Other (endothelial dysfunction, microalbuminuria, polycystic ovary syndrome, hypoandrogenism, nonalcoholic fatty liver disease, hyperuricemia)

ApoB, Apolipoprotein-B; *FIB,* fibrinogen; *HDL,* high-density lipoprotein; *hs-CRP,* high-sensitivity C-reactive protein; *LDL,* low-density lipoprotein; *PAI-1,* plasminogen activator inhibitor; *TGs,* triglycerides.

TABLE 71-4 CLINICAL CRITERIA FOR DIAGNOSING METABOLIC SYNDROME*

Criteria	Defining Value
Abdominal obesity	Waist circumference >102 (>88) cm in men (women)
Triglycerides	≥150 mg/dL
HDL cholesterol	<40 (<50) mg/dL in men (women)
Blood pressure	≥130/85 mm Hg
Fasting glucose	≥110 mg/dL

HDL, High-density lipoprotein.
*Three of five criteria must be met.

Inflammatory processes appear to play an important role in metabolic syndrome.[19] Adipose tissue has two major functions: (1) storage and release of energy-rich fatty acids and (2) secretion of proteins required for endocrine and autocrine regulation of energy metabolism. Adipocytes exert their metabolic effects by release of free fatty acids, a process enhanced by the presence of catecholamines, release of glucocorticoids, increased β-receptor agonist activity, and reduction of lipid storage mediated by insulin. Visceral adipose tissue has been identified as an important source of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6), as well as antiinflammatory cytokines such as adiponectin. Increased levels of proinflammatory cytokines likely contribute to the etiology of insulin resistance primarily by obstructing insulin signaling and contributing to down-regulation of peroxisomal proliferator-activated receptor-γ, processes that are fundamentally important regulators of adipocyte differentiation and control. Additionally, insulin resistance may promote inflammation through diminution of insulin's antiinflammatory effects. Finally, oxidative stress is increased in obesity, primarily as a result of excessive intake of macronutrients and a concomitant increase in metabolic rate. These factors may also contribute to the inflammatory response noted in obesity.[19]

Native immune responses act aberrantly in obese individuals. Natural killer (NK) cell cytotoxic activity is depressed in obesity, as are plasma levels of cytokines such as IL-12, IL-18 and interferon-γ known to regulate NK cell function.[28] Other cytokines (primarily IL-6 and TNF-α) and adipokines (leptin, adiponectin, and adipose-derived resistin) are two additional major groups of inflammatory proteins produced and released by adipose and adipose-associated tissue.[19] Both serum and adipose tissue obtained from obese subjects consistently have elevated levels of IL-6 and TNF-α, and circulating levels of IL-6 are consistently increased in individuals having either type 2 diabetes or impaired glucose tolerance. Proteins such as leptin and adiponectin, which are produced primarily by adipocytes, are classified as adipokines. Although leptin is primarily involved in appetite control, its immunologic effects include protection of T lymphocytes from apoptosis and regulation of T-cell activation and proliferation. Reduced leptin levels may increase appetite and slow metabolism, but they may also increase susceptibility to the toxicity of proinflammatory stimuli, such as endotoxin and TNF-α. Elevated leptin levels are proinflammatory, and this feature likely plays an important role in the progression of heart disease and diabetes, especially in obese patients. Serum levels of adiponectin correlate with insulin sensitivity and do not rise in obesity. Significantly reduced adiponectin levels are found in patients with type 2 diabetes. Adiponectin reduces both TNF-α production and activity. It also inhibits IL-6 production. Resistin, an adipokine that induces insulin resistance, is induced by endotoxin and cytokines. Resistin acts at the cellular level to up-regulate production of proinflammatory cytokines, most likely through the nuclear factor κB (NFκB) pathway. Resistin appears to present a molecular link among metabolic signaling, inflammatory processes, and the development of cardiovascular disease. Resistin levels have been associated with inflammatory markers apparently independently of BMI in humans.[19]

An understanding of the role of NFκB in insulin resistance is required to appreciate fully the links between obesity and inflammation. Both free fatty acids and TNF-α act through intracellular inflammatory cascade pathways to arrest insulin signaling. This process is mediated by activation of transcription factors present within the cell cytoplasm, which, following their translocation to the nucleus, eventually bind to transcription factors regulating the inflammatory process. The cytoplasm also contains NFκB, another transcription factor whose activation is implicated in a number of diseases, including diabetes. NFκB is also induced by hypoxia, and it increases production of proinflammatory cytokines TNF-α and IL-6, both of which are frequently increased in patients with OSA syndrome.[19] Therefore, inflammation provides the common linkage underlying the association of obesity, metabolic syndrome, and OSA.[29]

OBSTRUCTIVE SLEEP APNEA AND HYPOPNEA SYNDROME

OSA and obstructive sleep hypopnea are related conditions characterized by recurrent episodes of upper airway obstruction occurring during sleep (see Chapters 14 and 38).[30] OSA is defined as episodic complete cessation of airflow during breathing lasting 10 seconds or longer despite maintenance of neuromuscular ventilatory effort, occurring five or more times per hour of sleep, and accompanied by a decrease of at least 4% in arterial oxygen saturation (Sa_{O_2}). Obstructive sleep hypopnea is defined as episodic partial reduction of airflow of more than 50% lasting at least 10 seconds, occurring 15 or more times per hour of sleep, and accompanied by a decrease of at least 4% in the Sa_{O_2}. The diagnosis can be made only in patients who undergo polysomnography, or a sleep study, during which the patient's electroencephalogram, electrocardiogram, electrooculogram, capnogram, nasal or oral airflow, esophageal pressure, arterial blood pressure, pharyngeal and extremity electromyograms, pulse oximetry, and room noise are typically monitored and recorded.[30] Results of polysomnography are reported as the apnea/hypopnea index (AHI), which is derived from the total number of apneas and hypopneas divided by the total sleep time. A normal lower limit for AHI has not yet been defined in an epidemiologic study of healthy subjects. Most sleep centers commonly use an AHI between 5 and 10 events per hour as a normal limit. The severity of OSA/hypopnea syndrome (OSAHS) is arbitrarily defined, but recommendations for disease classification are as follows[30]:

Mild disease: AHI of 5 to 15 events per hour
Moderate disease: AHI of 15 to 30 events per hour
Severe disease: AHI of greater than 30 events per hour

Because of the risks of developing systemic and pulmonary hypertension, left ventricular hypertrophy, cardiac arrhythmias, cognitive impairment, persistent daytime somnolence, and other factors, treatment is recommended for patients with either moderate or severe disease. Treatment partly depends on the severity of the

sleep-disordered breathing, but the consensus view is that patients with moderate or severe disease should be treated with continuous positive airway pressure (CPAP) during sleep. Other conservative treatment measures may include weight loss, avoidance of alcohol before bedtime, and sleeping on one's side.

Obesity is the greatest risk factor for OSAHS. Approximately 70% of patients (≤80% of men and ≤50% of women) with OSAHS are obese. Severe sleep apnea disease is more common in men, and a strong negative correlation between the AHI and minimum Sa_{O_2} has been observed. The diagnosis of OSAHS may be missed until the patient presents for surgery. In a study of 170 patients presenting for surgery, only 15% had already been diagnosed with sleep apnea, but on preoperative testing, 76% of the patients in the study were found to have OSAHS.[31] I believe it is important for obese patients presenting for bariatric surgery to undergo preoperative polysomnography testing for OSAHS. Preoperative diagnosis and appropriate interventional management can have the following benefits: less postoperative sleep deprivation, improved response to analgesic and anesthetic drugs, and normalization of cardiovascular disturbances.[32]

Anatomically, obese patients with OSAHS typically have increased amounts of adipose tissue deposited into oral and pharyngeal tissues including the uvula, tonsils, tonsillar pillars, tongue, aryepiglottic folds, and lateral pharyngeal walls. An inverse relationship exists between the degree of obesity and pharyngeal area. Deposition of fat in the lateral walls decreases the size of the airway and changes the shape of the oropharynx into an ellipse with a short transverse and long anteroposterior axis.[33-35] This configuration can contribute to both the development and severity of airway obstruction and can also increase the expectation that it will be more difficult to maintain airway patency during mask ventilation and to perform direct laryngoscopy for endotracheal intubation with general anesthesia.[36,37] Additionally, airway obstruction following tracheal extubation is likely to be complicated by the use of opiate and sedative drugs needed for postoperative pain management because these drugs tend to decrease pharyngeal dilator tone and increase the likelihood of upper airway collapse.[36]

OSA also plays an important role in inflammation and metabolic syndrome.[19,29] The hypopneic and apneic events that occur in OSAHS are part of the cycle of events that involves both arousal from rapid eye movement (REM) sleep and oxyhemoglobin desaturation. Sympathetic nervous system activation results as patients with untreated OSA undergo cyclic episodes of hypoxia and reoxygenation. This process leads to elevation of proinflammatory cytokines and may also induce oxidative stress of vascular endothelium, thus inducing an even more heightened state of systemic inflammation in obese patients with OSA.[29] Levels of many different inflammatory mediators, including IL-6, high-sensitivity C-reactive protein (hs-CRP), leptin, TNF-α, IL-1, reactive oxygen species, and adhesion molecules, such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), are increased in patients with OSAHS.[19] Thus, obesity, metabolic syndrome, and OSAHS are interrelated diseases that significantly alter a patient's inflammatory disease profile and increase multiple health risks, particularly those of cardiovascular and airway origin. Surgical intervention causes weight loss and improves obesity-related respiratory disease,[13] but significant and sustained increases in plasma adiponectin levels can occur. In addition, both IL-6 and hs-CRP levels[38] decrease as well as improve NK cell function, and they increase IL-12, IL-18, and interferon-γ plasma levels.[28]

NONSURGICAL MANAGEMENT OF OBESITY

The primary goals of nonsurgical management of obesity involve weight loss, treatment of abnormalities associated with metabolic syndrome, and prevention of type 2 diabetes and cardiovascular disease–related events. Treatment of metabolic syndrome needs to follow an aggressive, multifaceted approach to address multiple underlying metabolic abnormalities and coexistent risk factors simultaneously.[23] Appropriate initial treatment of obesity and metabolic syndrome is therapeutic lifestyle change. This change includes dietary modification, weight loss, physical activity, and discontinuation of smoking. The treatment aim is improvement in health, and it is the primary reason for advocating weight loss. Modification of energy homeostasis is not easily achieved because a strong brain-gastrointestinal axis drives both food intake and satiety. This axis has hormonal components involving endogenous production of ghrelin, an orexigenic peptide that is produced by the foregut of the stomach and that stimulates appetite.[39] Therefore, the effects of treatment on risk factors and comorbidities at the systems, organ, cell, and molecular levels should be monitored. Treatment success should be reflected in the decreasing need to treat other coexisting diseases.

The goal for weight loss in therapeutic lifestyle change is not achievement of normal or ideal body weight. Even a modest weight loss, in the range of 5% to 10% from the patient's presentation weight, can result in significant initial improvement in the comorbidities of diabetes, dyslipidemia, and hypertension by lowering total cholesterol and triglyceride levels, raising HDL cholesterol, lowering arterial blood pressure, and lowering blood glucose values while reducing insulin resistance.[23,40] Obesity guidelines stress the need for weight reduction using behavioral change to reduce caloric intake and increase physical activity. Reduced-energy diets are more effective and healthier for achieving long-term weight loss. Long-term maintenance of any weight loss achieved is best accomplished with the inclusion of regular exercise as a staple of the weight-reduction regimen. Regular physical exercise improves several risk factors associated with obesity and metabolic syndrome.[41] The standard exercise recommendation is a daily minimum of 30 minutes of moderate-intensity physical activity that is practical to perform. Larger weight loss goals are more appropriate for more profoundly obese individuals who are contemplating surgical interventions. Even with surgery, ideal weight is hardly ever achieved, and after a number of years at a plateau, weight gain often recurs. In some patients, especially those with severe comorbidities, simple prevention of additional weight gain may be the most reasonable goal.

Beyond the beneficial effects of therapeutic lifestyle change, specific intervention may be required to treat the dyslipidemia and hypertension associated with obesity and metabolic syndrome.[42] Most commonly, patients with metabolic syndrome have elevated triglyceride levels and low HDL cholesterol levels. Many patients receive statin therapy as the treatment of choice when low-density lipoprotein (LDL) cholesterol levels are excessive. Statins reduce cardiovascular disease risk in patients with type 2 diabetes and metabolic syndrome. Ezetimibe, which selectively inhibits intestinal cholesterol absorption, can be combined with statin therapy to further reduce LDL cholesterol by 15% to 20%. Fibrates effectively decrease triglyceride levels while increasing HDL cholesterol. Fibrates lower LDL cholesterol levels mildly, but when combined with statin therapy, fibrates may increase the risk of myopathy. Omega-3 fatty acids decrease triglyceride levels and improve insulin resistance in patients with metabolic syndrome. These fatty acids are often used in combination therapy with other classes of hypolipidemic drugs. Nicotinic acid is highly effective in raising HDL cholesterol levels in patients with metabolic syndrome. Nicotinic acid decreases the concentration of small, dense LDL particles and also lowers serum levels of lipoprotein (a).[42]

Dietary salt restriction and therapeutic lifestyle change are the primary means to address hypertension in obesity and metabolic syndrome. Patients whose blood pressure is higher than 140/90 mm Hg require antihypertensive drug therapy. No specific antihypertensive agent is recommended as a first-line treatment in these patients, and generally the goal of antihypertensive therapy requires that polypharmacy be employed. A considerable element of the risk reduction resulting from antihypertensive therapy is decreasing arterial blood pressure.

The treatment of insulin resistance and hyperglycemia in metabolic syndrome, type 2 diabetes, and obesity is usually achieved with oral hypoglycemic drugs.[42] Several different drug groups (and drugs within each group) that work through various mechanisms of action are available to treat hyperglycemia. These include α-glucosidase inhibitors, sulfonylureas, meglitinides, D-phenylalanine derivatives, diguanides, and thiazolidinediones.[42] Anesthetic implications include the need to assess and treat abnormal blood glucose levels in the perioperative period while being especially careful in the use of insulin in patients who are both insulin resistant and temporarily unable to continue oral medication. The anesthetic management of patients who are taking metformin is not clear. Postoperative lactic acidosis can develop in patients using this drug. This possibility has led some physicians routinely to cancel or delay surgical procedures if metformin has been ingested within 48 hours of the scheduled surgery. Other physicians, however, have their patients continue taking metformin, both before and after surgery, without interruption if possible. Overall, patients taking metformin have a reduced risk for complications. It appears that metformin may be safely used in the perioperative period.[43]

Patients with metabolic syndrome and obesity may also be prescribed antiplatelet therapy. The American Heart Association currently recommends that low-dose aspirin be used as a form of primary prevention in patients with metabolic syndrome whose 10-year risk for cardiovascular disease is 10% or greater as determined by Framingham risk scoring.

BEHAVIORAL INTERVENTIONS AND MODIFICATION

Behavioral interventions and behavioral modification are essential for obese patients to change their learned habits related to eating and physical activity to produce weight loss and long-term weight reduction.[42] This applies to both nonsurgical and surgical approaches to weight loss. The key features of typical behavioral programs include self-monitoring, goal setting, nutrition and exercise education, stimulus control, problem solving, cognitive restructuring, and relapse prevention. Patients often benefit from referral to multidisciplinary weight loss programs that incorporate diet, physical activity, and behavioral interventions to achieve their weight loss goals because these combined interventions provide the best weight loss and weight maintenance results without pharmacologic or surgical intervention. However, it is essential to identify and treat patients with eating disorders or major psychiatric disorders who require specialized psychiatric and psychological treatment to achieve meaningful weight loss.

PHARMACOTHERAPY FOR WEIGHT LOSS

Recommendations for pharmacotherapy as a treatment of obesity first and foremost stress lifestyle and behavioral modifications as the initial approaches to weight loss.[29] Patients who do not reach their established reasonable weight loss goals by a combination of diet and exercise may be directed to pharmacotherapy to increase weight loss. Some weight loss drugs have been approved by the U.S. Food and Drug Administration (FDA) and are currently prescribed for long-term use. These drugs are typically used adjunctively with diet and exercise for patients having a BMI of 30 or greater (≥27 for patients with obesity-related risk factors or comorbid diseases). In current practice, only two categories of weight loss drugs (appetite suppressants and lipase inhibitors) have been approved, and only two drugs are currently available for the specific indication of weight loss—phentermine and orlistat.[42] Phentermine, an adrenergic reuptake inhibitor, augments adrenergic signaling within the central nervous system and peripheral tissues. Phentermine decreases appetite and food intake and increases resting metabolic rate to promote weight loss. Its side effects include tachycardia and hypertension. Orlistat, a lipase inhibitor, reversibly binds to lipase and prevents both absorption and digestion and absorption of certain dietary fats. Because orlistat also interferes with the absorption of fat-soluble vitamins, patients using this drug need to supplement fat-soluble vitamins A, D, E, and K. Orlistat has significant gastrointestinal side effects including diarrhea, steatorrhea, flatulence, fecal incontinence, and oily rectal discharge. A third drug, sibutramine, which is a centrally acting serotonin-orepinephrine reuptake inhibitor that suppresses appetite and increases thermogenesis, was

removed from the United States market in 2010 because of an increased risk of stroke and acute coronary syndrome.

DIETARY AND HERBAL MEDICATIONS

Allison and colleagues reviewed the literature on dietary and herbal medications for weight loss.[44] These drugs are marketed as food supplements, thereby escaping the purview of the FDA. Even though these supplements cannot legally claim to treat a disease, they can claim to reduce the risk of a disease. According to the review, claims for weight loss have been made for multiple products such as chitosan, chromium picolinate, conjugated linoleic acid, ephedra alkaloids (*ma huang*),[45] and *Garcinia cambogia*.[44] Most of the reports involving these compounds are from poor-quality studies without any randomization, control groups, or blinding, thereby placing in question both the efficacy and safety of these compounds. The only studies involving herbals that have consistently demonstrated weight loss involve combinations of ephedrine and caffeine.[46,47] Pharmacologically, this effect is expected because ephedrine, an adrenergic agonist, is known to be an appetite suppressant and a thermogenic agent. For this reason, *ma huang*, a natural source of the ephedra alkaloid, is added to most, if not all, dietary supplements marketed for weight loss. The success of ephedrine as a weight loss drug, in combination with caffeine and or aspirin, is well established. Unfortunately, multiple cases of cardiac and neurologic issues, including hypertension, stroke, seizure, and even death have been reported,[48] possibly related to the inconsistent doses in the preparations and the lack of medical supervision in people consuming these products for weight loss. Consequently, the National Institutes of Health has banned these products from any recommended weight loss regimen.

IMPLANTED ELECTRICAL STIMULATORS

Implantable gastric stimulators are subcutaneously placed devices that resemble cardiac pacemakers and stimulate along the lesser curvature of the stomach. These gastric stimulators have been tried since the early 2000s and have been found to cause modest weight loss with few side effects.[49,50] These studies have been performed in Europe, and trials are ongoing in the United States. One study documented a 25% excess weight loss, improved response to oral glucose tolerance test, decreases in blood pressure, and an improvement in symptoms of gastroesophageal reflux disease, along with an increased parasympathetic drive. No serious side effects were noted in the first 65 patients reported on in this study[49] or in the 20 patients followed in another study.[50] Ghrelin levels may play a role in the success of these devices.

SURGICAL MANAGEMENT OF OBESITY

Adult obesity is rooted in childhood obesity. One of the principal predictors of adult obesity is childhood obesity. Large children grow up and become large adults. Unfortunately, pediatric obesity is the most common childhood nutritional disorder in the United States. This is one of the tragedies of the current obesity epidemic: the significant and increasing prevalence of obesity in the young. The concern has increased such that public policy has been developed to regulate placement of vending machines in schools and availability of sweetened snacks and soft drinks in public places as a means to help control the epidemic of pediatric obesity. The diagnosis of pediatric obesity, however, is commonly attained by a definition rendered by the Centers for Disease Control and Prevention (CDC) that uses BMI-, age-, and sex-specific clinical growth charts.[51] These percentile curves apply to the ages of 2 to 20 years, and because BMI exhibits nonlinear variation during growth, percentile ranges are used. The CDC defines children with BMIs in the 5th to 85th percentiles as having "healthy weight." Children whose BMIs are in the 85th to 95th percentile are "at risk for overweight," whereas those having BMIs higher than the 95th percentile are classified as "overweight." These children were previously regarded as "overweight" and "obese," respectively. This switch in terminology continues to be a source of confusion. Exceeding the 99th percentile is referred to as extreme pediatric obesity.

The National Health and Nutrition Examination Survey (NHANES) 2007 to 2008 data show that the prevalence rates of overweight children for age 2 to 5 years, 6 to 11 years, and 12 to 19 years are 10.4%, 19.6%, and 18.1%, respectively. Gender does not appear to influence the prevalence of overweight children after the age of 6 years. However, in the cohort of children 2 to 5 years old, girls have exhibited a doubling in prevalence of obesity since the 1990s, whereas boys have undergone an increase of only 25%. Some developing countries have childhood obesity prevalence rates higher than those of the United States.[52] This finding indicates that adolescent obesity is becoming pervasive.

Treatment of pediatric obesity is based on the balance of caloric intake and expenditure. These lifestyle changes are most successful with family intervention and support. The three pillars of success in this treatment are better eating habits, increased physical activity, and decreased sedentary activity.[53] Success involves more than education of the child and family; it incorporates goal setting, self-monitoring, incentives, and stimulus control. Drugs approved for the treatment of pediatric obesity include orlistat, which is discussed earlier in this chapter.

Although in 2000, less than 1% of all bariatric surgery patients in the United States were younger than 20 years of age,[54] the total number continues to increase. More adolescents are presenting for weight loss surgery, usually gastric banding, after failing to reduce weight and/or comorbidities in medically supervised and pharmacologically assisted weight loss programs. Even though many adult bariatric surgery programs are well qualified to provide safe and effective perioperative care for these patients, they may not be as well equipped to handle the unique metabolic and psychological needs of teenagers. Because of the shorter duration of obesity and fewer age-related comorbidities, adolescent patients have shorter length of stay and lower immediate postoperative mortality when compared with adults.[54]

Consent is an important issue in this population. Is parental consent to a semielective, relatively high-risk

procedure appropriate? Does the child really understand the concept of high risk of death in the month after surgery? These and other such questions of ethics in medicine need to be addressed, but they are beyond the scope of this chapter.

The rapid increase in the prevalence of both morbid obesity and superobesity, together with the increased risk of early demise within the obese population, has significantly increased the number of bariatric surgical procedures performed annually. The term *bariatric surgery* refers to surgical alteration of the small intestine or stomach with a view toward producing weight loss. It is estimated that more than 225,000 bariatric surgical procedures are performed annually in the United States. Care of obese patients is not limited to obesity surgery, however, because these patients present for all types of operations. Nonetheless, the benefits of surgical treatment of obesity now appear to have clear endocrinologic and cardiovascular value for reversing pathophysiologic effects of metabolic syndrome, type 2 diabetes, and other comorbidities of obesity, in addition to providing a mechanical means of enhancing weight loss.[55-61] Several alternative procedures are performed in bariatric surgery, which has evolved from early procedures based on creating malabsorptive gut pathways to newer procedures aimed at altering hormonal regulation of caloric intake drive and satiety.[62] The available operations all fall into one of two groups at present: (1) gastric restrictive procedures and (2) procedures that combine gastric restriction with induction of nutrient malabsorption.[63-72]

RESTRICTIVE PROCEDURES

The surgical goals of restrictive operative procedures are to reduce and limit the patient's food intake capacity.[69] These goals are most commonly achieved by creating a small pouch from the proximal stomach just distal to the gastroesophageal junction. Construction of the newly created pouch allows it to drain through only a narrow opening. This configuration increases the mechanical resistance to gastric emptying for ingested solids, whereas emptying of liquids proceeds normally. The vertical band gastroplasty (VBG) was a widely practiced restrictive procedure in the 1990s and early 2000s, but it has been largely replaced by the minimally invasive laparoscopic gastric band procedure (LGB), which is illustrated in Figure 71-2. A specific advantage of the LGB is avoidance of permanent alteration of gastric anatomy through tissue stapling. Laparoscopic gastric banding has an exceptional safety record with an exceedingly low operative mortality, although reoperation rates for minor problems are nontrivial.[72]

MALABSORPTIVE PROCEDURES

The surgical goal of malabsorptive procedures is to cause weight loss both by gastric restriction and nutrient malabsorption. Historically, early surgical procedures involved creation of a long jejunoileal bypass. Patients achieved significant weight reduction, but this was commonly accompanied by an unacceptable incidence of serious vitamin and protein malabsorption, osteoporosis, and hepatic failure.

At present, gastric bypass (GBP), which is illustrated in Figure 71-3, and biliary pancreatic diversion (BPD) are the two commonly performed malabsorptive operations, and both have achieved success in safety and efficacy.[69] Newer modifications, such as robotic bariatric surgery[73] and the single-incision transumbilical laparoscopic[74] approach to bariatric surgery, are used to achieve the same surgical manipulation of the gastrointestinal tract, and they alter only the cost of the procedure and decrease the wound size and resultant cosmesis of the operation performed. GBP is more commonly performed than BPD, and it is considered the safer of the two malabsorption procedures. GBP involves the creation of a small gastric pouch by stapling or banding the stomach. This results in an element of gastric restriction. GBP also involves the creation of a Roux-en-Y anastomosis, in which the small gastric pouch is directly connected to the middle portion of the jejunum.[75] The path for food through the gastrointestinal tract subsequently bypasses the gastric remnant and the upper portion of the duodenum. This procedure can be performed with a laparotomy incision or by using laparoscopic techniques.[74,76] Although this operation is considered safe, the associated perioperative mortality is higher than that of LGB.[66] Additionally, some important long-term complications such as vitamin B_{12} deficiency, anemia, incisional hernia, cholelithiasis, and staple line failure occur with significant frequency. Often, cholecystectomy is performed concurrently to prevent future cholelithiasis.[77]

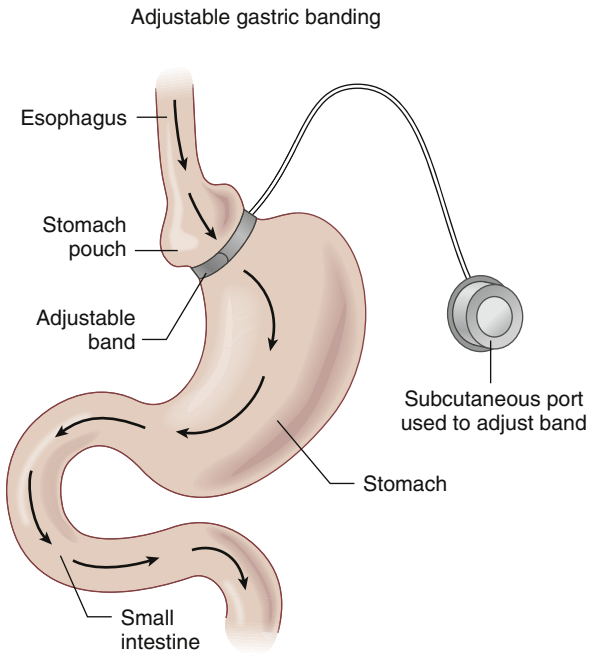

Figure 71-2. Gastric banding: An adjustable band is placed on the stomach. Connected to the band is a piece of tubing with a port at the other end. The port is placed just under the skin. To adjust the tightness of the band, a special needle is inserted in the port. Fluid can be added to the band to make the passageway smaller or remove fluid from the band to make the passageway larger.

BPD is also a form of Roux-en-Y GBP reconstructive alimentary anatomy in which the bypassed intestinal segment includes the portion of duodenum at the point of entry of biliary and pancreatic secretions. This allows the bypassed intestine to be exposed to bile and pancreatic juice. The antrum is removed to avoid peptic ulceration, and food intake is only affected to a limited degree. The essential element of this operation is division of the small intestine about midlength, with the distal end of the alimentary limb anastomosed to a generous gastric remnant. The more proximal biliopancreatic limb is anastomosed to the alimentary limb approximately 50 cm from the ileocecal valve. Following either the GBP or BPD form of bariatric operation, patients require lifelong follow-up and may need micronutrient replacement long term.

HEALTH BENEFITS OF BARIATRIC SURGERY

The two most significant outcome measures of bariatric surgical success are weight loss and resolution of comorbidities. Major effects of bariatric operations have been nicely summarized in three extensive meta-analyses,[57,78,79] as well as in a major literature review.[78] Absolute weight loss averaged 46.4 kg for BPD, 43.5 kg for GBP, 39.8 kg for VBG, and 28.6 kg for gastric banding. This magnitude of weight loss is far greater than what is commonly achievable by nonsurgical methods, and it is considerably closer to patients' desired and expected weight loss. Long-term maintenance of weight loss of this magnitude can also be maintained for more than a decade.

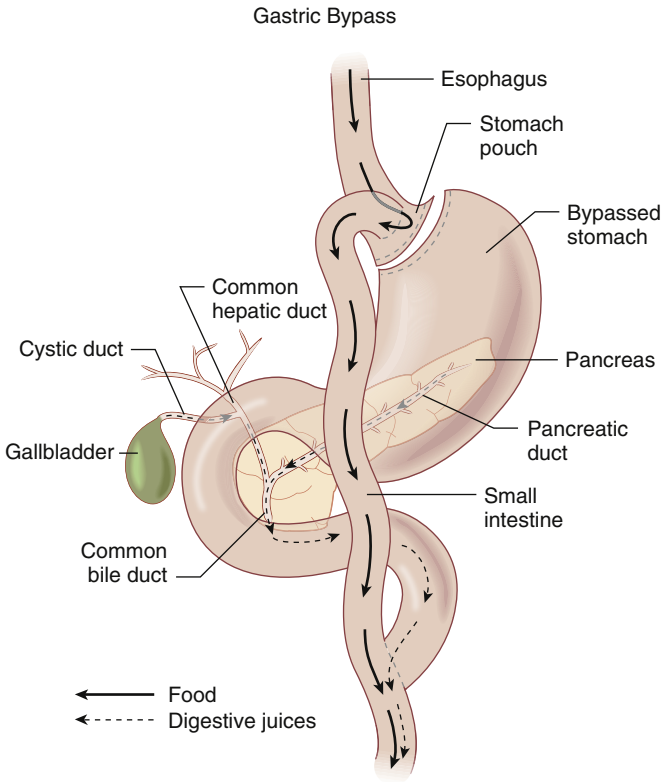

Figure 71-3. Roux-en-Y gastric bypass: Part of the stomach is detached from the rest, to create a small pouch. The pouch is connected to a lower part of the small intestine by a piece of small intestine, resembling a Y. As a result, parts of the stomach and small intestine are bypassed. However, digestive juices (bile acids and pancreatic enzymes) can still mix with the food, thus enabling the body to absorb vitamins and minerals and reducing the risk of nutritional deficiencies.

Improvements in obesity-related and metabolic syndrome–related comorbidities have also been evaluated.[57,79-81] Diabetes improved in more than 85% of patients and resolved in more than 75% overall (98.9% for BPD, 87.3% for GBP, 71.6% for VBG, and 47.9% for gastric banding). Resolution of diabetes following surgery is inversely related to the preoperative duration of the disease and occurs more in those patients whose diabetes is controlled using oral hypoglycemic agents. This finding clearly distinguishes surgical treatment of obesity as an important endocrinologic intervention, especially because the modest improvement in diabetes management that is produced by nonsurgical weight loss is accompanied by relapsing disease in nearly 100% of patients within 5 years. Surgical effects on hyperlipidemia are similarly impressive. Approximately 70% of the entire population experienced improvement, with greatest, intermediate, and least change occurring after BPD, GBP, and gastric banding, respectively. Hypertension resolved in more than 60% of patients, and it improved in more than 18% more patients. Postsurgical effects on hypertension were greatest after BPD (83%), intermediate after GBP (67.5%) and VBG (69%), and least after gastric banding (43%). Resolution of OSAHS seems to be independent of the specific bariatric surgical procedure employed; resolution occurred overall in 85.7% of patients. Postsurgical improvements in other comorbidities have also been demonstrated; improvement in fatty infiltration of the liver, enhanced respiratory function and reduced asthmatic symptoms, reversal of the cardiomyopathy of obesity, and improvements in joint pain and mobility have all been reported.[61,82-86] The reduction in obesity-related comorbidities endures, as determined by 5-year follow-up assesments.[87] Although bariatric surgery has been shown to provide greater weight loss when compared with nonsurgical lifestyle interventions, comorbidities do resolve and risk factors do improve similarly with successful conservative treatments.[81]

ANESTHETIC MANAGEMENT OF THE BARIATRIC SURGICAL PATIENT

Patients undergoing bariatric surgery are receiving what is now the best long-term treatment for morbid obesity. However, their presurgical state is an agglomeration of abnormal physiologic conditions involving multiple organ systems. For that reason, considerable risks of mortality and morbidity are associated with all types of bariatric surgery. Preoperative risk stratification can be used to identify patients at highest risk for significant morbid or fatal events related to bariatric surgery.[88] However, detailed planning of anesthesia care for the perioperative, intraoperative, and postoperative phases must be pursued for the purposes of patients' safety.

PREOPERATIVE EVALUATION

The preoperative assessment for anesthesia should include consideration of hypertension, diabetes, heart failure, and obesity hypoventilation syndrome (see also Chapters 14 and 38). Results of the patient's sleep study are important. An AHI score greater than 30, implying severe sleep apnea, is a warning sign and a predictor for rapid and severe desaturation during induction of anesthesia. CPAP levels more than 10 cm H_2O imply a patient with the potential for difficult ventilation by mask.

Another useful piece of information in the preoperative evaluation is gleaned by examining the history of prior surgical procedures, their anesthetic challenges (i.e., ease or difficulty in securing the airway, intravenous access), need for admission to an intensive care unit, surgical outcomes, and the weight of the patient at that time. This information may either help ease some concerns or allow us to better prepare for the upcoming anesthetic care. Recommended preoperative laboratory evaluations include fasting blood glucose, lipid profile, and serum chemistries (evaluating renal and hepatic function), complete blood count, ferritin, vitamin B_{12}, thyrotropin, and 25-hydroxyvitamin D.

If appropriately evaluated, ideally prepared, and optimally managed perioperatively, even patients with well-known coronary artery disease (CAD) have morbidity and mortality comparable to those in patients without CAD.[89] The effect of OSA on perioperative risk remains controversial,[90] but most patients are screened for OSA with overnight oximetry or polysomnography, or both, if appropriate. If identified with OSA and recommended for CPAP, then patients are encouraged to initiate therapy at home, and this therapy should be continued throughout the perioperative period.

Liver function abnormalities are common in this patient population, especially nonalcoholic fatty liver disease, with the extent of disease a determining factor for perioperative risk and postoperative outcomes. Cirrhotic liver disease with portal hypertension may be considered a contraindication to bariatric surgery.[90] Gastrointestinal symptoms of dyspepsia may indicate the presence of *Helicobacter pylori* infection, which requires treatment by standard medical regimen.

Factors that may be considered contraindications for bariatric surgery include unstable CAD, uncontrolled severe OSA, uncontrolled psychiatric disorder, mental retardation (IQ < 60), inability to understand the surgery, perceived inability to adhere to postoperative restrictions, continued drug abuse, and malignant disease with a poor 5-year survival prognosis. In most situations, preoperative management of the medical morbidities can help optimize risk and convert high-risk patients to patients with acceptable risk.

The anesthetic care of patients with OSA is complicated by the side effects of anesthetic drugs on an already compromised respiratory system. The common comorbidities in this patient population only accentuate the problem.[91] The change in perioperative risk based on the anesthetic agent used is deduced only from anecdotal reports of different cases. Few trials have been conducted to answer that question definitively. Several questions commonly arise and cannot yet be answered on the basis of scientific evidence: Is it safe to perform procedures in patients with sleep apnea and treat them as outpatients or day surgery patients? What procedures pose sufficient risk to the patient to recommend an overnight hospital stay? Does narcotic use affect this decision? Would the increased role of nonsteroidal antiinflammatory drugs change these recommendations? Factors such as neck size and open versus laparoscopic surgery are being studied with regard to their impact on outcomes. Further research on these and other patient safety–related questions is continuing.

INTRAOPERATIVE CARE

Obese patients present special challenges for the anesthesia provider in airway management, positioning, monitoring, choice of anesthetic technique and anesthetic drugs, pain control, and fluid management. Many of these issues are equally important in the postoperative care of these patients. The most significant and best studied are airway management, including endotracheal intubation, pulmonary physiology, and techniques of maintaining adequate blood oxygenation and lung volume. Specific interventions, techniques, and approaches employed by the anesthesia care team providing anesthesia for obese patients are important determinants of outcomes.

Patient Positioning

Even though no evidence-based studies are available to demonstrate that obese patients have more frequent complications from positioning, it seems fairly intuitive that morbidly obese patients do require extra care in positioning (see also Chapter 41). Even in the supine position, rhabdomyolysis from pressure on gluteal muscles, thus leading to renal failure[92] and death,[93] has been reported. For obese patients placed in the prone position, cushioning gel pads or other weight-bearing rolls may have excessive weight placed on them. Pressure points must be checked carefully, and even though pressure sites may be carefully padded, skin breakdown can still occur. This may cause tissue necrosis and infections, especially in lengthy surgical procedures.[94] It is difficult to protect the dependent hip from pressure effects with patients placed in the lateral decubitus position. Obese patients have excess axillary tissue that may make it impossible or unnecessary to place a traditional axillary roll in this position. In the lithotomy position, the challenge may be in supporting the weight of the patient's legs by using regular, and not oversized, stirrups. To minimize the risk of tissue compression injury or development of compartment syndrome, the duration during which legs are held in stirrups should be as short as possible.[95]

Airway Management

No positioning issue is more important than positioning of the obese individual for laryngoscopy and endotracheal intubation (see also Chapters 41 and 55). These procedures are often considered to be much more difficult to perform in obese patients than in patients having a normal BMI. Difficulty with laryngoscopy and intubation usually results from an obese patient's short, thick neck, large tongue, and significant redundant pharyngeal soft tissue. However, the

correlation between morbid obesity and difficult laryngoscopy and tracheal intubation is not universally observed in clinical practice. It is possible that no difference exists between laryngoscopy and intubation in thin and obese patients. Success is likely to result from a simple but important approach to clinical care, with careful attention paid to patient positioning before induction of general anesthesia. Appropriate positioning plays an important role in providing optimal conditions for successful placement of the endotracheal tube under direct vision.

Studies have been conducted to determine the incidence of difficult laryngoscopy or intubation in the obese population, with mixed findings. One study found an association between oropharyngeal Mallampati classification and BMI as predictors of difficult laryngoscopy.[96] During laryngoscopy, the patients' heads were placed in optimum sniffing position, regardless of BMI. In a study conducted exclusively in obese patients, BMI was not found to be associated with intubation difficulties.[37] A high Mallampati score was identified as a predictor of "potential intubation problems," but intubation by direct laryngoscopy was successful in 99 of 100 patients studied. All patients were positioned with pillows or towels under their shoulders, with the head elevated and neck extended. Another group studied both lean and obese patients and found a Mallampati score of III or IV to be the only independent risk factor for difficult intubation in the obese patients in the study.[97] The authors demonstrated that the Mallampati score had low specificity and low positive predictive values (62% and 29%, respectively) for difficult intubation. They concluded that intubation was more difficult in the obese patients. During intubation, patients were placed in a semirecumbent position (30-degree elevation) with the head in the sniffing position.

In another study, ultrasound was used to quantify the amount of soft tissue between the skin and the anterior aspect of the trachea at the level of the vocal cords.[98] These authors also assessed the airway by measurement of thyromental distance, mouth opening, degree of neck mobility, Mallampati score, neck circumference, and presence of OSA. Only an abundance of pretracheal soft tissue measured ultrasonically and neck circumferences were found to be positive predictors of difficult intubation with laryngoscopy performed with patients in the sniffing position. A meta-analysis of 35 studies was conducted to determine the diagnostic accuracy of preinduction tests for predicting difficult intubation in patients having no airway disease.[99] The incidence of difficult intubation in obese patients was three times higher compared with the nonobese population. This finding may have resulted from suboptimal patient positioning, which was not clearly described in any of the preceding studies. Patient positioning, including ramped positioning or elevating the upper body and head of morbidly obese patients to align the ear with the sternum horizontally, improves laryngoscopic view.[100] In this study, morbidly obese patients were assigned to be in either sniffing position or ramped position for airway management. The study demonstrated a statistically significant difference in laryngeal view, with ramped position providing the superior view.

Based on the evidence from randomized controlled trials and other literature on airway management of obese patients, the trachea should be readily intubated by direct laryngoscopy if the patient is placed carefully in ramped position. This positioning can be achieved using commercially available positioning devices[101] or by building a ramp from blankets or sheets to achieve the desired placement of the patient's head relative to the thorax.[102] Obese patients must be examined for the common objective signs of potential difficult intubation, which include small mouth opening, large and protuberant teeth, limited neck mobility, and retrognathia. Alternative airway management techniques include the use of videolaryngoscope equipment for intubating obese patients,[103] because this equipment is rapidly becoming more readily available. Performance of a topicalized direct laryngoscopy with modest sedation in an awake patient can also be used to assess laryngoscopic view in deciding whether to proceed with induction of general anesthesia or fiberoptic intubation in an awake and sedated patient. Of course, the equipment for emergency airway management, including laryngeal masks and a fiberoptic bronchoscope, should be immediately available.

Another area that requires specific attention during the perioperative period is the obese patient's pulmonary physiology. It is especially important to appreciate techniques to maintain oxygenation and lung volume in caring for the obese patient. First, obese patients have multiple pulmonary abnormalities, including decreased vital capacity, inspiratory capacity, expiratory reserve volume, and functional residual capacity. Second, closing capacity in obese individuals is close to or may fall within tidal breathing, particularly in the supine or recumbent position. Moreover, both lung compliance and respiratory system compliance are low in obesity because patients breathe at lung volumes that are abnormally low.[104] As a result of the underlying physiology, the obese patient is likely to undergo rapid oxygen desaturation, particularly during periods of apnea such as occurs during induction of general anesthesia. The presence of OSA by itself does not independently increase the risk of the patient desaturating during induction of general anesthesia as long as appropriate precautions are instituted.[105] However, after induction of anesthesia and tracheal intubation, patients may continue to derecruit gas exchange units throughout the anesthetic course.[106] Various maneuvers have been studied to preserve oxygenation and maintain lung volume specifically in the obese population.

In one study of the rate of development of hypoxemia in patients during apnea, patients received 100% oxygen by facemask to achieve denitrogenation before induction of general anesthesia.[106] The apneic period was continued after induction of anesthesia until peripheral oxygen saturation (SpO_2) decreased to 90%. Obese patients reached the end point in less than 3 minutes, whereas it took 6 minutes in patients having a normal BMI. Efforts to prevent atelectasis formation and desaturation during induction of general anesthesia in obese individuals include application of continuous positive airway pressure (CPAP) during preoxygenation,[107-109] as well as mask application of positive end-expiratory pressure (PEEP), and mechanical ventilation following induction of anesthesia.[109] Use of

10 cm H_2O CPAP during preoxygenation with the patient in the supine position resulted in a higher arterial partial pressure of oxygen (PaO_2) after intubation and decreased the amount of atelectasis that developed.[83] The combination of CPAP during preoxygenation and PEEP or mechanical ventilation after induction significantly increased the nonhypoxemic apnea duration from 2 minutes, found in controls not receiving CPAP or PEEP, to 3 minutes. Use of 7.5 cm H_2O CPAP during 3 minutes of preoxygenation while supine, however, did not change the time required for obese patients to desaturate to an SpO_2 of 90%.[108] Preoxygenation using 25-degree head-up (back inclined), as opposed to supine, positioning without positive airway pressure did increase the elapsed time needed for anesthetized, apneic, obese individuals to desaturate to an SpO_2 of 92%.[110] The patients in head-up position had a significantly higher PaO_2 after preoxygenation, just before induction. The obesity-associated gas exchange defect depended on the waist-to-hip ratio, an index of the distribution of adipose tissue surrounding the thorax.[111] This study further demonstrated that morbidly obese men are more likely to have poorer pulmonary gas exchange than are morbidly obese women.

In a study conducted to assess the relationship between patient positioning and the development of hypoxemia in obese patients during apnea after anesthetic induction and intubation, patients were ventilated with a 50% oxygen/50% air mixture for 5 minutes before the ventilator circuit was disconnected.[112] Apnea was continued until the SpO_2 decreased to 92%, at which time ventilation was resumed. Patients in the supine position reached the end point in 2 minutes, but it took 30 seconds longer if the supine position with the back elevated 30 degrees was used and 1 minute longer if a 30-degree reverse Trendelenburg position was used. Use of a 30-degree reverse Trendelenburg position in obese patients undergoing bariatric surgery was also shown to reduce the alveolar-to-arterial oxygen difference, as well as increase total ventilatory compliance and reduce peak and plateau airway pressures when compared with the supine position.[113] Vital capacity decreases to a greater extent under general anesthesia in obese patients compared with patients of normal weight.[114]

Various intraoperative maneuvers to maintain lung volume and oxygenation have also been studied. Increasing tidal volume incrementally from 13 to 22 mL/kg in obese patients ventilated under general anesthesia did not improve the gas exchange defect but did increase airway pressures.[115] Use of 10 cm H_2O PEEP has a greater effect in obese patients compared with normal subjects on improving ventilatory mechanics, increasing PaO_2, and decreasing alveolar-to-arterial oxygen difference during general anesthesia with neuromuscular blockade.[116] In addition to PEEP alone, use of a recruitment maneuver such as sustained lung inflation to 55 cm H_2O for 10 seconds, followed by application of PEEP, has been demonstrated to prevent atelectasis from developing and to improve oxygenation, whereas neither PEEP nor a recruitment maneuver alone achieved the same degree of maintenance of pulmonary function.[117]

Pneumoperitoneum during laparoscopic procedures increases pulmonary resistance and decreases dynamic lung compliance.[118] During pneumoperitoneum, alterations in body position, tidal volume, and respiratory rate had no effect on the alveolar-to-arterial oxygen difference in obese patients.[119] During pneumoperitoneum for laparoscopic bariatric surgery, alveolar recruitment by repeated sustained lung inflation to 50 cm H_2O followed by mechanical ventilation with 12 cm H_2O PEEP increased PaO_2 intraoperatively, at the expense of causing hypotension that required vasopressor use.[120] In an attempt to optimize PEEP in obese patients undergoing LGB surgery, a normal functional residual capacity was maintained with 15 ± 1 cm H_2O PEEP. Infusion of intravascular volume expanders was required to prevent PEEP-induced hemodynamic compromise.[121]

In summary, the most favorable patient position or optimal amount of PEEP during preoxygenation, induction of anesthesia, or intraoperatively has not been clearly established for the obese patient. Furthermore, the application of noninvasive modes of ventilation including pressure support and bilevel ventilation delivered by mask for preoxygenation, induction, and maintenance of anesthesia to maintain oxygenation and ventilatory mechanics in obese patients has not been sufficiently studied. Ideal patient positioning, use of PEEP, and special modes of ventilation just before emergence and extubation to maintain pulmonary function and gas exchange after extubation have not been identified. Currently, no published guidelines are available to address the issues of maintenance of oxygenation and ventilatory mechanics in obese patients undergoing general anesthesia. Considering both the airway management issues detailed previously and the oxygenation, lung volume, and ventilatory mechanics issues described here for obese individuals, anesthesia care providers should position patients to achieve the combined goals of providing a superior laryngoscopic view for ease of endotracheal intubation while establishing optimal conditions for oxygenation and preservation of pulmonary mechanical function.

It is the practice at our institution that obese patients are initially placed in a ramped position and are then moved into a reverse Trendelenburg position, if needed, to achieve a 25- to 30-degree incline of the thorax before preoxygenation. Patients are then given 100% oxygen under positive pressure. For those patients receiving CPAP at home for OSA, my colleagues and I use CPAP or pressure support ventilation by facemask at a pressure level identical to the patient's home CPAP setting. Otherwise, CPAP of 8 to 10 cm H_2O is appropriate. Following induction of anesthesia, 10 to 12 cm H_2O PEEP can be maintained intraoperatively, but care must be taken to treat any hypotension that may occur. Finally, if the patient's position must be changed intraoperatively, the patient must be returned to the head-up position before emergence and tracheal extubation.

In preparation for emergence from anesthesia, neuromuscular blockade must be fully reversed before the trachea is extubated. Given the advent of a pressure support ventilation mode on many newer models of anesthesia machines, the bariatric patient can be maintained by pressure support during emergence once spontaneous ventilation has resumed. When adequate muscle strength has returned, as demonstrated by sustained tetanus using

the nerve stimulator and performance of a 5-second head lift, the awake patient who is following commands can be tracheally extubated. Pressure support or CPAP can be delivered immediately by mask applied to the face, as is done during preoxygenation prior to induction of anesthesia. Various devices are available to provide CPAP during patient transport from the operating room. We use CPAP during recovery, especially in those patients already prescribed CPAP for their OSA. The basic premise that must be respected with regard to airway management and its integral relationship with pulmonary function is that morbid obesity incurs significant derangements of lung function and pulmonary mechanics. These factors must be managed carefully to minimize intraoperative and postoperative pulmonary complications.[122,123]

Anesthetic Drugs and Dosing

Anesthetic drugs such as opioids, propofol, and benzodiazepines are all well known to have exaggerated responses in patients with OSA. They may decrease pharyngeal musculature tone, which is essential in maintaining airway patency.[36,124] Volatile anesthetics diminish ventilatory response to carbon dioxide, at least in children with tonsillar hypertrophy, in the setting of OSA. Spontaneously breathing tracheally intubated children, with a history of OSA, have depressed ventilation and many have apnea with 0.5 μg/kg of intravenous fentanyl (see also Chapter 92). Although these data are from the pediatric literature, it would be prudent to apply the same principles in obese adult patients until proven otherwise. It therefore becomes attractive to use short-acting drugs and nondepressors of ventilation such as the α_2-agonist dexmedetomidine. This approach should, at least in theory, speed up the return to baseline respiratory function.[94]

Doses of commonly used anesthetic drugs can be determined using total body weight (TBW) or ideal body weight (IBW), based on lipid solubility. In the past, IBW was interpreted to mean fat-free weight, thus implying that it could be used as a substitute for lean body weight or, more correctly, lean body mass (LBM), usually approximated as 120% of IBW. LBM is a good weight approximation to use for doses of hydrophilic medications. As expected, volume of distribution is changed in obese patients with regard to lipophilic drugs. This is especially true of benzodiazepines and barbiturates, among the commonly used anesthetic drugs. Two exceptions to this rule are procainamide[125] and remifentanil,[126] which even though highly lipophilic, have no relationship between properties of the drug and their volume of distribution.[127] Consequently, commonly used anesthetic drug dosing is based on IBW for propofol, vecuronium, rocuronium and remifentanil. In contrast, doses of midazolam, succinylcholine, cisatracurium, fentanyl, and sufentanil should be determined on the basis of TBW. Another caveat to this recommendation is that maintenance doses of propofol should be based on TBW and, conversely, on IBW for sufentanil.[127] This implies that one can use, based on the patient's weight, larger amounts of benzodiazepines, fentanyl, or sufentanil, although these are best titrated to desired clinical effect. Conversely, based on real body weight, smaller amounts of propofol are needed to anesthetize the patient.

With vecuronium or rocuronium, the initial dose should be based on IBW, with additional doses based on monitoring with a peripheral nerve stimulator (see Chapter 53). Complete blockade in the morbidly obese patient is necessary not just for the surgeon's convenience but also to facilitate mechanical ventilation. The drug chosen is not as important as the depth of the state of paralysis.

Volatile anesthetics are chosen based on physical characteristics of tissue solubility, which are expressed as blood-gas partition coefficients and fat-blood partition coefficients. Desflurane may be the anesthetic of choice based on consistent and rapid recovery profile, as opposed to sevoflurane and propofol.[128,129] Some anesthesiologists state that the differences in immediate recovery between sevoflurane and desflurane are not clinically significant.[130]

Even though nitrous oxide provides some analgesic effect and is rapidly eliminated, we prefer to avoid it based on the high oxygen demands in obese patients. The entry of nitrous oxide into air spaces in short intraabdominal surgical procedures may not be a significant factor, but in bariatric surgery, especially when done laparoscopically, any increase in bowel gas volume could make a challenging surgical procedure even more difficult for the surgeon.

Induction of Anesthesia

Obesity, the risk of aspiration of gastric contents, and the need to provide aspiration prophylaxis have been the subjects of considerable debate.[131] Abdominal bloating or fullness and female sex are associated with delayed gastric emptying of solids and liquids in diabetic patients.[132] Although many obese patients have type 2 diabetes, separate studies of gastroesophageal reflux during anesthesia have not demonstrated body habitus to be a predictor of reflux rates.[133] Gastric fluid volume and pH have been shown to be the same in obese patients who are fasting or who have oral intake of up to 300 mL of clear liquid 2 hours before being anesthetized.[134] Obesity itself does not increase the risk of aspiration of gastric contents. However, acid aspiration prophylaxis, including histamine (H_2)–receptor agonists or proton pump inhibitors, must be considered in patients having identifiable risks of aspiration. Awake fiberoptic intubation may also be considered in such patients.[36]

Based on experience from obstetric practice (see also Chapter 77), regional anesthesia, especially epidural and spinal, is safe and feasible in patients with large body habitus.[94] However, regional anesthesia is technically more difficult because of the physical challenge of placing the catheters and the tendency of these catheters to migrate out of the epidural space. Special equipment, in terms of longer needles or special ultrasound probes, may be needed for the correct placement of catheters in these patients. Care should be exercised with drug doses in these catheters because of the increased cephalad spread of the drug and the block as a result of the smaller epidural space compared with normal-weight patients.[135,136] The degree of respiratory compromise suffered by obese patients is also greater than in normal-weight patients with a high regional block.

Little evidence suggests that epidural pain management improves overall outcomes. Because the trend of

laparoscopic surgery is increasing compared with open laparotomies, this becomes less of an issue. In the morbidly obese patient who is having an open laparotomy, use of a thoracic epidural catheter to control pain has the most important benefit of reducing the attenuation of vital capacity postoperatively.[137]

Obesity itself does not require invasive monitoring, so GBP surgery can be performed safely with routine monitoring. The indications for invasive monitoring stem from the comorbidities present in these patients. Because these disorders tend to run together in patients needing surgery, the incidence of invasive monitoring in these patients thereby increases.[138] Morbidly obese patients having serious comorbidities such as obesity-hypoventilation syndrome, who present with pulmonary hypertension and cor pulmonale, may require a pulmonary artery catheter or intraoperative evaluation by transesophageal echocardiography. The rationale for central venous access may stem from difficulties in peripheral access, rather than any other indication. Many patients receive an inferior vena cava filter prophylactically because of the high risk of deep vein thrombosis and pulmonary embolism associated with obesity and bariatric surgery.[139] This procedure is often performed through the right internal jugular vein on the day before bariatric surgery, thus making it possible to have a central venous catheter left in place for the operation at the time the filter is inserted. It is recommended that a central line inserted at the time of surgery should be placed under ultrasound guidance to decrease complications as well as to increase ease of placement. Similarly, difficulty in noninvasive blood pressure measurements, secondary to body habitus–related difficulty in appropriate cuff placement, may be an indication for arterial catheter placement. Analysis of arterial blood gases may help to guide intraoperative ventilation and extubation of the trachea.

Postoperative pain management (see also Chapter 98) in patients undergoing weight loss surgery can involve intravenous analgesia, patient-controlled analgesia (PCA), or thoracic epidural analgesia (TEA). No data are available to prove the superiority of one technique over the other. In our practice, my colleagues and I tend to reserve epidural anesthesia for patients undergoing open GBP. Even with these drawbacks, we have approximately an 80% success rate with supermorbidly obese patients. Opioid-based PCA with local anesthetic wound infiltration and adjunct nonnarcotics is a reasonable alternative approach for most patients. Injection of local anesthetic in the incision site before making the incision may result in preemptive analgesia. Adjunct analgesia with nonnarcotic medications, unless contraindicated, decreases opioid requirements and thereby opioid-induced side effects as well.

Intraoperatively, using the appropriate table for the patient's weight is critical because the consequences of having a table not rated to the patient's weight can be serious for both the patient and the operating room personnel. It may be useful to keep the patient strapped throughout the period of sedation and sleep. Along with a safety strap, it may also be useful to apply a bean bag under the patient to keep the patient from sliding off the operating room table. Thermal management in the operating room is best accomplished by forced-air warmers (see also Chapter 54). Arm boards may need extra padding to keep the patient from having the arm and shoulder out of an anatomic position. If the arms are to be tucked by the side of the patient, then wide, well-padded sleds may be useful.

Intravenous fluid requirements are greater than predicted, and even a relatively short, 2- to 3-hour case may need 4 to 5 L of crystalloid fluid to prevent acute tubular necrosis (ATN) in the kidneys. Hypovolemia, which can cause a protracted prerenal state and contribute to the development of ATN, can be prevented by appropriate hydration. Retrospective data from the University of Pittsburgh Medical Center suggest that primary acute renal failure after weight loss surgery occurs in approximately 2% of patients. Other predisposing factors are BMI greater than 50 kg/m^2, prolonged surgical time, prior history of renal disease, and intraoperative hypotension.[140]

POSTOPERATIVE MANAGEMENT

In our practice, we prefer to have postbariatric surgery patients stay at the same location consistently. This allows skilled nursing and ancillary care to be provided to patients on a consistent basis. These patients are kept on their CPAP or biphasic positive airway pressure (BiPAP) machines as much as possible with monitoring of SpO_2 by pulse oximetry recommended. At the Hospital of the University of Pennsylvania in Philadelphia, patients identified as having difficult airways are distinguished with armbands, and with visible signs on their beds, their hospital charts, and on the electronic medical records for the remainder of their hospital stay. Additionally, a note by the attending anesthesiologist explaining the difficulty in intubation, as well as the means used to secure the airway in the operating room, is available in the room. In case of an unexpected emergency intubation, for whatever reason, we believe that this extra information is extremely useful to the resuscitation team.

MANAGEMENT OF COMPLICATIONS

Bariatric surgery is considered very safe, but not without potential complications, which are increasingly predictable.[141] In-hospital mortality rates for LGB and open GBP surgery are 0.27% and 0.81%, respectively, a statistically significant difference.[140] Mortality is associated with a need for reoperation during the same hospitalization,[142] with intestinal leakage a serious complication accounting for a large number of patient deaths.[143] Risk factors also include comorbid conditions of congestive heart failure or renal failure.

Morbidity occurring during the immediate postoperative in-hospital period typically falls into one of four categories of complications: wound, gastrointestinal, pulmonary, and cardiovascular. The complication rates are significantly lower in each category for patients undergoing laparoscopic rather than open procedures, and they range from 1.35% (wound complications) to 4.52% (gastrointestinal complications) following LGB and from 1.98% (wound complications) to 5.33% (gastrointestinal complications) following open GBP.[140] Table 71-5 provides a categoric listing of both specific and nonspecific complications of bariatric surgery.

TABLE 71-5 SPECIFIC AND NONSPECIFIC COMPLICATIONS OF BARIATRIC SURGERY

	All Surgical Procedures	Gastric Banding	Roux-en-Y
Early	Bleeding Infection Dehydration Peritonitis Bowel obstruction Perforation Pneumonia DVT or PE Death	Band slippage Band malfunction Infection at band site	Leak from anastomotic site
Late	Cholelithiasis Cholecystitis Pouch dilation GERD or dysphagia Herniation at surgical site Nutritional issues Vitamin deficiencies, especially fat-soluble vitamins and vitamin B_{12}	Anorexia Band slippage Band malfunction Infection at band site	Small bowel obstruction Marginal ulcers Pancreatitis Stricture

DVT, Deep vein thrombosis; *GERD,* gastroesophageal reflux disease; *PE,* pulmonary embolism.

The most common complications requiring reoperation include postoperative intraabdominal bleeding, anastomotic leakage, suture line dehiscence, small bowel obstruction, and deep wound infection,[143-148] all of which may require general anesthesia for laparotomy. Despite deep vein thrombosis prophylaxis therapy in the perioperative period, patients can also present postoperatively with deep vein thrombosis or pulmonary embolism and require anesthesia for placement of an inferior vena cava filter device. As mentioned earlier, filters are often placed before bariatric surgery.[139]

In all cases requiring reoperation shortly after the original bariatric procedure, it is prudent to review the anesthesia record. Specific attention should be paid to the documentation of patient position and technique employed for airway management in the prior anesthetic regimen. Patients may be hypovolemic from blood loss, inadequate hydration, vasodilatation, and insensitive fluid losses associated with fever and infection. It is especially important to consider additional or new risks of aspiration of gastric contents. These risks may result from the presence of postoperative ileus, small bowel obstruction, and surgical creation of a Roux-en-Y gastric bypass limb that excludes the pylorus as an element of protection from reflux of intestinal contents. Decompression of the gastric pouch in patients undergoing surgery to relieve small bowel obstruction can be achieved with careful introduction of a nasogastric or orogastric tube just before induction of general anesthesia. Although this may increase the risk of violating a fresh, competent anastomotic suture line, communication between anesthesiologist and surgeon can be pursued to determine the risks and benefits of performing this maneuver. During the ensuing laparotomy, any perforation of a fresh suture line resulting from the attempt to decompress the gastrointestinal tract can be repaired immediately, and the nasogastric or orogastric tube can subsequently be left in place for continued postoperative drainage.

Depending on the extent of reoperation, requirement for volume resuscitation, blood transfusion, degree of peritonitis with anastomotic leak, presence of sepsis, or other significant continued risks to health, patients undergoing reoperation may require prolonged postoperative ventilation. Requirements for postoperative pain management may also be considerably different from those associated with the initial bariatric procedure. In patients who are sufficiently hemodynamically stable immediately before reoperation, an epidural catheter can be placed before induction for pain management as part of the postoperative care. This is especially valuable in obese patients undergoing laparotomy, as described earlier in this chapter.

Certain potential major complications require surgical intervention weeks, months, or even years after a bariatric surgical operation has been performed. Patients may develop anastomotic strictures or ulcers, ventral hernias, gastrogastric fistulas, and severe reflux disorders requiring additional surgery.[77] Small bowel obstruction may appear weeks after the surgical procedure.[147] Patients may desire cosmetic operations to remove excess skin or liposuction procedures to sculpt dysmorphic body areas following significant weight loss. Patients may also require adjustment of a gastric band or pursue band removal. The anesthetic considerations for such patients should include a review of the prior anesthetic record to glean information regarding airway and pain management. The degree of weight loss achieved and the resolution of comorbidities, including diabetes, hypertension, and OSA, may significantly alter the approach used in the bariatric operation.

Some patients develop significant neurologic complications following GBP surgery.[149-151] These complications are known to include polyneuropathy, polyradiculoneuropathy, myelopathy, encephalopathy, and optic neuropathy. Myelopathy occurs most frequently but does not manifest until approximately 10 years postoperatively.[149] These patients have demonstrable nutritional deficiencies, but except for the vitamin B_{12} and copper deficiencies found in patients with myelopathy, no specific nutritional profile has been reported to correlate with neurologic complications. Although neurologic symptoms accompanying weight loss surgery are not likely to result in additional surgery, they represent new or additional comorbidities that should be fully considered by the anesthesiologist caring for patients having previously undergone bariatric surgery.

The nutritional and metabolic complications of bariatric surgery also include protein and protein-calorie malnutrition. Patients may have excessive weight loss occurring either too rapidly or beyond the predetermined goals, steatorrhea or severe diarrhea, hypoalbuminemia, marasmus, edema, and hyperphagia.[77,152-154] In cases of severe malnutrition, patients may require enteral or parenteral nutrition therapy. Surgical revision may be required to correct excessive weight loss and hypoalbuminemia. Under such circumstances, an anesthetic regimen accounting for decreased drug binding effects of a low serum albumin level must be considered.

CONSIDERATIONS FOR MANAGEMENT OF THE OBESE PATIENT PRESENTING FOR NONBARIATRIC SURGERY

Few studies have evaluated the importance of morbidity in obese patients during common surgical procedures. A study by Dindo and co-workers of 6336 patients did not find any difference in the incidence or severity of complications after elective general surgery, except surgical site infections.[155] Other studies assessed the effect of obesity on wound infections and showed that these infections are increased.[156,157] Multiple studies demonstrated that obese patients are at higher risk after gynecologic, orthopedic, cardiovascular, urologic, and transplantation surgery, whereas other studies did not show obesity-related risk differences.[158,159]

From the data of Dindo and associates regarding complications and the type of surgical procedure,[155] operative severity and open laparoscopic surgery were independent risk factors for postoperative complications. These investigators found no differences in the type of postoperative complications in obese and nonobese groups. This study provided data to decrease the prejudice that patients with obesity are implied to have a higher incidence of postoperative complications. This preconception may pertain more to the perception of the medical team as a result of technical difficulties on the anesthetic and surgical end. Surgical procedures may have lasted longer, approximately 25% more time for laparoscopic than for open cholecystectomy in morbidly obese patients. Significantly, the wound infection rate was much better after laparoscopic than after open surgery, a finding that supports the practice of performing laparoscopic surgery, rather than the alternative, in obese patients.

Chapter 72

Anesthesia and the Renal and Genitourinary Systems

VINOD MALHOTRA • VIJAYENDRA SUDHEENDRA • JEROME O'HARA • ANUJ MALHOTRA

Acknowledgment: The editors and publisher would like to thank Dr. Sudhir Diwan for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Innervation of the intraabdominal components of the genitourinary system—the kidney and the ureter—is primarily thoracolumbar (T8-L2). The nerve supply of the pelvic organs—the bladder, the prostate, the seminal vesicles, and the urethra—is primarily lumbosacral with some lower thoracic input.
- The spinal level of pain conduction for the external genitourinary organs is S2-4, except for the testes (T10-L1).
- The kidneys receive 15% to 25% of the total cardiac output, with most of this blood directed to the renal cortex. Renal medullary papillae are more vulnerable to ischemic insults. Kidneys successfully autoregulate their blood flow between 60 and 160 mm Hg mean arterial pressures.
- The glomerular filtration rate (GFR) is the best measure of glomerular function. Creatinine clearance is a good measure of the GFR; urine output is not.
- Hypervolemia, acidemia, hyperkalemia, cardiorespiratory dysfunction, anemia, and bleeding disturbances are manifestations of chronic renal failure.
- Although renal transplantation reverses most of the abnormalities in end-stage renal disease, dialysis improves only some, and introduces additional complications of its own.
- Newer techniques, such as laser prostatectomy, are making transurethral resection of the prostate (TURP) syndrome a rare event. TURP syndrome is a constellation of symptoms caused by the absorption of hypotonic bladder irrigants. Cardiovascular and neurologic changes are due to hypoosmolality, hyponatremia, hyperglycinemia, hyperammonemia, and hypervolemia.
- Regional anesthesia offers several advantages over general anesthesia for standard, but not laser, TURP. Yet, 30-day mortality rates remain unchanged at 0.2% to 0.8%.
- Laparoscopic surgery in urology frequently requires insufflation of carbon dioxide into the retroperitoneal space. In lengthy procedures, pneumomediastinum and subcutaneous emphysema of the head and neck may occur.
- Extracorporeal shock wave lithotripsy (ESWL) causes significant physiologic changes related to immersion if a water bath is used. Shock waves can cause arrhythmias and injury to the lungs. Pregnancy and untreated bleeding disorders are contraindications to ESWL.
- Regarding renal tumors, 5% to 10% extend into the renal vein, inferior vena cava, and right atrium. Complications ranging from circulatory failure to embolization of tumor during surgery may occur. Cardiopulmonary bypass may be necessary for surgery.
- Radical prostatectomy causes significant blood loss sometimes including intraoperative venous air emboli. Regional anesthesia with spontaneous ventilation is associated with less blood loss than general anesthesia and intermittent positive-pressure ventilation. Other advantages of epidural anesthesia include a decreased incidence of deep vein thrombosis and preemptive analgesia. Whether outcomes are dependent on the choice of anesthesia is not clear.
- Robotic radical prostatectomy is associated with reduced blood loss and postoperative pain compared with open radical prostatectomy. Anesthetic concerns are related to steep head-down tilt (also see Chapter 41) and pneumoperitoneum and include hypercarbia, hypoxemia, increased intraocular and intracranial pressures, decreased perfusion pressure to lower extremities, and positional injuries.

TABLE 72-1 PAIN CONDUCTION PATHWAYS AND SPINAL SEGMENT PROJECTION OF PAIN OF THE GENITOURINARY SYSTEM

Organ	Sympathetics, Spinal Segments	Parasympathetics	Spinal Levels of Pain Conduction
Kidney	T8-L1	CN X (vagus)	T10-L1
Ureter	T10-L2	S2-4	T10-L2
Bladder	T11-L2	S2-4	T11-L2 (dome), S2-4 (neck)
Prostate	T11-L2	S2-4	T11-L2, S2-4
Penis	L1 and L2	S2-4	S2-4
Scrotum	NS	NS	S2-4
Testes	T10-L2	NS	T10-L1

NS, Not significant for nociceptive function.

Patients requiring anesthesia for renal and genitourinary surgery are frequently at the extremes of age. In addition to the physiologic changes of aging in older patients (see also Chapter 80), concomitant cardiovascular and respiratory comorbidity is common. A medical history, physical examination, and appropriate laboratory tests are necessary to evaluate concomitant disease. In pediatric urologic patients, a careful history should exclude other nonurologic congenital lesions (see Chapter 93).

Urologic procedures are performed mostly on the kidneys, adrenals, ureters, urinary bladder, prostate, urethra, penis, scrotum, testis, and spermatic cord. Because their sensory nerve supply is primarily thoracolumbar and sacral outflow (Table 72-1), these structures are well adapted for regional anesthesia.

INNERVATION OF THE GENITOURINARY SYSTEM

The parts of the genitourinary system that are in the abdomen receive their nerve supply from the autonomic nervous system by means of sympathetic and parasympathetic pathways. The pelvic urinary organs and genitalia are supplied by somatic and autonomic nerves. Table 72-1 summarizes the pain conduction pathways and spinal levels of the genitourinary system.

KIDNEY AND ABDOMINAL URETER

Sympathetic nerves to the kidney originate as preganglionic fibers from the eighth thoracic through the first lumbar segments and converge at the celiac plexus and aorticorenal ganglia (Fig. 72-1). Postganglionic fibers to the kidney arise mainly from the celiac and aorticorenal ganglia. Some sympathetic fibers may reach the kidney via the splanchnic nerves. Parasympathetic input is from the vagus nerve.[1] Sympathetic fibers to the ureter originate from the tenth thoracic through the second lumbar segments and synapse with postganglionic fibers in the aorticorenal and superior and inferior hypogastric plexuses. Parasympathetic input is from the second through fourth sacral spinal segments.[1] Nociceptive fibers travel along the sympathetics to the same spinal segments.

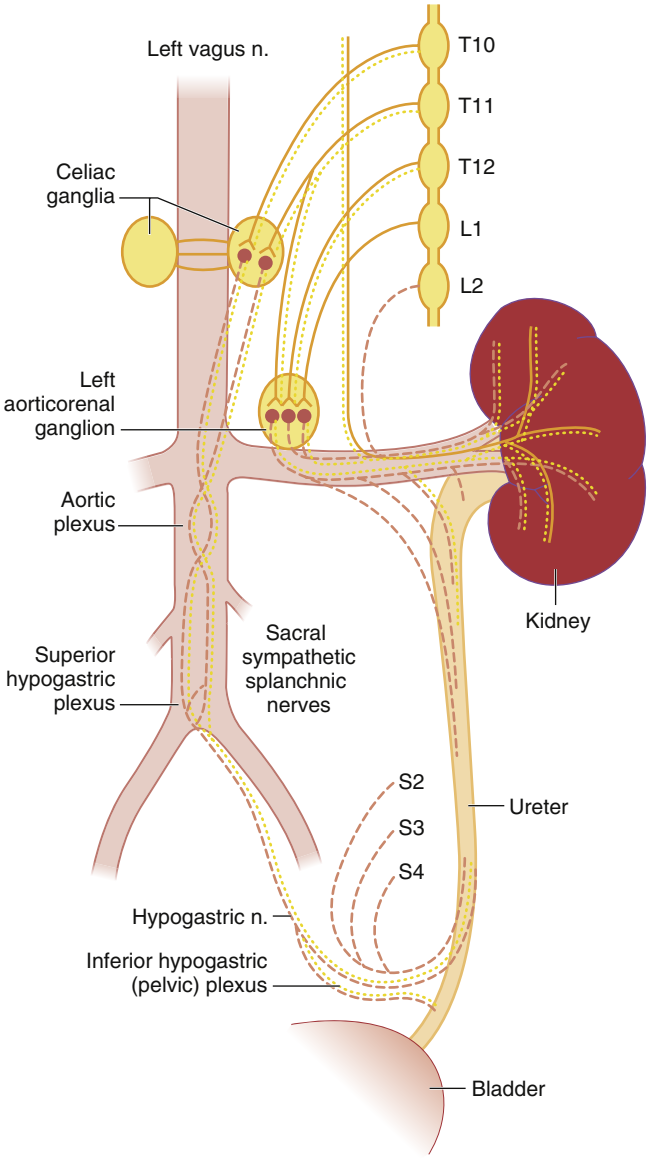

Figure 72-1. Autonomic and sensory innervation of the kidney and ureters. *Solid line* indicates preganglionic fibers; *dashed line* indicates postganglionic fibers; and *dotted line* indicates sensory fibers. *(From Gee WF, Ansell JF: Pelvic and perineal pain of urologic origin. In Bonica JJ, editor:* The management of pain, *ed 2, Philadelphia, 1990, Lea & Febiger, pp 1368-1378.)*

Pain from the kidney and ureter is referred mainly to the somatic distribution of the tenth thoracic through the second lumbar segments—the lower part of the back, flank, ilioinguinal region, and scrotum or labia. Effective neural block of these segments is necessary to provide adequate analgesia or anesthesia.

BLADDER AND URETHRA

Sympathetic nerves to the bladder and urethra originate from the eleventh thoracic to the second lumbar segments, travel through the superior hypogastric plexus, and supply the bladder through the right and the left hypogastric nerves.[2] Parasympathetic nerves arise from the second through the fourth sacral segments

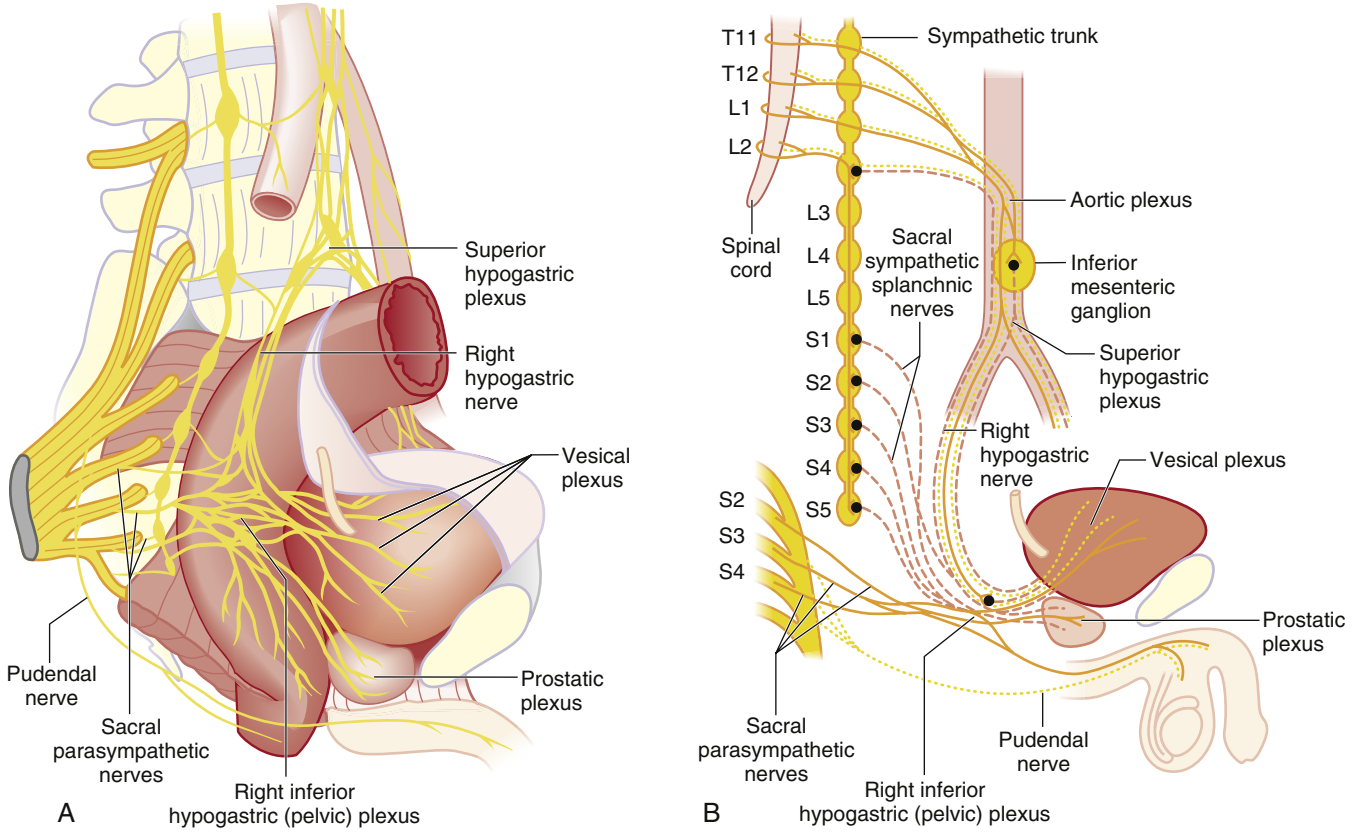

Figure 72-2. A, Nerve supply of the urinary bladder and prostate showing the relationship of the various nerve structures to the large intestine and their distribution in the bladder and prostate. **B,** Schematic illustration showing the segmental nerve supply to the bladder, penis, and scrotum. *Solid lines* indicate preganglionic fibers; *dashed lines* indicate postganglionic fibers; and *dotted lines* indicate sensory fibers. *(From Gee WF, Ansell JF: Pelvic and perineal pain of urologic origin. In Bonica JJ, editor:* The management of pain, *ed 2, Philadelphia, 1990, Lea & Febiger, pp 1368-1378.)*

and form the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. Vesical branches proceed toward the bladder base, where they provide the nerve supply to the bladder and proximal part of the urethra (Fig. 72-2). Parasympathetic fibers are the main motor supply to the bladder (with the exception of the trigone) and far outnumber sympathetic fibers in the bladder.[2]

The afferents carrying sensations of stretch and fullness of the bladder are parasympathetic, whereas pain, touch, and temperature sensations are carried by sympathetic nerves. Sympathetic fibers are predominantly α adrenergic in the bladder base and urethra, and β adrenergic in the bladder dome and lateral wall. Knowledge of these aspects of neuroanatomy is important to appreciate the pharmacologic effects on the urologic system of neural ablation or regional block and drugs with adrenergic or cholinergic effects.[2]

PROSTATE AND PROSTATIC URETHRA

The prostate and the prostatic urethra receive sympathetic and parasympathetic supply from the prostatic plexus arising from the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. The spinal origin of the nerve supply is primarily lumbosacral (see Fig. 72-2).[2]

PENIS AND SCROTUM

The autonomic supply to the penile urethra and the cavernous tissue comes from the prostatic plexus. Somatic fibers from the pudendal nerve (S2-4) supply the external sphincter. The dorsal nerve of the penis, the first branch of the pudendal nerve, is its main sensory supply. The scrotum is innervated anteriorly by the ilioinguinal and genitofemoral nerves (L1 and L2) and posteriorly by perineal branches of the pudendal nerve (S2 and S4).[2]

TESTES

The testes descend from their intraabdominal location to the scrotum during fetal development. Because they share their embryologic origin with the kidney, their nerve supply is similar to that of the kidney and upper part of the ureter and extends up to the T10 spinal segment.[2]

RENAL BLOOD FLOW

The kidneys receive approximately 15% to 25% of total cardiac output, or 1 to 1.25 L/min of blood through the renal arteries, depending on the state of the body. Most of the blood is received by the renal cortex, with only 5% of cardiac output flowing through the renal medulla, which

makes the renal papillae vulnerable to ischemic insults. Renal blood flow is regulated by various mechanisms that control the activity of vascular smooth muscle and alter vascular resistance. Sympathetic tone of renal vessels increases during exercise to shunt renal blood flow to exercising skeletal muscle; similarly, renal blood vessels relax during the resting condition of the body. Sympathetic stimulation resulting from surgery can increase vascular resistance and reduce renal blood flow, whereas anesthetics may reduce renal blood flow by decreasing cardiac output.

Glomerular capillaries separate afferent arterioles from efferent arterioles. Glomerular capillaries are high-pressure systems, whereas peritubular capillaries are low-pressure systems. Consequently, the glomerular capillaries are a fluid-filtering system, whereas the peritubular capillaries are a fluid-absorbing system. The vasa recta, a specialized portion of peritubular capillaries formed from efferent arterioles, are important in the formation of concentrated urine by a countercurrent mechanism. An intrinsic mechanism that causes vasodilation and vasoconstriction of renal afferent arterioles regulates the autoregulation of renal blood flow. A decrease in mean arterial pressure also decreases renal blood flow and eventually affects the glomerular filtration rate (GFR) when the pressure decreases to less than 60 mm Hg. A persistently low mean arterial pressure greater than 60 mm Hg affects renal blood flow, but does not affect the GFR because of the intrinsic mechanism of autoregulation (Fig. 72-3). Autoregulation maintains mean arterial pressure between 60 mm Hg and 160 mm Hg in intact and denervated kidneys.[3]

Although knowledge of neuroanatomy and renal blood flow is essential to provide adequate anesthesia, a thorough understanding of renal physiology and pharmacology is equally important. Genitourinary surgical patients frequently have mechanical or functional renal disease. Anesthetics and surgery can significantly alter renal function. Conversely, renal dysfunction significantly affects the pharmacokinetics and pharmacodynamics of anesthetics and adjuvant drugs. Evaluation of a patient with renal disease is discussed later.

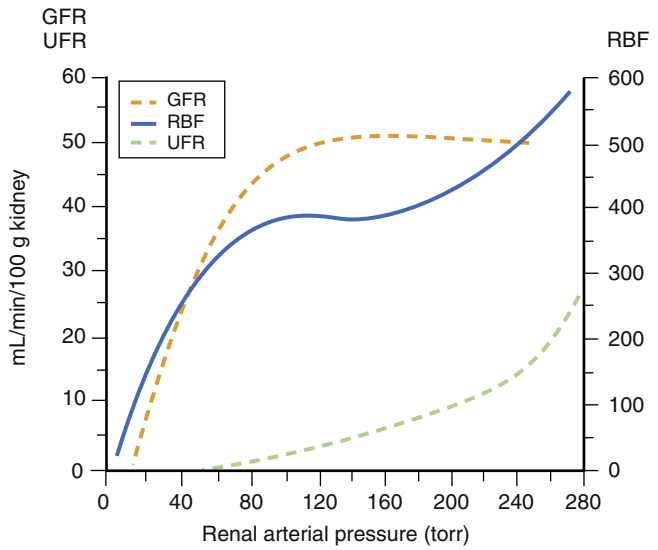

Figure 72-3. Autoregulation of renal blood flow (RBF) and the glomerular filtration rate (GFR). The relationships between RBF, GFR, and urine flow rate (UFR) and mean renal arterial pressure in dogs are shown as renal arterial pressure is varied from 20 to 280 mm Hg. Autoregulation of RBF and GFR is observed between about 80 mm Hg and 180 mm Hg. *(Redrawn from Hemmings HC: Anesthetics, adjuvants and drugs and the kidney. In Malhotra V, editor:* Anesthesia for renal and genitourinary surgery, *New York, 1996, McGraw-Hill, p 18.)*

ANESTHESIA FOR PATIENTS WITH RENAL DISEASE

EVALUATION OF RENAL FUNCTION

Renal disease can be discovered incidentally during a routine medical evaluation, or patients may exhibit evidence of renal dysfunction, such as hypertension, edema, nausea, and hematuria (see Chapter 23). The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases, this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the GFR. The history and physical examination, although equally important, are variable among renal syndromes; specific symptoms and signs are discussed in sections on each disease entity. Further diagnostic categorization is based on anatomic distribution: prerenal disease, postrenal disease, and intrinsic renal disease. Intrinsic renal disease can be divided further into glomerular, tubular, interstitial, and vascular abnormalities. Laboratory tests useful in evaluating renal function are described next (Table 72-2).

TABLE 72-2 **COMMONLY ORDERED RENAL FUNCTION TESTS**

Test Name	Reference Range	Units
Urea nitrogen	5-25	mg/dL
Creatinine	0.5-1.5	mg/dL
Sodium	133-147	mmol/L
Potassium	3.2-5.2	mmol/L
Chloride	94-110	mmol/L
CO_2	22-32	mmol/L
Uric acid	2.5-7.5	mg/dL
Calcium	8.5-10.5	mg/dL
Phosphorus	2.2-4.2	mg/dL
Urinalysis, routine		
Color	Straw-amber	
Appearance	Clear-hazy	
Protein	0	mg/dL
Blood	Negative	
Glucose	0	mg/dL
Ketones	0	mg/dL
pH	4.5-8.0	
Specific gravity	1.002-1.030	
Bilirubin	Negative	
Urinalysis, microscopic		
Red blood cells	0-3	per high-power field
White blood cells	0-5	per high-power field
Casts	0-2	per low-power field

GLOMERULAR FUNCTION

Glomerular Filtration Rate

The GFR is the best measure of glomerular function. Normal GFR is approximately 125 mL/min. Manifestations of reduced GFR are not seen, however, until the GFR has decreased to 50% of normal. When GFR decreases to 30% of normal, a stage of moderate renal insufficiency sets in. Patients remain asymptomatic with only biochemical evidence of a decline in GFR (i.e., an increase in serum concentrations of urea and creatinine). Further workup usually reveals other abnormalities, such as nocturia, anemia, loss of energy, decreasing appetite, and abnormalities in calcium and phosphorus metabolism.

As the GFR decreases further, a stage of severe renal insufficiency begins. This stage is characterized by profound clinical manifestations of uremia and biochemical abnormalities, such as acidemia; volume overload; and neurologic, cardiac, and respiratory manifestations. At the stages of mild and moderate renal insufficiency, intercurrent clinical stress may compromise renal function further and induce signs and symptoms of overt uremia. When the GFR is 5% to 10% of normal, it is called end-stage renal disease (ESRD), and continued survival without renal replacement therapy becomes impossible. Although most clinical abnormalities of corticotropin-releasing factor are reversed by renal transplantation, the response to dialysis is highly variable (Table 72-3).

Blood Urea Nitrogen

The blood urea nitrogen (BUN) concentration is not a direct correlate of reduced GFR. BUN is influenced by nonrenal variables, such as exercise, bleeding, steroids, and massive tissue breakdown. The more important factor is that BUN is not elevated in kidney disease until the GFR is reduced to almost 75% of normal.[4]

Creatinine and Creatinine Clearance

Measurements of creatinine provide valuable information regarding general kidney function. Creatinine in serum results from turnover of muscle tissue and depends on daily dietary intake of protein. Normal values are 0.5 to 1.5 mg/100 mL; values of 0.5 to 1 mg/100 mL are present during pregnancy. Creatinine is freely filtered at the glomerulus, and apart from an almost negligible increase in content because of secretion in the distal nephron, it is neither reabsorbed nor secreted. Serum creatinine measurements reflect glomerular function (Fig. 72-4),[4] and creatinine clearance is a specific measure of GFR. Creatinine clearance can be calculated by the following formula derived by Cockcroft-Gault that accounts for age-related decreases in GFR, body weight, and sex:

$$\text{Creatinine clearance (mL/min)} = [(140 - \text{Age}) \times \text{Lean body weight (kg)}]/[\text{Plasma creatinine (mg/dL)} \times 72]$$

This value should be multiplied by 0.85 for women because a lower fraction of body weight is composed of muscle.

TABLE 72-3 **CLINICAL ABNORMALITIES IN CHRONIC RENAL FAILURE AND THEIR RESPONSE TO DIALYSIS AND ERYTHROPOIETIN TREATMENT**

Improved by Dialysis	Improved by Adding Erythropoietin	Variable Response	Not Improved	Develop after Dialysis Therapy
Volume expansion and contraction	Fatigue	Secondary hyperparathyroidism	Increased lipoprotein level	Adynamic osteomalacia
Hypernatremia and hyponatremia	Impaired mentation	Hyperuricemia	Decreased high-density lipoprotein level	β_2-Microglobulinemia
Hyperkalemia and hypokalemia	Lethargy	Hypertriglyceridemia	Impaired growth and development	Muscle cramps
Metabolic acidosis	Pallor	Protein-calorie malnutrition	Infertility and sexual dysfunction	Dialysis dysequilibrium syndrome
Hyperphosphatemia	Anemia	Headache	Amenorrhea	Hypotension and arrhythmias
Hypocalcemia	Bleeding diathesis	Peripheral neuropathy	Sleep disorders	Hepatitis
Vitamin D–deficient osteomalacia		Restless legs syndrome	Pruritus	Idiopathic ascites
Carbohydrate intolerance		Paralysis	Lymphocytopenia	Peritonitis
Hypothermia		Seizures	Splenomegaly and hypersplenism	Leukopenia
Asterixis		Myopathy		Hypocomplementemia
Muscular irritability		Arterial hypertension		
Myoclonus		Cardiomyopathy		
Coma		Accelerated atherosclerosis		
Congestive heart failure or pulmonary edema		Vascular calcification		
Pericarditis		Hyperpigmentation		
Uremic lung		Peptic ulcer		
Ecchymoses		Gastrointestinal bleeding		
Uremic frost		Increased susceptibility to infection		
Anorexia				
Nausea and vomiting				
Uremic fetor				
Gastroenteritis				

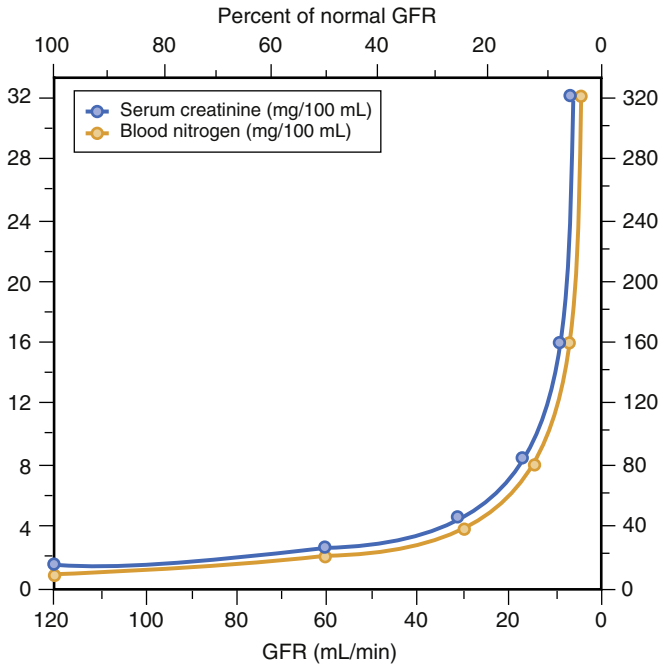

Figure 72-4. Theoretic relationship between blood urea nitrogen and creatinine versus glomerular filtration rate (GFR). *(Redrawn from Kassirer JP: Clinical evaluation of kidney function-glomerular function,* N Engl J Med *285:385, 1971.)*

Because there is such a wide range in normal values, a 50% increase in serum creatinine concentration, indicative of a 50% reduction in GFR, may go undetected unless baseline values are known. Also, excretion of drugs dependent on glomerular filtration may be significantly decreased despite what might seem to be only slightly elevated serum creatinine values (1.5 to 2.5 mg/100 mL). The serum creatinine concentration and clearance are better indicators of general kidney function and GFR than are similar measurements of urea nitrogen (Box 72-1). There are disease states, however, in which even the serum creatinine can be affected independent of the GFR (Table 72-4).

TUBULAR FUNCTION

Concentration

Urinary specific gravity is an index of the kidney's concentrating ability, specifically, renal tubular function. Determination of urinary osmolality (i.e., measurement of the number of moles of solute [osmoles] per kilogram of solvent) is a similar, more specific test. Excretion of concentrated urine (specific gravity, 1.030; 1050 mOsm/kg) is indicative of excellent tubular function, whereas a urinary osmolality fixed at that of plasma (specific gravity 1.010; 290 mOsm/kg) indicates renal disease. The urinary dilution mechanism persists after concentrating defects are present, so a urinary osmolality of 50 to 100 mOsm/kg still may be consistent with advanced renal disease.

Protein

Patients without renal disease can excrete 150 mg of protein per day; greater amounts may be present after strenuous exercise or after standing for several hours. Massive proteinuria (i.e., >750 mg/day) is always abnormal and usually indicates severe glomerular damage.

BOX 72-1 ***Conditions Affecting BUN Independently of Glomerular Filtration Rate***

INCREASED BUN

- Reduced effective circulating blood volume (prerenal azotemia)
- Catabolic states (gastrointestinal bleeding, corticosteroid use)
- High-protein diets
- Tetracycline

DECREASED BUN

- Liver disease
- Malnutrition
- Sickle cell anemia
- SIADH

BUN, Blood urea nitrogen; *SIADH,* syndrome of inappropriate secretion of antidiuretic hormone.

TABLE 72-4 **CONDITIONS AFFECTING SERUM CREATININE INDEPENDENTLY OF GLOMERULAR FILTRATION RATE**

Condition	Mechanism
Conditions Causing Elevation	
Ketoacidosis	Noncreatinine chromogen
Cephalothin, cefoxitin	Noncreatinine chromogen
Flucytosine	Noncreatinine chromogen
Other drugs—aspirin, cimetidine, probenecid, trimethoprim	Inhibition of tubular creatinine secretion
Conditions Causing Decrease	
Advanced age	Physiologic decrease in muscle mass
Cachexia	Pathologic decrease in muscle mass
Liver disease	Decreased hepatic creatine synthesis and cachexia

Glucose

Glucose is freely filtered at the glomerulus and is subsequently reabsorbed in the proximal tubule. Glycosuria signifies that the ability of the renal tubules to reabsorb glucose has been exceeded by an abnormally heavy glucose load and is usually indicative of diabetes mellitus. Glycosuria also may be present in hospitalized patients without diabetes who are receiving intravenous glucose infusions.

ADDITIONAL DIAGNOSTIC TESTS

Urinalysis and Appearance

Gross and microscopic observation of urine and its sediment, along with determination of urinary pH, specific gravity, protein content, and glucose content, is one of the most readily available, inexpensive, and informative laboratory tests. The gross appearance of urine may indicate the presence of bleeding or infection in the genitourinary tract. Microscopic examination of urinary

sediment may reveal casts, bacteria, and various cell forms, supplying diagnostic information in patients with renal disease.

Serum and Urine Electrolytes

pH and Blood Gases. Sodium, potassium, chloride, and bicarbonate concentrations should be determined if impairment in renal function is suspected. The results of these tests usually remain normal until frank renal failure is present, however, and hyperkalemia does not occur until patients are uremic.[5] Measuring urinary sodium or chloride excretion is especially useful when attempting to differentiate between causes of hyponatremia, as seen in volume contraction (whether a decrease in total circulatory volume or a decrease in effective arterial blood volume), versus conditions associated with increased salt loss, such as the syndrome of inappropriate secretion of antidiuretic hormone, salt-losing nephropathy, or adrenal insufficiency.[6] If significant renal disease is present, patients consuming a diet high in animal protein may have metabolic acidosis.

Electrocardiogram. The electrocardiogram (see Chapter 47) reflects the toxic effects of potassium excess more closely than determination of the serum potassium concentration.

Imaging Studies

Computed Tomography Scan of Kidneys. A stone protocol computed tomography (CT) scan of the kidneys, ureter, and bladder has become the study of choice for the detection of kidney stones because of its ability to detect stones of all kinds, including uric acid stones and nonobstructing stones in the ureter. Masses in the kidney can be evaluated using either contrast-enhanced CT or renal ultrasound.[6]

Computed Tomography Angiography. Computed tomography angiography is used for the evaluation of renal artery stenosis and is emerging rapidly as a useful study. Although it is comparable to magnetic resonance angiography as a noninvasive tool, it requires the use of iodinated contrast material, which may cause renal dysfunction in patients with chronic kidney disease.[7]

Magnetic Resonance Imaging with Magnetic Resonance Angiography. The use of magnetic resonance imaging (MRI) with magnetic resonance angiography has revolutionized the evaluation of renovascular disease. The test is highly sensitive, but tends to overestimate the degree of stenosis. Its accuracy in detecting fibromuscular dysplasia causing renal artery stenosis has not been well validated. MRI also can be used to evaluate renal masses. The main advantages of MRI are that it is a noninvasive test and does not require iodinated contrast material.

IMPORTANT PATHOPHYSIOLOGIC MANIFESTATIONS OF CHRONIC RENAL FAILURE (See also Chapter 23)

Hypervolemia

Total-body contents of Na^+ and H_2O are increased in chronic renal failure (CRF),[4] although this increase might not be clinically apparent until the GFR is reduced to very low levels. Weight gain is usually associated with volume expansion and is offset by the concomitant loss of lean body mass. The combination of loop diuretics with metolazone, which acts by inhibiting the Na-Cl cotransporter of the distal convoluted tubule, can overcome diuretic resistance.

TABLE 72-5 METABOLIC ACIDOSIS IN CHRONIC RENAL FAILURE

	$Paco_2$ (mm Hg)	pH	HCO_3^- (mEq/L)	K^+ (mEq/L)
Preoperative	32	7.32	17	5
Intraoperative	40	7.25	18	5.3
Postoperative	44	7.21	19	5.6
	48	7.18	19	5.9

The patient is a 36-year-old man with severe diabetic nephropathy and end-stage renal failure undergoing cadaver renal transplantation. Preoperatively, the patient has a chronic metabolic acidosis (HCO_3^-, 17 mEq/L) with partial respiratory compensation ($Paco_2$, 32 mm Hg; pH 7.32). Potassium is high normal at 5 mEq/L. Intraoperatively, he is given "standard" mechanical minute ventilation, and with "normal" $Paco_2$ (40 mm Hg), the metabolic acidosis is unmasked (pH 7.25), and potassium increases to 5.3 mEq/L. His trachea is extubated at the end of the procedure, but graft function is sluggish, and the metabolic acidosis remains unchanged. With residual opioid-induced narcosis, moderate CO_2 retention occurs ($Paco_2$, 44 mm Hg and 48 mm Hg), pH decreases further to 7.18, and a dangerous degree of hyperkalemia develops (K^+, 5.9 mEq/L).

Acidemia

Although urine can be acidified normally in most patients with CRF, these patients have a reduced ability to produce ammonia. In the early stages, the accompanying organic anions are excreted in urine, and the metabolic acidosis is of the non–anion gap variety. With advanced renal failure, a fairly large "anion gap" can develop (to approximately 20 mmol/L), however, with a reciprocal decrease in plasma HCO_3^- concentration. This acidemia is usually corrected by hemodialysis. Although acidemia is well compensated in moderate CRF, patients can become acidemic and hyperkalemic[8] in the postoperative period (Table 72-5).

Hyperkalemia

The approximate daily filtered load of K^+ is 700 mmol. Most of this filtered load is reabsorbed in tubule segments, and most of the K^+ excreted in the final urine reflects events governing K^+ handling at the level of the cortical collecting tubule and beyond. K^+ excretion in the gastrointestinal tract is augmented in patients with CRF. Hyperkalemia may be precipitated, however, in numerous clinical situations, including protein catabolism, hemolysis, hemorrhage, transfusion of stored red blood cells (see Chapter 61), metabolic acidosis, and exposure to various medications that inhibit K^+ entry into cells or K^+ secretion in the distal nephron.

Cardiac and Pulmonary Manifestations

Hypertension is a common complication of CRF and ESRD (see Chapter 39). Because hypervolemia is the major cause of hypertension in uremia, normotension

is usually restored by the use of diuretics in predialysis patients or by dialysis in ESRD patients. Despite therapy, patients continue to be hypertensive because of the vasodilators required for the management of overwhelming hyperreninemia. Patients generally have left ventricular hypertrophy and accelerated atherosclerosis (disordered glucose and fat metabolism). Pericarditis can be observed in patients with inadequate dialysis versus patients with CRF who undergo regular dialysis.

A unique form of pulmonary congestion and edema can occur even in the absence of excessive intravascular volume and is associated with normal or mildly increased intracardiac and pulmonary capillary wedge pressure. This entity, characterized radiologically by peripheral vascular congestion giving rise to a "butterfly wing" distribution, is due to increased permeability of alveolar capillary membranes. This "low-pressure" pulmonary edema and the cardiopulmonary abnormalities associated with excessive intravascular volume usually respond promptly to vigorous dialysis.[9]

Hematologic Manifestations

Chronic renal failure usually causes a normochromic, normocytic anemia. Anemia is generally observed when the GFR decreases to less than 30 mL/min and is due to insufficient production of erythropoietin by the diseased kidneys. Other factors are iron deficiency, either related to or independent of blood loss from repeated laboratory testing, blood retention in the dialyzer, or gastrointestinal bleeding.[10] Treatment of anemia with iron, darbepoetin alfa, and human recombinant erythropoietin (Table 72-6) restores a normal hematocrit and avoids repetitive red blood cell transfusions, reduces the requirement for hospitalization, and decreases cardiovascular mortality by about 30%.[11]

Prolongation of the bleeding time because of decreased activity of platelet factor 3, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption contributes to the clotting defects. The abnormality in platelet factor 3 correlates can be corrected with dialysis, although prolongation of the bleeding time can be observed in well-dialyzed patients. Abnormal bleeding times and coagulopathy in patients with renal failure may be managed with desmopressin, cryoprecipitate, conjugated estrogens, blood transfusions, and erythropoietin use.[10]

TABLE 72-6 MANAGEMENT GUIDELINES FOR CORRECTION OF ANEMIA OF CHRONIC RENAL DISEASE

Erythropoietin	
Starting dosage	50-150 U/kg/wk IV or SC (once, twice, or three times per week)
Target hemoglobin	11-12 g/dL
Optimal rate of correction	Increase hemoglobin by 1-2 g/dL over 4 wk
Darbepoetin alfa	
Starting dosage	0.45 mg/kg administered as single IV or SC injection once weekly 0.75 mg/kg administered as a single IV or SC injection once every 2 wk
Target hemoglobin	12 g/dL
Optimal rate of correction	Increase hemoglobin by 1-2 g/dL over 4-wk period
Iron	
Monitor iron stores by TSat and serum ferritin	
If patient is iron-deficient (TSat <20%; serum ferritin <100 g/L), administer iron, 50-100 mg IV twice per week for 5 wk; if iron indices are still low, repeat the same course	
If iron indices are normal but hemoglobin is still inadequate, administer IV iron as outlined above; monitor hemoglobin, TSat, and ferritin.	
Withhold iron therapy when TSat >50% or ferritin >800 ng/mL (>800 g/L)	

IV, Intravenous; *SC,* subcutaneous; *TSat,* percent transferrin saturation.

EFFECTS OF DRUGS IN PATIENTS WITH REDUCED RENAL FUNCTION

Most anesthetic drugs are weak electrolytes and are lipid soluble in the un-ionized state; they are extensively reabsorbed by renal tubular cells (see Chapters 26 and 30). Termination of their action does not depend on renal excretion; redistribution and metabolism produce this effect. After biotransformation, these drugs are excreted in urine as water-soluble, polar forms of the parent compound. They are usually pharmacologically inactive, and their retention is harmless.[10] Most drugs with prominent central and peripheral nervous system activity in this category include most narcotics, barbiturates, phenothiazines, butyrophenone derivatives, benzodiazepines, ketamine, and local anesthetics.[12] Several drugs are lipid insoluble or are highly ionized in the physiologic pH range, however, and are eliminated unchanged in urine. Their duration of action may be extended in patients with impaired renal function. Drugs in this category include muscle relaxants, cholinesterase inhibitors, thiazide diuretics, digoxin, and many antibiotics (Table 72-7).[13]

Opioids

Renal failure has implications of major clinical importance with respect to morphine and meperidine (see Chapter 31). For the fentanyl congeners, the clinical importance of renal failure is less marked.[14]

Morphine is an opioid with active metabolites that depend on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver, and the water-soluble glucuronides (morphine-3-glucuronide and morphine-6-glucuronide) are excreted via the kidney. The kidney also plays a role in the conjugation of morphine, accounting for nearly 40% of its metabolism.[15] Patients with renal failure can develop high levels of morphine-6-glucuronide and life-threatening respiratory depression.[14] In view of these changes induced by renal failure, morphine might not be a good choice in patients with severely altered renal clearance mechanisms.

The clinical pharmacology of meperidine also is significantly altered by renal failure. Normeperidine, the chief metabolite, has analgesic and central nervous system (CNS) excitatory effects.[16] Because the active metabolites

TABLE 72-7 DRUGS USED OR ENCOUNTERED IN ANESTHESIA PRACTICE THAT SIGNIFICANTLY DEPEND ON RENAL ELIMINATION

Completely Dependent	Partially Dependent
Digoxin, inotropes (used frequently; monitoring of blood levels indicated in chronic renal failure)	Intravenous anesthetics—barbiturates
Others—aminoglycosides, vancomycin, cephalosporins, and penicillins	Muscle relaxants—pancuronium
	Anticholinergics—atropine, glycopyrrolate
	Cholinesterase inhibitors—neostigmine, edrophonium
	Others—milrinone, hydralazine, cycloserine, sulfonamides, and chlorpropamide

are subject to renal excretion, this potential CNS toxicity secondary to normeperidine accumulation is especially a concern in patients in renal failure.

The clinical pharmacology of the fentanyl congeners is not grossly altered by renal failure, although a decrease in plasma protein binding potentially can alter the free fraction of the fentanyl class of opioids.[14] Fentanyl clearance is not altered by renal failure. As with fentanyl, sufentanil pharmacokinetics are not altered in any consistent fashion by renal disease, although greater variability exists in the clearance and elimination half-life of sufentanil when patients have impaired renal function.[17] An increased clinical effect is likely with alfentanil in renal failure because of a decreased initial volume of distribution and an increased free fraction of alfentanil.[18] No delay in recovery after alfentanil administration should be expected, however. Neither the pharmacokinetics nor the pharmacodynamics of remifentanil are altered by impaired renal function.[18]

Hydromorphone,[19] as the parent drug, does not substantially accumulate in hemodialysis patients. Conversely, an active metabolite, hydromorphone-3-glucuronide, quickly accumulates between dialysis treatments, but seems to be effectively removed during hemodialysis. With careful monitoring, hydromorphone can be used safely in patients who require dialysis. It should be used with caution, however, in patients with a GFR less than 30 mL/min and who have yet to start dialysis or who have withdrawn from dialysis.

Inhaled Anesthetics

All inhaled anesthetics (see Chapters 25, and 26) are biotransformed to some extent, with the nonvolatile products of metabolism eliminated almost entirely by the kidney.[20] Reversal of the CNS effects of inhaled anesthetics depends on pulmonary excretion; therefore, impaired kidney function would not alter the response to these anesthetics. From the viewpoint of selecting an anesthetic that would not be harmful to patients with mild or moderate impairment of renal function, all the modern potent anesthetics are suitable. Enflurane is biotransformed to inorganic fluoride, but levels after 2 to 4 hours of anesthesia average only 19 μM in patients with mild to moderate kidney disease, significantly lower than the nephrotoxic threshold of 50 μM, which is frequently reported after the administration of methoxyflurane.[21,22] This level of fluoride should not cause further renal impairment. Fluoride levels after isoflurane increase by only 3 to 5 μM,[23] and by only 1 to 2 μM after halothane[22]; therefore, these anesthetics have no nephrotoxic potential.

Desflurane and sevoflurane, two newer inhaled anesthetics, are remarkably different in their molecular stability and biotransformation. Desflurane is highly stable and resists degradation by soda lime[24] and the liver. The mean inorganic fluoride concentration after 1 minimum alveolar concentration (MAC)-hour exposure to desflurane was less than 1 μM.[25] The safety of desflurane in renal failure patients has been confirmed.[26] In addition, more sensitive indices of renal function—urine retinol-binding protein and β-*N*-acetylglucosaminidase—showed no evidence of renal damage. Prolonged exposure to desflurane (7 MAC-hours) has been associated with normal renal function.[26]

Sevoflurane is not very stable. Soda lime causes it to decompose,[27] and it is biotransformed by the liver. Plasma inorganic fluoride concentrations approaching nephrotoxic levels (50 μmol/L)[28] have been reported after prolonged inhalation of sevoflurane. No evidence of gross changes in renal function was found in humans, however.[29] In one study, sevoflurane was used at low flow (1 L/min), and there was no relationship to compound A and renal function.

Inhaled anesthetics cause a transient reversible depression in renal function. GFR, renal blood flow, urine output, and urinary excretion of sodium are decreased (Table 72-8). Probable mechanisms include reduced renal blood flow, loss of renal autoregulation, neurohumoral factors (e.g., antidiuretic hormone, vasopressin, renin), and neuroendocrine responses. Although most inhaled anesthetics have been shown to reduce GFR and urinary excretion of sodium, their effects on renal blood flow have yielded conflicting results, which can be explained by differences in experimental methodology. Data suggest that renal blood flow is maintained with halothane, isoflurane, and desflurane,[30,31] but it is decreased with enflurane and sevoflurane.[32,33]

Intravenous Anesthetics

Reversal of CNS effects after the administration of ultrashort-acting barbiturates such as thiopental and methohexital occurs as a result of redistribution, and hepatic metabolism is the sole route of elimination of these drugs (see Chapter 30). Thiopental is 75% to 85% bound to albumin,[34] the concentration of which may be markedly reduced in uremia. Because it is a highly bound drug, reduced binding permits a greater proportion of an administered dose of thiopental to reach receptor sites. In addition, thiopental is a weak acid, with its pK_a in the

Although conflicting reports of anesthetic effects on RBF have been reported because of different investigative methods, the current literature seems to support these data.

physiologic range; acidosis results in more un-ionized, nonbound, active thiopental. In combination, these changes produce an increase in the free fraction of thiopental from 15% in normal patients to 28% in patients with CRF.[35] With thiopental metabolism essentially unchanged in renal disease, the dose to produce and maintain anesthesia should be reduced.[35] The same considerations are true for methohexital, although metabolism plays a slightly greater part in the termination of its therapeutic effect.[36]

Propofol does not adversely affect renal function as reflected by measurements of creatinine concentration. Prolonged infusions of propofol may result in the excretion of green urine because of the presence of phenols in the urine. This discoloration does not affect renal function. Urate excretion is increased after the administration of propofol and is usually manifested as cloudy urine when urate crystallizes under conditions of low pH and temperature.[37]

There are no reports of the disposition of narcotics and tranquilizers when used in large dosage for anesthesia in uremic patients. These drugs are extensively metabolized before excretion; therefore, when combined with 30% to 50% nitrous oxide, they should not have a particularly prolonged effect. The benzodiazepines, especially diazepam,[13] have a long half-life and tend to accumulate. Because of the greater ease of reversibility of the potent inhaled anesthetics versus intravenous drugs, inhaled anesthetics may offer some advantages for the induction of general anesthesia in uremic patients.

Muscle Relaxants and Their Antagonists (See Chapters 34 and 35)

Succinylcholine has been used without difficulty in patients with decreased or absent renal function. Its metabolism is catalyzed by pseudocholinesterase to yield the nontoxic end products succinic acid and choline. The metabolic precursor of these two compounds, succinylmonocholine, is excreted by the kidneys. Large doses of succinylcholine, which might result from prolonged infusion, should be avoided in patients with renal failure. Although pseudocholinesterase levels are reduced in uremia,[38] these reductions are insufficient and cause a prolonged block. Hemodialysis has been reported to have no effect on cholinesterase levels.[39]

Administration of succinylcholine causes a rapid, transient increase of 0.5 mEq/L in the serum potassium concentration. In traumatized, burned, or neurologically injured patients, the increase may be 5 to 7 mEq/L, probably as a consequence of denervation supersensitivity of the muscle membrane to succinylcholine and to acetylcholine,[40] which can result in cardiovascular collapse. An exaggerated increase in serum potassium could be particularly dangerous in uremic patients with hyperkalemia; therefore, the use of succinylcholine is inadvisable, unless the patient has undergone dialysis within 24 hours before surgery. If the patient has recently undergone dialysis or has normal serum potassium, the use of succinylcholine is reportedly safe.

The disposition of nondepolarizing muscle relaxants has been well studied. Renal failure influences the pharmacology of nondepolarizing muscle relaxants by producing either decreased elimination of the drug or its metabolites by the kidney or decreased activity of enzymes that metabolize the drug, such as in the case of mivacurium (Table 72-9). Consequently, the duration of action of muscle relaxants may be prolonged in patients with renal failure.

Approximately 40% to 50% of pancuronium is excreted in urine. A portion of this excretion occurs after biotransformation to the less active metabolite 3-hydroxypancuronium.[41] Pancuronium has a prolonged terminal elimination half-life in patients with reduced renal function (see Table 72-9)[42]; therefore, it should be administered cautiously, particularly when several doses are required.

Two nondepolarizing muscle relaxants, atracurium and vecuronium, were introduced into clinical practice during the early 1980s. Atracurium is degraded by enzymatic ester hydrolysis and nonenzymatic alkaline degradation (Hofmann elimination) to inactive products that are not dependent on renal excretion for termination of action.[43] Predictably, their terminal elimination half-life and indices of neuromuscular blockade (onset, duration, and recovery) are the same in patients with normal and absent renal function.[44]

Approximately 30% of a dose of vecuronium is eliminated by the kidneys. Lynam and colleagues[45] found that the duration of neuromuscular blockade after the administration of vecuronium was longer in patients with renal failure than in patients with normal renal function (99 versus 54 minutes) because of a longer elimination half-life (83 versus 52 minutes) and lower plasma clearance

(3.1 mL/kg/min versus 5.3 mL/kg/min). In a related area, an interaction between the solvent of cyclosporine (Kolliphor EL) with atracurium and vecuronium has been reported, with the action of these muscle relaxants potentiated in cats,[46] but it is unknown whether such potentiation also occurs in human renal transplant recipients.

Cisatracurium is the single *cis* isomer of atracurium. Organ-independent mechanisms (Hofmann elimination) account for 77% of the total clearance of cisatracurium. Because renal excretion accounts for only 16% of the elimination of cisatracurium, renal failure should have little effect on its duration of action.[44]

The short-acting drug mivacurium is metabolized by plasma pseudocholinesterase. Its effect has been shown to be lengthened by 10 to 15 minutes in patients with ESRD, most likely because of a decrease in plasma cholinesterase activity in these patients associated with uremia or hemodialysis[47,48] and a decrease in the mivacurium requirement by infusion in anephric patients.[48]

The elimination half-life of rocuronium is increased in renal failure because of an increase in the volume of distribution with no change in clearance. This explanation might account for a longer duration of action in anephric patients, although its clinical significance is uncertain.[49]

Pharmacokinetics data for the cholinesterase inhibitors neostigmine, pyridostigmine, and edrophonium for normal, anephric, and renal transplant patients are presented in Table 72-10; there are no major differences among the three drugs.[50-52] Renal excretion is of major importance for the elimination of all three reversal drugs, with approximately 50% of neostigmine and 70% of pyridostigmine and edrophonium excreted in urine. Excretion of all the cholinesterase inhibitors is delayed in patients with impaired renal function to the same or perhaps to a slightly greater extent than is elimination of muscle relaxants. Reappearance of neuromuscular blockade after pharmacologic reversal of neuromuscular blockade in a patient with renal failure is, in most cases, due to some other cause. Table 72-10 contains data indicating that the pharmacokinetics of all the cholinesterase inhibitors is similar in healthy patients and in patients with well-functioning newly transplanted kidneys.

Vasopressors and Antihypertensive Drugs (See Chapter 16)

Patients with severe renal disease are frequently given antihypertensive and other cardiovascular medications. More than 90% of the thiazides[53] and 70% of furosemide[54] are excreted by the kidneys and they have prolonged durations of action in patients with abnormal or absent renal function. Propranolol is almost completely metabolized in the liver, and esmolol is biodegraded by esterases in the cytosol of red blood cells; therefore, their effects are not prolonged in patients with abnormal or absent renal function.[55] The calcium channel–blocking agents nifedipine, verapamil, and diltiazem are extensively metabolized in the liver to pharmacologically inert products; they can be administered in usual doses to patients

with renal insufficiency.[56] Nitroglycerin is useful because it is metabolized rapidly, with less than 1% excreted unchanged in urine.[57]

Sodium nitroprusside has had a resurgence in use since its initial introduction as a hypotensive drug in the 1920s. Cyanide is an intermediate in the metabolism of sodium nitroprusside, with thiocyanate being the final metabolic product. Although cyanide toxicity as a complication of sodium nitroprusside therapy is well described,[58] it is less well appreciated that thiocyanate is also potentially toxic. The half-life of thiocyanate is normally more than 4 days, and it is prolonged in patients with renal failure.[58] Hypoxia, nausea, tinnitus, muscle spasm, disorientation, and psychosis have been reported when thiocyanate levels are more than 10 mg/100 mL. Sodium nitroprusside is less desirable for prolonged administration than either trimethaphan or nitroglycerin.

Hydralazine is slower acting than the other three drugs discussed previously. Its action is terminated by hydroxylation and subsequent glucuronidation in the liver, with approximately 15% excreted unchanged in urine.[59] The elimination half-life of hydralazine is prolonged in patients with uremia; therefore, caution is required when it is administered.[60] After a single intravenous dose of 0.5 mg/kg of labetalol, the volume of distribution, clearance, and elimination half-life were similar in patients with ESRD and in healthy volunteers.[61] Esmolol is independent of renal function because it is metabolized by red blood cell cytosol esterases.[62]

If administration of a vasopressor is necessary, a direct β-adrenergic–stimulating drug such as phenylephrine would be effective. This type of vasopressor causes the greatest interference with renal circulation. Although β-adrenergic–stimulating drugs such as isoproterenol maintain heart and brain perfusion without renal vasoconstriction, they also increase myocardial irritability. When possible, it is best to substitute simple measures such as blood volume expansion for drug therapy. If these measures are inadequate, β-adrenergic–stimulating drugs or dopamine should be used.

ACUTE KIDNEY INJURY AND HEMODIALYSIS

Until recently the definition of acute kidney injury (AKI) was not standardized.[63] Authors have used terms such as renal insufficiency, renal dysfunction, acute renal failure (ARF), and renal failure requiring dialysis somewhat interchangeably. Parameters used to define these terms include (Fig. 72-5) absolute and percentage changes in creatinine values, absolute and percentage changes in estimated GFRs, and reduction in output.[64] The incidence of AKI depends on the type of surgery and preexisting kidney function (Box 72-2 and Table 72-11).

In cardiac surgery, incidence is between 7.7% and 11.4%[65] when defined broadly, whereas frequency of AKI requiring dialysis is generally lower, ranging between less than 1% and 5%. In gastric bypass surgery, the incidence is 8.5%[66] and after aortic aneurysm surgery, it is around 15% to 16%.[67] Similarly, liver transplant is also associated with a high frequency of AKI. It is reported that 48% to 94%[68] of patients suffer from acute worsening renal function after liver transplantation.

In noncardiac surgery, several independent risk factors for AKI have been identified by Kheterpal and co-workers[69]: age, emergent surgery, liver disease, body mass index, high-risk surgery, peripheral vascular disease, and chronic obstructive pulmonary disease (requiring chronic bronchodilator therapy). Based on incremental score, the frequency of renal failure increased, ranging between 0.3% and 4.5%, respectively.

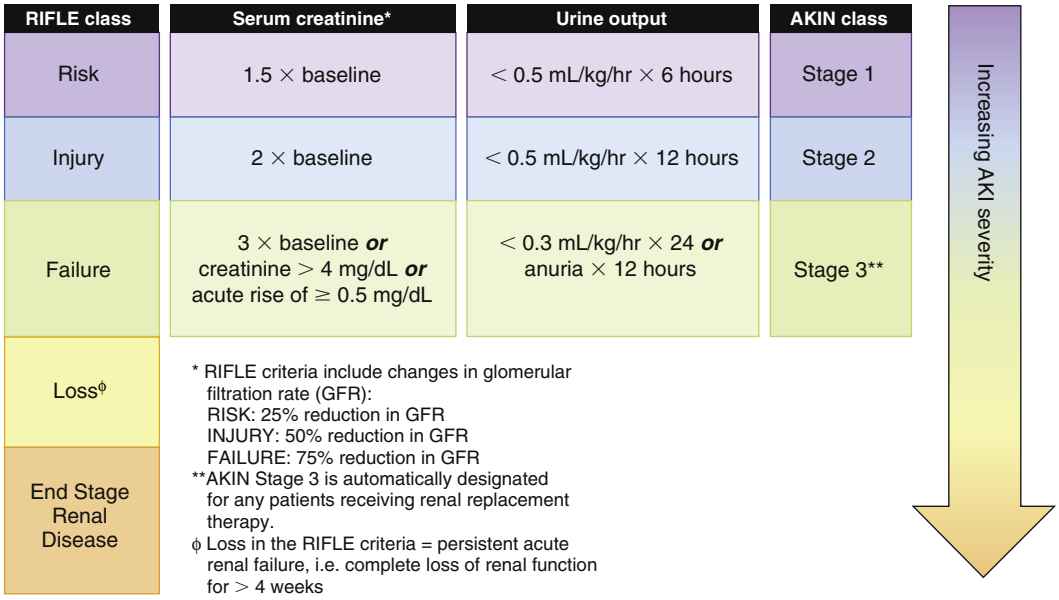

Figure 72-5. Parameters used to define acute kidney injury. *(From Mehta RL, Kellum JA , Shah SV, et al: Acute Kidney Injury Network: Report of an initiative to improve outcomes in kidney injury,* Crit Care *11:R31, 2007.)*

PERIOPERATIVE MANAGEMENT OF PATIENTS WITH ACUTE KIDNEY INJURY

Although many factors have been shown to contribute to AKI in surgical patients, there are few interventions demonstrated to prevent AKI. Of these interventions, there is no obvious cure for perioperative renal injury. Although a complete review of such interventions is beyond the scope of this chapter, some deserve mention.[64]

Dialysis

Dialysis may not decrease perioperative AKI; however, it can treat the associated acidosis, hyperkalemia, and hypervolemia. For certain surgeries, such as aortic, dialysis actually reduces 30-day mortality rates in patients who develop loss of renal function.[70] As many as 75% of these survivors regain kidney function and become independent of dialysis.

BOX 72-2 ***Risk Factors for Development of Postoperative Acute Kidney Injury***

Preoperative Factors

- Preoperative renal dysfunction
- Increasing age
- Heart disease (ischemic or congestive)
- Smoking
- Diabetes mellitus
- ASA PS 4 or 5

Intraoperative Factors

- Emergency surgery or intraperitoneal, intrathoracic, suprainguinal vascular surgeries
- Erythrocyte transfusion
- Inotrope use
- Aortic cross-clamp time
- CPB: furosemide use, urine output, need for a new pump run

Postoperative Factors

- Erythrocyte transfusion
- Vasoconstrictor use
- Diuretic use
- Antiarrhythmic drug use

Data from Abelha FJ, Botelho M, Fernandes V, et al: Determinants of postoperative acute kidney injury, Crit Care *13:R19, 2009; and Parolari A, Pesce LL, Pacini D, et al: Risk factors for perioperative acute kidney injury after adult cardiac surgery: role of perioperative management,* Ann Thorac Surg *93:584-591, 2012.*

ASA PS, American Society of Anesthesiologists Physical Status classification; *CPB,* cardiopulmonary bypass.

Nondialytic Management

Optimal therapy for renal dysfunction is not clear as to whether such as ACE-I therapy or diuretic therapy prevents decline in kidney function around the time of surgery.[65]

Normal hemodynamic variables probably should be preserved during the operative period in an attempt to prevent AKI. Scavengers of oxygen free radicals such as mannitol and *N*-acetylcysteine have been given to prevent ischemia-reperfusion injury. Recent studies, however, have failed to show benefit in reduction of AKI in cardiac surgery patients. For years, mannitol was administered before aortic clamping, especially suprarenal clamping, during abdominal aortic aneurysm surgery. It is not clear whether this approach reduces the incidence of renal failure in this population of patients.[71]

Both dopamine[72] and atrial natriuretic peptide initially showed promise in the prevention of AKI because of their vasoactive effects leading to increased renal blood flow. Studies have shown neither dopamine nor atrial natriuretic peptide to be associated with improved mortality. Likewise, fenoldopam, a selective renal dopamine receptor agonist, initially showed potential renoprotective benefit. In large studies, fenoldopam was not beneficial in prevention of AKI.[73]

RENAL AND GENITOURINARY PROCEDURES

TRANSURETHRAL RESECTION OF THE PROSTATE

Pathophysiology of Prostate Hypertrophy

The prostatic gland consists of four closely integrated zones—the anterior, peripheral, central, and preprostatic zones. Each zone consists of secretory, smooth muscle, and fibrotic tissue. All four zones are enclosed in one capsule. The gland is rich in blood supply. Arteries and veins penetrate the prostatic capsule and branch inside the gland. The venous sinuses adjacent to the capsule are particularly large. Nodules begin to develop by the fourth decade of life in the preprostatic zone and form middle, lateral, and posterior lobes. The middle and posterior lobes are most often associated with symptoms of urinary tract obstruction.[74]

TABLE 72-11 COMMON CAUSES OF POSTOPERATIVE DECREASED URINE OUTPUT AND ACUTE KIDNEY INJURY

Surgical Procedures

Transurethral resection of the prostate (TURP) is performed by inserting a resectoscope through the urethra and resecting prostatic tissue with an electrically powered cutting-coagulating metal loop or using laser-vaporization energy. This can be accomplished with either a monopolar TURP (M-TURP) or bipolar TURP (B-TURP) technique. Laser energy for TURP has also been used for many years. With each technique, as much prostatic tissue as possible is resected, but the prostatic capsule is usually preserved. If the capsule is violated, large amounts of irrigation solution can be absorbed into the circulation via the periprostatic, retroperitoneal, or peritoneal space.

Bleeding during TURP is common, but usually controllable; however, when large venous sinuses are opened, hemostasis becomes difficult. If bleeding becomes uncontrollable, the procedure should be terminated as quickly as possible, and a Foley catheter should be passed into the bladder and traction applied to it. The catheter's inflated balloon exerts lateral pressure on the prostatic bed and reduces bleeding. Bleeding requiring transfusion occurs in approximately 2.5% of TURP procedures.[75]

Irrigation Solutions

Ideally, an irrigation solution for TURP should be isotonic, electrically inert, nontoxic, transparent, easy to sterilize, and inexpensive. Such a solution does not exist. Distilled water is electrically inert and inexpensive and has excellent optical properties, but it is extremely hypotonic. When absorbed into the circulation in large amounts, plain water causes hemolysis, shock, and renal failure.

Numerous nearly isotonic irrigation solutions are available. Commonly used solutions are glycine 1.2% and 1.5%, mannitol 3% to 5%, glucose 2.5% to 4%, sorbitol 3.5%, Cytal (a mixture of sorbitol 2.7%, and mannitol 0.54%), and urea 1% (Table 72-12). These solutions are purposely moderately hypotonic to preserve their transparency.

Although these irrigation solutions cause no significant hemolysis, excessive absorption of them can lead to other complications, such as pulmonary edema and hyponatremia. In addition, the solutes can have adverse effects. Glycine can cause cardiac and retinal toxic effects, mannitol rapidly expands the blood volume and can cause pulmonary edema in cardiac patients, and glucose can cause severe hyperglycemia in diabetic patients. These complications are discussed in detail later.

TABLE 72-12 OSMOLALITY OF IRRIGATION SOLUTIONS USED FOR TRANSURETHRAL RESECTION OF THE PROSTATE

Solution	Osmolality (mOsm/kg)
Glycine, 1.2%	175
Glycine, 1.5%	220
Sorbitol, 3.5%	165
Mannitol, 5%	275
Cytal (see text)	178
Glucose, 2.5%	139
Urea, 1%	167

Replacement of distilled water with nearly isosmotic solutions has eliminated hemolysis and its sequelae as a complication of M-TURP. The incidence of severe CNS problems associated with extreme hyponatremia, such as convulsions and coma, has been reduced. The other major problem associated with the absorption of large volumes of irrigating solution, overhydration, still remains, however. With B-TURP and laser-TURP (L-TURP) techniques normal saline as the bladder irrigating solution can be used which significantly helps to minimize or eliminate TURP syndrome.

Anesthetic Techniques

Previously, spinal anesthesia was the most frequently used anesthetic for TURP in the United States, and it is believed to be the technique of choice when traditional M-TURP is performed. Spinal anesthesia provides adequate anesthesia for the patient with good relaxation of the pelvic floor and the perineum for the surgeon. The signs and symptoms of water intoxication and fluid overload can be recognized early because the patient is awake. Accidental bladder perforation also is recognized easily if the spinal level is limited to T10 because the patient would experience abdominal or shoulder pain. Satisfactory regional anesthesia for TURP involves achieving an anesthetic block level that interrupts sensory transmission from the prostate and bladder neck. In addition, the uncomfortable sensation of bladder distention must be considered.[76,77]

As explained earlier, the visceral pain sensation from the prostate and bladder neck is transmitted by afferent parasympathetic nerve fibers derived mostly from the second and third sacral roots traveling with the pelvic splanchnic nerves. Bladder sensation is supplied by sympathetic nerves of the hypogastric plexus, derived from nerve roots extending inferiorly from T11 to L2. Regional anesthesia resulting in a sensory level to T10 is required to eliminate the discomfort caused by bladder distention and other aspects of this procedure; however, slightly lower sensory levels often suffice for smaller lesions. In one study in which bladder pressure was monitored and kept low, anesthetic levels to T12 or L1 were adequate, but midlumbar blocks to L3 were not.[78] Sensory levels above T9 should not be sought because the capsular sign (i.e., pain on perforation of the prostatic capsule) would not be present should perforation occur.

Subarachnoid anesthesia is generally preferred over continuous epidural anesthesia for the following reasons. It is technically easier to perform in elderly patients, and the duration of surgery is generally not long. The incomplete block of sacral nerve roots that occasionally occurs with the extradural technique is usually avoided with subarachnoid anesthesia.

Caudal and sacral blockade also has been used effectively for prostate surgery, and bladder distention is avoided with the use of continuous irrigation. Caudal anesthesia has been used effectively in high-risk patients undergoing laser prostatectomy.[79] Hemodynamic stability is the main advantage with this technique. Local infiltration of the perineum and the prostatic fossa also has been advocated by some anesthesiologists for limited TURP procedures, although the operative analgesia afforded

by local infiltration is not comparable in quality to spinal anesthesia. General anesthesia may be necessary in patients who require ventilatory or hemodynamic support, have a contraindication to regional anesthesia, or refuse regional anesthesia.

Advantages of Regional Anesthesia over General Anesthesia

Regional anesthesia offers several advantages over general anesthesia for TURP (see Chapter 56). The incidence of deep vein thrombosis is decreased, and the amount of operative blood loss is reduced with regional anesthesia compared with general anesthesia. The reduction in operative blood loss when regional rather than general anesthesia is used has been shown to be the case in other pelvic procedures in addition to TURP, such as cystectomy and major vaginal surgery.[80] The decrease in systemic blood pressure secondary to the sympathetic blockade produced by the regional technique was determined not to be the only factor in reducing blood loss. Good evidence indicates that peripheral venous pressure and central venous pressure decrease during regional anesthesia and spontaneous ventilation. It is postulated that this decrease in peripheral venous pressure might result in reduced blood loss during prostatic and other surgery.

Additional factors influencing blood loss during TURP are the vascularity and size of the gland and the duration of surgery. An increase in fibrinolysis during prostate resection as a result of the release of urokinase from prostate tissue also factors into the blood loss that occurs. Other factors that affect blood loss during TURP include the size of the gland, the duration of the procedure, the number of sinuses opened during resection, the presence of infection, and prostate inflammation from repeated or recent catheterizations. These factors make it difficult to compare studies evaluating blood loss during TURP or to arrive at conclusive findings based on meta-analysis.[75,77]

Patients undergoing prostatectomy are prone to deep vein thrombosis for many reasons, including advanced age and the presence of malignancy, cardiac disease, varicose veins, and obesity. In this case, the increased blood flow resulting from the sympathetic blockade of regional anesthesia may play a role in reducing deep vein thrombosis formation.[81] Regional anesthesia decreases the hypercoagulable tendency in the postoperative period and helps maintain normal coagulation and platelet function; these benefits are believed to be due to modulation of the neuroendocrine response to tissue injury. Homeostasis of the neuroendocrine system and the immune response are better preserved after regional anesthesia than after general anesthesia.[81]

TURP is associated with a particular set of complications with anesthetic implications. These problems must be considered, along with the usual considerations, such as the general health of the patient, the length of the procedure, and patient and surgeon preferences, when choosing an anesthetic technique.

The use of regional anesthesia for TURP allows monitoring the patient's mental status intraoperatively. Excessive vascular absorption of a hypoosmolar bladder irrigating fluid during the procedure produces numerous problems with cardiovascular and neurologic implications. A change in the patient's mental status provides an early indication that excessive absorption of irrigating fluid has occurred. These changes are described more fully in the next section.

Visual disturbances, such as blurred vision and transient blindness, have been reported in association with TURP (see Chapter 100). The biotransformation of absorbed glycine to ammonia has been implicated in these and other CNS abnormalities. Another potential complication during TURP is bladder perforation secondary to overdistention with irrigation fluid or contact of the bladder wall with the surgeon's resectoscope. Conscious patients might experience symptoms related to perforation well before it becomes apparent to the surgeon, alerting the operating team early on. Signs and symptoms of bladder perforation include bradycardia, hypotension, restlessness, diaphoresis, nausea, abdominal pain, dyspnea, shoulder pain, and hiccups. Extraperitoneal perforation may be manifested as pain in the periumbilical, inguinal, or suprapubic area. Intraperitoneal bladder perforation, a less frequent event, may cause symptoms related to diaphragmatic irritation (i.e., pain referred to the upper part of the abdomen, precordial area, shoulder region, or neck).[81]

Regional anesthesia for TURP offers some advantages over general anesthesia. Although laboratory monitoring of electrolytes is useful intraoperatively, a change in mental status in a conscious patient provides an early indication of electrolyte disturbances. Bladder perforation is recognized earlier in a conscious or lightly sedated patient, as noted previously.

Sensory levels above T9 are undesirable because pain caused by perforation of the prostatic capsule (capsular sign) would not be apparent to the patient if this complication occurs. Another benefit of regional anesthesia for TURP is a decreased requirement for analgesics in the immediate postoperative period compared with general anesthesia.[82]

Morbidity and Mortality after Transurethral Resection of the Prostate

Although spinal anesthesia offers certain distinct advantages over general anesthesia for TURP surgery, mortality and many markers of patient outcome have been similar for both groups. What constitutes the safest anesthetic for prostatectomies was debated in 1924, with proponents of regional anesthesia gaining ground quickly thereafter.[83] The 30-day mortality rate associated with M-TURP is reported to be 0.2% to 0.8%.[77] Mortality rates are similar in patients receiving regional anesthesia or general anesthesia.[84] With mortality rates as low as 0.2%, however, many more patients need to be studied than previously examined in any of the studies to draw a meaningful and statistically significant conclusion.[76] The postoperative morbidity rate in one study was 18%.[77] Increased morbidity was found in patients with resections exceeding 90 minutes, gland size larger than 45 g, acute urinary retention, and age older than 80 years.[77] Ashton and coworkers[85] studied 250 men undergoing TURP and observed one postoperative myocardial infarction (0.4%) resulting in one death. The incidence of postoperative complications, including myocardial infarction, pulmonary embolism,

cerebrovascular accidents, transient ischemic attacks, renal failure, hepatic insufficiency, and the need for prolonged ventilation, is similar when comparing patients receiving regional anesthesia with patients receiving general anesthesia.[75,77]

Many investigators have studied postoperative cognitive function after TURP performed under general versus regional anesthesia. Most studies have failed to show any significant difference in cognitive function in patients receiving regional anesthesia and patients receiving general anesthesia.[86] Postoperative behavioral changes in TURP patients are believed to be related to fluid absorption and increased cerebral fluid; cerebral oximetry studies have confirmed this relationship.[87] Preoperative mental impairment in elderly patients also influences postoperative mental function, which makes another case against the use of heavy sedation in these patients.

COMPLICATIONS OF TRANSURETHRAL RESECTION OF THE PROSTATE

Absorption of Irrigating Solution

Because the prostate gland contains large venous sinuses, it is inevitable that irrigating solution would be absorbed. Simple principles govern the amount of absorption: (1) The height of the container of irrigating solution above the surgical table determines the hydrostatic pressure driving fluid into prostatic veins and sinuses, and (2) the time of resection is proportional to the quantity of fluid that is absorbed. On average, 10 to 30 mL of fluid is absorbed per minute of resection time, with 6 to 8 L absorbed in some procedures lasting up to 2 hours. Whether patients experience complications as a consequence of the absorption of irrigating fluid depends on the amount and type of fluid absorbed.[88,89]

Excessive Circulatory Volume, Hyponatremia, and Hypoosmolality

Solutions such as normal saline and lactated Ringer's solution would be well tolerated when absorbed intravascularly, but these electrolyte solutions are highly ionized and facilitate the dispersion of high-frequency current from a monopolar resectoscope. Solutions of nonelectrolytes, such as glucose, urea, glycine, mannitol, sorbitol, and Cytal, have replaced distilled water. Of all the irrigating solutions available today (see Table 72-12), glycine and Cytal are the two most commonly used.[88]

Replacement of distilled water with nearly isosmotic solutions has eliminated hemolysis and its sequelae as a complication of TURP. The incidence of severe CNS problems associated with extreme hyponatremia, such as convulsions and coma, has been reduced[89]; however, the other major problem associated with the absorption of large volumes of irrigating solution, overhydration, remains. Under usual conditions, only 20% to 30% of a load of crystalloid solution remains in the intravascular space; the remainder enters the interstitial space. When intravascular pressure is increased, movement of fluid into the interstitial space and the development of pulmonary edema are favored. Whether symptoms of circulatory overload develop in a given patient depends on the patient's cardiovascular status, the amount and rapidity of absorption of irrigating fluid, and the extent of surgical blood loss.[89]

The situation is dynamic, and patients must be monitored carefully. In this regard, spinal or epidural anesthesia, supplemented with only light intravenous sedation, has the advantage of allowing the patient's subjective judgment to contribute to assessment of his condition during surgery. In addition, the cardiovascular depression associated with the administration of potent inhaled anesthetics is avoided. Another advantage of regional anesthesia is that the sympathetic block that it produces increases venous capacitance and tends to mitigate intraoperative fluid overload. When the block dissipates, venous capacity acutely decreases, and circulatory overload can occur.

Concomitant with the excessive intravascular volume caused by significant absorption of irrigating fluid are usually hyponatremia and hypoosmolality. TURP syndrome has been typically described as being caused by hyponatremia and subsequent water intoxication. It is now recognized that the classic CNS signs of TURP are not caused by hyponatremia per se, but are due to the accompanying acute serum hypoosmolality that allows movement of water into cells and causes cerebral edema.[88,89]

The use of nonelectrolyte isosmotic irrigating solutions has reduced the incidence of severe CNS complications because extreme extracellular fluid hypoosmolality does not occur, and the subsequent development of cerebral edema is avoided.[88,89] That CNS symptoms occur at all is probably due to the fact that the incidence and extent of hyponatremia are unchanged. The concentration of extracellular sodium must be in the physiologic range for depolarization of excitable cells and production of the action potential. CNS symptoms, which include irritability, apprehension, confusion, and headache, provide early warning signs of rapidly developing hyponatremia. Further progression of hyponatremia (sodium ≤ 102 mEq/L) and decreased serum osmolality lead to the development of seizures and coma. The CNS effects become apparent at sodium levels less than 120 mEq/L. The cardiovascular effects of severe hyponatremia include negative inotropy, hypotension, and dysrhythmias. At sodium levels less than 115 mEq/L, electrocardiogram changes are made manifest by QRS widening and ST-segment elevation.[81]

When extracellular sodium levels are less than 100 mEq/L, consciousness is lost, and convulsions may ensue.[89] Signs and symptoms of cardiovascular dysfunction secondary to hyponatremia also may occur, including arrhythmias, hypotension, and pulmonary edema.[90] It is often impossible, however, to separate the latter events from events attributable to fluid overload.

Glycine Toxicity

Since the early 1980s, attention has turned to the absorption of glycine (HO_2—CCH_2—NH_2), a nonessential amino acid, as a possible cause of some CNS symptoms associated with TURP. In one publication, five cases of transient blindness were attributed to glycine toxicity.[91] Glycine has a distribution similar to that of aminobutyric acid, the latter being an inhibitory transmitter in the brain; it has been suggested that glycine is a major inhibitory

transmitter acting in the spinal cord and brainstem.[91] Normal plasma glycine levels are 13 to 17 mg/L, whereas levels of 1029 mg/L were measured during one episode of blindness. Twelve hours later, the glycine level in this case had declined to 143 mg/L, by which time vision had returned; however, an overall correlation between plasma glycine levels and CNS toxicity has not been established. This relationship, although interesting, still must be considered speculative. Glycine also has been implicated in the myocardial depression and hemodynamic changes associated with TURP syndrome.[92]

Ammonia Toxicity

Absorption of glycine can result in CNS toxicity because of oxidative biotransformation of glycine to ammonia.[93,94] In a report of delayed awakening after TURP in three patients,[93] an association with elevated blood ammonia concentrations was noted. Blood ammonia levels of 500 M were noted in this and another case report.[94] Deterioration of CNS function is said to occur when ammonia levels are greater than 150 M. In a prospective study examining glycine metabolism, blood ammonia levels were increased postoperatively in 12 of 26 patients in whom 1.5% glycine was used as the irrigating solution for TURP.[93] Blood glycine levels also were measured. Glycine and ammonia levels did not correlate; the opposite relationship was prevalent. High ammonia levels were not associated with CNS symptoms of toxicity. Although the investigators postulated that delayed awakening and other CNS symptoms were due to ammonia toxicity, it is unclear whether this hypothesis is correct.

Perforation

Another common complication of TURP is perforation of the bladder.[95] Perforations usually occur during difficult resections and are most often made by the cutting loop or knife electrode. Some are made by the tip of the resectoscope, whereas others result from overdistention of the bladder with irrigation fluid. Most perforations are extraperitoneal, and in a conscious patient they result in pain in the periumbilical, inguinal, or suprapubic regions. The urologist may also note the irregular return of irrigating fluid. Less often, the perforation is through the wall of the bladder and is intraperitoneal, or a large extraperitoneal perforation may extend into the peritoneum. In such cases, pain may be generalized in the upper part of the abdomen or be referred from the diaphragm to the precordial region or the shoulder. Other signs and symptoms, such as pallor, sweating, abdominal rigidity, nausea, vomiting, and hypotension, have been reported; the number and severity depend on the location and size of the perforation and the type of irrigating fluid. In an early series of 2015 cases in which the incidence of complications of TURP was examined, perforation occurred in 25 patients (1.2%).[96] Four deaths and five additional major complications occurred in 12 patients in whom suprapubic cystostomy was delayed more than 2 hours after perforation. Distilled water was the bladder irrigant in most of these cases; therefore, it is unclear whether these morbidity and mortality data are still relevant.

Transient Bacteremia and Septicemia

The prostate harbors many bacteria, which can be a source of intraoperative and postoperative bacteremia through the prostatic venous sinuses. This risk is increased further by the presence of an indwelling urinary catheter. Bacteremia is usually asymptomatic and easily treated with commonly used antibiotic combinations that are effective against gram-positive and gram-negative bacteria; however, septicemia may occur in 6% to 7% of patients.[77] Common manifestations include chills, fever, and tachycardia. In severe cases, bradycardia, hypotension, and cardiovascular collapse can occur, with mortality rates of 25% to 75%. Aggressive treatment with antibiotics and cardiovascular support is warranted.

Hypothermia

Irrigating fluids stored at room temperature are frequently used during TURP. Heat loss as a result of irrigation and significant absorption of this fluid can lead to a decrease in the patient's body temperature and cause shivering. The use of warmed irrigating solutions has been shown to be efficacious in reducing heat loss and the resultant shivering.[97] Although one may believe that warming of fluids might cause increased bleeding because of vasodilation, such is not the case, as shown by study of Heathcote and Dyer.[98] The use of systemic and intrathecal opioids decreases postoperative shivering from cold.[99]

Bleeding and Coagulopathy

A hypertrophied prostate is highly vascular, and operative bleeding can be significant. The blood is washed into the draining bucket and mixed with ample quantities of irrigant fluid. Estimation of blood loss is inaccurate and extremely difficult. Efforts have been made to quantify blood loss based on resection time (2 to 5 mL/min of resection time) and size of the prostate in grams (20 to 50 mL/g); however, these guidelines are rough estimates at best, and the patient's vital signs and serial hematocrit values should be monitored to assess the blood loss and need for transfusion. Because adrenergic receptors are abundant in prostate tissue, the use of adrenergic agonists would cause vasoconstriction of prostatic blood vessels and a decrease in blood loss.

Abnormal bleeding after TURP occurs in less than 1% of cases; it is believed by some clinicians to be due to systemic fibrinolysis secondary to plasmin. The prostate releases plasminogen activator, which converts plasminogen to plasmin. Other clinicians believe that the fibrinolysis is secondary to disseminated intravascular coagulation triggered by the systemic absorption of resected prostate tissue, which is rich in thromboplastin.[75] If primary fibrinolysis is suspected, aminocaproic acid can be effective when given intravenously in a dose of 4 to 5 g during the first hour, followed by 1 g/hr.[75]

Treatment of Transurethral Resection of the Prostate Syndrome

Treatment of TURP syndrome (Table 72-13) consists of fluid restriction and a loop diuretic such as furosemide. Hypertonic saline (3% sodium chloride) is rarely, if ever, necessary and should be considered only in patients with severe hyponatremia. CNS complications of hypertonic

TABLE 72-13 **SIGNS AND SYMPTOMS OF TRANSURETHRAL RESECTION OF THE PROSTATE SYNDROME**

Cardiovascular and Respiratory	Central Nervous System	Metabolic	Other
Hypertension	Agitation/confusion	Hyponatremia	Hypoosmolality
Bradyarrhythmias, tachyarrhythmias	Seizures	Hyperglycinemia	Hemolysis
Congestive heart failure	Coma	Hyperammonemia	
Pulmonary edema and hypoxemia	Visual disturbances (blindness)		
Myocardial infarction			
Hypertension			

saline include cerebral edema and pontine myelinolysis.[76,89] Cardiovascular support should be provided as necessary.

Anesthetic considerations for TURP should include positioning (see Chapter 41). TURP is usually performed in the lithotomy position with a slight Trendelenburg tilt. This positioning results in changes in pulmonary blood volume; a decrease in pulmonary compliance; a cephalad shift of the diaphragm; and a decrease in lung volume parameters such as residual volume, functional residual volume, tidal volume, and vital capacity. Cardiac preload may increase. Nerve injuries to the common peroneal, sciatic, and femoral nerves can occur.[76]

B-TURP, L-TURP, AND MICROWAVE ABLATION OF PROSTATE

Traditional M-TURP electrode prostate surgery has been challenged with new urethral prostate resection techniques. B-TURP offers the advantage of a bipolar electrode resection, which allows normal saline to be used as the bladder irrigating fluid. The electrical current is self-contained in the bipolar design, which prevents it from dispersing through the bladder irrigating fluid or patient. Using normal saline avoids the morbidity associated with hypoosmolar bladder irrigants, such as glycine if absorbed, but does not prevent the possibility of volume overload.

Issa[100] reviewed 16 studies conducted over a 10-year period comparing the safety properties of M-TURP and B-TURP. They found a statistically significant decrease in overall complication rate, transfusion rate, and TURP syndrome with B-TURP. A randomized outcome study by Chen and colleagues,[101] in which M-TURP and B-TURP were compared, found that B-TURP was associated with significantly less fluid absorption, less change in serum sodium and in hemoglobin, and comparable urologic efficacy in prostate symptom scores. Two meta-analytic studies comparing M-TURP and B-TURP also reported favorable outcomes in the B-TURP groups.[102,103] A prospective, randomized trial comparing complications and clinical outcomes 18 months after TURP, concluded that fewer postoperative readmissions, faster postoperative recovery, and equivalent long-lasting results were found in B-TURP than in M-TURP.[104]

L-TURP is replacing conventional TURP. Laser therapy delivers vaporization energy creating a thin resecting coagulation treatment zone during prostate resection. The neodymium:yttrium-aluminum-garnet (Nd-YAG) laser has been replaced by holmium and potassium-titanyl-phosphate lasers. The laser incorporates a 532-nm wavelength energy that is selectively absorbed by hemoglobin. When directed to the prostate, the laser vaporizes a layer of tissue in millimeter resection zones. An evolution of these lasers has occurred from 80 to 120 watts, to the currently available 180-watt laser. The increased wattage provides more efficient tissue ablation resulting in a decreased TURP resection time. These lasers produce varying degrees of coagulation and vaporization of prostate tissue. The main advantages over M-TURP include minimal blood loss (50 to 70 mL) and minimal fluid absorption, which should nearly eliminate these two major complications of TURP; however, other potential complications are introduced, including coagulation through the prostatic fossa and sloughing of prostatic debris in the postoperative period, with subsequent urinary obstruction and urinary retention.[105-109] Protective eyewear and a means to evacuate the smoke plume are needed.[110] In critically ill patients, caudal anesthesia has been used successfully for L-TURP because the use of continuous irrigation combined with minimal bleeding obviates the need for copious irrigation and minimizes bladder distention.[79]

Hanson and associates[111] reviewed the anesthetic implications of the newer prostate laser resection therapies. The described advantages included minimal bladder irrigating fluid absorption, a minimized risk of TURP syndrome, potential to perform the procedure on anticoagulated patients, delivery in an outpatient setting, and less emphasis on describing regional as the preferred anesthetic technique. General anesthesia is acceptable because of the decreased risk of TURP syndrome.

In a systematic review of randomized, controlled trials evaluating the efficacy and safety of L-TURP techniques versus conventional TURP for symptomatic benign prostatic obstruction, the authors observed that L-TURP provided slightly greater improvement in urinary symptoms and flow. Laser procedures resulted in fewer transfusions and strictures and shorter hospitalizations. Reoperation was required more often after laser procedures.[112] As suggested, L-TURP is feasible when anticoagulation therapy withdrawal is considered a significant patient risk perioperatively.[113]

When M-TURP, B-TURP, and bipolar plasma vaporization TURP were compared in a prospective, randomized long-term comparison study, capsular perforation and intraoperative bleeding were less in bipolar plasma vaporization TURP. Postoperative hematuria, blood transfusion, and clot retention rates were higher in M-TURP.[114]

Transurethral microwave thermotherapy (TUMT) ablation of the prostate is considered a minimally invasive office-based technique that can be performed under local or sacral block. High-energy TUMT has received

reconsideration for use instead of current TURP techniques in certain patient populations. It can be performed as an outpatient procedure and lacks significant side effects. Although it is still reported to be less effective than TURP in relieving urinary outflow obstruction long term, it is an option especially in elderly or high-risk patients.[115]

LASER LITHOTRIPSY

Laser lithotripsy is used for ureteral stones that are low in the ureter and not amenable to extracorporeal shock wave lithotripsy (ESWL). A pulsed dye laser is generated with a laser beam of 504-nm wavelength passing through an organic green dye.[116] This laser beam is easily absorbed by the stones, and pulsatile energy is released that causes disintegration of the stones. The beam is carried over a bare wire passed through a rigid ureteroscope, which is longer and more pointed than a cystoscope, so the risk of ureteral perforation exists. Ideally, general anesthesia with paralysis should be maintained to avoid patient movement. If regional anesthesia is chosen, a spinal level of T8 to T10 is required. The bare laser wire is sharp and can cause mucosal injury to the ureter. These lasers are not well absorbed by red blood cells or other tissues, however, which provides safety against tissue coagulation or thermal injury. Because the laser beam is reflective, the user, other personnel, and the patient should wear protective eyeglasses. Some hematuria always occurs; good intravenous hydration is recommended.[116]

LAPAROSCOPIC SURGERY IN UROLOGY

Urologic laparoscopic surgery continues to pioneer new surgical approaches for treatment of diseases previously performed by an open surgery. Advances in this area now routinely include laparoscopic varicocelectomy, hernia repair, adrenalectomy, partial adrenalectomy, renal pelvis or ureter percutaneous stone retrieval, nephrectomy, radical prostatectomy, extra-adrenal pheochromocytoma, nephropexy, pyeloplasty, nephrectomy, partial nephrectomy, and cystectomy. Many of these surgeries are robot assisted for tumor resection and reconstruction. During robotic laparoscopic surgery, the surgeon is stationed in the operating room away from the operating room table while working at a computer console with a three-dimensional view of the operating field and manual controls at the console for robotic instruments placed in the abdomen via laparoscopy trocars.

For radical prostatectomy, the objectives of laparoscopic surgery are to reduce perioperative morbidity compared with conventional surgery and allow a more precise operative procedure. The quality of surgery can be improved by better visualization of the operative site as a result of optical magnification and the maneuverability of the laparoscope, which provides a hitherto unobtainable anatomic view. The laparoscopic approach not only improves the postoperative course, but also allows better preservation of periprostatic vascular, muscular, and neurovascular structures.[117]

A unique challenge in nephron-sparing laparoscopic surgery is achieving successful renal hypothermia for renal preservation during renal artery occlusion. Techniques described for renal hypothermia include laparoscopic deployed ice slush kidney surface cooling (preferred option), endoscopic retrograde cold saline infusion, and transarterial renal hypothermia via femoral artery catheter approach.

Although all the conventional complications and concerns associated with laparoscopy are applicable to urologic procedures, two unique problems also are identified. First, because the urogenital system is mainly retroperitoneal, the large retroperitoneal space and its communications with the thorax and subcutaneous tissue are exposed to the insufflated carbon dioxide. Significant subcutaneous emphysema can occur in these patients and may extend all the way up to the head and neck.[118] The upper airway is at risk for compromise in the most severe cases because of pharyngeal swelling secondary to submucous carbon dioxide. This complication should be kept in mind before extubation of the trachea in these patients. Second, the procedures can be lengthy, allowing for sufficient absorption of carbon dioxide to result in acidemia and marked acidosis.[118] Because of significant increases in intra-abdominal and intrathoracic pressure as a result of insufflated carbon dioxide, a steep Trendelenburg position, and lengthy procedures, general anesthesia with controlled ventilation is the method of choice. Despite adequate intravascular hydration, intraoperative oliguria may occur and be followed by diuresis in the immediate postoperative period. Although the exact mechanism is unclear, increased perirenal pressure exerted by the insufflated gas in the retroperitoneal space is a likely explanation.

EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY

Extracorporeal shock wave lithotripsy has become the treatment of choice for disintegration of urinary stones in the kidney and upper part of the ureter. The first clinical model of the lithotripter introduced into common practice (Dornier HM-3) used a water bath in a steel tub and a metal gantry chair to support the patient suspended in a sitting position. This first-generation lithotripter is still used in some institutions and presents complex challenges of immersion physiology and monitoring difficulties. Second-generation and third-generation lithotripters (e.g., Siemens, Lithostar, Wolf Piezolith, Dornier HM-4, MFL 5000, MPL 9000) have evolved mainly in the direction of eliminating the water bath and minimizing patient discomfort. All lithotripters share similar technologic principles in having three main components: (1) an energy source, most commonly a spark plug (alternatively, an electromagnetic membrane or piezoelectric elements); (2) a system to focus the shock wave, such as ellipsoid or reflecting mirrors; and (3) fluoroscopy or ultrasound to visualize and localize the stone in focus.[119]

Technical Aspects

An electrode (or spark plug) located in an ellipse creates a spark causing explosive vaporization of water. The sudden expansion of air bubbles created sets up a pressure wave (shock wave) which is focused by the ellipse to a

focal point called the F2 focus (the tip of the electrode is the F1 focus). The shock wave travels through water and body tissues without significant localized dissipation of energy because the acoustic impedance of the two media is similar. When the shock wave arrives at the entry surface of the stone, however, it encounters a sudden change in impedance that causes it to release compressive energy. Similarly, when the wave exits on the opposite surface of the stone, an interface is encountered again, and shock wave energy is released. Repeat applications cause the stone to disintegrate. Shock wave energy is most concentrated in the F2 focal zone and rapidly decreases beyond it.[120]

Biomechanical Effects of Shock Wave Therapy

For shock waves to be most effective, the stone should remain in the F2 focus during treatment.[79] Pressure energy measurements show an exponential decrease beyond this small focal zone. The kidneys and the kidney stone follow the up-and-down movements of the diaphragm during respiration. The stone is likely to move in and out of focus during respiration. In the past, ventilatory techniques such as decreased tidal volumes with increased respiratory rates and high-frequency jet ventilation have been used to increase the efficacy of the treatment.[121] However with contemporary lithotripsy machines, sedation and therefore spontaneous ventilation is the only option.

For effective stone disintegration, shock waves should reach the stone unimpeded. The flank area should be kept free of any medium that would provide an interface for the dissipation of shock wave energy. Nephrostomy dressings should be removed, and the nephrostomy catheter should be taped clear of the blast path. Although shock waves pass through most tissues relatively unimpeded, they do cause tissue injury, the extent of which depends on the tissue exposed and the shock wave energy at the tissue level. Skin bruising and flank ecchymoses can occur at the entry site. Painful hematoma in the flank muscles may occur. Hematuria is almost always present at the end of the procedure and results from shock wave–induced endothelial injury to the kidney and ureter. Adequate hydration is necessary to prevent clot retention. Lung tissue is especially susceptible to injury by shock waves. Air trapped in alveoli presents a classic water (tissue)-air interface to the shock wave and causes dissipation of energy. Massive hemoptysis and death from pulmonary damage have been reported in laboratory animals after a single exposure of the thorax to a shock wave.[122] Shock wave–induced hemoptysis in a child and a pulmonary contusion with life-threatening hypoxemia in an adult have been reported.[123,124] Children are more likely to sustain pulmonary damage from shock waves because of the shorter distance of the lung bases from the kidneys than in adults. It is recommended that a Styrofoam sheet or Styrofoam board be placed under the back in children to shield the lung bases from shock waves during ESWL.[123,124]

Shock wave–induced cardiac arrhythmias previously reported in 10% to 14% of patients undergoing lithotripsy are extremely rare nowadays.[125,126] These arrhythmias are believed to be due to mechanical stress on the conduction system exerted by the shock waves. The intricate grounding system of the lithotripter ensures that any current-induced arrhythmias are unlikely. Artifacts on electrocardiogram also are common. Artifacts and arrhythmias usually disappear when the lithotripsy is stopped.

Physiologic Changes during Immersion Lithotripsy

Water immersion with the Dornier HM-3 lithotripter produces significant changes in the cardiovascular and respiratory systems (Box 72-3).

Anesthetic Choices for Lithotripsy

Anesthetic regimens used successfully for lithotripsy include general anesthesia, epidural anesthesia, spinal anesthesia, flank infiltration with or without intercostal blocks, and analgesia-sedation, including patient-controlled analgesia.[127-135] General anesthesia offers the advantages of rapid onset and control of patient movement. Ventilatory variables can be controlled to decrease stone movement with respiration. With epidural anesthesia using loss of resistance to air to identify the epidural space, only the smallest amount of air necessary should be injected. Air in the epidural space provides an interface and can cause dissipation of shock wave energy and local tissue injury. Korbon and associates[136] found a decrease in epidural compliance and pain on injection with repeat epidurals for subsequent lithotripsies in their patients. In animal experiments, they were able to show epidural tissue damage after injection of air and exposure to shock waves.[137] It is reassuring, however, that in most lithotripsies performed under epidural anesthesia worldwide, neurologic injury has not been a problem.[138]

The main disadvantage of epidural anesthesia is its slow onset. Spinal anesthesia offers a reasonable alternative with its rapid onset. The incidence of hypotension (the patient is in a sitting position for treatment) is higher, however. In one series, the incidence of hypotension with general, epidural, and spinal anesthesia was 13%, 18%, and 27%, respectively.[139] Local anesthetic infiltration of the flank with or without intercostal blocks provides adequate anesthesia when combined with intravenous sedation and avoids hypotension.[127] Intravenous analgesia-sedation in various combinations has been used successfully.[129,130]

BOX 72-3 *Changes on Immersion during Lithotripsy*

Cardiovascular	Increased	Central blood volume
	Increased	Central venous pressure
	Increased	Pulmonary artery pressure
Respiratory	Increased	Pulmonary blood flow
	Decreased	Vital capacity
	Decreased	Functional residual capacity
	Decreased	Tidal volume
	Increased	Respiratory rate

Newer Lithotripters

Newer lithotripters have no water bath, and they tend to use multifunctional tables that allow other procedures, such as cystoscopy and stent placement, to be accomplished without moving the patient off the table. The shock waves are tightly focused; therefore, they cause less pain at the entry site, and intravenous analgesia-sedation is the mainstay of anesthesia with these newer lithotripters. Other incidental interventions, such as cystoscopy, stone manipulation, or stent placement, alter anesthetic requirements. Many of these newer lithotripters have a much smaller focal zone for the shock waves. It is even more imperative that adequate analgesia and sedation be provided, so that stone excursion with respiration is limited to the focal zone. Most analgesia-sedation combinations are adequate. Even patient-controlled analgesia with alfentanil and a combination of propofol and alfentanil has been used.[140,141] Many centers routinely use general anesthesia with short-acting inhaled or intravenous anesthetics and use laryngeal mask airway for ventilation.

Contraindications

Pregnancy and untreated bleeding disorders are the only contraindications to lithotripsy. Women of childbearing age must have a pregnancy test that is documented to be negative before lithotripsy. Standard tests of coagulation, such as the platelet count, prothrombin time, and partial thromboplastin time, should be obtained as indicated by medical history. Pacemakers, automatic implanted cardioverter-defibrillators (AICDs), abdominal aortic aneurysm, orthopedic prostheses, and obesity are no longer considered contraindications.

Patients with pacemakers can be treated safely if the pacemaker is pectorally placed and the following precautions are observed (see Chapter 48).[142-144] Pacemaker programmability should be established before the treatment, and the pacemaker should be switched to a nondemand mode in case the shock waves interfere with pacemaker function. Alternative means of pacing should be available. Although most pacemakers located pectorally are at a safe distance from the blast path, some may be damaged. Weber and co-workers[142] examined 43 different pacemakers and found that 3 were affected. Dual-chamber pacemakers tend to be more sensitive to interference. Treatment should be started at a low energy level and gradually increased while observing pacemaker function.

Manufacturers of AICDs and lithotripters have considered an AICD a contraindication for lithotripsy; however, patients with AICDs have been treated successfully with lithotripsy.[143] AICD devices should be shut off immediately before lithotripsy and then reactivated immediately after treatment.[145]

Patients with small aortic aneurysms have been treated safely, provided that the stone is not close to the aneurysm. Orthopedic prostheses, such as hip prostheses and even Harrington rods, are not a problem if they are not in the blast path, which is usually the case. Positioning of obese patients may be problematic at times. Not only do extremely obese patients present anesthetic challenges related to obesity, but also focusing of the stone may be extremely difficult in the very obese. It is prudent for focusing of the stone to be attempted before administering any anesthetic in this high-risk population.

RADICAL SURGERY IN UROLOGY

Radical surgery includes radical nephrectomy, radical cystectomy, and radical retropubic prostatectomy. Common features include lengthy procedures, associated sudden and significant blood loss, and attention to renal function preservation. With radical nephrectomy, significant cardiorespiratory changes attendant to the flank position are a concern. Respiratory changes include decreases in thoracic compliance, tidal volume, vital capacity, and functional residual capacity. Dependent atelectasis is common and can lead to hypoxemia. Pneumothorax may occur and can have significant respiratory and hemodynamic consequences intraoperatively. It is common to see a decrease in blood pressure when the kidney rest is raised. This decrease is usually due to compression of the inferior vena cava. In addition, hepatic encroachment on the vena cava and mediastinal shift may reduce venous return and stroke volume further. Cervical plexus, brachial plexus, and common peroneal neuropathies can occur because of stretch or compression of nerves in the lateral position.

Radical Nephrectomy for Renal Cell Carcinoma

The most common malignancy of the kidney is renal cell carcinoma; 85% to 90% of all solid renal masses are renal cell carcinoma.[146] Because renal cell carcinoma is refractory to chemotherapy and radiation therapy, surgical resection or ablation can offer curative treatment of localized disease (Box 72-4). Recently, resection of the ipsilateral adrenal gland has been reserved for patients with large upper pole lesions or when the adrenal gland is enlarged or appears abnormal.[147] Partial nephrectomy (nephron-sparing surgery) is considered for patients with small lesions or bilateral tumors or for patients at risk because of other diseases, such as diabetes or hypertension.[146-149]

In 5% to 10% of patients, the tumor extends into the renal vein and the inferior vena cava and right atrium.

BOX 72-4 ***Anesthetic Implications of Radical Nephrectomy for Tumors***

- 85%-90% are for renal cell cancer
- 5%-10% extension to the IVC and right atrium
- Large-bore IV access, A-line, IJV line (preferably on left side if IVC is involved)
- Paraneoplastic syndrome
- Hypercalcemia, eosinophilia; increased prolactin, erythropoietin, and glucocorticoids
- Occurs more frequently in men than women
- Chronic smoking history usually associated
- CAD, COPD
- Renal failure

CAD, Coronary artery disease; *COPD,* chronic obstructive pulmonary disease; *IJV,* internal jugular vein; *IVC,* inferior vena cava.

Tumor extension into the inferior vena cava and atrium occurs more frequently with right-sided renal cell carcinoma. Several problems can occur in these patients, ranging from circulatory failure as a result of complete occlusion of the vena cava by tumor to acute pulmonary embolization of tumor fragments during surgery. To operate on these patients safely, the extent of the lesion must be defined preoperatively. Cardiopulmonary bypass can be required. Central venous pressure in such cases might not reflect intravascular volume accurately, because venous return through the inferior vena cava is impaired by the thrombus and intraoperative transesophageal echocardiography may be of value.[150] A decrease in venous return also predisposes the patient to hypotension during induction of anesthesia. Venous obstruction can lead to dilation of the epidural veins and the development of abdominal wall and retroperitoneal collaterals. The emphasis is on appropriate preoperative preparation, which is possible only when the full extent of the lesion has been defined.[149]

Radical Prostatectomy

Localized prostate cancer is treated by either radiation therapy or radical prostatectomy (Box 72-5). Radical prostatectomy has become more commonly performed because of routine prostate-specific antigen testing in men older than 50 years and popularization of the nerve-sparing surgery to reduce the risk of impotence. Although originally described in 1905 via the transperineal approach, the retropubic approach is mostly used now. The prostate, the ejaculatory ducts, the seminal vesicles, and part of the bladder neck are removed along with the pelvic lymph nodes.

Traditionally, the procedure was performed by open laparotomy, but laparoscopic and robotic surgery are being used more frequently. A potential intraoperative problem with open radical prostatectomy is hemorrhage and massive blood loss requiring blood transfusion. Autologous predonation, preoperative recombinant erythropoietin therapy, intraoperative isovolemic hemodilution, and cell salvage are commonly practiced to reduce the patient's exposure to allogeneic blood. Early postoperative complications, including deep vein thrombosis, pulmonary embolism, hematoma, seroma, and wound infection, occur in 0.5% to 2% of cases.[151] Late complications include incontinence, impotence, and bladder neck contracture.[152] Patients undergoing radical prostatectomy are placed supine in steep Trendelenburg position with the back extended, which places the pubis above the head. Air embolism from the prostatic fossa caused by a gravitational gradient between the prostatic veins and the heart has been reported.[153]

BOX 72-5 ***Anesthetic Implications of Radical Prostatectomy***

- Disease of the elderly
- CAD, COPD, and renal dysfunction
- Significant blood loss
- Wide-bore IV access and invasive monitoring
- Acute normovolemic hemodilution versus autologous blood donation
- Hyperextended position
- Nerve injuries, soft tissue injury, joint dislocations
- Venous air embolism
- Anesthesia
- Benefits of regional anesthesia versus general anesthesia debated
- Not known to influence mortality
- Epidural anesthesia with spontaneous ventilation decreases blood loss
- General or combined anesthesia with IPPV increases blood loss

CAD, Coronary artery disease; *COPD,* chronic obstructive pulmonary disease; *IPPV,* intermittent positive-pressure ventilation; *IV,* intravenous.

Comparison of Anesthetic Techniques for Radical Prostatectomy

Epidural anesthesia, spinal anesthesia, general anesthesia, and combined epidural and general anesthesia have been used for this surgery. For the epidural component of combined techniques, a thoracic or a lumbar approach to anesthesia or analgesia has been used, and spontaneous ventilation or intermittent positive-pressure ventilation (IPPV) has been used for the general anesthesia component. Many investigators have reported their findings in comparing the three anesthetic techniques for radical retropubic prostatectomy,[154-157] and certain trends emerge.

Intraoperative blood loss is significantly less if epidural anesthesia or a combined epidural and general anesthetic with spontaneous ventilation is used. In one study, blood loss in the general anesthesia and the combined anesthesia group with IPPV was significantly more than in the epidural anesthesia group despite little difference in arterial pressure among the three groups.[154] It was postulated that the increased venous pressure as a result of IPPV was the most likely cause of increased bleeding in the general and the combined anesthesia groups during radical prostatectomy. Previous studies have shown that central and peripheral venous pressure is lower in patients during spontaneous ventilation under epidural anesthesia or combined epidural-general anesthesia than in patients receiving IPPV during general anesthesia.[158] Epidural anesthesia alone or when added to a general anesthetic decreases the risk of thromboembolism,[159] decreases postoperative pain and analgesic requirements,[160] and speeds recovery of bowel function. The length of stay and the cost of hospitalization can be decreased with the judicial use of epidural anesthesia and established clinical pathways.[161,162] In one study, 80% of patients were satisfactorily discharged after 1 day, and the mean length of stay was 1.34 days.[163]

Possible differences in patient outcome with general versus epidural anesthesia are not clear. Local practices are therefore based on the preferences of the urologist, the anesthesiologist, and the patient.

Robotic Assisted Radical Prostatectomy

Many surgical advantages of robotic assisted radical prostatectomy (RARP) are described, including better visualization, more controlled finer movements of robotic arms allowing better dissection, decreased blood loss, less scarring and pain, shorter recovery time, faster return to daily activity, and possibly improved continence and potency

rates (although these last outcomes have been suggested only given the short-term follow-up at this time). Anesthetic concerns are primarily related to steep head-down tilt and pneumoperitoneum required for surgery.

Ventilatory and respiratory changes resulting from pneumoperitoneum include decreased compliance, increased airway pressures, and increased ventilation-perfusion mismatch. Application of positive end-expiratory pressure improves oxygenation in these patients.[164] Hypercapnia develops within 15 to 30 minutes of carbon dioxide insufflation with resultant hypercarbia, acidosis, tachycardia, arrhythmias, and other deleterious hemodynamic and CNS effects.[165] Increase in mechanical ventilation can obviate these changes in most patients, and most healthy patients tolerate the changes even though they are clinically significant. Extraperitoneal insufflation of carbon dioxide is associated with larger increases in arterial P_{CO_2} than in intraperitoneal insufflation.[166] Hemodynamic changes include decreased venous return with decreased cardiac output despite an increase in filling pressures indicative of increased intrathoracic pressures.

Physiologic changes resulting from steep Trendelenburg position include hemodynamic effects such as decreased perfusion pressure of lower extremities, increased mean arterial pressure at the circle of Willis, increased central blood volume, decreased cardiac output, and a decreased perfusion of vital organs in a normovolemic patient. Increased myocardial oxygen consumption, ischemia, arrhythmias, and decreased oxygen delivery are potential risks in patients with cardiac disease. Despite an observed twofold to threefold increase of right- and left-sided filling pressures in ASA I and II patients during RARP, Lestar and colleagues[167] observed no significant changes in cardiac performance. Respiratory effects of steep head down tilt—decreased compliance, reduced vital capacity and functional residual capacity, 20% decrease in lung volumes, and ventilation-perfusion mismatch—compound the effects of pneumoperitoneum. Pulmonary congestion and edema have been reported in susceptible patients. A transient increase in serum creatinine secondary to pneumoperitoneum during robotic prostatectomy has been reported.[168] Regurgitation in this position in patients with history of reflux increases their risk of aspiration of gastric contents. Maintaining normothermia may be a problem in some cases because of prolonged pneumoperitoneum with dry cold gases.

Other significant effects of steep head down tilt include increased intracranial pressure, increased intraocular pressure, venous air embolism, brachial plexopathy, arthralgias, compartment syndrome, and finger injuries. It has been recommended to perioperatively assess the function of a patient with a ventriculoperitoneal shunt scheduled for any laparoscopic procedure.[169] Issues of increased intracranial pressure or consequences of a malfunctioning shunt with pneumoperitoneum in steep Trendelenburg position need to be realized. Kalmar and associates concluded patients overall clinically tolerated the influence of prolonged steep Trendelenburg position with CO_2 pneumoperitoneum on cardiovascular, cerebrovascular (including cerebral perfusion pressure and oxygenation), and respiratory homeostasis during robotic prostatectomy.[170] Significant increases in intraocular pressure have been reported in robotic prostatectomy, but the clinical significance is unknown.[171] Of concern is the reporting of at least six cases of postoperative visual loss following radical prostatectomy, three open and three robot-assisted laparoscopic prostatectomy cases.[172] Chemosis (conjunctival edema) is common in RARP, but is usually self-limiting once the patient is taken out of the steep Trendelenburg position.

Compared with retropubic radical prostatectomy, RARP is usually associated with much less blood loss, except for one study.[173] Mild to moderate pain is expected postoperatively, and low pain scores of 0 to 4 have been reported after retropubic radical prostatectomy and robotic assisted radical prostatectomy using preemptive analgesia with ketorolac given intraoperatively combined with rescue opiate or nonopiate analgesia.[174] Most patients are discharged home the day after surgery. The use of robots in urologic surgery has been extended to include radical cystectomy, pyeloplasty, and renal and adrenal surgery in adults and children, and newer indications are developing. Other considerations in robotic surgery focus on the rigidly placed intraabdominal trocars attached to the robotic arms. Patient movement during the surgery could result in visceral or vascular injury. A constant need to assess degree of muscle relaxation intraoperatively is suggested. A plan among the perioperative team to dismantle the robotic arms in the unlikely event of cardiac arrest and need for advanced cardiac life support measures needs to be rehearsed.

UROGENITAL PAIN SYNDROMES

Pain syndromes of the urogenital system can result from infection, anatomic anomaly, obstructive uropathy, nerve entrapment, or malignancy. The site, referral pattern, and quality of pain aid the clinician in identifying the source of pain—visceral, somatic, or neuropathic—and appropriate treatment (see Chapter 98).

BENIGN RENAL TUMORS

Flank pain is a common symptom in adults with angiomyolipomas, which consist of abnormal growth of blood vessels, smooth muscle, and fat. This benign neoplasm can create a mass effect that affects renal function and acute worsening of pain should raise suspicion for rupture and hematoma formation. Angiomyolipomas can be associated with tuberous sclerosis, but are more commonly found in otherwise healthy individuals. Treatment is symptomatic with acetaminophen and neuromodulatory agents. Care should be taken with nonsteroidal anti-inflammatory drug (NSAID) use because renal function can be compromised.

PEDIATRIC TUMORS

Wilms' tumor (nephroblastoma) generally occurs unilaterally and is painless on initial presentation (see Chapter 93). It may be associated with congenital malformations such as Beckwith-Wiedemann syndrome. Treatment consists of surgical resection most often

supplemented by chemotherapy, because the tumor is highly responsive to this modality. Perioperative pain can be addressed with epidural anesthesia, acetaminophen, and opioids. Chemotherapy-induced neuropathy can best be treated with antineuropathic agents.

RENAL CELL CARCINOMA

Renal cell carcinoma is described as having a classic triad of hematuria, flank pain, and renal mass; however, pain can be a late presentation and may indicate metastatic disease. In cases of metastasis, prognosis is often poor and pain is widespread. Early consideration of an intrathecal catheter for continuous delivery of opioids, local anesthetic, or ziconotide can improve patient quality of life. Flank pain may be due to stretching of the Gerota fascia, and metastasis is primarily local along the renal vein and inferior vena cava or into the intercostal nerves, which produces segmental neuralgia. In these cases, intercostal nerve blocks and neurolysis or radiofrequency can be of use and accomplished under fluoroscopic or ultrasound guidance.

INFECTIOUS RENAL DISEASES

Infectious renal diseases producing flank pain include pyelonephritis and perinephric abscess. Fever is an important associated finding that suggests the presence of infection. Because the kidneys are retroperitoneal organs, peritoneal signs are absent. Differential diagnosis must include inflammatory or infectious disease of surrounding organs, including lower lobe pneumonia, pancreatitis, appendicitis, and cholecystitis. Oral or parenteral narcotics are effective for pain control in the acute setting. Systemic antibiotics are curative in most cases, although surgical intervention may be warranted, and a focal nidus for infection (stone, urethral reflux, recurrent urinary tract infections) should be pursued.

NEURALGIAS

Pseudorenal pain syndromes are caused by entrapment of nerves colocalized with the urinary system in the lower abdomen and groin. Neuralgia of the genitofemoral nerve is common after hernia surgery, given its close proximity and variable relation to the spermatic cord. Pain radiates to the inguinal ligament via the femoral branch and to the testicle via the genital branch. Injury to the iliohypogastric or ilioinguinal nerves can occur with lower abdominal incisions or trocar placement for laparoscopy, resulting in neuralgia radiating to the lower abdomen and groin. Pain sensation is generally neuropathic in these conditions and dermatomal testing will reveal sensory deficits. Nerve blocks can be performed under ultrasound guidance[175] to help establish the diagnosis, differentiate from urogenital pain, and for therapeutic benefit. Antineuropathic drugs are also of help should nerve injury be confirmed (see Chapter 64).

POLYCYSTIC KIDNEY DISEASE

Polycystic kidney disease is most often inherited in an autosomal dominant manner and can lead to massive enlargement of the kidneys with compromised renal function. Renal pain is caused by distention of the cysts and stretching of the Gerota fascia. Hemorrhage into the cysts, rupture of the cysts, or infection can exacerbate pain. Percutaneous drainage of renal cysts can relieve the symptoms. Opioids are appropriate in the acute phase.

OBSTRUCTIVE UROPATHY

Obstruction of the urinary tract causes severe, spasmodic pain in the flank. Pain from the upper third of the ureter may be referred to the lower abdomen and back, pain from the middle third to the iliac fossa, and pain from the lower third to the suprapubic and groin area. Minimal fluid intake and a high concentration of stone-forming salts predispose to nephrolithiasis. Renal colic, hematuria, and radiopaque stones on radiography (70% to 75% of calculi) or noncontrast CT confirms the diagnosis.[176] Opioids and NSAIDs are best for severe symptoms. Ketorolac through the intramuscular or intravenous route may be of use if oral medications are not tolerated. Of note, intravenous hydration has not demonstrated benefit despite widespread use.

URINARY RETENTION

Bladder pain is most commonly described as a poorly localized ache in the suprapubic region, typical of visceral pain. Acute bladder distention is manifested as severe suprapubic pain with associated urinary frequency. This can occur postoperatively after surgery without Foley catheter placement or after neuraxial local anesthetic and opioid administration resulting in urinary retention. Initial presentation can include emergence delirium. Drainage of the bladder, either by voiding or by catheterization, is recommended when volume exceeds 600 mL to avoid overdistention of the bladder with associated sequelae. Obstruction from urethral stone or prostatic hypertrophy should be addressed if present.

INTERSTITIAL CYSTITIS

Interstitial cystitis (painful bladder syndrome) is a chronic pain condition marked by suprapubic pain related to bladder filling and symptoms of increased frequency and urgency in the absence of infection or malignancy.[177] Pathologic features of interstitial cystitis that may be evident, but are not necessary to make the diagnosis, include Hunner ulcers (discrete, bleeding areas on the bladder wall) and glomerulations (petechial bleeding after distention). The proposed pathophysiology is thought to be a deficient glycosaminoglycan layer that allows increased permeability of the bladder wall, resulting in inflammation and pain. Options for pain control include pentosan polysulfate (intended to repair the glycosaminoglycan layer), amitriptyline, antihistamines, dimethyl sulfoxide instillation, sacral nerve stimulators, and cystectomy.

UROTHELIAL TUMORS

The most common urothelial tumor is transitional cell carcinoma of the bladder. Painless hematuria is the most

common manifestation, although patients may complain of bladder irritability if there is involvement of the muscular layers. Surgical treatment includes fulguration, transurethral resection, or cystectomy. Pain control is best accomplished with NSAIDs, acetaminophen, opioids, and neuromodulatory agents.

TESTICULAR PAIN

Testicular pain can be the result of trauma, torsion, infection, or neoplasm. Trauma or torsion necessitate immediate restoration of blood flow, and emergency surgical exploration is the treatment of choice. Orchitis or epididymitis should be suspected based on a thorough history and if signs of localized or systemic infection accompany pain. Tumors of the testis are most often malignant; however, extratesticular tumors within the scrotum are usually benign. The earliest sign of tumor is usually a painless testicular mass. Pain is a late sign and is usually described as a dull ache or heaviness owing to mass effect, and it is most effectively addressed through debulking via surgery or radiotherapy.

PROSTATITIS

Acute prostatitis is usually caused by a bacterial infection and responds to antibiotic therapy. Chronic prostatitis has been more recently referred to as *chronic pelvic pain syndrome* to reflect that there is little certainty that inflammation of the prostate is responsible for symptoms.[178] Symptoms include genital/pelvic pain and sexual dysfunction, often accompanied by lower urinary tract symptoms. Moderate improvement has been noted with antibiotics, α-blockers, antiandrogens, NSAIDS, and pelvic floor physiotherapy.

PROSTATE CANCER

Adenocarcinoma of the prostate is the most common male cancer and is usually painless and discovered incidentally through routine physical examination. Epidural anesthesia can be of use for acute pain control if brachytherapy with seeding is part of treatment. Lumbar or sacral pain with prostatic cancer may be a sign of metastatic disease to bone. High-dose opioids and bisphosphonates are indicated, and placement of an intrathecal catheter should be considered early.

PRIAPISM

Priapism is a prolonged erection over 4 hours in duration and can be ischemic (veno-occlusive) or nonischemic (arterial). The former represents an acute emergency, and prompt therapy should be instituted to control pain and prevent subsequent impotence from fibrosis of the corpora cavernosa. Treatment consists of a penile dorsal nerve block (performed at the pubic symphysis with needle entry into the subpubic space), which must be performed with local anesthetic without epinephrine, after which aspiration of blood or intercavernosal phenylephrine can be performed.[179] Nonischemic priapism is most commonly posttraumatic and results from creation of an arteriolar-sinusoidal fistula. This type of priapism is typically not as painful and responds to conservative management. Sickle cell priapism is treated with hydration, alkalinization, and blood transfusion to increase hemoglobin to more than 10 mg/dL.

PEYRONIE DISEASE

Peyronie disease is a condition that causes severe penile pain during sexual intercourse because of excess curvature. The treatment of choice is surgery and NSAIDs as necessary for pain.

FEMALE GENITAL PAIN

Vulvodynia is a chronic pain condition associated with sexual inactivity or dysfunction because of vulvar pain. *Vestibulitis* refers to vulvodynia confined to the vestibule. Some success with tricyclic antidepressants, Sitz baths, local estrogen creams, and pudendal nerve blocks has been reported. Vaginismus is associated with increased tone of the muscles of the pelvic floor (pubococcygeus and levator ani) producing spasms and painful sexual dysfunction. Dyspareunia is defined as recurrent and persistent genital pain before or after intercourse not solely explained by infection, trauma, lubrication, or vaginismus. Psychological factors often play a major role. Treatment involves pelvic floor physiotherapy and desensitization techniques. Opioids are not indicated.

CHRONIC PELVIC PAIN

Chronic dysmenorrhea can be addressed with ovulation suppression or use of NSAIDs, which decrease uterine lining thickness and cramping via an antiprostaglandin effect.[180] Chronic pelvic pain may also be due to endometriosis, pelvic congestion, adhesions, or pelvic inflammatory disease—each of which is most responsive to correction of the underlying disorder for relief of pain. Cancer of the cervix or uterus can cause severe lower abdominal pain and requires aggressive opioids and referral for superior hypogastric plexus neurolysis or intrathecal medications.

ROLE OF SYMPATHETIC BLOCKS

The pelvic viscera in men and women—the urogenital organs, the distal colon, and the rectum—are supplied by afferent fibers from the distal lumbar sympathetic chain. Interruption of these pathways can be achieved with a superior hypogastric plexus block. The superior hypogastric plexus is a retroperitoneal structure situated along the anterior surface of the L5 and S1 vertebrae. It can be blocked using fluoroscopic guidance and instillation of phenol or ethanol.[181,182] The ganglion impar is another promising target for neurolysis, supplying mixed somatic, autonomic, and visceral fibers to the distal urethra, vulva, perineum, and distal third of the vagina. It can be blocked along the anterior surface of the sacrococcygeal junction.

GENERAL CONSIDERATIONS

Specific to renal compromise, meperidine and morphine should be avoided because of the accumulation of renally

excreted metabolites, including normeperidine and morphine-3-glucuronide, which lower the seizure threshold, and morphine-6-glucuronide, which maintains activity at the μ-opioid receptor. The antiprostaglandin effect of NSAIDs can also decrease renal blood flow in susceptible patients. These agents must be used with caution.

General considerations for genitourinary pain management follow the same principles of pain management elsewhere in the body. For nonmalignant acute pain, nonnarcotic medications such as acetaminophen, aspirin, and NSAIDs are indicated as first line drugs. Tricyclic antidepressants and anticonvulsant agents are useful adjuncts, particularly for neuropathic pain. Opioids may be indicated in the short term. For malignancy, opioids are often necessary and in high doses. When oral administration is not feasible, parenteral administration of narcotics should be used.

Interventional techniques are an integral part of pain control in chronic urogenital pain syndromes and particularly for malignancy. Appropriate blocks can obviate or greatly reduce the need for systemic analgesics. If intractable pain persists despite optimized oral or intravenous therapy, a tunneled catheter trial can be performed and an implantable drug delivery system should be considered. Continuous intrathecal infusions minimize fluctuation of drug levels in cerebrospinal fluid and allow for significant analgesia and use of spinal adjuncts (local anesthetic, ziconotide) and opioids with significantly lessened dose-limiting side effects.

Acknowledgment

The authors acknowledge the invaluable contribution and expertise of Dan Paloski, editorial assistant in the Department of General Anesthesiology at the Cleveland Clinic, in the preparation of this manuscript.

Chapter 73

Anesthesia and the Hepatobiliary System

DAVID M. ROTHENBERG • CHRISTOPHER J. O'CONNOR • KENNETH J. TUMAN

Key Points

- All volatile anesthetics decrease hepatic blood flow, but desflurane and sevoflurane have the least significant effect on total hepatic blood flow and hepatic oxygen delivery, whereas halothane induces the most profound reductions in hepatic blood flow.
- Advanced liver disease may impair the elimination, prolong the half-life, and potentiate the clinical effects of several drugs, including morphine, meperidine, alfentanil, vecuronium, rocuronium, mivacurium, benzodiazepines, and dexmedetomidine. These drugs should be used cautiously in patients with cirrhosis or end-stage liver disease from any cause, and their dosage and administration should be adjusted accordingly.
- Abnormal liver enzyme test results may be seen in up to 4% of normal individuals and up to 36% of psychiatric patients, although the prevalence of clinically significant hepatic dysfunction in these individuals is less than 1%, thus suggesting that further costly preoperative testing is unnecessary in asymptomatic patients.
- Patients with asymptomatic elevations in serum transaminase levels (less than two times normal values) may undergo surgery with minimal impact on perioperative outcome.
- Retrospective data suggest that patients with acute hepatitis from any cause are at increased risk for hepatic failure and death after elective surgery. Thus, elective surgery should be delayed in these individuals until resolution of acute hepatocellular dysfunction can be confirmed.
- Asymptomatic patients with any form of chronic hepatitis should be carefully assessed before elective surgery, and meticulous care should be taken to maintain hepatic perfusion in the perioperative period and to avoid any hepatotoxic drugs or significant hypotension that could precipitate liver failure or hepatic encephalopathy.
- Based on large retrospective studies, patients with cirrhosis who are undergoing abdominal surgery, especially those in Child-Turcotte-Pugh (CTP) class C, appear to have an increased risk of perioperative death. Elective surgery in these individuals should be avoided, if possible, in favor of less invasive procedures.
- Postoperative jaundice may occur as a result of intraoperative hepatobiliary injury, anesthetic-induced hepatotoxicity, severe hepatic hypoperfusion (e.g., cardiogenic or hypovolemic shock), and a variety of medications.
- Patients with the most advanced forms of liver disease (e.g., CTP class B or C cirrhosis) should receive management designed to maximize hepatic perfusion and hepatic oxygen delivery and to prevent and treat the complications of hepatic encephalopathy, cerebral edema, coagulopathy, hemorrhage, and portal hypertension.

The liver is the largest organ in the body, and it plays a critical role in the homeostasis of many physiologic systems, including nutrient and drug metabolism, synthesis of plasma proteins and critical hemostatic factors, and detoxification and elimination of many endogenous and exogenous substances.[1] Acute or chronic liver dysfunction can impair the response to anesthesia and surgery in several critical ways, whereas certain anesthetics and hemodynamic disturbances can induce unique and serious alterations in postoperative hepatic function.

This chapter reviews the anesthetic implications of acute and chronic liver disease, the impact of anesthetics

on hepatic function, evaluation of perioperative changes in liver function test results and hepatobiliary function, and periprocedural considerations for some selected surgical procedures involving the liver and gallbladder.

EFFECT OF ANESTHETICS ON HEPATIC FUNCTION

This section focuses on the impact of volatile and intravenous anesthetics on liver blood flow and hepatic function. Halothane hepatitis and related volatile anesthetic–induced hepatotoxicity are discussed in Chapter 26.

VOLATILE ANESTHETICS

Volatile anesthetics variably influence blood flow to the liver, whereas intravenous anesthetics and opioids probably have a less significant impact. However, many potential confounding variables can influence hepatic blood flow and liver function, including the animal species studied, the subject's age, intravascular volume status, the type of mechanical ventilation used, body position at the time of physiologic measurements, simultaneous surgical procedures, changes in arterial blood pressure, concomitant use of vasopressors and local anesthetics, and alterations in hemoglobin and arterial oxygen concentrations. Yet reasonably firm conclusions can be reached regarding the impact and probable clinical significance of anesthetic drugs on hepatic function in normal and cirrhotic patients.

The impact of volatile anesthetics on hepatic blood flow (including hepatic arterial and portal venous blood flow), oxygen delivery, and hepatic oxygen supply-to-demand ratios has been determined for all the major volatile anesthetics, primarily in rat and pig experimental models. Human studies also support the findings of these early experimental investigations.[2,3] Many measurement techniques have been used to assess hepatic and portal venous blood flow, although plasma clearance of indocyanine green is most commonly used to assess hepatic blood flow. Transesophageal echocardiography can also evaluate hepatic vein flow, but it is only an indirect measurement of hepatic perfusion and oxygenation (see also Chapter 46). A novel technique involving pulsed Doppler probes implanted in animals and in humans undergoing cholecystectomy has allowed accurate measurement of hepatic arterial and portal vein blood flow.[4] Most anesthetics decrease portal blood flow (PBF) because of decreased cardiac output; however, hepatic arterial blood flow (HABF) may increase, although often not sufficiently to restore total hepatic blood flow (THBF) to normal values.[5] THBF is equal to the sum of PBF and HABF. Mean arterial blood pressure (MAP) and cardiac output decrease with all volatile anesthetics, but a more pronounced reduction in PBF, HABF, and THBF occurs with halothane and enflurane than with isoflurane and sevoflurane (Fig. 73-1).[2-4,6-10] These changes generally apply across a range of minimum alveolar concentrations (MACs). Volatile anesthetics also alter portal venous and hepatic arterial vascular resistance to variable degrees; these changes, in conjunction with decreases in cardiac output, MAP, and mesenteric sympathetic tone, modify the hepatic vascular supply.[11]

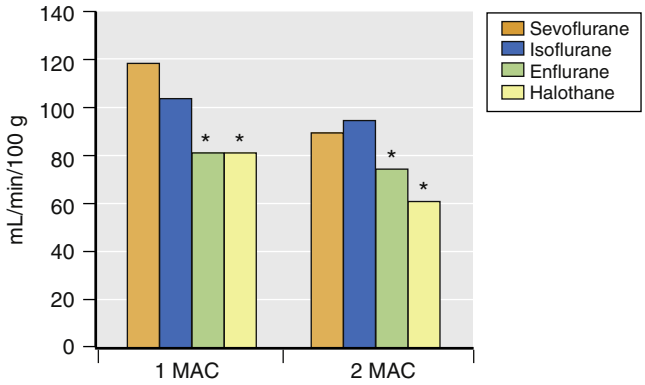

Figure 73-1. Impact of halothane, enflurane, isoflurane, and sevoflurane at 1.0 and 2.0 minimum alveolar concentration (MAC) on total hepatic blood flow (THBF) in dogs. THBF decreased with increasing anesthetic concentrations of each volatile agent. Sevoflurane and isoflurane were similar in their modest effect on THBF, whereas halothane caused a dramatic decrease in THBF, especially at 2-MAC exposure. *Differs from sevoflurane and isoflurane at comparable MAC values ($P < .05$). *(Data from Frink EJ, Morgan SE, Coetzee A, et al: The effects of sevoflurane, halothane, enflurane, and isoflurane on hepatic blood flow and oxygenation in chronically instrumented greyhound dogs,* Anesthesiology *76:85-90, 1992.)*

Although all volatile anesthetics decrease MAP and PBF, halothane has a more consistently dramatic impact on HABF. Halothane causes vasoconstriction in the hepatic arterial vascular bed, as reflected by an increase in hepatic arterial resistance.[4,12] In vivo videomicroscopy after halothane exposure in rats demonstrated reduced sinusoidal blood flow as a result of decreased sinusoidal diameter, thus providing direct evidence of vasoconstriction at the microvascular level.[12] In contrast, isoflurane increased flow velocity in hepatic sinusoids and in this way preserved microvascular blood flow more than halothane or enflurane.[12] Benumof and colleagues demonstrated markedly reduced HABF after halothane administration in two patients during hepatic arteriography; hepatic blood flow returned to normal 20 minutes after discontinuation of halothane anesthesia.[13]

Halothane also reduces hepatic oxygen delivery and hepatic venous oxygen saturation (Fig. 73-2).[14] These changes are related to decreased MAP and more dramatic reductions in cardiac output with halothane than with any other volatile anesthetics.[5] Gelman and associates demonstrated that during surgical stress in pigs, fentanyl or isoflurane anesthesia, which decreases MAP by less than 30%, provided adequate oxygen supply, whereas halothane anesthesia, which decreases arterial blood pressure more than 30%, provided inadequate hepatic oxygen supply.[9] This finding also applied to episodes of hepatic ischemia, in which fentanyl or isoflurane provided better protection than halothane or enflurane. In addition to vascular changes, hepatic function, as measured by serum transaminase levels, also suggests an unfavorable impact of halothane versus isoflurane.[3]

Volatile anesthetic–induced alterations in hepatic blood flow are, in part, mediated by an autoregulatory

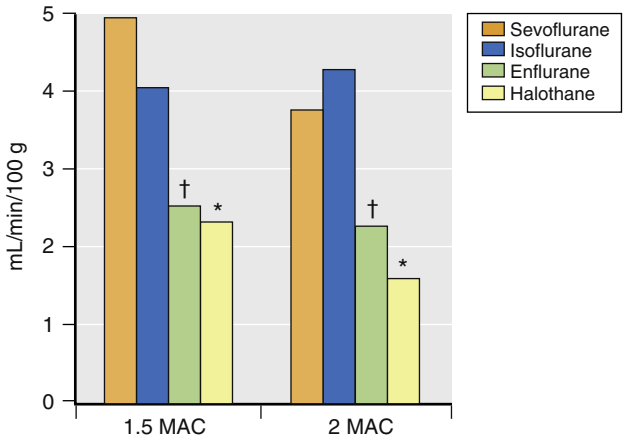

Figure 73-2. Impact of halothane, enflurane, isoflurane, and sevoflurane at 1.5 and 2.0 minimum alveolar concentration (MAC) on hepatic arterial oxygen delivery in chronically instrumented dogs. Halothane produced the greatest reduction in hepatic arterial oxygen delivery, whereas sevoflurane and isoflurane had insignificant effects on oxygen delivery at any MAC level. *Differs from isoflurane and sevoflurane at comparable MAC values ($P < .05$). †Differs from sevoflurane at comparable MAC values ($P < .05$). *(Data from Frink EJ, Morgan SE, Coetzee A, et al: The effects of sevoflurane, halothane, enflurane, and isoflurane on hepatic blood flow and oxygenation in chronically instrumented greyhound dogs,* Anesthesiology *76:85-90, 1992.)*

mechanism that maintains constant THBF. This physiologic adaptation is termed the *hepatic arterial buffer response* (HABR), which matches reductions in PBF with increases in HABF to maintain total blood flow to the liver constant in the presence of profound hypovolemia, indirect effects of major abdominal surgery, or severe hemorrhage.[15] Halothane disrupts this compensatory response, whereas sevoflurane and isoflurane maintain HABR.[15,16] Sevoflurane further suppresses hepatic arterial vasoconstriction and thus maintains HABF more effectively than does halothane.[17] Sevoflurane is also consistently equivalent or superior to isoflurane in maintaining HABF, hepatic oxygen delivery, and oxygen delivery-to-consumption ratios.[10,18,19] In addition, laboratory studies demonstrated insignificant changes in conventional liver function test results after exposure to isoflurane or desflurane, with the most favorable profiles with desflurane and sevoflurane as compared with other volatile anesthetics.[3,20-23]

The encouraging results obtained with sevoflurane versus older volatile anesthetics are further supported by the observation that compound A produced by prolonged, low-flow sevoflurane anesthesia does not adversely affect hepatic function in adult surgical patients as determined by liver function testing or measurement of arterial ketone body ratios, a putative measure of hepatocyte function.[24-28] In a large clinical study of sevoflurane, Bito and co-workers noted mild postoperative increases in bilirubin and transaminase values in 100 surgical patients receiving low- and high-flow sevoflurane or isoflurane anesthesia, but no evidence of clinical hepatotoxicity.[28] Routine liver function test results are often mildly increased after surgery and anesthesia with volatile anesthetics, although the specific contribution of the anesthetic itself is debatable.[3,24,25,29]

Administration of either sevoflurane[26,27,30] or desflurane[31,32] to human volunteers not undergoing surgery produced no significant abnormalities in liver function test results, thus suggesting that other perioperative surgical factors may induce mild, transient alterations in plasma transaminase levels. In fact, early human investigations found steep decreases in estimated hepatic blood flow immediately after the induction of anesthesia correlated with the decreases in arterial blood pressure.[33] Hepatic blood flow rapidly returned to normal soon after the start of surgery, a finding suggesting global reductions in cardiac output and blood pressure as mechanisms responsible for the reduced hepatic blood flow, rather than a sustained adverse influence of specific volatile or intravenous anesthetics on hepatic blood flow. In experimental and human ischemia-reperfusion injury studies,[34,35] sevoflurane had favorable effects on hepatic function through an ischemic-preconditioning effect. These data are consistent with the favorable cardiac ischemic-preconditioning effect of sevoflurane.

Desflurane had effects similar to those of isoflurane on hepatic blood flow and function when assessed in animal and human investigations. In chronically instrumented dogs, Merin and associates demonstrated slight but significant decreases in THBF at 1.75 MAC as a result of decreased PBF, but no significant differences between desflurane and isoflurane in any measure of hepatic blood flow over a range of MAC values.[36] Armbruster and coworkers observed decreased THBF at 1 MAC desflurane in pigs, but only at levels of hypotension unlikely to be encountered clinically and without alterations in liver function test results.[21] Other canine data suggested better preservation of THBF with desflurane than with halothane or isoflurane (Fig. 73-3).[37] Subsequent studies in human volunteers examining hepatic function rather than hepatic blood flow failed to demonstrate any hepatotoxic effects of desflurane.[30-32]

In contrast to healthy volunteers and surgical patients, substantially less information is available describing the impact of anesthetics on hepatic function in patients with advanced liver disease. Desflurane and isoflurane may not change perioperative liver function test results in adult surgical patients with chronic liver disease.[38] Experimental models of hepatic injury showed lesser increases in hepatic enzymes and no evidence of microscopic hepatocyte injury with sevoflurane compared with halothane-treated rats.[39] Isoflurane was more efficient at preserving hepatic blood flow in cirrhotic animals than is ketamine or halothane,[40] although other studies showed no difference in hepatic function in cirrhotic rats exposed to fentanyl, halothane, enflurane, or isoflurane.[41] However, halothane decreases both hepatic blood flow and hepatic function and should not be given to patients with advanced liver disease. Given the current availability of other volatile anesthetics and the overall marked decreased use of halothane, this issue is primarily of historical interest. Moreover, as a consequence of the hepatotoxic potential of halothane, halothane should not be used in healthy adults or in any patient with significant hepatic dysfunction.

In this regard, other anesthetics devoid of hepatotoxicity are available. Xenon, an inert gas first described as

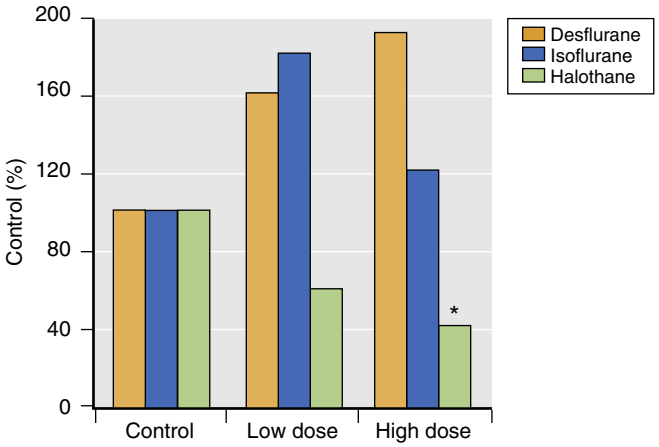

Figure 73-3. Influence of low- and high-dose desflurane, halothane, and isoflurane on total hepatic blood flow (THBF) as measured with radioactive microspheres in chronically instrumented dogs. In contrast to desflurane and isoflurane, which increased THBF, halothane caused a significant decrease in THBF at high doses. *Significantly different from conscious control ($P < 0.05$). *(Data from Hartman JC, Pagel PS, Proctor LT, et al: Influence of desflurane, isoflurane and halothane on regional tissue perfusion in dogs,* Can J Anaesth *39:877-887, 1992.)*

having anesthetic properties in 1951,[42] has been considered to be an ideal inhaled anesthetic because it is nonexplosive and nonflammable, exhibits low toxicity, has no known teratogenic effects, and has rapid induction and recovery profiles resulting from its extremely low blood-gas coefficient of 0.115, the lowest of all known anesthetics.[43,44] Xenon has no significant effect on left ventricular function, systemic vascular resistance, or systemic blood pressure. [44-46] Its hemodynamic profile is similar to that of propofol anesthesia in humans,[45] and it caused less hypotension and had no effect on left ventricular function when compared with isoflurane in human studies.[46,47] Although animal investigations suggested a substantial increase in cerebral perfusion with xenon when compared with intravenous anesthetics, xenon has no effect on other regional organ perfusion, including liver perfusion. It does not alter HABF, and given the absent effect on cardiac output, it should, in theory, have no impact on THBF (unlike all other volatile anesthetics). It also does not alter liver function tests. In an experimental model, Reinelt and colleagues noted higher hepatic venous oxygen content levels in pigs exposed to 73% to 78% xenon versus intravenous anesthesia with pentobarbital and buprenorphine.[48] These observations were believed to be secondary to a possible reduction of plasma catecholamine levels and subsequent reduced hepatic metabolism and increased hepatic venous oxygen content. Xenon may therefore prove to be an ideal anesthetic with regard to hepatic perfusion. Larger clinical trials in patients with both normal and abnormal hepatic function are necessary before definitive conclusions can be reached relative to its safety in patients with acute and chronic liver disease.

In summary, the influence of volatile anesthetics on hepatic blood flow and function is complex and is related not only to features unique to the anesthetic itself but also to other patient-related variables such as the severity of underlying liver dysfunction, the presence of advanced age, and the impact of surgical stress and intraabdominal surgical manipulation. However, sevoflurane, desflurane, and isoflurane have been consistently shown to preserve hepatic blood flow and function better than halothane or enflurane.

INTRAVENOUS ANESTHETICS

When compared with volatile anesthetics, less information is available regarding the impact of intravenous anesthetics on hepatic function (see also Chapters 31 to 33). Early investigations suggested that etomidate and thiopental decreased hepatic blood flow, either from increased hepatic arterial vascular resistance or from reduced cardiac output and blood pressure,[49] whereas ketamine has little impact on hepatic blood flow, even in large doses.[50] With the use of sensitive radiolabeled microsphere determinations of organ blood flow in animals, propofol was found to increase THBF in both the hepatic arterial and portal venous circulations, thus suggesting a significant splanchnic vasodilator effect of this drug.[51,52] THBF was maintained in some animal models even with significant reductions in MAP,[53] whereas other animal models showed decreased mean hepatic blood flow despite increased MAP, a finding attributed to species-specific effects of propofol.[54] Limited human data suggest a more favorable splanchnic and hepatic oxygen delivery balance with propofol than with halothane.[55] Meierhenrich and colleagues demonstrated increased hepatic blood flow with propofol in humans by using transesophageal echocardiographic, Doppler-derived measurements of hepatic blood flow, a technique considered more accurate than hepatic clearance of indicator dyes.[56] Studies using indicator dyes in humans and animals suggested decreased hepatic blood flow with propofol,[57,58] whereas other animal investigations using techniques not involving dye showed improved hepatic blood flow under propofol anesthesia.[52,59] Overall, an antioxidant effect may occur with propofol in patients undergoing liver surgery and orthotopic liver transplantation (see also Chapter 74),[60,61] although the ultimate effect of this drug on ischemia-reperfusion injury may be modest, at best, in these patient populations. In summary, based on limited clinical and experimental data, it appears that intravenous anesthetics have only a modest impact on hepatic blood flow and no meaningful adverse influence on postoperative liver function when blood pressure and cardiac output are adequately maintained.

CENTRAL NEURAXIAL ANESTHESIA

The effect of spinal or epidural anesthesia on liver blood flow and hepatic function is not clearly an anesthetic drug–induced alteration in hepatic function (see Chapter 56). Kennedy and colleagues showed that hepatic blood flow decreased during high spinal and epidural anesthesia and appeared to mirror simultaneous reductions in MAP.[62,63] Other animal data suggested reduced PBF and unchanged HABF with high epidural blockade, thus causing a decrease in THBF.[64] This finding was confirmed in humans undergoing thoracic epidural anesthesia in which echocardiography confirmed reductions in hepatic venous blood flow.[65] These adverse changes

may be reversed and hepatic blood flow maintained with the administration of vasopressors (e.g., dopamine or ephedrine) to restore PBF[66–68] or fluid administration to maintain normal arterial blood pressure,[69] although vasopressors may actually further reduce hepatic blood flow.[65] Presumably, hypotension-induced reductions in hepatic blood flow are secondary to decreased splanchnic blood flow and thus reduced PBF. The impact of absorbed local anesthetic, with or without epinephrine, on cardiac output or splanchnic vascular resistance is unknown.

EFFECT OF HEPATIC DYSFUNCTION AND HEPATOBILIARY DISEASE ON ANESTHETIC DRUG PHARMACOKINETICS

Liver disease may have a significant impact on drug metabolism and pharmacokinetics as a result of alterations in protein binding, reduced levels of serum albumin and other drug-binding proteins, altered volume of distribution because of ascites and increased total-body water compartments, and reduced metabolism secondary to abnormal hepatocyte function (see Chapters 24 and 74). In addition, sedatives and opioids may have exaggerated effects in patients with advanced liver disease and may either induce or worsen hepatic encephalopathy.[70] The impact of long-term alcohol ingestion on hepatic enzyme induction may also influence the ultimate effect of drugs in patients with cirrhosis.

The impact of liver disease on drug disposition depends not only on the elimination pathways for a given drug but also on the severity of the underlying hepatic dysfunction. The efficiency of drug removal by the liver is determined by several factors, including hepatic blood flow, hepatic enzyme activity and efficiency, the extent of plasma protein binding, cholestasis-induced alterations in the enterohepatic circulation and metabolism of enteral drugs, and the presence of portosystemic shunts that exclude certain drugs from elimination by the diseased liver.[71] In addition, the influence of liver disease on drug elimination differs for enteral and parenteral drugs.[70] In general, severe liver disease predictably alters the metabolism of drugs with large extraction ratios, such as lidocaine and meperidine, in which clearance primarily depends on hepatic blood flow or portosystemic shunting. Conversely, the metabolism of low-extraction drugs, such as the benzodiazepines, is influenced mainly by protein binding, in which unbound drug is available for elimination, and by intrinsic hepatic clearance and metabolism, which are reduced in accordance with the severity of hepatocellular dysfunction.[70,71] However, an increased free fraction of a drug because of reduced levels of plasma proteins may counter the impact of reduced hepatic metabolism and lead to modest changes in the ultimate effect of the drug.[71] Finally, greater free fractions of available drug as a result of reduced protein binding may lead to greater drug deposition in tissues (and a potentially increased volume of distribution), which in conjunction with reduced hepatic metabolism may increase drug half-life.[71] It is thus evident that drug pharmacokinetics in the presence of advanced liver disease is complex. The impact on different classes of drugs is discussed separately.

OPIOIDS

The significantly reduced metabolism of morphine in patients with advanced cirrhosis leads to a prolonged elimination half-life, markedly increased bioavailability of orally administered morphine, decreased plasma protein binding, and potentially exaggerated sedative and respiratory-depressant effects (see also Chapter 31).[71] Although extrahepatic metabolism may contribute to morphine clearance in patients with cirrhosis, the administration interval should be increased 1.5- to 2-fold in these patients and the oral dose of the drug reduced because of increased bioavailability.[71] Similar changes occur with meperidine, in which a 50% reduction in clearance and a doubling of the half-life have been observed. In addition, clearance of normeperidine is reduced, and patients with severe liver disease may experience neurotoxicity from accumulation of normeperidine.[71]

In contrast to these drugs, fentanyl is a highly lipid-soluble synthetic opioid that has a short duration of action after a single intravenous bolus dose because of rapid redistribution into storage sites. With repeated administration or continuous infusions, accumulation may occur and lead to prolonged effects.[71] Because fentanyl is almost completely metabolized in the liver, its elimination should be predictably prolonged in patients with advanced liver disease. However, fentanyl elimination is not appreciably altered in patients with cirrhosis.[71,72] Whether the limited extent of liver disease in the study patients affected the pharmacokinetic data or whether continuous infusions or repeated doses in cirrhotic patients produce more exaggerated and pronounced effects is unknown.

Sufentanil, a more potent but similar synthetic lipophilic opioid, is also extensively metabolized by the liver and is highly protein bound. Single-dose pharmacokinetics is not significantly altered in patients with cirrhosis, although the impact of continuous infusions and reduced protein binding is as ill-defined for sufentanil as for fentanyl.[73] Alfentanil, a short-acting opioid less potent than fentanyl, is also exclusively metabolized by the liver and is highly protein bound.[71] However, unlike with fentanyl or sufentanil, the half-life of alfentanil is almost doubled in patients with cirrhosis, and higher free fractions of the drug are observed; these higher free fractions can potentially lead to a prolonged duration of action and enhanced effects.[74,75] Remifentanil is a synthetic opioid with an ester linkage that allows for rapid hydrolysis by blood and tissue esterases; such hydrolysis leads to high clearance, rapid elimination, and recovery that is almost independent of the dose or duration of infusions.[76] Predictably, the clearance and elimination of remifentanil are indeed unaltered in patients with severe liver disease or in those undergoing liver transplantation.[71,77-79]

SEDATIVE-HYPNOTIC DRUGS

Thiopental has a small hepatic extraction ratio, and therefore its metabolism and clearance should be adversely affected in patients with liver disease (see also Chapter 32). However, the elimination half-life of thiopental is unchanged in cirrhotic patients, possibly

because of a large volume of distribution.[80,81] A prolonged effect from standard doses of thiopental thus seems unlikely in this patient population. In contrast, other intravenous anesthetics, including methohexital, ketamine, etomidate, and propofol, are highly lipid soluble, are metabolized by the liver, have a large hepatic extraction ratio, and should have diminished clearance in the presence of advanced liver disease.[76] Despite this pharmacokinetic profile, etomidate clearance is unchanged in cirrhotic patients, although increased volumes of distribution may prolong the elimination half-life and result in unpredictable recovery times.[82] Other investigators have shown altered pharmacokinetics of etomidate infusions in cirrhotic patients, presumably because of the drug's impaired hepatic clearance.[83] In contrast to the situation in cirrhotic patients, etomidate requirements in individuals with obstructive jaundice, as measured by predefined bispectral index values, were significantly less than in control patients. [84] Methohexital and propofol also have an elimination kinetic profile in cirrhotic individuals that is similar to that observed in normal patients,[76] both after single-bolus administration of propofol[85] and after propofol infusion,[86] an effect that may result from extrahepatic metabolism of propofol.[87] However, mean clinical recovery times may be longer after discontinuation of propofol infusions in cirrhotic patients.[86] The reduced clearance of midazolam in patients with end-stage liver disease produces prolonged elimination half-lives.[88,89] In conjunction with reduced protein binding and increased free fractions of midazolam, a prolonged duration of action and an enhanced sedative effect should be anticipated in patients with severe liver disease, especially after multiple doses or prolonged infusions. Similar changes have also been observed with diazepam.[89]

Dexmedetomidine, an α_2-adrenergic agonist with sedative and analgesic properties, is primarily metabolized in the liver with minimal renal clearance. Data from patients with hepatic failure of varying severity demonstrated significantly decreased clearance, prolonged half-lives, and lower bispectral index values than in normal control patients.[90] Dosage adjustments are therefore indicated when dexmedetomidine is used in patients with significant hepatic dysfunction. This evidence mirrors, in part, findings from dexmedetomidine use in individuals with renal dysfunction, in whom prolonged sedation despite unchanged pharmacokinetics has been attributed to altered protein binding, a factor that also applies to patients with hepatic dysfunction.[91,92]

In summary, despite substantial hepatic metabolism of most intravenous anesthetic induction agents, limited evidence from single-dose pharmacokinetic studies suggests that cirrhosis has minimal impact on the pharmacokinetic profile of sedative-hypnotic drugs. Given that the clinical effect and duration of action of benzodiazepines are more pronounced in the presence of severe liver disease, it would therefore be prudent to administer these drugs cautiously when using repeated dosing or prolonged infusions, either in the operating room or in the intensive care unit, where drug accumulation, prolongation of effects, and increased risk of hepatic encephalopathy can be anticipated.

NEUROMUSCULAR BLOCKING DRUGS

In contrast to opioids and intravenous anesthetics, more comprehensive information is available regarding the impact of cirrhosis on the pharmacokinetics and pharmacodynamics of neuromuscular blocking drugs (see also Chapter 34). Vecuronium is a steroidal muscle relaxant that undergoes hepatic elimination.[93,94] This drug has decreased clearance, a prolonged elimination half-life, and prolonged neuromuscular blockade in patients with cirrhosis (Fig. 73-4).[95,96] The impact of alcoholic liver disease is less definite, with clearance and elimination half-lives typically unchanged.[97] Rocuronium also undergoes hepatic metabolism and elimination.[98] Hepatic dysfunction can increase the volume of distribution of rocuronium, thus prolonging its elimination half-life,[98] as well as producing a longer clinical recovery profile and return of normal twitch tension.[98,99] Gao and associates observed a 24% decrease in rocuronium infusion requirement in 17 patients during the anhepatic phase of liver transplantation.[100] Although the initial clinical recovery of neuromuscular function is not affected by liver disease, larger initial doses or repeated administration will typically prolong the effect of rocuronium in the presence of significant hepatic dysfunction.[98]

The increased volume of distribution for some drugs observed in cirrhotic patients can also prolong the elimination half-life of pancuronium.[101] Muscle relaxants that undergo organ-independent elimination, such as atracurium (nonspecific ester hydrolysis) and cisatracurium (Hofmann elimination), have elimination half-lives and clinical durations of action similar to those observed in normal patients and in patients with end-stage liver disease.[102-104] The unique elimination of mivacurium by plasma cholinesterase is, however, altered by cirrhosis.

Mivacurium is associated with significantly longer recovery of twitch tension and has a longer elimination half-life (18 versus 34 minutes in normal versus cirrhotic patients, respectively) and a longer residence time in patients with hepatic failure than in normal patients, a finding closely correlated to reduced plasma cholinesterase activity in cirrhotic patients.[105-107] This reduced activity is related to reduced clearance by plasma cholinesterase of the two active isomers of mivacurium, *cis-trans* and *trans-trans*.[107] Infusion rates of mivacurium should be adjusted accordingly in patients with advanced liver disease. The impact of liver disease on mivacurium's pharmacokinetics is likely of historical interest, as the drug is no longer available in the United States. The changes observed with mivacurium are predictably expected with succinylcholine if decreased plasma cholinesterase levels are present because of advanced liver disease. Lowered cholinesterase levels have been observed in these individuals,[108] and they may prolong the effect of succinylcholine.

Sugammadex "reverses" neuromuscular blockade from steroidal neuromuscular blocking drugs (vecuronium and rocuronium) by a mechanism completely different from that of neostigmine. Sugammadex encapsulates rocuronium, so it cannot cause neuromuscular blockade. The sugammadex-rocuronium complex is then transported through perfusion mainly to the kidney for excretion. Sugammadex is excreted unchanged in the urine.[109]

In summary, cirrhosis and other forms of advanced liver disease predictably reduce the elimination of vecuronium, rocuronium, and mivacurium and prolong the duration

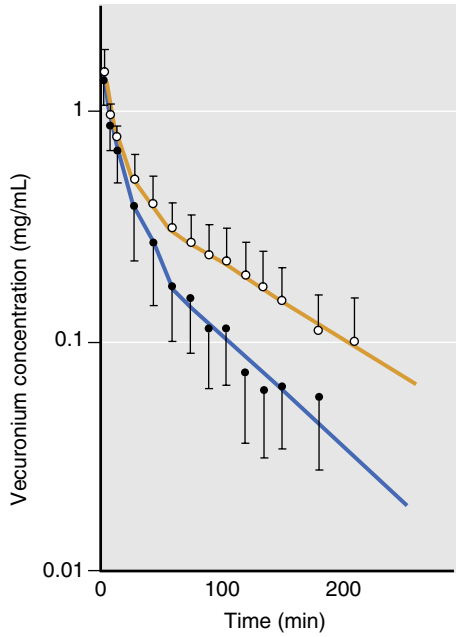

Figure 73-4. Disappearance of vecuronium from plasma after a single bolus dose of 0.2 mg/kg. A semilogarithmic plot of plasma concentration versus time shows that the vecuronium concentration remained at a much higher level during the elimination phase in patients with cirrhosis (*open circles*) than in normal control patients (*black circles*). This difference reflects the markedly decreased plasma clearance of vecuronium, increased elimination half-life, and increased duration of neuromuscular blockade in patients with cirrhosis versus normal individuals. *(From Lebrault C, Berger JL, D'Hollander AA, et al: Pharmacokinetics and pharmacodynamics of vecuronium (ORG NC 45) in patients with cirrhosis,* Anesthesiology *62:601-605, 1985.)*

of neuromuscular blockade, especially after repeated doses or the use of prolonged infusions. Atracurium and cisatracurium are not dependent on hepatic elimination and can be used without modification of dosing in patients with end-stage liver disease. Careful monitoring of neuromuscular function is recommended whenever muscle relaxants are used in this patient population.

RISK FACTORS FOR POSTOPERATIVE HEPATOBILIARY COMPLICATIONS

The anesthesia literature is replete with detailed descriptions of preoperative assessment of cardiac and renal risk for noncardiac surgery.[110,111] Because preoperative risk factors for the development of postoperative hepatic dysfunction or failure after nonhepatic surgery have not been clearly elucidated, anesthesiologists have based decisions regarding the care of patients with preoperative hepatic dysfunction on data derived in the 1960s and 1970s. Unfortunately, prospective studies addressing these issues in the current era of newer anesthetic and surgical techniques are lacking. Assessment of risk factors for postoperative hepatic insufficiency requires consideration of the following: (1) asymptomatic elevations in preoperative liver enzyme test results; (2) acute hepatitis (viral, drug, toxin), steatosis, chronic hepatitis, and cirrhosis; and (3) the types of surgical procedures that potentially predispose to postoperative liver dysfunction.

ASYMPTOMATIC PREOPERATIVE LIVER ENZYME TEST ABNORMALITIES

Unnecessary laboratory test screening may reveal abnormally elevated liver enzyme test results in otherwise healthy patients. Abnormalities in standard liver enzyme tests, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase, occur in 0.1% to 4% of the general population,[112,113] as well as in as many as 36% of psychiatric patients, in whom alcohol and illicit drug abuse is prominent.[114] However, the overall prevalence of clinically significant hepatic dysfunction in asymptomatic patients is less than 1%. A retrospective analysis of 91 noncirrhotic patients with serum liver enzyme levels greater than 1.5 times normal who were undergoing surgery reported no development of hepatic failure or postoperative complications related to hepatic dysfunction.[115] Of these patients, 34 had hepatology consultations resulting in additional laboratory and ultrasonographic testing that failed to influence either the management or outcome of their cases. Thus, pursuing more extensive evaluation with costly tests such as ultrasonography, radionuclide imaging, or liver biopsy is rarely indicated.

In general, the most appropriate initial approach to a surgical patient with abnormal liver enzyme test results consists of a detailed history and physical examination. Symptoms of fatigue, anorexia, nausea, vomiting, biliary colic, pruritus, fever, or dark-colored urine warrant further evaluation because these findings may suggest clinically active hepatobiliary disease and thus potentially preclude elective surgery. If, however, the patient is asymptomatic, the significance of abnormal enzyme test results can be questioned. The patient should be further asked about a history of associated diseases such as chronic hepatitis, a family history of Wilson disease, hemochromatosis, α_1-antitrypsin deficiency, diabetes mellitus, hyperthyroidism or hypothyroidism, and previous transfusion history. All medications, including vitamins and herbal or other homeopathic remedies, should be reviewed for potential hepatotoxic side effects. The patient should be further questioned regarding alcohol or other illicit drug use, the presence of tattoos, sexual promiscuity, and consumption of raw seafood because they are potential risk factors for infectious hepatitis.

Physical examination may reveal findings consistent with active liver disease, such as icterus, palmar erythema, spider angiomas, gynecomastia, hepatosplenomegaly, ascites, or peripheral edema. Although these findings invariably suggest a diagnosis of cirrhosis, it is reasonable to repeat the test if a complete history and physical examination fail to suggest a cause of the biochemical abnormality. Minor increases in liver enzyme test results are defined as less than twice the normal value,[116] and, given a negative history and physical examination, they do not warrant additional testing before anesthesia and surgery.[115] Assessment of larger increases in liver enzyme test results requires an analysis of the specific abnormality.

AST and ALT are sensitive indicators of hepatocyte integrity. AST is present in hepatocyte cytoplasm and mitochondria, but it is also ubiquitous in cardiac and skeletal muscle; in kidney, brain, pancreas, and lung tissue; and in red and white blood cells. AST is therefore a less specific index of cellular injury than is ALT, which is

primarily found in the cytoplasm of hepatocytes. Both enzymes are released when the hepatic cell membrane is injured, although a correlation appears to exist between the degree of injury and serum aminotransferase levels. The AST/ALT ratio may also be helpful in distinguishing between alcohol-induced hepatitis and viral hepatitis. Alcohol tends to damage hepatocyte mitochondria preferentially, thereby causing an elevation in AST usually greater than twice the ALT.[117] In addition, ALT activity is diminished in patients with alcohol-induced liver disease because these individuals tend to have deficiencies of pyridoxal 5-phosphate, a vitamin necessary for ALT function. In contrast, a decrease in the AST/ALT ratio is more consistent with a diagnosis of viral hepatitis. Aminotransferases also increase in choledocholithiasis, cholangitis, and ischemic hepatitis. Ischemic hepatitis may not uncommonly produce levels greater than 10,000 International Units/L.

Similar to AST, alkaline phosphatase is present in many tissues, including bone, intestine, kidney, and placenta, as well as in leukocytes. The enzyme catalyzes the hydrolysis of orthophosphate from ester substrates at an alkaline pH. In hepatocytes, alkaline phosphatase is synthesized by biliary epithelial cells and is released in relation to the degree of bile duct obstruction. Measuring serum γ-glutamyltransferase (GGT), an enzyme found predominantly in hepatocytes and biliary epithelial cells, may aid in distinguishing between hepatic and bone causes of increased alkaline phosphatase. Although GGT is a very sensitive indicator of the presence or absence of hepatobiliary disease, by itself it lacks specificity because it is also increased in patients with myocardial infarction, renal disease, diabetes mellitus, and chronic obstructive pulmonary disease. If both alkaline phosphatase and GGT levels are elevated, the abnormality probably reflects hepatobiliary disease. Increased levels of alkaline phosphatase and GGT usually occur in extrahepatic bile duct obstruction and intrahepatic cholestasis from infiltrative diseases such as sarcoidosis, from mass lesions such as primary or metastatic carcinoma, or from drug-induced cholestasis.

Although liver enzyme elevation is an indication of active disease, synthetic hepatic function is best measured by serum bilirubin, albumin, and the prothrombin time. The bilirubin concentration in plasma varies in accordance with its production and inversely with hepatic clearance. Hepatic microsomal enzymes convert unconjugated bilirubin to the more water-soluble form, thereby permitting excretion in bile and preventing central nervous system toxicity. Total bilirubin levels represent both conjugated (direct bilirubin) and unconjugated (indirect bilirubin) forms. Unconjugated hyperbilirubinemia suggests hemolysis or an inherited disorder of bilirubin metabolism such as Gilbert syndrome. If more than 50% of the total serum bilirubin is conjugated, cholestasis or hepatocellular dysfunction is implied. Albumin is synthesized solely in the liver and, in healthy adults, has a half-life of approximately 21 days. The normal level of 3.5 g/dL usually decreases in long-standing and severe liver disease but is also influenced by overall nutritional status.

Finally, hepatobiliary dysfunction can cause an abnormal prothrombin time by impairing synthesis of the essential clotting factors II (prothrombin), VII, IX, and X. Hepatic synthesis of these factors depends on vitamin K, a fat-soluble vitamin found in certain foods and produced by intestinal bacteria, so abnormalities in prothrombin activity (as expressed by the international normalized ratio [INR]) may also occur in patients with malnutrition or malabsorption syndromes. The plasma half-time of these vitamin K–dependent factors is very short (<24 hours), and hence the INR responds rapidly to changes in synthetic function. This rapid response makes this test a more sensitive index of hepatic function than serum albumin.

Although no prospective, randomized, controlled studies have been designed to assess the perioperative risk of anesthesia or surgery in asymptomatic patients with elevated liver enzyme test results, a suggested approach to these patients is outlined in Figure 73-5.

ACUTE HEPATITIS

The diverse roles of the liver in drug metabolism, hemostasis, and coagulation function, in association with surgery and anesthesia-related alterations in hepatic perfusion, make it an organ extremely susceptible to clinically important hepatocellular injury induced by viruses or by alcohol or other drugs. Consensus opinion, based largely on data derived from older, predominantly retrospective studies, is that acute hepatitis, whether viral, alcohol induced, or drug induced, is a risk for the development of hepatic failure or death after elective surgery. In 1982, Powell-Jackson and co-workers described 36 patients who underwent exploratory laparotomy for either suspected extrahepatic biliary tract obstruction or intraabdominal malignancy, all of whom were ultimately found to have viral or alcoholic hepatitis, cirrhosis, or Budd-Chiari syndrome.[118] Of these patients, 61% suffered significant morbidity, including postoperative liver failure, and 31% died within 1 month of surgery. One hundred percent of patients with histologically proven hepatitis died. Greenwood and associates also reported high mortality rates in patients with alcoholic hepatitis who were undergoing open liver biopsy.[119] Bell and colleagues, however, noted that survival rates were not influenced by the presence of biopsy-proven hepatitis in 164 patients with alcoholic cirrhosis who required emergency portocaval shunts for esophageal variceal bleeding.[120]

In the current era of advanced diagnostic testing and imaging in which nonoperative management of extrahepatic biliary tract obstruction can be performed with endoscopic retrograde cholangiopancreatography (ERCP), invasive procedures such as open liver biopsy or exploratory laparotomy can be avoided. The preponderance of earlier information on perioperative morbidity and mortality indicates that elective surgery should be delayed in patients with acute hepatitis of any origin until resolution of hepatocellular dysfunction can be confirmed.[70] The influence of the type of surgery on patients with hepatitis is described later.

STEATOSIS AND STEATOHEPATITIS

Patients with chronic, asymptomatic increases in serum aminotransferase levels are often found by liver biopsy to

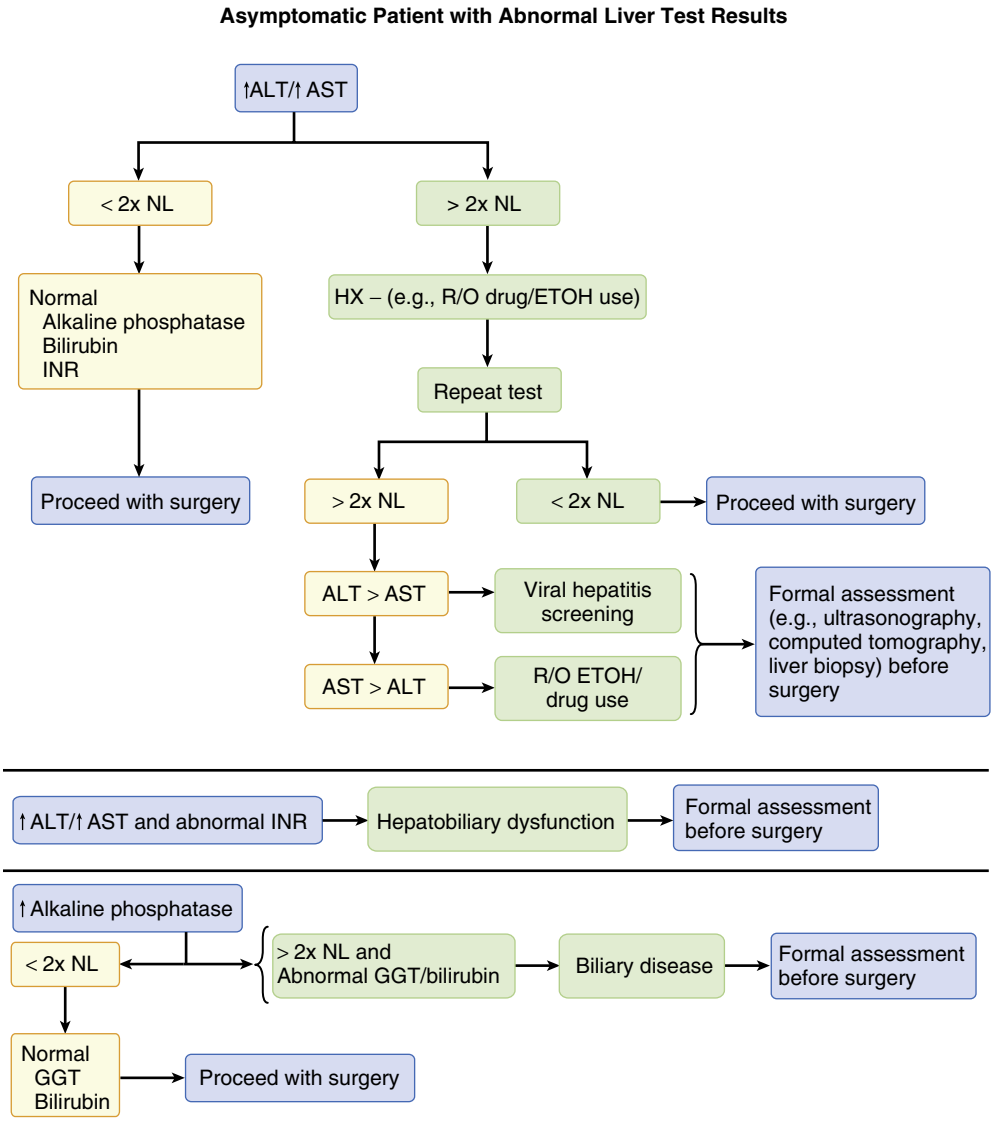

Figure 73-5. Approach to asymptomatic patients with abnormal liver test results who are presenting for surgery. *ALT,* Alanine aminotransferase; *AST,* aspartate aminotransferase; *ETOH,* ethanol; *GGT,* γ-glutamyltransferase; *HX,* history; *INR,* international normalized ratio; *NL,* normal; *R/O,* rule out.

have steatosis (fatty liver) or steatohepatitis.[121] Hultcrantz and co-workers studied 149 asymptomatic patients with at least a 6-month history of elevated aminotransferase levels that were found incidentally during routine laboratory screening.[122] Liver biopsy confirmed the diagnosis of steatosis in 64% of these patients, most of whom were obese or diabetic or had a history of excessive alcohol use. In a subsequent study, Hay and colleagues demonstrated a 21% incidence of steatohepatitis in a similar patient population.[121] Both studies concluded that chronic hepatitis or cirrhosis cannot be differentiated from steatosis or steatohepatitis based solely on clinical laboratory or noninvasive radiologic or ultrasonographic criteria. In a retrospective analysis of 135 patients who underwent hepatic resection, Behrns noted an increased incidence of postoperative liver failure and mortality when histopathologic examination revealed hepatocytes with greater than 30% fatty infiltration.[123] Brolin and associates noted a 6% incidence of biopsy-proven nonalcoholic steatohepatitis and subclinical cirrhosis in patients undergoing gastric bypass surgery; postoperative mortality was higher in affected patients than in those with normal hepatic histologic features.[124] Despite recommendations to the contrary,[125] steatosis and steatohepatitis should probably be considered significant risk factors for postoperative complications, especially after abdominal procedures. For this reason, patients with asymptomatic, chronic (>6 months) elevations in hepatic enzyme levels should be thoroughly evaluated before elective surgery.

CHRONIC HEPATITIS

The extent of anesthetic or surgical risk imposed by chronic forms of hepatitis primarily relates to the severity of associated hepatic synthetic dysfunction. Runyon retrospectively studied 20 asymptomatic patients who had chronic hepatitis B or C and were undergoing general or spinal anesthesia for a total of 34 surgical procedures, most of which were at operative sites distant from the liver.[126] Liver enzyme test results did not worsen postoperatively, nor did any patient experience postoperative liver failure or death. Higashi and colleagues assessed the postoperative outcomes of 119 patients with chronic hepatitis who were undergoing liver resection for primary hepatocellular

carcinoma (HCC).[127] Patients with the most impaired liver enzyme test results had a higher incidence of hepatic failure, recurrent HCC, and death.[128] Abnormal liver enzyme test results in an otherwise healthy patient reflect either a subclinical acute process such as viral or toxin-mediated hepatitis or a chronic disorder such as chronic hepatitis.

Asymptomatic patients with any form of chronic hepatitis should be screened before elective surgery for evidence of hepatic dysfunction, with the INR being the most sensitive indicator of the severity of hepatocellular dysfunction. When surgery cannot be avoided, hepatic perfusion should be maintained, and factors that could precipitate liver failure, hepatic encephalopathy, or both, should be avoided (see later).

CIRRHOSIS AS A PERIOPERATIVE RISK FACTOR

Cirrhosis is a syndrome of end-stage liver disease pathologically characterized by severe fibrosis and nodular regeneration of the liver parenchyma (see also Chapter 74). Alcohol abuse remains the most common cause of cirrhosis. Other causes include chronic hepatitis, primary biliary cirrhosis, hemochromatosis, Wilson disease, and idiopathic cirrhosis. The Child-Turcotte-Pugh (CTP) and the Model for End-Stage Liver Disease (MELD) scoring systems are the most frequently used tools to predict perioperative risk in cirrhotic patients undergoing abdominal surgery, exclusive of portosystemic shunt procedures (Table 73-1).[129,130] The CTP scoring system assigns points based on levels of serum albumin and bilirubin, the INR, the degree of ascites, and the presence and grade of encephalopathy and stratifies risk in order of severity as class A, B, or C. Several studies have used this system to predict perioperative outcome in cirrhotic patients undergoing a variety of surgical procedures. Originally used to predict mortality following transjugular intrahepatic portosystemic shunt (TIPS) procedures, the MELD (see later) scoring system uses serum bilirubin, creatinine, and INR in a calculation that predicts survival in patients with end-stage liver disease: MELD = 3.78 (serum bilirubin) (mg/dL) + 11.2 (INR) + 9.57 (serum creatinine) + 6.43. A score of 40 or more is equated with a predicted mortality rate higher than 70%, whereas a score lower than 9 predicts less than a 2% mortality rate.

Garrison and co-workers retrospectively evaluated outcomes in 100 patients with histologically proven cirrhosis who were undergoing surgery predominantly for biliary tract procedures (cholecystectomy, choledochotomy), as well as for gastroduodenal repair, colon and small bowel resection, and open liver biopsy.[131] An overall operative mortality rate of 30% and an additional perioperative morbidity rate of 30% were noted, with sepsis-mediated multiorgan system failure the major cause of death (87%). When stratified to CTP classes A, B, or C, mortality was 10%, 31%, and 76%, respectively. Excluding the CTP classification, the authors also performed a multivariate analysis of other perioperative variables and concluded that preoperative prolongation of the prothrombin time, decreased serum albumin, and a total leukocyte count greater than 10,000/cm^3 predicted increased mortality. Finally, operative mortality was considerably higher in patients requiring urgent versus elective surgery (57% versus 10%). More than a decade later, Mansour and associates retrospectively analyzed 92 cirrhotic patients who were undergoing abdominal procedures and described nearly identical results, with mortality rates of 10%, 30%, and 82% in patients with CTP classes A, B, and C, respectively.[132] Other retrospective studies have also shown increased perioperative risk during major abdominal surgery, especially under emergency circumstances and in CTP class C cirrhotic patients.[133-136]

Rice and colleagues, however, described the lack of predictability of the CTP classification in patients with chronic liver failure who were undergoing not only abdominal surgery but also coronary bypass grafting, orthopedic procedures, and other peripheral surgical procedures.[137] In this retrospective analysis of 40 patients, perioperative prolongation of the INR and clinical evidence of encephalopathy were the only variables most closely associated with increased mortality (10 and 35 times that of normal individuals, respectively).

Ziser and co-workers, in the largest of all these retrospective studies, established an 11.6% 30-day mortality rate in 773 patients with cirrhosis who were undergoing a variety of surgical procedures involving local, regional, or general anesthesia.[138] Multivariate analysis identified male gender, CTP class C, ascites, azotemia, perioperative infection, higher American Society of Anesthesiologists (ASA) physical classification, a diagnosis of cryptogenic cirrhosis, and surgery of the respiratory system as risk factors independently associated with mortality. Further analysis identified additional risk factors for perioperative complications (Fig. 73-6). Teh and associates retrospectively reported the utility of the MELD score in predicting mortality of cirrhotic patients undergoing nonhepatic surgery.[139] Comparing 777 cirrhotic patients undergoing major surgery with 303 cirrhotic patients undergoing minor procedures, the authors showed that MELD score, age, and ASA classification could quantify risk of mortality in cirrhotic patients, independent of the procedure

TABLE 73-1 MODIFIED CHILD-TURCOTTE-PUGH SCORING SYSTEM

	Modified CTP Score*		
Parameters	**A**	**B**	**C**
Albumin (g/dL)	>3.5	1.8-3.5	<2.8
Prothrombin time			
Seconds prolonged	<4	4-6	>6
International normalized ratio	<1.7	1.7-2.3	>2.3
Bilirubin (mg/dL)†	<2	2-3	>3
Ascites	Absent	Slight-moderate	Tense
Encephalopathy	None	Grade I-II	Grade III-IV

CTP, Child-Turcotte-Pugh.

*Class A = 5 to 6 points, B = 7 to 9 points, and C = 10 to 15 points.

†For cholestatic diseases (e.g., primarily biliary cirrhosis), the bilirubin level is disproportionate to the impairment in hepatic function, and an allowance should be made. For these conditions, assign 1 point for a bilirubin level less than 4 mg/dL, 2 points for a bilirubin level of 4 to 10 mg/dL, and 3 points for a bilirubin level greater than 10 mg/dL.

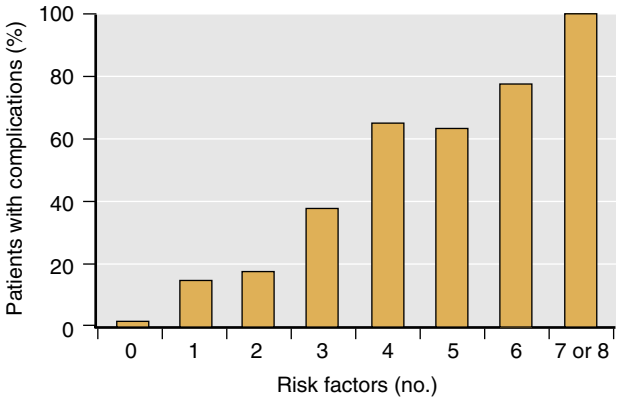

Figure 73-6. Effect of the number of risk factors on the perioperative complication rate in cirrhotic patients undergoing surgery. Risk factors included the Child-Turcotte-Pugh score, the presence of ascites, a diagnosis of cirrhosis other than primary biliary cirrhosis, serum creatinine concentration, a diagnosis of chronic obstructive pulmonary disease, preoperative infection, preoperative upper gastrointestinal bleeding, higher American Society of Anesthesiologists physical status score, intraoperative hypotension, and higher surgical severity score. *(From Ziser A, Plevak DJ, Wiesner RH, et al: Morbidity and mortality in cirrhotic patients undergoing anesthesia and surgery,* Anesthesiology *90:42-53, 1999.)*

performed.[139] The MELD scoring system appears to be accurate in predicting perioperative mortality in cirrhotic patients undergoing nontransplant surgery.[140-142]

Despite the lack of prospective studies, cirrhosis is likely a major risk factor for patients undergoing nonhepatic surgery; elective surgery is considered contraindicated in CTP class C patients.[143] In addition, elective surgery probably should be avoided in cirrhotic patients with a prolonged INR, hypoalbuminemia, and evidence of preoperative infection or encephalopathy. Alternatives to extensive abdominal procedures, such as cholecystostomy or laparoscopic cholecystectomy versus open cholecystectomy, should be considered for the treatment of cholelithiasis.[144,145] Preoperative decompression of portal hypertension by TIPS may also improve postoperative outcomes in certain patients.[146] Finally, elective abdominal surgery should probably be avoided if a diagnosis of cirrhosis is made fortuitously at the time of surgery.[124]

SURGICAL PROCEDURES THAT INCREASE THE RISK OF POSTOPERATIVE LIVER FAILURE

In addition to the severity of preoperative hepatic dysfunction, the actual surgical procedure performed may be the most important risk factor for postoperative liver failure.[147] Under normal circumstances, the liver is able to adapt to changes in perfusion pressure by altering either HABF or PBF. In a diseased state, pathologic changes may diminish the capacity of this dual blood supply and predispose the liver to the deleterious effects of surgery. Abdominal surgery per se appears to reduce THBF significantly. Surgical manipulation of the splanchnic bed may reduce both PBF and HABF, in part because of resultant systemic arterial hypotension mediated by prostacyclin-induced dilation of the venous capacitance vessels.[148] The effect of pneumoperitoneum on hepatic blood flow remains controversial. However, Meierhenrich and colleagues, using transesophageal echocardiography, noted an increase in hepatic perfusion with carbon dioxide insufflation in healthy patients undergoing laparoscopic hernia repair.[149]

In addition to surgery of the biliary tract, stomach, and colon, hepatic resection for HCC is a known risk factor for the development of liver failure in patients with preoperative hepatic dysfunction. Most patients with HCC have liver dysfunction associated with either chronic hepatitis or cirrhosis.[128,150] The diminished functional hepatic reserve of these patients may decrease the amount of tissue that can be resected without compromising viable parenchyma and causing liver failure, the most common cause of death after this surgical procedure. Wu and coworkers retrospectively analyzed cirrhotic patients undergoing hepatic resection for HCC based on their degree of hepatic dysfunction.[151] By limiting the amount of tissue resection in patients with significant hepatic dysfunction (i.e., poorer CTP class), the authors noted 5-year survival rates comparable to those in patients with less severe forms of cirrhosis who underwent more extensive resections. Perioperative hemorrhage is a common occurrence in cirrhotic patients undergoing resection for HCC because of contributing factors such as portal hypertension, coagulation abnormalities, and highly vascular adhesions in patients with previous abdominal surgery. Preoperative evaluation of patients with HCC by indocyanine green 15-minute retention,[151,152] or by direct measurement of the hepatic venous pressure gradient,[153] can be beneficial in predicting postoperative outcomes in cirrhotic patients undergoing hepatic resection for HCC.

Cardiothoracic surgery is associated with a high mortality rate in patients with preexisting liver disease.[138,154,155] Hepatic dysfunction is often exacerbated by cardiopulmonary bypass (CPB), although the precise mechanism of this dysfunction has not been clearly elucidated. In a canine model of hypothermic nonpulsatile CPB, Koizumi and colleagues noted a decrease in PBF and HABF without a concomitant change in hepatic oxygen metabolism.[158] Normothermic CPB was associated with a similar decline in PBF, but HABF was maintained. Increasing the dose of fentanyl from 10 to 50 μg/kg/hr significantly suppressed HABF and impaired hepatic oxygen metabolism in both normothermic and hypothermic CPB, thus suggesting the possibility of fentanyl-mediated peripheral venous pooling and subsequent lowering of cardiac output. Okano and co-workers assessed hepatosplanchnic oxygenation in 25 patients with no history of hepatic dysfunction who were undergoing elective coronary artery bypass grafting with either normothermic (>35° C) or hypothermic (<32° C) CPB.[156] Hepatic venous desaturation and functional impairment of hepatic sinusoidal endothelial cells occurred in both groups, but hepatocellular dysfunction was not observed.

In addition to the possible effects of hepatic artery and portal venous perfusion, other potential determinants of hepatic dysfunction after CPB include hypotension, low cardiac output syndrome, hypoxemia, microembolism or macroembolism, cytokine and oxygen free radical formation, and the influence of vasoactive and anesthetic drugs.

Small retrospective studies showed 11% to 30% mortality rates in CTP class A and B patients undergoing nonemergency cardiac surgery.[154,155,157] Although more deaths occurred in the CTP class B group, significant morbidity, particularly in the form of postoperative hemorrhage and infection, was seen in the CTP class A patients. Noncardiac, thoracic surgery has also been suggested as a risk factor for postoperative mortality in patients with cirrhosis, although the basis for this association remains speculative.[138]

Finally, patients with cirrhosis have an increased risk of developing both inguinal and umbilical hernias possibly related to an increase in intraabdominal pressure related to ascites. Successful surgical repair of an umbilical hernia under general anesthesia and of an inguinal hernia under local anesthesia have been described for all CTP classifications.[159,160]

POSTOPERATIVE JAUNDICE

Postoperative jaundice occurs as a result of overproduction and underexcretion of bilirubin, direct hepatocellular injury, or extrahepatic obstruction.[161] Most causes of postoperative jaundice manifest within 3 weeks of surgery and can be classified as either mild (<4 mg/dL) or severe (>4 mg/dL). Box 73-1 lists the most common causes of postoperative jaundice based on the nature of the pathophysiology.[161] If jaundice is secondary to hemolysis, the liver's capacity to conjugate bilirubin (normal rate of production, ≈250 to 300 mg/day) has been exceeded. Hemolysis-induced anemia is therefore associated with unconjugated (indirect) hyperbilirubinemia and, in the perioperative period, can usually be attributed to either drug-induced or mechanically induced erythrocyte destruction. The primary mechanisms by which certain drugs cause hemolysis and subsequent jaundice are as follows: (1) the drug adsorption type, whereby an antibody (immunoglobulin G [IgG]) reacts with a drug bound to the red blood cell membrane; (2) the neoantigen type (so-called innocent bystander), whereby the drug combines with the erythrocyte membrane and an antibody reacts with the newly formed antigenic site to activate the complement cascade; and (3) the autoimmune type, caused by an autoantibody (IgG) to erythrocytes. Medications commonly used perioperatively and associated with one or more forms of hemolytic anemia are listed in Box 73-2.[162]

The degree of associated jaundice is related to the rate of hemolysis and excess production of bilirubin, with the neoantigen mechanism most likely to cause acute anemia, hemoglobinuria, and renal failure. The diagnosis is made by the laboratory constellation of anemia, indirect hyperbilirubinemia, positive direct antiglobulin test, low serum haptoglobin, and a peripheral blood smear noteworthy for fragmented erythrocytes and reticulocytosis. Mechanical destruction of erythrocytes can also occur from surgically implanted prosthetic heart valves or from intrinsically diseased valves.[163]

Multiple blood transfusions can increase levels of unconjugated bilirubin because approximately 10% of stored whole blood undergoes hemolysis within 24 hours of transfusion (see also Chapter 61). Each 0.5-L unit of blood stored in citrate-phosphate-dextrose-adenine (CPDA-1) yields 7.5 g of hemoglobin, which is then converted to approximately 250 mg of bilirubin.[164] Multiple units of blood may therefore overwhelm the liver's ability to conjugate and excrete bilirubin. Finally, reabsorption of extravasated blood, as occurs with retroperitoneal or intraabdominal hematomas, may increase the bilirubin load and cause postoperative jaundice. This cause is not uncommon after major trauma or repair of ruptured aortic aneurysms.

Hepatocellular injury can cause postoperative jaundice (as previously discussed) by drug-induced, ischemic, or virally mediated mechanisms. In addition to potential anesthetic-induced hepatotoxicity, some commonly prescribed drugs can cause hepatocellular injury that mimics either hepatitis or cholestasis based on liver test abnormalities (Tables 73-2 and 73-3). With the exception of acetaminophen, which can directly cause hepatocyte necrosis, drug-induced hepatotoxicity is primarily the result of either idiosyncratic reactions or alterations in bile flow resulting in cholestasis.

Postoperative jaundice may also result from hepatic hypoperfusion. Cardiogenic and noncardiogenic shock can decrease HABF and PBF and cause hepatocellular

BOX 73-1 ***Etiology of Postoperative Jaundice by Time Course***

Immediate postoperative jaundice (<3 wk)
- Hemolysis
- Anesthesia
- Hypotension or hypovolemia
- Drugs
- Infection or sepsis
- Bleeding or resorption of hematoma
- Bile duct ligation, stricture, or surgical injury
- Hepatic artery ligation
- Retained common duct stone
- Postoperative pancreatitis or cholecystitis
- Acute viral hepatitis
- Gilbert syndrome or Dubin-Johnson syndrome
- Inflammatory bowel syndrome
- Heart failure
- Pulmonary postoperative jaundice
- Blood transfusion

Delayed postoperative jaundice (>3 wk)
- Drugs
- Blood transfusion
- Status after intestinal bypass
- Total parenteral nutrition

BOX 73-2 ***Medications Associated With Hemolysis***

- Acetaminophen
- Cephalosporins
- Hydralazine
- Ibuprofen and other nonsteroidal antiinflammatory drugs (e.g., diclofenac, tolmetin)
- Insulin
- Intravenous contrast media
- Penicillin and all derivatives (e.g., ampicillin, methicillin)
- Procainamide
- Ranitidine
- Sodium thiopental

necrosis. Marked elevations in aminotransferase levels are common, with hyperbilirubinemia usually a late finding. In addition to hemodynamic alterations in hepatic blood flow, sepsis or the systemic inflammatory response syndrome is associated with cholestasis and jaundice, presumably because of the effects of circulating endotoxins or other inflammatory mediators on bile formation and flow.[165] Finally, viral hepatitis should be eliminated as the cause of postoperative jaundice because viral exposure may have occurred before surgery.

Obstruction of the common bile duct by a gallstone, stricture, or tumor can result in failure to excrete conjugated bilirubin (obstructive jaundice) with significant perioperative morbidity and mortality. Factors associated with a poor outcome after surgery in patients with obstructive jaundice include extrahepatic obstruction as a result of malignancy, malnutrition, hypoalbuminemia, low hematocrit (<30%), azotemia, and the level and duration of hyperbilirubinemia.[166,167] Dixon and colleagues cited an overall mortality rate of 9.1% in a retrospective analysis of 373 patients requiring surgery for obstructive jaundice, but a 60% mortality rate for patients with anemia, malignancy, and marked hyperbilirubinemia (>11 mg/dL).[168] Of paramount significance is the association of acute renal failure with obstructive jaundice.[169,170] The incidence of postoperative acute renal failure is approximately 8% to 10% and correlates directly with the degree of hyperbilirubinemia, with mortality rates as high as 70% to 80% reported. Neither bilirubin nor bile acids themselves are directly nephrotoxic, but experimental evidence suggests a negative chronotropic, vasodilatory, and diuretic effect of bile salts that results in systemic and thus renal hypoperfusion. The changes appear to be related to enhanced absorption of endotoxin from the gastrointestinal tract because of low intestinal levels and high serum levels of bile acids. This process stimulates release of inflammatory mediators, in particular endothelin, a potent renal vasoconstrictor that leads to a further decline in renal perfusion.[171,172] Other experimental data have implicated endotoxemia-induced nitric oxide release as a further mediator of renal hypoperfusion.[173] Clinicians rely on the limitations of urine output as a method of monitoring renal perfusion. It is more reliable to monitor effective blood volume and cardiac function with either a central venous or pulmonary artery catheter or to perform transesophageal echocardiography, with the goal of maintaining renal perfusion by augmenting cardiac output.[114] No data have documented the clinical benefit of mannitol, furosemide, or dopamine in perioperative renal protection,[111,174] and the potential benefit of endothelin receptor blockers has yet to be thoroughly assessed in clinical studies.[171]

PERIOPERATIVE MANAGEMENT OF PATIENTS WITH ASYMPTOMATIC OR CHRONIC LIVER DYSFUNCTION

The goal of perioperative management of patients with asymptomatic elevations in aminotransaminase, alkaline phosphatase, or bilirubin levels or in patients with preexisting chronic liver disease is prevention of acute liver failure or further hepatic deterioration. Acute liver failure, defined by encephalopathy in the setting of acute liver injury (e.g., viral hepatitis, toxin ingestion, idiosyncratic drug reaction, sepsis, or shock), is further categorized into hyperacute, acute, or subacute forms based on the time interval between the onset of jaundice and encephalopathy (0 to 7 days, 8 to 28 days, or >28 days, respectively).[175] Patients with the hyperacute form of acute liver failure tend to have a more favorable survival rate (35%), whereas those with the acute and subacute forms have poorer prognoses, with mortality rates of 93% and 86%, respectively.[175] Perioperative risks should be identified, and therapy should be directed to minimize hepatotoxicity and maximize hepatic oxygen delivery. For example, drugs such as acetaminophen or combined drugs such as acetaminophen with hydrocodone probably should not be administered to patients with asymptomatic increases of liver enzyme test results or chronic liver dysfunction. In patients with cholelithiasis and biliary tract obstruction, the use of opiates should be limited preoperatively because these drugs can cause spasm of the choledochoduodenal sphincter (sphincter of Oddi) and a subsequent increase in intrabiliary tract pressure.[176,177] These effects appear to be more pronounced for fentanyl, morphine, and meperidine and less severe for opiate agonist-antagonists.[176,177] Intraoperatively, opiates may be used with the recognition that the possible development of sphincter of Oddi spasm can be treated directly with naloxone or by relaxing smooth muscle tone with either glucagon or nitroglycerin[177,178] (which induces release of nitric oxide[179,180]).

Remifentanil has an effect similar to that of other opiates on the sphincter of Oddi. Fragen and colleagues studied remifentanil given to six healthy adult volunteers who underwent radionuclide imaging of the gallbladder before and after remifentanil infusion.[181] The recovery time for dye to appear in the duodenum after discontinuation of the infusion was significantly greater than in the control phase of the study. The authors noted, however, that this delay in recovery of gallbladder function was shorter than in studies using morphine or meperidine. Finally, no data support the benefit or detriment of regional versus general anesthesia, nor do data suggest particular anesthetic agents that should be administered or avoided in patients with preexisting hepatic dysfunction, with the exception of halothane, as previously discussed.

Patients with more advanced liver disease (e.g., CTP class B or C cirrhosis) require an anesthetic plan designed to maximize hepatic oxygen delivery and prevent and treat the complications of encephalopathy, cerebral edema, coagulopathy, hemorrhage, and portal hypertension. Hepatic encephalopathy commonly occurs in patients with chronic liver disease because of the following: accumulation of circulating neurotoxins such as

unmetabolized ammonia, gut-derived false neurotransmitters, γ-aminobutyric acid (GABA), and endogenous GABA receptor agonists; altered neurotransmission by the excitatory neurotransmitter glutamate; or altered cerebral energy homeostasis.[182] Clinically, hepatic encephalopathy is manifested by neuropsychiatric abnormalities ranging from subtle personality changes and cognitive dysfunction to more advanced depression of consciousness, delirium, and coma. Clinical signs include abnormalities in psychometric testing and apraxia, as well as the more severe findings of asterixis, hyperreflexia, and decerebration. When hepatic encephalopathy occurs with acute liver failure, it often has a rapid onset and is invariably complicated by cerebral edema. Cerebral edema develops as a result of the osmotic effect of accumulated glutamine that produces astrocyte cell swelling or as a result of cerebral vasodilation caused by loss of autoregulation, or because of both mechanisms.[183] These patients invariably require urgent liver transplantation.

Many factors may precipitate hepatic encephalopathy in patients with chronic liver disease. Potassium levels should be monitored, and hypokalemia should be treated to decrease the effect of decreased potassium levels on renal production of ammonia. Arterial pH should be maintained near normal because systemic alkalemia is also noted to increase the diffusion of ammonia across the blood-brain barrier, a process that can potentially worsen the degree of encephalopathy.[182] Effective circulating blood volume should be maintained, and anemia should be corrected to maintain hepatic oxygenation and promote the metabolism of circulating toxins. Benzodiazepines should be used judiciously because they may activate the central GABA-benzodiazepine receptor ligand and worsen hepatic encephalopathy. All psychoactive drugs have potentially deleterious effects on hepatic encephalopathy by further suppressing a vulnerable central nervous system. Moreover, propofol can be used as an anesthetic for cirrhotic patients undergoing endoscopic procedures. Compared with benzodiazepines and opioids, propofol appears to have a greater safety profile; it allows for a more rapid and predictable awakening, it does not precipitate hepatic encephalopathy, and it is associated with few side effects, as well as having no effects on liver function tests.[184-189] Hepatic encephalopathy is also a recognized complication of the TIPS procedure.[190]

When patients remain obtunded or comatose after anesthesia and surgery, therapy is often directed toward decreasing ammonia production. Lactulose is administered either by nasogastric tube or by enema to create an osmotic, cathartic effect and to lower intestinal pH, thereby decreasing the survival of ammonia-producing bacteria.[191] Flumazenil, a specific antagonist of central benzodiazepine receptors, can improve the level of consciousness in selected cirrhotic patients with severe hepatic encephalopathy.[192]

Perioperative hemorrhage in patients with significant liver dysfunction may occur because of bleeding diatheses or the complications of portal hypertension, or both. Synthetic hepatic function, as measured by the INR, is useful to assess the severity of the coagulopathy and to gauge therapy, including the subcutaneous administration of vitamin K, transfusion of fresh frozen plasma, use of recombinant factor VII or other factors, and plasmapheresis.[193] In patients with acute liver failure, plasmapheresis may have potential benefit because it promotes rapid correction of coagulopathy while minimizing the chances of excessive intravascular volume, but this approach has not been validated.[194]

Hemorrhage may also occur as a result of gastrointestinal bleeding from rupture of esophageal or gastric varices as a complication of portal hypertension. Intraoperatively, it is advisable to avoid the placement of a transesophageal echocardiography probe, to avoid initiation of bleeding in patients with esophageal varices. Pharmacologic therapy for acute esophageal variceal bleeding includes use of the combination of vasopressin and nitroglycerin, somatostatin, or octreotide, a synthetic analogue of somatostatin.[195,196]

Portal hypertension may also lead to the development of ascites. Ascites occurs in patients with advanced liver disease secondary to renal retention of sodium and water and localization of this excess fluid in the peritoneal cavity because of portal hypertension. In addition to the general measures of sodium and water restriction and diuretic therapy, therapeutic paracentesis may be indicated if a patient presents for surgery with tense ascites.[197] Relief of tense ascites may improve pulmonary gas exchange and reduce the risk of gastric aspiration. Care should be taken, however, to prevent circulatory collapse by the concomitant administration of intravenous colloid solutions because intravascular volume reequilibration occurs 6 to 8 hours after the removal of a larger volume of ascitic fluid.[195] Finally, patients with end-stage liver disease are at risk for the development of either hepatorenal or hepatopulmonary syndrome. *Hepatorenal syndrome* is a state of functional renal failure characterized by azotemia, hyperosmolar urine, and urinary sodium excretion less than 10 mEq/L.[198] Although the pathogenesis of this syndrome has not been clearly elucidated, there appears to be a decrease in renal perfusion pressure related to systemic vasodilation in combination with a loss of renal autoregulation because of increased sympathetic activity.[197] The diagnosis of hepatorenal syndrome in patients with end-stage liver disease usually signals the need for orthotopic liver transplantation. In the event that transplantation is not possible, management is supportive and consists of the use of intravenous volume challenges and large-volume paracentesis to relieve tense ascites.

Hepatopulmonary syndrome, which is defined by the triad of end-stage liver disease, increased alveolar-arterial gradient, and intrapulmonary vascular dilation, is characterized by the clinical features of digital clubbing, cyanosis, dyspnea, platypnea, and orthodeoxia, in addition to the other clinical characteristics of portal hypertension. *Orthodeoxia,* defined as arterial oxygen desaturation that is more pronounced in the upright position and relieved by recumbency, is a common phenomenon of hepatopulmonary syndrome.[199] The pathogenesis of hepatopulmonary syndrome is considered to be primarily related to intrapulmonary vascular dilation, which is diagnosed by contrast-enhanced echocardiography, perfusion lung scanning, or pulmonary arteriography. Current pharmacologic therapy for this disorder is limited; however, orthotopic liver transplantation may lead to a reversal of these pulmonary changes.

ANESTHETIC CONSIDERATIONS FOR PROCEDURES INVOLVING THE LIVER AND BILIARY SYSTEM

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT PROCEDURE

TIPS is a percutaneously created intrahepatic connection of the portal and systemic circulations. This procedure is typically used in patients with end-stage liver disease to decrease portal pressure and attenuate the complications related to portal hypertension, such as variceal bleeding or refractory ascites. Diversion of PBF into the hepatic vein is achieved by placement of an expandable intraparenchymal tract (Fig. 73-7).

Although most patients can undergo TIPS placement with sedation, some clinicians prefer to use general anesthesia in selected patients because of the prolonged nature of the procedure, the potential respiratory-depressant effects of sedatives in cirrhotic patients with underlying pulmonary dysfunction as a result of ascites and/or hypoxemia from the hepatopulmonary syndrome, and concern regarding possible gastric aspiration. Regardless of the anesthesia technique chosen, appropriate intravascular volume resuscitation is often necessary before the procedure, especially in patients who have had variceal bleeding. In addition, patients with cirrhosis who are undergoing a TIPS procedure frequently have severe coagulopathy that requires preprocedural procoagulant therapy.

Several complications can occur during placement of TIPS that may require intervention by the anesthesiologist. Pneumothorax or neck vessel injury can occur during vessel puncture. These complications may be reduced by ultrasonographic guidance during jugular vein puncture. Additionally, cardiac dysrhythmias can be mechanically induced during intracardiac catheter passage. Finally, acute, life-threatening hemorrhage caused by hepatic artery puncture in conjunction with a hepatic capsular tear or by extrahepatic portal venous puncture can occur. Hemodynamic status can deteriorate, with the development of pulmonary edema and congestive heart failure, in patients with borderline cardiac reserve.[200]

HEPATIC RESECTION

Preoperative considerations (as previously described) before hepatic resection involve risk assessment primarily using CTP and MELD scores (see also Chapter 74). Surgical procedures should be limited to patients with CTP class A and significantly compensated CPT B status. MELD scores higher than 10 pose significant risk of postoperative liver failure in cirrhotic patients with HCC. Severe thrombocytopenia or large varices represent major perioperative risk factors and should preclude surgery.[201] Significant anemia and coagulopathy, if present, should be corrected preoperatively. Decisions regarding the choice and doses of anesthetics should account for any baseline hepatic parenchymal dysfunction, as well as the potential postoperative dysfunction resulting from resection of a major portion of the liver parenchyma. No data show hepatoxicity with either sevoflurane or desflurane, and thus both drugs are safe to administer, provided hepatic hypoperfusion is avoided. Indeed, hepatic preconditioning with sevoflurane has been shown to decrease postoperative complications in patients undergoing hepatic resection.[35]

Although the risk of significant intraoperative blood loss is well known and the need for appropriate monitoring and sufficient vascular access to permit rapid transfusion is widely accepted, overall fluid management during major hepatic resection is controversial. At some centers, fluid and blood administration is used liberally, beginning early in the course of resection, with the goal of increasing intravascular volume as a buffer against sudden blood loss. Other centers favor maintenance of low central venous pressure during resection to minimize blood loss from hepatic venous radicals, major hepatic veins, or the vena cava. These sites typically contribute to most bleeding during hepatic resection. Notably, reduction of intrahepatic venous pressure can also be achieved by using a modest degree of the Trendelenburg position, an approach that potentially maintains or even increases cardiac preload and cardiac output, as well as reducing the risk of air embolism from disrupted hepatic veins. In patients without preexisting renal dysfunction, the latter approach does not appear to have a significant impact on postoperative renal function.[202]

Although basic postoperative management concerns are similar to those of other major abdominal procedures, several aspects of care are notable. Intravenous fluids should be supplemented with either sodium or potassium phosphate, which is often needed to prevent severe hypophosphatemia and to facilitate liver regeneration. Decreased clearance of hepatically metabolized drugs is important in selecting and titrating methods of postoperative analgesia.

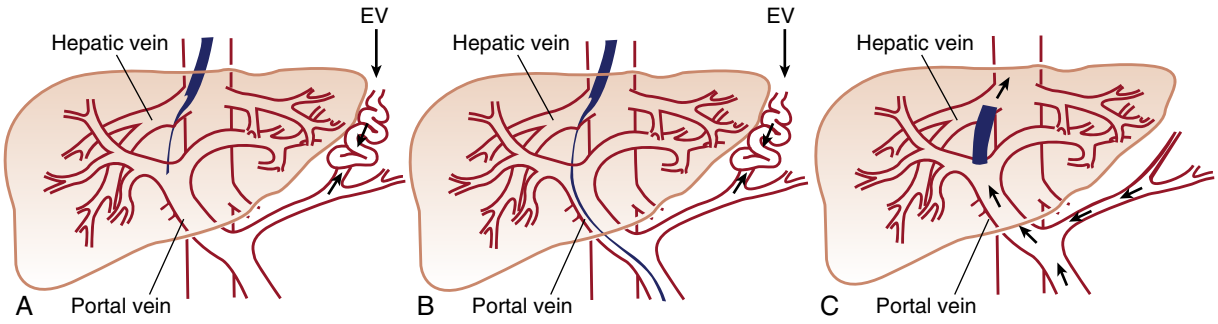

Figure 73-7. Transjugular intrahepatic portosystemic shunt (TIPS) procedure. A stent (or stents) is passed through the internal jugular vein over a wire into the hepatic vein (**A**); dilated esophageal varices (EV) are apparent. The wire and stent or stents are then advanced into the portal vein (**B**), after which blood can pass through the portal vein into the hepatic vein and bypass and decompress dilated esophageal veins (**C**). *(Reproduced with permission from University of Michigan Health System: <www.med.umich.edu/1libr/topics/liver09.htm/>*

HEPATIC CRYOTHERAPY

Hepatic cryotherapy involves the application of material at subzero temperature by multilumen probes positioned intraoperatively under sonographic guidance. This procedure is used to treat nonresectable malignant hepatic tumors. Preanesthetic considerations for hepatic cryotherapy are similar to those for hepatic resection. Heat conservation measures should be instituted during the procedure, with continual monitoring of core temperature. Intraoperative bleeding is rarely significant enough to cause hemodynamic instability. Postoperative pulmonary, renal, and coagulation problems may manifest as sequelae of the "cryoshock syndrome," even after a procedure with unequivocal intraoperative stability.[203]

Acknowledgment

The authors gratefully acknowledge the assistance of Kelly Lewis, PharmD, in the preparation of Tables 73-2 and 73-3.

Chapter 74

Anesthesia for Abdominal Organ Transplantation

RANDOLPH H. STEADMAN • CHRISTOPHER L. WRAY

Acknowledgment: The editors and the publisher would like to thank Drs. C. Spencer Yost and Claus U. Niemann who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Survival after abdominal organ transplantation continues to improve.
- The imbalance between organ supply and demand is increasing.
- To increase the supply of organs, living donors and extended criteria deceased donors are being used more frequently.
- Knowledge of the pathophysiologic changes associated with end-stage disease is required to provide optimal care for patients undergoing transplant surgery.
- The kidney is the most frequently transplanted organ.
- Kidney transplant recipients are older and are more likely to have chronic illnesses than in the past.
- The perioperative and long-term risk of cardiovascular disease is increased in patients with end-stage renal disease.
- Maintenance of renal perfusion pressure in the perioperative period is critical for graft function.
- Liver transplant recipients are older in age and have more comorbidities than in the past.
- The Model for End-stage Liver Disease (MELD) score prioritizes candidates for organ allocation.
- The pathophysiologic changes associated with liver disease affect nearly every organ system.
- Intraoperative care requires preparation for massive transfusion, management of coagulation abnormalities, and hemodynamic instability.
- Pancreatic transplantation is definitive treatment for diabetes mellitus.
- Pancreatic transplants are performed simultaneously with kidney transplantation (SPK), after kidney transplantation (PAK), or alone (PTA).
- Patients who are younger than 50 years with diabetes and end-stage renal disease benefit from simultaneous kidney and pancreas transplantation.
- Frequent monitoring of blood glucose concentrations is required during the perioperative period.
- Diabetic patients are at significant risk for cardiovascular disease.

ABDOMINAL ORGAN TRANSPLANTATION

The success of transplantation over the past decade corresponds to improved survival for recipients. Three-year posttransplant recipient survival is 80% for livers and 90% for patients receiving kidneys (Fig. 74-1). Three-year survival for liver transplantation matches that of heart transplantation. Increasingly, indications for transplantation have broadened. Patients with conditions previously considered contraindications, such as advanced age and some types of cardiopulmonary disease, are no longer precluded from transplantation.

Among the various organs, the kidney is the most transplanted organ. In 2011, more than 17,000 kidney transplants were performed. In the same year, liver was the second most commonly transplanted organ, with more than 6300 transplants performed. The heart is third, with more than 2000 transplants.

As of mid-year 2011, there are over 275,000 patients living with functioning transplants in the United States.

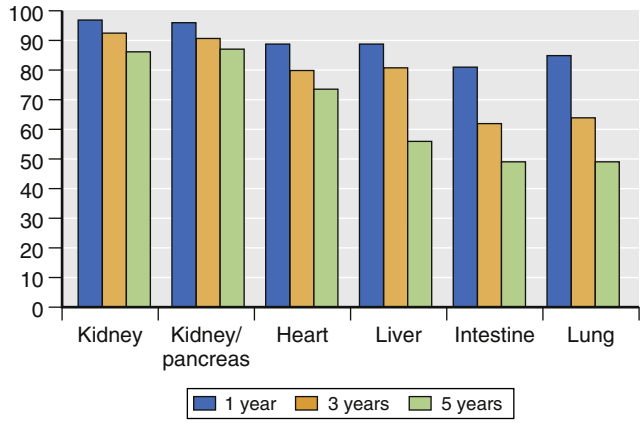

Figure 74-1. Patient survival 1, 3, and 5 years after transplant, by organ. Data are for U.S. transplants performed during 1997 to 2004. *(From http://optn.transplant.hrsa.gov/latestData/rptStrat.asp. Accessed December 2012)*

This number has nearly doubled in the past 8 years. The majority of these patients are kidney recipients (180,000), followed by liver (62,000), heart (25,000) and lung (10,000) recipients. Thoracic organ transplantation is reviewed elsewhere (see Chapters 66 and 67). Approximately 1000 intestinal recipients are living with functioning grafts.

Despite these successes, the number of patients who could benefit from transplantation far exceeds those who receive an organ. The imbalance between supply and demand is highlighted by the size of the waitlists for each organ, which is approximately threefold the number of annual transplants for kidney (more than 54,000) and double the number of annual transplants (more than 12,000) for liver. In 2011, for every two patients who undergo liver transplantation, one patient dies on the liver waitlist. For every three patients who undergo kidney transplantation, one patient dies while waiting for a kidney.[1]

Solutions to organ shortage include living donor transplantation, which is used more commonly for kidney transplants (one third of kidney transplants in 2011) than liver transplantation (less than 5% of liver transplants in 2011). Other strategies include the use of extended criteria donors, which is discussed in detail elsewhere (see Chapter 75).

The evaluation of patients for transplantation varies among transplant centers, but the goals are similar. These include ascertaining that: (1) transplantation is indicated for the management of the prospective recipient, (2) comorbidities do not preclude transplantation, and (3) emotional and social resources permit a major surgery and its associated rehabilitation, including compliance with long-term immunosuppression therapy. The center's transplant selection committee typically consists of physicians (nephrologist and hepatologist for kidney and liver transplantation, respectively), transplant surgeon, psychiatrist, dietitian, social worker, and additional consultants as indicated. Anesthesiologists consult for patients with high operative risk, such as pulmonary hypertension, coronary artery disease (CAD), or patients with prior anesthetic complications.

Reasons to deny transplantation vary among transplant centers. Critically ill patients receiving life support, vasopressors, or dialysis have decreased posttransplant survival.[2] Additional comorbidities can exacerbate the risk to a level that may be unacceptable to some centers. Medical reasons include comorbidities such as significant CAD, moderate or severe pulmonary hypertension, metastatic disease, uncontrolled intracranial hypertension, and untreated sepsis. Psychosocial contraindications include alcohol or recreational drug use, and the lack of social support, which might preclude compliance with immunosuppression regimens, follow-up care, or both. Age alone is generally not a contraindication.

The success of organ transplantation relies heavily on a highly specialized team approach that includes the organ procurement organization, transplant coordinators, nurses, physicians, and allied health care providers. With the exception of kidney transplantation, most abdominal organ transplants are performed at tertiary medical centers with extensive resources available to support the program. Many of these centers have specialized anesthesia teams, particularly for liver transplantation.

This chapter reviews the anesthetic considerations for kidney, liver, pancreas, and intestinal transplantation in adults. The overall care of pediatric patients is described in Chapter 93. The management of heart and lung, but not renal, is described in Chapter 94. In Chapter 95, the intensive care clinical care is described in pediatric patients who are receiving a kidney transplant.

KIDNEY TRANSPLANTATION

The first kidney transplantations were performed in the 1950s; however, renal transplantation did not become widespread until the development of effective immunosuppression in the 1960s. Since then, kidney transplantation has become the most common organ transplant surgery performed. Kidney transplants have steadily increased over the past 40 years worldwide, with the growth of kidney transplant programs throughout Europe, North America, and Asia, as well as in many developing countries. There are differences in the distribution of living versus cadaveric donor organs between regions; many countries in Africa and Asia rely exclusively on living donation, whereas many countries in Europe perform mainly cadaveric renal transplants.[3] During the past decade in the United States, there has been a steady increase in the number of patients on the kidney transplant waitlist (Fig. 74-2). The demographics of patients on the waitlist have changed; patients are older (more than half are older than age 50) and are more likely to have developed end-stage renal disease (ESRD) secondary to chronic hypertension and advanced diabetes. The incidence of chronic kidney disease (CKD) among individuals older than 65 years continues to increase in the United States (Fig. 74-3). Although it is not known how many patients with CKD progress to ESRD, the prevalence of ESRD in the United States has steadily increased over the past 30 years. At the end of 2009, nearly 900,000 people in the United States were being treated for ESRD.[4] The waiting time for kidney transplantation has increased in the United States as well, reflecting that the need for organs outstrips

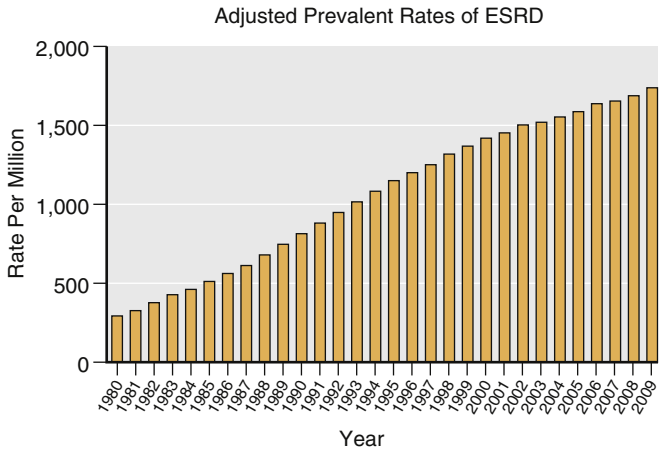

Figure 74-2. Prevalent rates of end-stage renal disease (ESRD). Although the prevalence is increasing, the number of new cases per year has been stable since 2001. *(From* Kidney Disease Statistics for the United States, *National Kidney and Urologic Diseases Information Clearinghouse, NIH Publication No. 12-3895, June 2012.)*

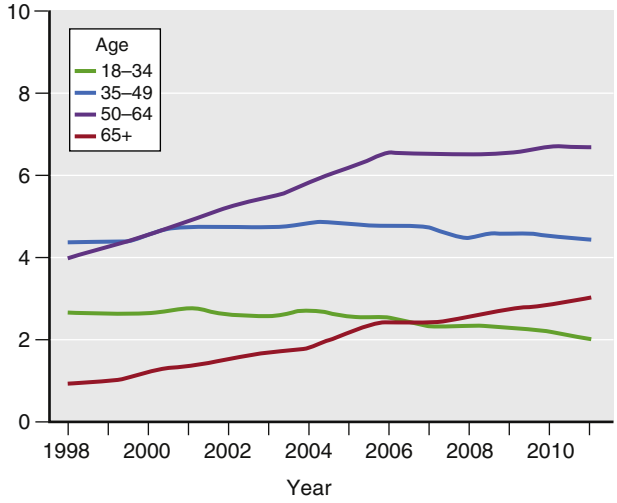

Figure 74-3. Adult kidney transplants in thousands, by year. The lines illustrate trends in recipient age. The number of recipients aged 50 to 64 years and older than 65 years is increasing over the past decade. *(OPTN & SRTR Annual Data Report 2011. U.S. Department of Health and Human Services Health Resouces and Services Administration, p 28, figure KI 4.2)*

the organ supply. Recent data showed that there were more than 80,000 patients on the waitlist in the United States (active and inactive), and approximately 16,000 kidney transplants were performed in 1 year. More than 5000 patients were removed from the waitlist in the same year because of death, whereas almost 2000 were removed after becoming too ill for transplantation.[5] These national trends reflect a kidney transplant population that is older and more likely to suffer from chronic diseases, which has significant implications regarding perioperative risk during kidney transplant. Nevertheless, current 3-year posttransplant survival for adults is 96% for living donor kidney transplants and 90% for deceased-donor transplants.[1]

Paired kidney donations have increased from fewer than 100 per year in 2006 to more than 400 per year in 2011. Paired donation consists of two incompatible donor-recipient pairs exchanging kidneys to create two compatible pairs. With the development of donor chain transplants and establishment of a national system for paired donation, these techniques are expected to become more common.

INDICATIONS FOR KIDNEY TRANSPLANTATION

Kidney transplantation is indicated in patients with ESRD caused by any one of a variety of underlying conditions. Glomerular disease, congenital diseases, and polycystic kidney disease are common indications in younger patients. Nephropathies associated with hypertension and diabetes are now the most common indications for kidney transplantation in the United States.[6] Renal graft failure is an increasingly common indication for transplantation in the United States as well.[7]

PATHOPHYSIOLOGY OF END-STAGE RENAL DISEASE

End-stage renal disease refers to the final progression of CKD, when renal function is irreversibly impaired and the development of uremia is imminent. Essential functions of the kidney include regulation of the ionic composition of the plasma, maintenance of fluid volumes, elimination of nitrogenous wastes and drugs, synthesis of erythropoietin, and adjustment of plasma pH. Significant declines in glomerular filtration rate (GFR) and urine production occur when these critical functions are significantly damaged, resulting in the clinical manifestations of uremia. After the development of ESRD, renal replacement therapy is required. ESRD has an effect on nearly every organ system, and it has a major impact on patient mortality despite chronic therapy including hemodialysis.

ESRD results in abnormalities of fluid balance and electrolytes. With the onset of uremia and oliguria, expansion of the extracellular fluid volume ensues, presenting with edema, hypertension, and signs and symptoms of volume overload. Disorders of sodium, calcium, magnesium, and phosphate can result in chronic changes in bone metabolism, hyperparathyroidism, and vascular calcifications. The development of hyperkalemia, with its effects on the myocardium, is the most critical electrolyte abnormality. Failure of the renal elimination of organic acids results in the development of an anion-gap metabolic acidosis.

ESRD has a significant effect on the cardiovascular system. Cardiovascular disease is the most common cause of morbidity and mortality in patients with ESRD, accounting for 35% to 40% of all deaths in patients receiving hemodialysis.[8] As GFR decreases, the risk of cardiac mortality increases.[9] Following successful kidney transplantation, cardiovascular disease remains the most common cause of death.[10] Kidney transplant recipients are at increased risk for the development of myocardial infarction (MI), congestive heart failure, and atrial fibrillation.[11-13] ESRD increases the development of atherosclerosis and is a major risk factor for the development of ischemic vascular disease, which can affect the coronary, cerebrovascular, and peripheral vascular systems. The likelihood of CAD, which

can present as angina, MI, arrhythmia, or sudden cardiac death, is even greater in patients with ESRD, hypertension, and diabetes. Hypertension may be the etiology of ESRD in nearly 30% of patients, or conversely, hypertension may result from hyperreninemia, hypervolemia, and renal vasculature changes associated with ESRD. Concentric left ventricular hypertrophy and diastolic dysfunction occur in the early stages of CKD, and are the two most common echocardiographic abnormalities in patients with ESRD.[14] Patients with ESRD are at particular risk for diastolic congestive heart failure, especially in the setting of excessive intravascular volume. Heart failure owing to dilated cardiomyopathy with decreased systolic function can occur in patients with ESRD as well. The cardiorenal syndrome is defined by an interconnection between the renal and cardiac systems, where the decline of one organ influences the decline of the other. There is evidence that correction of renal function by renal transplantation can improve systolic dysfunction and reverse left ventricular dilation and hypertrophy.[15] A variety of arrhythmias can occur in ESRD because of progression of cardiac disease, myocardial ischemia, or electrolyte disturbances. Atrial fibrillation occurs in 13% to 27% of patients on hemodialysis, and it is associated with a significant risk of stroke.[16] Pericardial disease is common in patients with uremia, manifesting as pericarditis or pericardial effusion.

Characteristic hematologic and hemostatic abnormalities occur with ESRD. Normochromic, normocytic anemia secondary to lack of erythropoietin is common and may be exacerbated by iron deficiency, chronic inflammation, and bone marrow fibrosis. Anemia decreases quality of life in ESRD and is associated with adverse cardiac outcomes. Erythropoiesis-stimulating drugs and iron are commonly prescribed for the treatment of uremic anemia, and hemoglobin levels of 11 to 12 gm/dL are typically achieved[17] (see Chapters 61 and 63). ESRD is associated with abnormal hemostasis because of a broad spectrum of platelet function abnormalities, including decreased platelet activity, aggregation, and adhesiveness. Production of von Willebrand factor and factor VIII is decreased. Historically, renal failure increases the likelihood of bleeding; however, ESRD is also associated with a hypercoagulable state owing to complex abnormalities involving increased coagulation and endothelial activation.[18] These hematologic changes of hypercoagulability resolve in patients with ESRD after successful kidney transplantation.[19]

Gastrointestinal signs and symptoms including nausea, vomiting, abdominal pain, and abnormal gastric motility occur in ESRD patients. Using electrogastrography, impairments in gastric myoelectrical activity exist in patients with symptomatic ESRD as compared to patients with normal renal function.[20] Patients with ESRD have delayed gastric emptying, regardless of the timing of their last oral intake. The presence of diabetes, obesity, or both can further impair gastric emptying.

Central nervous system and neuromuscular abnormalities can occur in ESRD secondary to uncleared nitrogenous molecules. These abnormalities can range from mild changes in memory or attention to signs and symptoms of neuromuscular irritability. Severe neurologic manifestations of uremia with asterixis, seizures, and decreased mental status are rare with regular dialysis. Autonomic and peripheral neuropathies can occur in patients with ESRD and are possibly reversible with kidney transplantation.

ANESTHESIA FOR KIDNEY TRANSPLANTATION: PREOPERATIVE EVALUATION

Before kidney transplantation, patients typically undergo a prolonged and intense pretransplant evaluation by a multidisciplinary transplant committee to determine their candidacy for transplantation. In general, the preoperative evaluation of patients for kidney transplant should focus on the multiorgan manifestations of ESRD, with the goals of risk stratification and optimization of the medical status of the patient before transplant (see Chapter 39). Cadaveric kidney transplantation is an urgent procedure, because harvested organs tolerate a finite duration of cold ischemia, usually less than 24 hours. Living donor kidney transplants are scheduled well in advance, allowing for a more thorough preoperative assessment before surgery.

Before surgery, patients receiving hemodialysis should be maintained on their regular dialysis schedules, whether hemodialysis or peritoneal dialysis. Ideally, dialysis should be performed before surgery, especially in patients with excessive intravascular volume or with documented hyperkalemia or acidosis. A comprehensive laboratory panel that includes electrolytes, complete blood count, and platelet count is appropriate before surgery. A type and screen or type and cross for packed red blood cells should be obtained (see Chapter 61). Although major blood loss during routine kidney transplantation is not common, the surgery involves major vascular structures with the potential for rapid bleeding. Documentation of an increased potassium level immediately before surgery, especially with electrocardiogram (ECG) changes consistent with hyperkalemia, should prompt consideration of immediate dialysis to correct potassium levels before surgery. Preoperative vital signs should be closely assessed, especially heart rate and arterial blood pressure trends in hospitalized patients. Preoperative intravascular volume status should be assessed. Comparing the patient's current weight to their known euvolemic weight, or "dry weight," may be helpful. Patients undergoing surgery immediately after dialysis may be significantly hypovolemic and prone to intraoperative hypotension. Orthostatic assessments and the presence of resting hypotension and increased heart rate may identify significant hypovolemia. Preoperative volume resuscitation with non–potassium-containing saline solutions or colloids can prevent hypotension on induction of anesthesia. Conversely, patients who have preoperative body weights heavier than their euvolemic weight may have an excessive intravascular volume, and they may be prone to congestive heart failure during kidney transplantation. A thorough cardiopulmonary examination is indicated in all patients, and findings of significant excessive intravascular volume may be an indication for immediate preoperative dialysis before surgery.

As discussed previously, the current demographic of kidney transplant patients has a frequent association with cardiac disease, which has a major effect on

posttransplant outcome. As a result, preoperative cardiac evaluation is of critical importance in this patient group (see Chapter 39). Compared with the routine preoperative evaluation of noncardiac surgery patients, which focuses on the perioperative period, the renal transplant patient should be assessed to consider both short- and long-term cardiac outcomes. The goal of the preoperative cardiac evaluation is ultimately to decrease the morbidity and mortality associated with cardiovascular disease in kidney transplant candidates. Although decisions regarding candidacy in high-risk patients are usually made well before surgery, the anesthesiologist should be involved in the routine cardiac risk assessment of the kidney transplant patient before surgery. The main focus of the preoperative cardiovascular assessment in kidney transplant patients is to identify occult ischemic heart disease in an asymptomatic patient.

The 2007 American College of Cardiology Foundation/American Heart Association (ACC/AHA) Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery suggests a preoperative algorithm designed to assist in the risk stratification of surgical patients. The algorithm identifies active cardiac conditions that are associated with major risk (unstable coronary syndromes, decompensated heart failure, significant arrhythmia, and severe valvular disease) and then stratifies patients based on functional capacity. No further testing is recommended when functional status is adequate (more than four metabolic equivalent tasks [METS]). If functional status is less than four METS, further ischemia testing is then determined by the type of surgery (low, intermediate, or high risk) and by the presence of further risk factors (history of ischemic heart disease, heart failure, diabetes, renal insufficiency, and cerebrovascular disease).[21] Kidney transplantation is considered an intermediate-risk procedure in the ACC/AHA Guidelines. The utility of the 2007 ACC/AHA Guidelines to detect patients with ischemic heart disease has been called into question in the kidney transplant population.[22] Silent myocardial ischemia can occur more frequently in patients with ESRD than in the general population, making the detection of unstable coronary syndromes more difficult. One study reported that chest pain presenting at the time of acute MI was less common in patients with ESRD requiring dialysis compared with patients not using dialysis (44% versus 68%).[23] Decreased functional status might not be a specific or sensitive indicator of cardiovascular risk in kidney transplant candidates. One study of 204 kidney transplant candidates examined the effectiveness of various guidelines to detect asymptomatic CAD. Of the 204 patients, 178 underwent noninvasive ischemia testing; 17 patients with ischemia were identified. The authors determined that if the ACC/AHA guidelines had been strictly applied to this group of patients, only 39 of the 178 candidates would have undergone noninvasive testing, and only 4 of the 17 patients with ischemia would have been detected.[24] Finally, renal insufficiency is itself a risk factor. The unique characteristics of ESRD patients, along with discrepancies among guidelines, has called into question the applicability of available recommendations regarding cardiac testing in the kidney transplant population.[22]

Noninvasive testing methods for CAD have been well studied in the kidney transplant population. In studies that compared either dobutamine stress echocardiography (DSE) or myocardial perfusion studies with angiography in patients with renal failure, both methods had decreased accuracy compared to their accuracy in nonrenal failure patients. DSE had sensitivities of 0.44 to 0.89 and specificities of 0.71 to 0.94. Myocardial perfusion studies had sensitivities of 0.29 to 0.92 and specificities of 0.67 to 0.89.[22] Although noninvasive testing has variable sensitivity and specificity for CAD in transplant cohorts, abnormal noninvasive test results correlate with adverse cardiac events and mortality in patients with ESRD. A meta-analysis of studies using either DSE or myocardial perfusion studies in patients with ESRD demonstrated that patients with inducible ischemia or fixed defects had a significantly increased risk of cardiac death compared to patients with normal studies.[25]

Before 2010, several guidelines and consensus-based recommendations regarding preoperative cardiac risk assessment in kidney transplant candidates had been published. The risk assessment of asymptomatic kidney transplant candidates is of prime importance.[26,27] Likewise, surveys of practice patterns in the United States demonstrate a spectrum of approaches for the screening of asymptomatic kidney transplant candidates.[28,29] Although preoperative cardiac evaluation recommendations have not been standardized for kidney transplant candidates, a stepwise process including a comprehensive cardiovascular history and assessment of signs and symptoms of advanced cardiac disease, assessment of functional status, and identification of risk factors should be assessed.

A baseline ECG is an appropriate initial screening test in most kidney transplant patients, especially in patients older than 40 years. ECG abnormalities associated with cardiac disease are common in patients with ESRD. A preoperative ECG should be obtained in patients with known CAD, peripheral vascular disease, and cardiac symptoms.[22] Noninvasive testing may be considered in asymptomatic patients with multiple risk factors for CAD. Using a revised list of risk factors, one study demonstrated an improvement in the sensitivity and specificity for the detection of occult CAD in transplant candidates compared to using the established ACC/AHA risk factors.[24] Based on this study's results, risk factors associated with an increased risk of CAD in renal transplant candidates include diabetes, history of cardiovascular disease, more than 1 year of dialysis, left ventricular hypertrophy, age older than 60 years old, smoking, hypertension, and dyslipidemia.[22] Preoperative assessment of left and right ventricular function by echocardiography is an appropriate test in most kidney transplant candidates.[22] The likelihood of structural cardiac abnormalities and the potential for left ventricular dysfunction in ESRD is significant, and transthoracic echocardiography provides detailed information regarding resting cardiac function and structure with few testing risks.

An increased prevalence of occult pulmonary hypertension occurs in patients with ESRD receiving dialysis. A 40% incidence of pulmonary hypertension existed in a series of 58 ESRD patients receiving chronic

hemodialysis. The mechanism involves both uremia-induced pulmonary vasoconstriction and increased cardiac output secondary to an arteriovenous fistula. Pulmonary hypertension may be reversible after kidney transplantation. The identification of pulmonary hypertension is important because its presence in patients with ESRD is associated with decreased survival.[30] A screening ECG can identify patients with pulmonary hypertension (see Chapter 47). In addition, right heart catheterization is likely indicated in patients with evidence of significant pulmonary hypertension by echocardiography.

Patients with cardiac conditions may remain on transplant lists for a long duration (i.e., many months or even years) before undergoing transplantation. During this time, cardiac disease can progress. Although routine periodic noninvasive screening in asymptomatic patients awaiting transplant is not warranted, patients with known cardiac disease should undergo regular repeat cardiac assessments; however, the ideal frequency of assessments is not known.[22]

A detailed list of the patient's cardiovascular medications should be obtained, and the patient should be clearly advised which medications should be taken before surgery. In general, most patients with ESRD receive multiple medications for the chronic treatment of hypertension; however, the ideal combination of drugs is not clear. Strategies for the perioperative administration of antihypertensive blood pressure medications are important; however, the urgency of donor kidney transplantation often allows only the immediate preoperative administration of antihypertensive medications. Perioperative β-adrenergic blocker therapy apparently decreases the incidence of perioperative MI and mortality in high-risk and intermediate-risk surgical patients,[31,32] but perioperative β-adrenergic blockade has not been effective in other studies with low–cardiac risk patients and with patients with diabetes.[33,34] One study demonstrated that perioperative β-adrenergic blockade decreased short- and long-term mortality in renal failure patients undergoing vascular surgery.[35] To clarify this issue, there are unfortunately no randomized, prospective trials that have investigated perioperative β-adrenergic blockade in kidney transplant patients. The ACC/AHA 2007 Guidelines recommend that patients previously receiving β-adrenergic blockers should continue to receive them.[21] Based on recommendations for nontransplant surgical patients, perioperative β-adrenergic blockade may be initiated in renal transplant candidates with known CAD, with CAD risk factors (diabetes, heart failure, and atherosclerosis), and with myocardial ischemia that occurs during preoperative noninvasive stress testing.[22] In asymptomatic kidney transplant patients not previously receiving β-adrenergic blockers without two or more CAD risk factors, perioperative β-adrenergic blockade should not be initiated because of the risk of perioperative bradycardia and hypotension observed in nontransplant cohorts.[22]

Patients with ESRD are at risk for atherosclerosis and may be receiving lipid-lowering medications at the time of surgery. Although there are no studies that definitively show that hyperlipidemia therapy improves outcomes in ESRD, lipid-lowering medications probably should be continued during the perioperative period in patients previously receiving them.[22]

As mentioned previously, there is an increasing prevalence of diabetes in the kidney transplant population. There have been many studies assessing the risks and benefits of glycemic control with intravenous insulin therapy in surgical patients. A recent meta-analysis found that the use of perioperative insulin infusions is associated with episodes of hypoglycemia, although overall mortality may be reduced.[36] A multinational randomized trial in intensive care unit (ICU) patients comparing "tight" glucose control with intensive insulin therapy (target glucose levels ranging 81 to 108 mg/dL) to conventional insulin therapy (target glucose levels < 180 mg/dL) demonstrated a more frequent 90-day mortality with tight glucose control.[37] Perioperative glycemic therapy should be started in patients with diabetes who are undergoing kidney transplant, yet a benefit from strict blood glucose control in the kidney transplant population has not been demonstrated in the literature. On the morning of surgery, blood glucose levels should be measured, and insulin therapy may be initiated in patients before surgery for significant hyperglycemia, with appropriate serial blood glucose measurements during the perioperative period. As in all types of surgery, orally administered antihyperglycemic medications should be withheld on the morning of surgery in patients with non–insulin-dependent diabetes (see Chapter 39).

ANESTHESIA FOR KIDNEY TRANSPLANT: INTRAOPERATIVE MANAGEMENT

General anesthesia with endotracheal intubation is the preferred anesthetic method for kidney transplantation in most kidney transplant centers. The goals of anesthesia are to facilitate an adequate depth of anesthesia while maintaining hemodynamic stability and to provide appropriate muscle relaxation to facilitate surgical conditions. As mentioned previously, patients with ESRD are considered a risk for aspiration of gastric contents secondary to the presence of uremic gastropathy and other conditions, such as obesity (see Chapter 71) and diabetes. An oral nonparticulate antacid and intravenous administration of an H-2 blocker, such as ranitidine, probably should be given before induction of anesthesia. A rapid-sequence induction of anesthesia with continuous cricoid pressure is the preferred method of induction for general anesthesia. Succinylcholine can be used safely in standard doses in patients with ESRD when potassium levels are within normal limits (usually <5.5 mEq/L). Potassium transiently increases 0.5 to 1.0 mEq/L for 10 to 15 minutes before returning to baseline levels in patients with ESRD and those with normal renal function.[38] A modified rapid sequence induction using rocuronium 0.8 to 1.2 mg/kg intravenously is an appropriate substitute for succinylcholine when hyperkalemia or other contraindications to succinylcholine exist. A meta-analysis of 26 studies that compared the intubating conditions produced by succinylcholine and rocuronium found that intubation conditions were clinically similar when propofol was used as the induction anesthetic.[39] The hemodynamic response to laryngoscopy may be accelerated in patients with ESRD with underlying chronic hypertension. Tachycardia and hypertension can be attenuated with supplemental

opioids, esmolol, lidocaine, or nitroglycerin titrated to effect. Following the stress of tracheal intubation kidney transplant patients may develop hypotension before surgical incision, especially in patients who have been rendered hypovolemic from recent dialysis or in patients receiving renin-angiotensin blocking drugs.

Intraoperative monitoring may be limited to standard noninvasive monitors in younger, healthier transplant recipients and in select living donor recipients. Intraarterial blood pressure monitoring can be beneficial, especially in patients with uncontrolled hypertension, CAD, or heart failure. Pulmonary artery catheter or transesophageal echocardiographic monitoring may be considered in patients with advanced CAD, left or right ventricular dysfunction, and pulmonary hypertension. Central venous pressure monitoring is a standard monitoring technique in some centers; however, central venous pressure is not a reliable monitor of fluid status or responsiveness.[40] The insertion of a central line provides reliable venous access for intravascular fluid resuscitation and transfusion, and access for administration of immunosuppression drugs and vasoactive infusions. Large-bore venous access is necessary for appropriate intravascular volume administration in the perioperative period. Intravenous access can be challenging in some kidney transplant patients, because intravenous sites may be limited by the presence of an upper extremity arteriovenous fistula. Conversely, central venous access may be difficult to accomplish in patients with ESRD who have undergone multiple previous central venous dialysis catheter placements, especially if central venous thrombosis has been documented.

Maintenance of anesthesia is typically performed using a combination of intravenous and inhaled anesthetics. Volatile inhaled anesthetics are titrated to the level of surgical stimulation, which varies during the phases of the procedure. Desflurane and isoflurane are not associated with nephrotoxicity. Although sevoflurane has potential nephrotoxic effects from the metabolites compound A and fluoride ion, detrimental effects on renal function have not been demonstrated in patients with renal insufficiency[41,42] (see Chapter 26). A study of 200 renal transplant recipients retrospectively compared outcomes in recipients that received anesthetics using sevoflurane versus isoflurane. There was no difference between patient groups in postoperative creatinine levels, the need for dialysis, or graft rejection up to 6 months after transplantation.[43] Although large prospective studies are lacking in kidney transplant patients, the use of sevoflurane during kidney transplantation appears to be a reasonable anesthetic choice.

Analgesia during the intraoperative period can be provided with the synthetic opioids fentanyl, sufentanil, alfentanil, and remifentanil, because their pharmacokinetics and pharmacodynamics are not affected by renal insufficiency. Morphine, oxycodone, and meperidine should be used sparingly in patients with renal failure, because these drugs have active metabolites that accumulate in these patients (see Chapter 30).

Appropriate neuromuscular blockade during kidney transplantation is important for optimizing surgical conditions (see Chapters 34 and 35); however, recovery from neuromuscular blockade may be variable in patients with ESRD, regardless of the drug used.[6] Both vecuronium and rocuronium have prolonged durations of action in renal failure patients, because their clearances rely both on renal and hepatic metabolism. Cisatracurium is likely the muscle relaxant of choice in patients with ESRD, because it undergoes organ-independent clearance. Pancuronium is primarily eliminated by the kidneys, and probably should be avoided in patients with renal failure. For patients with ESRD who are undergoing kidney transplantation, judicious use of neuromuscular blocking drugs is a necessity. Titration to surgical conditions and close monitoring of the level of neuromuscular blockade are crucial (see Chapter 53).

The surgical procedure involves placement of the renal allograft in the left or right extraperitoneal fossa, although the right side is usually preferred (Fig. 74-4). A vertical curvilinear incision 20 to 25 cm long is typically made, extending from the pubis symphysis to above the anterior superior iliac spine. The abdominal musculature is divided, and the peritoneum is entered and retracted. During the initial incision and dissection, surgical stimulation is increased and hemodynamic responses may be exaggerated in some patients. Adequate analgesia, depth of anesthesia, and muscle relaxation should be appropriately titrated to effect. The external iliac vein and artery are identified and mobilized. Occasionally, different vascular structures are chosen for the renal anastomoses. Heparin may be administered before clamping of the vessels. The external iliac vein is clamped first, and the renal vein anastomosis is performed. Next, the external iliac artery is clamped and the renal artery anastomosis is performed. During the anastomoses of the renal vessels, expansion of intravascular volume with normal saline should be initiated. Furosemide and mannitol are administered before reperfusion to stimulate diuresis. Mannitol, along with adequate intravascular volume resuscitation, decreases the likelihood of acute tubular necrosis in renal transplantation.[44] Adequate intravascular volume expansion with crystalloid or colloids increases renal blood flow, which improves immediate graft function.[6] At the time of removal of the vascular clamps, additional intravascular volume expansion may be required to stabilize hemodynamics. On rare occasions, removal of vascular clamps may be associated with acute bleeding requiring further resuscitation and transfusion. Hypotension following reperfusion will result in hypoperfusion of the graft. Hypotension may precipitate renal injury owing to ischemia and can contribute to vascular thrombosis of the graft. Appropriate decreases in the depth of volatile anesthetic and volume expansion will maintain adequate renal perfusion pressures in most patients. In the event of hypotension, adrenergic vasopressors are typically avoided because of renal vasoconstrictive effects. Hypotension unresponsive to volume expansion may require interventions to increase cardiac output, especially in high-risk patients. Invasive hemodynamic monitoring is invaluable in this situation. Dopamine is typically the first vasoactive infusion used in kidney transplant patients; however, this is controversial. In an

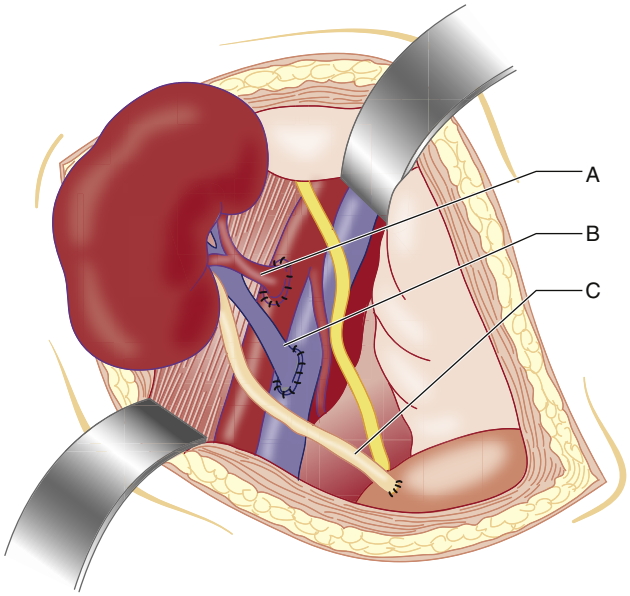

Figure 74-4. Renal transplantation. **A,** Renal artery anastomosis performed end-to-side to the external iliac artery. **B,** Renal vein anastomosis performed end-to-side to the external iliac vein. **C,** Ureteral anastomosis to the bladder mucosa. *(From Hardy JD:* Hardy's Textbook of Surgery*, ed 2. Philadelphia, 1988, JB Lippincott.)*

observational study of 105 kidney transplants, there was no difference in renal function parameters in recipients who received dopamine versus those who did not.[45] Furthermore, dopamine can increase heart rate and myocardial oxygen requirements potentially inducing myocardial ischemia in patients with CAD. The routine perioperative use of dopamine in kidney transplants has not been recommended because it has not been proven to prevent graft complications.[22] After completion of the vascular anastomoses, the donor graft ureter is implanted into the recipient bladder. The bladder is filled with antibiotic saline irrigation solution by way of a three-way Foley catheter, allowing for implantation of the donor ureter. A temporary ureteral stent may be placed as well. After completion of the bladder anastomosis, the wound is closed in layers. Neuromuscular blockade should be maintained until the fascial layer has been closed to prevent straining or coughing that could potentially disrupt the graft position or vascular connections. During emergence, exaggerated hemodynamic responses are common, especially in patients with poorly controlled hypertension. Appropriate titration of short-acting drugs to attenuate these responses upon emergence is helpful, especially in patients at risk for CAD. Careful neuromuscular blockade monitoring and appropriate administration of reversal agents are central to avoiding postoperative pulmonary complications (see Chapters 34 and 35). Likewise, ESRD patients may demonstrate delayed emergence from anesthesia and have exaggerated responses to opioids and sedative-hypnotics. Extubation of the trachea should occur after the patient demonstrates the ability to protect the airway, because kidney transplant patients are still considered a risk for aspiration of gastric contents at the completion of surgery.

ANESTHESIA FOR KIDNEY TRANSPLANT: POSTOPERATIVE MANAGEMENT

After extubation of the trachea, the kidney transplant recipient requires careful monitoring in the postanesthesia care unit. Close monitoring of urine output in the initial postoperative period is important. Acute decreases in urine output should initiate a rapid evaluation of the etiology and appropriate treatment. A prerenal etiology should be treated with aggressive intravascular volume resuscitation. In some patients, additional invasive hemodynamic monitoring may be required. Postrenal etiologies owing to technical problems with the ureteral anastomosis may require early surgical re-exploration. Postoperative complications include vascular thromboses (1% to 2%), wound hematomas (1% to 2%), and infection. High-risk patients with advanced cardiac and pulmonary disease may require further postoperative monitoring in the intensive care setting. Variable rates of admission to ICUs have been reported by different centers, but in general, postoperative intensive care admissions for kidney transplant recipients are much less common than for liver and kidney-pancreas transplant recipients. One single-center study of 1015 consecutive kidney transplants over a 10-year period found an ICU admission rate of 6%. The mortality rate in patients that required intensive care admission may be more frequent (40%) than in other nontransplant ICU patients (20%). Most patients were admitted for sepsis and required ventilator support.[46]

Postoperative pain control is usually provided with synthetic opioid analgesics without active metabolites (see Chapter 98). Pain after kidney transplant is highly variable; in some patients, pain may be severe and challenging to treat effectively. Patient-controlled opioid analgesia is commonly initiated in the postanesthesia care unit. Regional anesthesia for kidney transplantation is controversial. One report demonstrated effective postoperative analgesia in kidney transplant recipients with epidural analgesia.[47] However, the concern for uremic coagulopathy and the potential for hypotension with epidural analgesia has limited its use in kidney transplant recipients. One pilot study in kidney transplant recipients demonstrated that a supplemental transversus abdominis plane block before incision improved postoperative pain scores and decreased opioid requirements compared with control patients who received standard opioid therapy and acetaminophen.[48]

ORGAN MATCHING AND ALLOCATION

Organ matching for kidney transplantation involves several steps to determine compatibility between donor and recipient. Initially, matching of the major ABO blood group is determined for all donors and recipients. Before the transplant surgery, a crossmatch is performed by mixing recipient blood with donor blood cells. This crossmatch is performed to identify any recipient antibodies that are reactive against donor antigens. Histocompatibility matching is an important part of the matching process, in which the human lymphocyte antigen (HLA) profile of the recipient is determined and compared with the HLA

profile of the donor. Organ rejection by the recipient's immune system is mediated by the recognition of mismatched (non-self) HLAs located on the surface of donor cells. Many standard HLAs are compared between potential donors and recipients before transplantation. In general, survival rates are worse with HLA-mismatched grafts. Although better immunosuppression has improved the overall survival rates for kidney transplants during the past 3 decades, the graft loss rate for HLA-mismatched kidneys has remained twice as frequent as HLA-matched grafts.[49] For all potential recipients awaiting a deceased donor, their HLA profile is compared to the donor profile, and an appropriate donor-recipient pairing is made based on the best match. For living donors, HLA matching is performed well in advance of the surgery.

Currently, deceased-donor kidneys in the United States, unlike other organs, are allocated primarily based upon the recipient's accrued time on the waitlist. With improvements in immunosuppression, HLA matching is not as prominently weighted in the kidney allocation process as previously. Despite the increase in living donor transplants within the past 20 years, efforts have been made to revise the current deceased-donor kidney allocation system in the United States to allocate organs to the highest acuity patients, similar to liver graft allocation. Ideally, a new allocation system would decrease the number of recipient deaths before transplant while matching donor and recipient characteristics to maximize posttransplant recipient survival.

ANESTHESIA FOR PATIENTS AFTER KIDNEY TRANSPLANTATION

After successful kidney transplantation, most patients are classified as having National Kidney Foundation stage 2 or 3 CKD with usual GFRs more than 30 mL/min. GFR typically deteriorates by 1.4 to 2.4 mL/min/yr in renal transplant recipients.[50] Posttransplant mortality increases as renal graft function deteriorates. Renal function is followed closely within the first few years after transplant to assess for rejection, which is identified by worsening organ function. In post–kidney transplant patients undergoing nontransplant surgery, renal function should be assessed before surgery. Most patients will be under the care of a nephrologist within the first years of a kidney transplant; assessment of the patient's medical records or renal function tests should be obtained preoperatively. Rejection should be ruled out before nontransplant surgery, as surgery during an episode of rejection can increase morbidity.[51]

Cardiovascular disease is the most common cause of death in kidney transplant patients. As described previously, cardiovascular disease is involved in the pathogenesis of renal failure and is a consequence of kidney disease. Ischemic heart disease, cerebrovascular disease, and peripheral vascular disease significantly affect the survival of kidney transplant patients. Progression of preexisting CAD can occur in the posttransplant patient, as immunosuppression contributes to the development of de novo hyperlipidemia, hypertension, and diabetes. The incidences of hypertension (80%), hyperlipidemia (60% to 80%), and new-onset diabetes (25%) are increased in kidney transplant recipients.[50] Obesity and the development of metabolic syndrome are common after kidney transplant (see Chapter 71). More than 60% of renal transplant patients received a diagnosis of metabolic syndrome within 6 years following kidney transplant in one study.[52] Because long-term studies on cardiac outcomes following nontransplant surgery in kidney transplant recipients are lacking, specific recommendations for regular cardiovascular testing are lacking as well. For previous kidney transplant patients undergoing nontransplant surgery, the ACC/AHA guidelines for the preoperative evaluation for noncardiac surgery should be used to guide preoperative cardiovascular testing[21] (see Chapter 38).

Other disease processes related to kidney disease and immunosuppression should be sought. Kidney transplant patients are at increased risk for posttransplant malignancies, anemia, and osteodystrophy. Infection is a constant concern in kidney transplant recipients, because they are at risk for both opportunistic and community-acquired infections. Cytomegalovirus (CMV) infection is the most common infection in kidney transplant patients, and it is rarely acquired by transfusion (see Chapter 61). CMV-negative blood should be used when transfusions are required in patients who are CMV negative.

Anesthesia for nontransplant surgery can be accomplished safely with general, regional, and local sedation techniques. Most anesthetic drugs are safe in posttransplant patients, assuming the presence of adequate hepatic and renal function.[51] Although preoperative creatinine may be near normal in kidney transplant recipients, GFR in these patients is usually reduced, resulting in prolongation of the activity of drugs cleared by the kidneys. Obviously, drugs that cause nephrotoxicity should be avoided.

PANCREAS TRANSPLANTATION

Surgical treatment for diabetes includes pancreas transplant alone (PTA) and, in patients with diabetes and ESRD, pancreas after kidney transplant (PAK) and simultaneous pancreas-kidney transplant (SPK). Usually, whole pancreas is transplanted from deceased donors. Less commonly, the distal pancreas is transplanted from a living donor. In 2008, there were 432 pancreas transplants performed in the United States (223 PTAs and 209 PAKs), and 826 SPKs. The total number of pancreas transplants performed in the United States for all three groups has decreased annually over the past several years (Fig. 74-5). The reasons for this decline are not well understood.[53] The 5-year patient survival for pancreas transplant is 90% for PTA, 86% for PAK, and 88% for SPK. The 5-year graft survival for pancreas transplant is 73% for SPK, 52% for PTA, and 55% for PAK.[5]

INDICATIONS FOR PANCREAS AND KIDNEY-PANCREAS TRANSPLANTATION

Pancreas transplantation provides patients with insulin-dependent diabetes mellitus a permanent source of endogenous insulin, thus restoring normoglycemia. SPK and PAK transplants are indicated in patients with diabetes

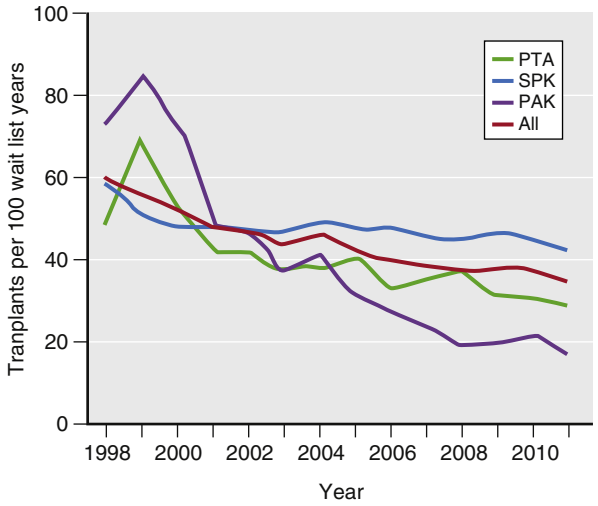

Figure 74-5. Pancreas transplant rates per 100 waitlist years. The pancreas transplantation rate is decreasing. *PTA,* Pancreas transplant alone; *SPK,* simultaneous pancreas-kidney transplant; *PAK,* pancreas transplant after kidney transplant. *(OPTN & SRTR Annual Data Report 2011. U.S. Department of Health and Human Services Health Resouces and Services Administration, p 7, Figure PA 1.4)*

and ESRD who are deemed appropriate candidates for kidney transplantation or who have already undergone kidney transplantation. PTA is indicated in patients with diabetes without indications for kidney transplantation and who have a history of severe frequent metabolic complications, or who have a history of problems maintaining insulin therapy that result in intractable diabetic complications.[54] Most patients who undergo pancreas transplant have type 1 diabetes mellitus. Rare indications for pancreas transplant include select cases of type 2 diabetes mellitus, chronic pancreatitis that has developed endocrine deficiency, cystic fibrosis with endocrine deficiency, and prior total pancreatectomy.

For patients with diabetes and ESRD, those younger than 50 years have better survival than older patients when undergoing pancreas transplantation at the time of kidney transplantation.[55] The survival benefit in SPK may be due to long-term decreases in CAD complications.[56] For patients with normal renal function who undergo PTA, long-term survival appears be the same as in patients receiving chronic insulin therapy[57]; however, pancreas transplant has a favorable effect on the progression of retinopathy. The progression of retinopathy is decreased or reversed in a significant percentage of PTA patients compared to diabetic patients treated with conventional insulin therapy.[58]

PATHOPHYSIOLOGY OF PANCREATIC INSUFFICIENCY

Type 1 diabetes mellitus occurs secondary to destruction of pancreatic islet cells resulting in a permanent functional loss of the endogenous production of insulin, necessitating life-long exogenous insulin therapy. The underlying cause of type 1 diabetes mellitus remains unknown. Type 2 diabetes mellitus results from peripheral resistance to the effects of insulin. Both diseases produce chronic increases of blood glucose concentrations resulting in the multiorgan manifestations of diabetes.

The chronic complications of diabetes that have the greatest effect on patient morbidity and survival are those that affect the cardiovascular system. CAD, cerebrovascular disease, and peripheral vascular disease occur in patients with diabetes owing to acceleration of atherosclerosis. Both macrovascular and microvascular disease occurs. Patients with diabetes develop CAD earlier, are more likely to have atypical symptoms, and have a higher mortality rate from MI than nondiabetics.[59] Peripheral and autonomic neuropathies develop in diabetes, resulting in gastroparesis, lower extremity paresthesia, ulcerations, orthostatic hypotension, and labile heart rate and arterial blood pressure. Patients with diabetes have a high cumulative prevalence of blindness (16%), renal failure (22%), lower extremity amputation (12%), MI (21%), and stroke (10%)[60] (see Chapter 39).

Acute complications of type 1 diabetes mellitus typically involve conditions associated with severe hyperglycemia, such as diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic coma. Hypoglycemia is a direct result of exogenous insulin administration. Patients with type 1 diabetes are prone to large fluctuations in blood glucose levels. Hypoglycemic episodes contribute to acute morbidity and mortality in diabetic patients.

ANESTHESIA FOR PANCREAS TRANSPLANTATION: PREOPERATIVE EVALUATION

The preoperative evaluation for the patient undergoing pancreas transplantation involves an assessment of all of the potential acute and chronic complications of type 1 diabetes. Pancreas transplant centers pursue a comprehensive, multidisciplinary evaluation and selection process before listing candidates. This evaluation should address the organ systems most affected by long-standing diabetes, including the cardiovascular, renal, and neurologic systems. Assessment for the presence and severity of CAD should be undertaken in all candidates, including noninvasive ischemia testing, evaluation of ventricular function, and coronary angiography in select patients. Previously, patients considered for pancreas transplantation were younger than 40 years and had a lower risk for the cardiac and vascular sequelae of diabetes. Older patients are now considered for pancreas transplantation, but have a significantly higher risk for CAD and vascular disease.[61] Strategies to reduce cardiac complications, such as maintenance of β-adrenergic blockade and continuation of drugs that decrease blood lipid concentrations during the perioperative period, should be applied when appropriate.[21]

In most cases, pancreas transplantation involves a deceased-donor organ with a 24-hour maximum cold ischemia time; therefore, pancreas transplantation is considered an urgent procedure. Preoperative evaluation by the anesthesiologist should focus on any acute changes in the patient's medical status, especially those involving acute diabetic complications such as ketoacidosis and hypoglycemia. Blood glucose measurements should be assessed closely before surgery, and recent insulin administration should be noted. Evaluation of renal function in

all candidates is important before surgery. Most patients with diabetes listed for pancreas transplant have ESRD as well and will undergo SPK. A full evaluation of electrolytes, including creatinine and potassium, should be obtained before surgery. Serial trends in heart rates and arterial blood pressures in hospitalized patients should be assessed, as most patients will have a history of hypertension requiring multiple medications, especially patients with renal failure. Preoperative assessment of intravascular volume status is especially important in patients with ESRD on hemodialysis (see Chapter 38). Finally, a directed physical examination focusing on the airway and cardiopulmonary system should be performed. The incidence of difficult tracheal intubations in patients with long-standing diabetes was thought to be more frequent because of anatomic changes of the upper airway; however, two recent reports did not concur.[62,63] Nevertheless, attention to anatomic signs of a potentially difficult airway is important in patients with diabetes, especially those with cervical arthritis and significant obesity.

ANESTHESIA FOR PANCREAS TRANSPLANTATION: INTRAOPERATIVE MANAGEMENT

General anesthesia with endotracheal intubation is required for all types of pancreas transplantation. The surgical procedure is typically prolonged, and an adequate depth of anesthesia and muscle relaxation is required for optimal surgical conditions. Diabetic patients and those with ESRD have a high likelihood of gastropathy and may have an increased risk for aspiration of gastric contents. Administration of an oral nonparticulate antacid preoperatively should be considered. A rapid-sequence induction of anesthesia with continuous cricoid pressure is the safest approach to securing the airway. Patients with diabetes, ESRD, cardiovascular disease, and autonomic neuropathy may be prone to wide fluctuations in heart rate and arterial blood pressure. Vital signs should be closely monitored, and maintenance of hemodynamic stability should be a primary anesthetic goal, especially during and immediately following anesthetic induction. Invasive monitoring is standard for pancreas transplantation. Arterial monitoring allows for beat-to-beat arterial blood pressure measurements, as well as access for analysis of arterial blood gases and blood glucose monitoring. Central venous access may be indicated for central administration of vasoactive infusions and immunosuppression drugs. Central venous pressure monitoring is used in some centers; however, the usefulness of this practice has been questioned, as central venous pressure might not be a reliable indicator of intravascular fluid responsiveness.[40] Arterial line placement before induction of anesthesia may be considered, especially in patients with severe hypertension or CAD. Anesthesia is typically maintained with a balanced technique using volatile anesthetics, opioids, and muscle relaxants. In patients with renal failure, medications should be chosen that are not dependent on the kidneys for elimination. All the caveats for the anesthetic management of patients undergoing kidney transplantation should be applied for patients undergoing SPK.

A midline surgical incision is made for both pancreas and kidney-pancreas transplant surgeries. Extensive retraction necessitates adequate muscle relaxation. Prolonged exposure of the abdominal viscera results in significant third-space losses; adequate volume expansion with crystalloid or colloids is often required. The pancreas graft is usually placed in the iliac fossa. The arterial vascular supply to the pancreas graft is usually provided by an anastomosis to the iliac artery. Venous drainage from the pancreas graft can be delivered to either the iliac vein or the native portal vein. Usually the venous outflow from the pancreas is delivered to the iliac vein, which is associated with a lower rate of venous thrombosis. Alternatively, venous outflow may be directed to the native portal vein, which is the physiologically normal pattern of pancreatic venous efflux. There appears to be no significant advantage to portal venous drainage over systemic venous drainage for pancreas transplantation.[56]

Pancreatic exocrine drainage can be delivered to either the bladder or the intestine (Fig. 74-6). Although enteric pancreatic drainage is physiologically normal, this method is associated with surgical complications that can result in graft dysfunction, thrombosis, and early rejection. Exocrine drainage to the bladder allows for measurement of urinary amylase levels, which can be used to diagnose early rejection episodes before blood glucose levels are affected. Exocrine bladder drainage is associated with urologic complications and metabolic acidosis. Currently, most pancreas transplants utilize enteric drainage as there is no difference in graft or patient survival compared to bladder drainage.[64,65]

Prior to completion of the vascular anastomoses during pancreas transplantation, blood glucose levels should be assessed at least hourly as levels frequently fluctuate in brittle diabetic patients. Blood glucose should be maintained at less than 200 mg/dL, using intravenous insulin and dextrose infusions if necessary. Sliding scale insulin infusion protocols may be applied. Dextrose prevents the development of ketoacidosis during the early stages of the procedure. Before unclamping of the vascular anastomoses, adequate volume resuscitation should be initiated. Adequate cardiac preload and normal arterial blood pressures should be the hemodynamic goals before unclamping.

After unclamping of the vascular connections, adequate perfusion pressure to the graft is critical. Hypotension should be corrected rapidly, and intravascular volume status should be optimized. If hypotension occurs because of myocardial dysfunction, intracardiac pressure monitoring or transesophageal echocardiography can assist in the diagnosis and may help to guide therapy. Blood transfusions, colloids, and vasoactive medications may be required for the treatment of hypotension after reperfusion of the pancreatic graft. Therapy should also be guided by frequent arterial blood gas analyses with assessment of electrolytes and hemoglobin.

One of the most important intraoperative care points for pancreas transplantation is the management of blood glucose following pancreas reperfusion. After unclamping, the pancreas may release insulin into the circulation within several minutes. Blood glucose should be measured approximately every 30 minutes for the remainder

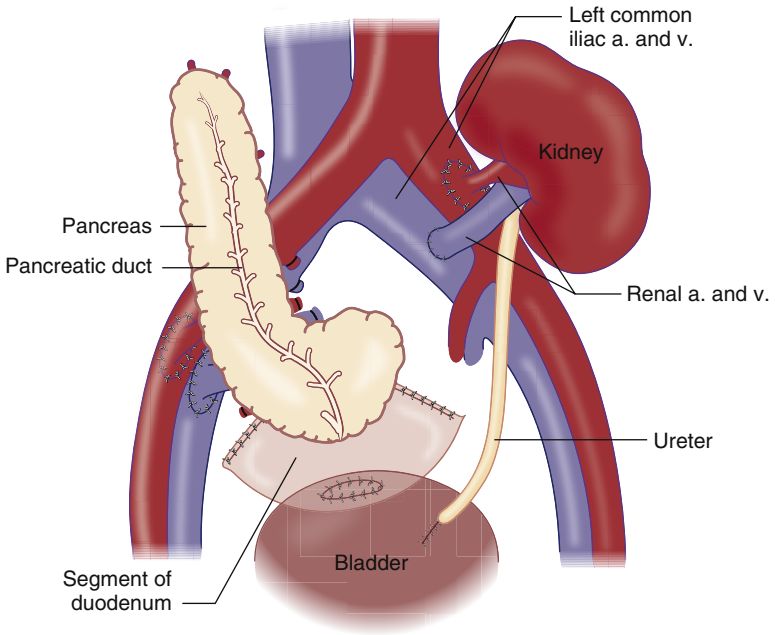

Figure 74-6. Pancreas transplantation. Bladder drainage is through a pancreatic duodenocystostomy. A renal transplant is shown with the common iliac vessels used for vascular anastomoses. *(Modified from Moody FG, editor:* Surgical Treatment of Digestive Diseases*, ed 2. St Louis, 1990, Mosby–Yearbook.)*

of the procedure. After successful transplantation, insulin requirements rapidly decline, and patients may be at risk for hypoglycemia. Delayed graft function can be identified by the presence of hyperglycemia. In this event, insulin infusion should be titrated to maintain blood glucose levels less than 200 mg/dL.[60]

ANESTHETIC MANAGEMENT OF PANCREAS TRANSPLANTATION: POSTOPERATIVE MANAGEMENT

After the completion of surgery, complete reversal of neuromuscular blockade, hemodynamic stability, normothermia, and the ability of the patient to protect the airway will facilitate tracheal extubation. Pancreas transplant patients should be monitored closely in the postanesthesia care unit and ICU. Regular blood glucose measurements should be continued in the postoperative period to avoid hypoglycemia. Electrolytes, complete blood count, and analysis of arterial blood gas should be obtained immediately postoperatively, because acid-base disturbances, anemia, and electrolyte imbalances are common. Euvolemia should be maintained. Depending on the patient's age and underlying risk for CAD, serial troponins and ECG may be assessed for the presence of myocardial ischemia or infarction, because cardiac symptoms may be lacking in this population. Postoperative pain can be severe, given the extensive surgical wound and duration of surgery. Postoperative pain usually is managed with opioids in the perioperative period with transition to patient controlled analgesia in the early postoperative period (see Chapter 98). Epidural analgesia may be appropriate for pancreas transplant recipients, although the possibility of hypotension in the early postoperative period can be problematic. For SPK, the usual postoperative strategies for kidney transplant patients including close monitoring of urine output should be applied.

Surgical complications occur in 7% to 9% of all pancreas transplants and usually require reoperation. Technical complications are associated with the potential for graft loss and patient morbidity.[66] Graft thrombosis is the most important early complication and requires emergent surgical exploration. Intra-abdominal bleeding can occur secondary to coagulopathy induced by anticoagulation for the treatment of graft thrombosis. Late complications include bladder or enteric leaks, intra-abdominal sepsis, and rejection.

ORGAN MATCHING AND ALLOCATION

The organ matching process for pancreas transplantation is similar to that for kidney transplant organ matching. Blood group and HLA matching are initially performed to match the donor and recipient, followed by a crossmatch at the time of surgery. There has been a trend over the past decade toward less stringent HLA matching for all forms of pancreas transplantation. Despite this trend, pancreas transplant graft survival rates continue to improve, likely because of enhancements in surgical techniques and immunosuppression.[66,67]

Most organs allocated for pancreas transplantation are for diabetic recipients younger than 40 years. However, over the past decade, the average transplant recipient's age has become older because of the allocation of more organs for patients with type 2 diabetes.[61] In the United States, pancreas allocation is regulated initially for local distribution, followed by regional and national distribution. Unlike kidney transplantation, technical complications are the most common cause of pancreas transplant

graft failure. Donor risk factors that affect pancreas graft survival include donor age older than 45 years, donor body mass index (BMI) greater than 30 kg/m^2, and cerebrovascular or nontraumatic cause of death.[68] These factors have a significant effect on donor organ selection.

ANESTHESIA FOR PATIENTS AFTER PANCREAS TRANSPLANTATION

After successful pancreas transplantation, long-term normoglycemia is expected. For patients with a history of previous pancreas transplant presenting for surgery, a comprehensive posttransplant history of any episodes of surgical complications and episodes of rejection should be obtained. Blood glucose concentrations should be measured on the day of surgery. A detailed history and review of medical records focusing on CAD, renal disease, and vascular disease is critical, because pancreas transplant patients have a high prevalence of these conditions. Furthermore, disease progression can occur despite successful pancreas transplantation. There are no studies of cardiac outcomes in pancreas recipients undergoing nontransplant surgery; therefore, a stepwise approach to the preoperative cardiac evaluation, guided by the 2007 ACC/AHA Guidelines, is a reasonable approach for pancreas recipients undergoing subsequent nontransplant surgery.[21]

LIVER TRANSPLANTATION

In 1963, shortly after the effectiveness of azathioprine and prednisone was established for renal transplantation, Dr. Thomas Starzl performed the first human liver transplant.[69] The recipient, a 3 year-old child with biliary atresia, died in the operating room from massive hemorrhage caused by venous collaterals and uncontrollable coagulopathy. Four years later, Starzl performed the first successful transplant in an 18-month-old infant with hepatocellular carcinoma. The advent of cyclosporine in 1979, followed by the 1983 pronouncement of the National Institutes of Health Consensus Conference that liver transplantation was no longer experimental, ushered in the era of liver transplantation. Over the ensuing decades, liver transplantation centers were established around the world, and the field matured following continued improvements in surgical technique, immunosuppression, and the management of coagulopathy and infections.

The number of disciplines that have contributed to the advances in liver transplantation illustrates the team approach involved in the care of the liver transplant recipient. Hepatologists, surgeons, nephrologists, specialists in critical care medicine and infectious disease, anesthesiologists, pediatricians, radiologists, and pathologists have important roles. Key team members extend beyond physicians and include transplant coordinators, nurses, blood bank personnel, and procurement organizations.

Liver transplantation is unique among abdominal organ transplants in that a dedicated team is typically involved because of the unique challenges encountered during liver transplant surgery. The United Network of Organ Sharing (UNOS), which manages the U.S. organ transplant system under contract with the U.S. Department of Health and Human Services, recognizes the important role of anesthesiologists in the perioperative care of liver transplant candidates. In 2011, UNOS instituted a requirement that U.S. liver transplant programs designate a Director of Liver Transplant Anesthesia who meets qualifications based on experience and training. These qualifications parallel similar requirements for the transplant surgeon and physician (hepatologist). In addition, UNOS delineated the clinical responsibilities of the Director of Liver Transplant Anesthesia, which include preoperative assessment of transplant candidates, participation in candidate selection, intraoperative management, postoperative visits, and participation in mortality and morbidity conferences.[70] Lastly, the director is expected to maintain current knowledge in the field of transplant anesthesia by participating in continuing medical education activities related to transplantation.

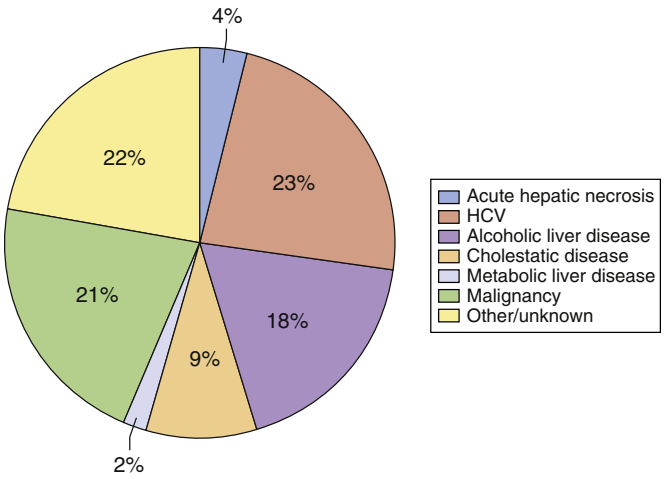

Figure 74-7. Indications for Adult Liver Transplants in the United States, 2011. *HCV: hepatitis C virus. (Adapted from OPTN & SRTR Annual Data Report 2011. U.S. Department of Health and Human Services Health Resouces and Services Administration, p 88, Figure Li 4.9)*

INDICATIONS FOR LIVER TRANSPLANTATION

Liver transplantation is the only definitive treatment for decompensated cirrhosis, unresectable primary hepatic malignancies, acute liver failure, and metabolic disease. Of these indications, decompensated cirrhosis accounted for 75% of adult liver transplants performed in the United States in 2011, followed by malignancy in 21%, acute liver failure in 4%, and metabolic disease in 2%.[1]

Cirrhosis is further categorized into hepatitis C viral disease (23% of the total transplants performed in 2011 in the United States), alcoholic liver disease (18%), cholestatic disease (9%), and a miscellaneous category (22%) that includes nonalcoholic steatohepatitis (NASH), autoimmune disease, and others (Fig. 74-7).

Advances in the treatment of chronic liver disease, particularly antiviral therapy and transjugular intrahepatic portosystemic shunt (TIPS) placement, have led to improvements in survival over the past decade.[71] In selected patients with advanced cirrhosis and active

TABLE 74-1 PROGNOSIS: COMPLICATIONS OF CIRRHOSIS

Event	Survival
Variceal bleeding	65%-70% at 1 year*
Ascites	48%-60% at 1 year†
Hepatorenal syndrome	50% at 3 months‡
Encephalopathy (grade 2/3)	40%-50% at 1 year§

Survival after complications is poor compared with 90% patient survival at 1 year after liver transplantation.

§Stewart C, Malinchoc M, Kim W, Kamath P: *Liver Transplant* 13:1366, 2007.

variceal bleeding, early placement of TIPS improved 1-year survival to 86% compared with 61% in a group randomized to similar therapy without early TIPS.[72] However, when life-threatening complications of liver failure such as encephalopathy, ascites, gastrointestinal bleeding or uremia develop, survival is improved by liver transplantation (90% 1-year survival) compared with medical therapy (Table 74-1). Referral for liver transplantation is appropriate in the presence of an index complication of cirrhosis.

Chronic liver disease and cirrhosis is the fifth leading cause of death in the United States for individuals aged 45 to 64 years; it is surpassed only by cancer, heart disease, accidents (unintentional injury), and chronic respiratory diseases. Among all age groups, liver disease accounted for more than 33,000 deaths in 2011, making it the twelfth leading cause of death.[73]

TRENDS IN LIVER TRANSPLANTATION

Over the past decade, the proportion of transplants performed for malignancy and cirrhosis owing to NASH is increasing. Malignancy accounted for just 4% of liver transplants in 2001, whereas it accounted for 21% in 2011. Currently NASH is the third most common indication for transplantation, and by 2025 it is expected to overtake cirrhosis owing to hepatitis C as the single most frequent indication for liver transplantation.[74] The number of transplants performed for hepatitis C has decreased from 31% to 23% of liver transplants over the past decade (2001 to 2011).[1]

The total number of liver transplants performed in the United States increased from 3900 in 1998 to 6000 in 2006. The number has since stabilized at approximately 6000 per year.[1] European transplant centers perform a similar number of transplants per year (approximately 6000) for similar indications.[75] During the past decade, the number of patients (adult and pediatric) living with a functioning liver transplant more than doubled, from 30,000 in 2001 to 62,000 in 2011.[1]

The median time to transplant in the United States for the period ending in 2011 was 12.6 months (interquartile range, 1.6-72 months).[76] Waiting times in the United States decreased drastically with the implementation of the current allocation system in 2002, which deemphasized wait times for organ allocation. Median wait times have steadily increased since 2005; however, this is overshadowed by geographic variation in waiting times across various regions, termed *donation service areas*, within the United States.[77]

Over the past decade, the proportion of recipients aged 50 years or older increased from 58% to 77%. The proportion of recipients aged 65 years or older has increased by 50%.[1] Although fewer females undergo liver transplant compared to males, the gender gap is narrowing. Finally, the trend toward combined organ transplantation, particularly liver-kidney transplant, has continued and in 2011 represented approximately 7% of transplants.

The primary limitation to liver transplantation is the continuing organ shortage, which has resulted in the death of approximately 12% of waitlisted transplant candidates each year for the past decade.[1] This number has plateaued, but the number of patients removed from the waitlist because they are too sick to undergo transplant has doubled over the past 3 years. Responses to these concerns have resulted in the use of expanded-criteria donors, including grafts donated after cardiac death, which increased from less than 2% of liver transplants in 2001 to 6% in 2011.[1] Living donation has decreased over the past 10 years, particularly for adult recipients. In 2001, more than 400 living donor grafts were transplanted into adult recipients. In 2011, fewer than 200 adults received living donor grafts.[1] This change highlights the concern over postoperative complications in living donors, particularly those providing a larger liver mass, as is the case with right lobe donation. Two living donor deaths were reported in 2010, further illustrating the risk to living donors.

The recurrence of hepatitis C after successful liver transplantation has been increasingly recognized as a challenge. Because hepatitis C is the most common indication for transplantation, recurrent infection and graft failure represents a formidable issue. The deleterious effects of immunosuppression on viral replication have led many centers to attempt to withdraw steroids in selected patients with viral infections.

The number of pediatric liver transplants in the United States has been stable at 500 to 600 per year over the past decade (2002 to 2011; see Chapter 93). During the same period, approximately 10% to 15% of pediatric recipients in the United States received grafts from living donors, down from 20% to 25% in the prior decade.[1] The most common indication for transplant in pediatric recipients is cholestatic disease (47%), followed by malignancy (14%), metabolic disease (13%), and acute hepatic necrosis (11%).[1] The European Liver Transplant Registry (ELTR) reports similar numbers of pediatric recipients, approximately 10% of the total number of liver recipients.[78]

PATHOPHYSIOLOGY OF END-STAGE LIVER DISEASE

Cirrhosis is the end product of chronic parenchymal inflammation and necrosis, which results in fibrosis and disruption of hepatic architecture. Resistance to blood flow leads to portal hypertension and the formation of vascular shunts between portal and systemic veins.[79]

When the pressure gradient between the portal and hepatic veins exceeds 10 to 12 mm Hg, portal hypertension is severe, and complications such as ascites, esophageal variceal bleeding, encephalopathy, and hepatorenal syndrome occur. Decompensated cirrhosis affects nearly every other organ system.[80] The preoperative assessment of liver transplant candidates requires a knowledge of the pathophysiologic changes associated with decompensated cirrhosis.

Cardiovascular Complications

Hyperdynamic circulation—characterized by a high cardiac output, low arterial blood pressure, and low systemic vascular resistance—is the hallmark of end-stage liver disease. Patients appear well perfused despite systolic arterial pressures less than 100 mm Hg. Pulmonary arterial pressures may be mildly elevated because of increased flow; however, the pulmonary vascular resistance (PVR) is usually within the normal range. These patients have an elevated intravascular volume that is sequestered into a dilated splanchnic vascular bed. The effective circulating volume is typically reduced.

Hyperdynamic circulation is the result of portal hypertension-induced production of vasodilators such as natriuretic peptides, vasoactive intestinal peptide, endotoxin, glucagon, and particularly nitric oxide.[81] Elevated production of nitric oxide has been observed to precede the formation of the hyperdynamic circulation in cirrhosis. The overproduction of vasodilators is responsible for reduced circulatory responsiveness to sympathetic stimulation.[82] Clinically, this frequently results in a need for increased doses of vasopressors.

In addition, patients with cirrhosis can have other cardiac functional abnormalities that are not immediately apparent in the baseline state. These abnormalities define a condition termed *cirrhotic cardiomyopathy* and include systolic and diastolic dysfunction, cardiac resistance to β-adrenergic stimulation, and electrophysiologic abnormalities. Systolic incompetence is revealed by physiologic or pharmacologic stress and is manifested by an inability to increase cardiac output in response to exercise, and an inability to increase ejection fraction despite an increase in end-diastolic volume. The severity of cardiac dysfunction seems to be correlated directly with the severity of liver disease.[83] Diastolic dysfunction has been described in patients with cirrhosis as well, on the basis of diagnostic echocardiographic findings of abnormalities in transmitral flow during diastole. These abnormalities consist of a decrement or reversal of the E/A wave ratio and prolongation of E wave deceleration time, reflecting ventricular resistance to diastolic filling. Diastolic dysfunction manifests as sensitivity to changes in cardiac filling and results in vulnerability to heart failure.

Autonomic dysfunction is present in a significant proportion of cirrhotic patients. It presents as chronotropic and hemodynamic incompetence in response to hemodynamic challenges. Prolonged QTc interval is also observed in patients with cirrhosis, and care should be taken when treating these patients with drugs known to prolong the QT interval.[84]

Risk factors for CAD in patients with cirrhosis are similar to those of other patient populations: hypertension, dyslipidemia, age, gender, and obesity. However, NASH has been recognized as an increasingly important cause for transplantation and carries with it the risks of obesity, diabetes, and chronic inflammatory state. The optimal test for identifying cirrhotic patients with significant CAD is unclear. Because many of these patients cannot exercise, pharmacologic stress testing is most commonly used. Unfortunately, studies investigating the predictive value of noninvasive functional testing, particularly dobutamine stress echocardiography, have generally shown poor sensitivity and varying negative predictive value (75% to 89%).[85] Thus, among liver transplantation candidates, consideration should be given to proceeding with coronary angiography if the patient is judged to have a high likelihood of CAD.[86] For less complex surgeries, however, this may not be warranted. There is evidence that patients with treated CAD have posttransplant survival similar to patients without angiographic evidence of CAD.[87]

Pulmonary Complications

As many as 50% to 70% of patients with chronic liver disease complain of shortness of breath.[88] The differential diagnosis includes ventilation-perfusion abnormalities associated with underlying obstructive airways disease, fluid retention, pleural effusion, and decreased lung capacities secondary to large volume ascites. Alpha-1 antitrypsin deficiency has both lung and liver manifestations, as does cystic fibrosis. In addition, there are two types of vascular abnormalities unique to the setting of portal hypertension, and they have significant morbidity and mortality. These abnormalities, hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPHTN), are unique entities that have discrete implications on liver transplant candidacy.

HPS is present in up to 20% of patients who present for liver transplantation.[89] The diagnostic criteria for HPS include portal hypertension, PaO_2 less than 80 mm Hg on room air (or alveolar-arterial oxygen gradient greater than 15 mm Hg), and evidence of intrapulmonary vascular dilation (IPVD).[90] Demonstration of IPVD can be made by contrast-enhanced echocardiography or by perfusion lung scanning using technetium-labeled macroaggregated albumin. In the absence of HPS, microbubbles and albumin macroaggregates injected into the venous circulation are trapped by the pulmonary capillary bed. The delayed (more than three cardiac cycles) appearance of microbubbles in the left atrium (on echocardiography) or increased (>5%) extrapulmonary uptake of technetium-labeled macroaggregated albumin suggests the presence of IPVD, which results in a massive increase in pulmonary capillary diameter, from between 8 to 15 μm to 50 to 500 μm. This increase, together with the usually hyperdynamic circulation of the cirrhotic patient, allows insufficient time for oxygen diffusion through the entire stream of capillary blood. As a result, the central stream of poorly oxygenated blood is functionally shunted. This lesion is typically correctable with the administration of oxygen. Because IPVDs predominate in the bases of the lungs, standing worsens hypoxemia compared with the supine position (orthodeoxia).

TABLE 74-2 **RIGHT HEART CATHETERIZATION DATA FROM FOUR REPRESENTATIVE PATIENTS WITH CIRRHOSIS AND SIMILAR ELEVATIONS IN MEAN PULMONARY ARTERY PRESSURE***

Patient	Mean PA Pressure (mm Hg)	Pulmonary Capillary Wedge Pressure (mm Hg)	Cardiac Output (L/m)	Pulmonary Vascular Resistance (dynes·sec·cm^{-5})	Diagnosis
1	35	10	5	400	Primary pulmonary hypertension
2	35	10	10	200	Hyperdynamic circulation
3	35	25	5	160	Fluid overload
4	35	25	10	80	Fluid overload in a patient w/ hyperdynamic circulation

PA, Pulmonary artery.
*Note that only the first patient has primary pulmonary hypertension, as evidenced by elevated pulmonary vascular resistance.

The natural history of HPS is usually one of progressive hypoxemia. Liver transplantation can be expected to correct hypoxemia in greater than 85% of patients, although it may take up to 1 year to do so.[91] In patients with HPS, survival with transplantation is considerably more frequent than without transplantation. Previously, $PaO_2 \leq 50$ mm Hg was considered a predictor of increased mortality with or without transplantation. However, in the largest single-center series of liver transplantation for HPS, the overall 5-year survival was 76%, comparable to transplantation in patients without HPS.[92] These findings suggest that timely transplantation in patients with HPS results in good outcomes. Accordingly, allocation exception points have been assigned to patients with HPS and room air $PaO_2 < 60$ mm Hg.[93]

PPHTN is defined as pulmonary hypertension in the presence of portal hypertension in a patient without other predisposing factors. The European Respiratory Society Task Force on Hepatopulmonary Disease diagnostic criteria are: (1) clinical evidence of portal hypertension with or without hepatic disease; (2) mean pulmonary artery pressure of 25 mm Hg at rest or 30 mm Hg during exercise; (3) mean pulmonary artery occlusion pressure less than 15 mm Hg or transpulmonary gradient (mean PA pressure minus wedge pressure) greater than 12 mm Hg; and (4) PVR greater than 240 dyn·s·cm^{-5} or 3 Wood Units.[94]

The requirement for calculation of the PVR is a reflection of the fact that many patients with cirrhosis have mildly elevated mean pulmonary artery pressure based simply on an elevated cardiac output (Table 74-2). Mild, moderate, and severe PPHTN are defined by mean PA pressure less than 35 mm Hg, 35 to 50 mm Hg, and greater than 50 mm Hg, respectively.

The prevalence of PPHTN is 2% in a population of patients with known portal hypertension,[95] as compared with 0.13% in an unselected population.[96] The prevalence is 4% to 6% among liver transplant candidates.[97] The occurrence of PPHTN is unrelated to the severity of the underlying liver disease. Similar to HPS, the symptoms of PPHTN are nonspecific, commonly consisting of dyspnea, generalized weakness, and decreased exercise tolerance.

The single best screening study for PPHTN is two-dimensional transthoracic echocardiography, which estimates right ventricular systolic pressure using the velocity of the tricuspid regurgitant jet. In the absence of pulmonary valvular stenosis, right ventricular systolic pressure is a good estimate of pulmonary arterial systolic pressure. Transthoracic echocardiography screening has a sensitivity of 97% and a specificity of 77% in diagnosing moderate to severe PPHTN in patients undergoing pretransplantation workup.[98] Right-sided cardiac catheterization is necessary, however, to confirm elevated pressures and to measure PVR.

Moderate and severe PPHTN are associated with increased mortality during liver transplantation. In a multicenter study of 36 patients with PPHTN who underwent liver transplantation, more than one third of the patients died during the hospitalization (within 3 weeks of surgery). Nonsurvivors (12 of 13 patients) had mean PA pressures greater than 35 mm Hg.[99] In addition to elevated mortality, the effect of successful liver transplantation on the natural course of PPHTN is unpredictable. Some patients experience a resolution with transplant, some continue to require medical therapy, and in some cases PPHTN worsens. This suggests that patients with moderate or severe PPHTN should undergo treatment for PPHTN before liver transplantation.

Vasodilator therapy consists of prostanoids (epoprostenol), phosphodiesterase inhibitors (sildenafil), and endothelin antagonists (bosentan). Calcium channel blockers, often used in noncirrhotic patients with pulmonary hypertension, are contraindicated in patients with cirrhosis because the associated mesenteric vasodilation worsens portal hypertension. Patients who respond to treatment sufficiently to reduce their mean PA pressure below 35 mm Hg and PVR below 400 dyn·s·cm^{-5} should be considered suitable transplant candidates.[99,100]

Renal Dysfunction

Renal dysfunction in patients with cirrhosis is the result of renal hypoperfusion and avid retention of sodium. Hepatorenal syndrome (HRS) is a prerenal abnormality caused by circulatory derangements of advanced cirrhosis. It is considered a functional disorder, based on successful transplantation of kidneys from patients with HRS.[101] Renal function is an important risk factor for mortality, a fact that is emphasized by its presence as one of only three variables used in calculating the Model for End-Stage Liver Disease (MELD) score.

In addition to HRS, patients with cirrhosis are also at risk for other causes of renal dysfunction, such as parenchymal renal disease, sepsis, nephrotoxicity, and hypovolemia. HRS is a diagnosis of exclusion, and other treatable causes must

be ruled out. HRS accounts for only about one fourth of the cases of acute kidney injury in hospitalized cirrhotic patients.[102] In patients with cirrhosis and ascites, the incidence of HRS is nearly 40% at 5 years.[103]

HRS is caused by the local production of vasodilators, particularly nitric oxide, in patients with portal hypertension. Splanchnic vasodilation leads to a decrease in the effective circulating blood volume and a decrease in arterial blood pressure, which activates the sympathetic, renin-angiotensin-aldosterone, and vasopressin systems. The net result is a severe reduction in renal perfusion and glomerular filtration.

Type I HRS is characterized by rapidly progressive renal failure and a doubling of serum creatinine over 2 weeks after a precipitating cause such as spontaneous bacterial peritonitis, sepsis, gastrointestinal bleeding, or surgical stress. Patients with type I HRS have a median survival of 2 to 4 weeks without therapy.[104,105] Patients with type II HRS have a median survival of about 6 months.[106]

Although renal vasoconstriction is the proximate cause of HRS, therapy aimed at directly increasing renal perfusion by the use of prostaglandins, dopamine agonists, or endothelin antagonists has not proven to be successful. Vasoconstrictor therapy targeting the underlying splanchnic vasodilation is more effective.[107]

These therapies include arginine vasopressin, somatostatin, and α-agonists such as norepinephrine and midodrine, combined with volume expansion. Terlipressin, the most studied vasopressor for HRS, is not available in the United States.[108,109]

Placement of a TIPS lowers portal pressures and can decompress the splanchnic circulation. Pilot studies have shown that a TIPS is capable of reversing both types of HRS, but because of extensive exclusionary criteria in trials and the risk of worsening hepatic encephalopathy, a TIPS might not be suitable for all patients with HRS.[110]

Liver transplantation is the definitive therapy for HRS. For patients with HRS who are transplant candidates, renal replacement therapy is the typical bridge to transplantation. Although renal recovery is anticipated, 35% of patients with pretransplant HRS will continue to require support in the immediate postoperative period, compared with 5% of patients without pretransplant HRS.[111] During the First International Liver Transplantation Society Expert Panel Consensus on Renal Insufficiency in Liver Transplantation, it was recommended that patients who received dialysis at least twice weekly for more than 6 weeks before liver transplantation be considered for combined liver-kidney transplantation.[112]

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a serious, albeit reversible neuropsychiatric complication that is a feature of both chronic and acute liver disease. Manifestations range from subtle, subclinical abnormalities to overt neurologic and behavioral derangements that are readily apparent at the bedside.

HE has been attributed to hyperammonemia, but the severity of HE does not necessarily correlate with ammonia levels. A number of other factors and mechanisms also contribute to HE, including other gut-derived neurotoxins, γ-aminobutyric acid (GABA) and other endogenous GABA-receptor agonists, oxidative stress, inflammatory mediators, hyponatremia, and abnormal serotonin and histamine neurotransmission.[113,114]

The initial step in evaluating the patient with liver disease who presents with encephalopathy is to rule out causes other than HE. The differential diagnosis includes other metabolic causes such as uremia, sepsis, glucose and electrolyte abnormalities, and endocrinopathies. Structural and vascular central nervous system lesions or infections should also be considered. Because cirrhotic patients are exquisitely sensitive to sedative medications and have impaired hepatic (and often renal) metabolism, a careful search for possible drug-related encephalopathy should be undertaken. Once other potential causes have been eliminated, the next step should be a systematic search for an underlying cause or precipitating factor, such as infections (e.g., spontaneous bacterial peritonitis, sepsis) or gastrointestinal bleeding.

Therapy to reduce ammonia levels consists of the nonabsorbable disaccharide lactulose and nonabsorbable antibiotics such as neomycin, metronidazole, and rifaximin. Nonabsorbable antibiotics appear to be equally effective to nonabsorbable disaccharides, but concerns about toxicity associated with long-term administration limit their use.

Ascites

Ascites is the most common complication of cirrhosis leading to hospitalization.[115] Patients have ascites should be referred for liver transplantation evaluation in the absence of contraindications. Nonhepatic causes account for 15% of ascites and include malignancy, cardiac failure, renal disease, pancreatitis, and tuberculosis. Paracentesis is an important aid in diagnosis.[115] A serum-ascites albumin gradient greater than 1.1 mg/dL indicates portal hypertension with 97% accuracy.[116] Rapid correction of hyponatremia is undesirable because patients with cirrhosis are at risk for central pontine myelinolysis, a potentially devastating neurologic complication. Observations in liver transplant recipients suggest limiting correction to less than 16 mEq/L during the intraoperative period.[117]

Once ascites becomes refractory to maximum standard medical therapy, therapeutic options are limited and include serial paracentesis, liver transplantation, TIPS placement, and peritoneovenous shunt.

Risk factors for development of spontaneous bacterial peritonitis include a prior episode of this acute infection, gastrointestinal bleeding, and an ascites albumin level of less than 1.5 g/dL. Long-term antibiotic prophylaxis with norfloxacin or trimethoprim/sulfamethoxizole is recommended for patients who have survived an episode of spontaneous bacterial peritonitis.[115]

Varices

Cirrhosis increases portal pressure as a result of chronic inflammation. Fibrosis and regenerative nodules cause resistance to splanchnic flow and lead to formation of portosystemic collaterals. Progression of portal hypertension leads to increased local production of nitric oxide and exacerbates splanchnic vasodilation. Rupture of the

high-pressure collaterals that are formed is a highly lethal and feared complication of portal hypertension.

Portal hypertension is diagnosed by measurement of the wedged hepatic venous pressure (WHVP). Although this is not a direct measure of portal pressure, WHVP has been demonstrated to correlate well with it.[118] This measurement is taken by advancing a catheter into a hepatic vein to the wedge position. To correct for the contribution of increased intra-abdominal pressure from ascites, a free hepatic venous pressure or an inferior vena cava (IVC) pressure should be subtracted from the measured WHVP to give the hepatic venous pressure gradient (HVPG). A normal HVPG is 3 to 5 mm Hg. Patients with varices have HVPGs of 10 to 12 mm Hg or greater.

Esophagogastroduodenoscopy is the gold-standard procedure for diagnosing varices. Risk for variceal bleeding correlates with size of varices, presence of red wale marks, and variceal pressure (i.e., HVPG). Therapeutic decisions are based on these observations and measurements. Nonselective β-adrenergic blockers reduce portal pressure by two mechanisms: a decrease in cardiac output (β_1) and splanchnic vasoconstriction (β_2). For patients who cannot tolerate β-adrenergic blockers or in whom they are contraindicated, another option for primary prophylaxis of variceal bleeding is endoscopic ligation. The TIPS procedure had been considered a backup procedure for variceal bleeding, but recently has been advocated for early treatment in select patients.[72] However, TIPS is associated with a higher incidence of encephalopathy; despite this, TIPS may decrease mortality in select patients.[72]

Acute variceal bleeding should be managed with a combination of intravascular volume resuscitation, correction of severe coagulopathy, pharmacologic manipulation of portal pressure, and endoscopic variceal ligation. Aggressive intravascular volume replacement can lead to resistant or recurrent bleeding because bleeding is a pressure-related phenomenon.[119,120] Elective intubation of the trachea for airway protection is often warranted. Medications to reduce portal pressure include vasopressin and somatostatin. Although β-adrenergic blockers can reduce portal pressures, their effect on systemic pressures makes them undesirable in this setting. Early endoscopic variceal ligation in combination with pharmacotherapy is the preferred treatment for acute variceal bleeding. Balloon tamponade can be effective for resistant variceal bleeding, but is associated with significant complications, including esophageal rupture and aspiration. It is recommended as a bridge to more definitive therapy such as surgical shunt, TIPS, or liver transplantation.

Hemostasis

Hemostasis is a dynamic process that is the product of interaction between coagulation, platelets, and fibrinolysis, resulting in the formation and revision of clot (see Chapter 62). Liver disease affects all of these components, both quantitatively and qualitatively. The liver is the site of synthesis for all procoagulant and anticoagulant factors, with the exception of tissue thromboplastin (III), calcium (IV), and von Willebrand factor (VIII). It is also the site for clearance of activated factors.

Patients with cirrhosis are customarily considered to have a bleeding diathesis based on abnormal results in conventional tests of coagulation, such as prothrombin time (PT) and partial thromboplastin time (PTT). However, such tests reflect the activity of only a portion of the procoagulant factors, and do not consider the concomitant decrease in anticoagulant factors, which are not assessed. It is the balance of procoagulant and anticoagulant forces, not the isolated measurement of either portion of the coagulation system, that indicates the effective generation of thrombin. Not surprisingly, PT and PTT abnormalities correlate poorly with bleeding complications following invasive procedures, such as liver biopsy.[121] There is evidence that decreased levels of protein C in cirrhotic patients balance the decreased levels of procoagulants, which can leave thrombin generation in vivo unaltered.[122]

If procoagulants predominate because of disproportionate reductions of anticoagulants (protein S and C, antithrombin III), accompanied by an increase in procoagulants (FVIII), a hypercoagulable state results.[123,124] This possibility is supported by studies reporting venous thromboembolism associated with cirrhotic and noncirrhotic liver disease.[125,126]

Thrombocytopenia is a well-known feature of cirrhosis. The primary cause is splenic sequestration in the setting of portal hypertension. Elevated levels of von Willebrand factor compensate for decreased platelets counts, augmenting the platelet–endothelial cell interaction on vessel walls.

The fibrinolytic system in cirrhotic patients has many abnormalities, which may account for accelerated fibrinolysis. The liver is the site of tissue plasminogen activator clearance, and elevated tissue plasminogen activator levels have been noted in patients with cirrhosis.[127] The liver is also the site of synthesis for plasmin inhibitors, such as plasmin activator inhibitor-1 (PAI-1) and thrombin-activatable fibrinolysis inhibitor (TAFI). A balance of factors that promote and inhibit fibrinolysis is desired. Commonly used studies for assessing the presence and severity of accelerated fibrinolysis include euglobulin clot lysis time and thromboelastography.

Disseminated intravascular coagulation (DIC) is primarily a thrombotic diathesis, followed by widespread secondary fibrinolysis. As factors are consumed, DIC becomes a bleeding diathesis of factor and platelet deficiency. Whether or not DIC is a feature of stable chronic liver disease is controversial. Standard laboratory tests cannot distinguish between consumption and decreased synthesis, and so have little utility. Instead, assays to assess for excessive thrombin production are used. These assays include the cleaved by-products of coagulation factor activation such as prothrombin fragment F1+2, fibrinopeptide A, and thrombin-antithrombin complexes. These assays suggest that overt DIC is not a feature of stable chronic liver disease[128]; however, accelerated intravascular coagulation and fibrinolysis has been described, which is a low-grade consumptive process.[129] Patients who exhibit accelerated intravascular coagulation and fibrinolysis are at increased risk of DIC in the presence of a known stimulus, such as sepsis or spontaneous bacterial peritonitis.

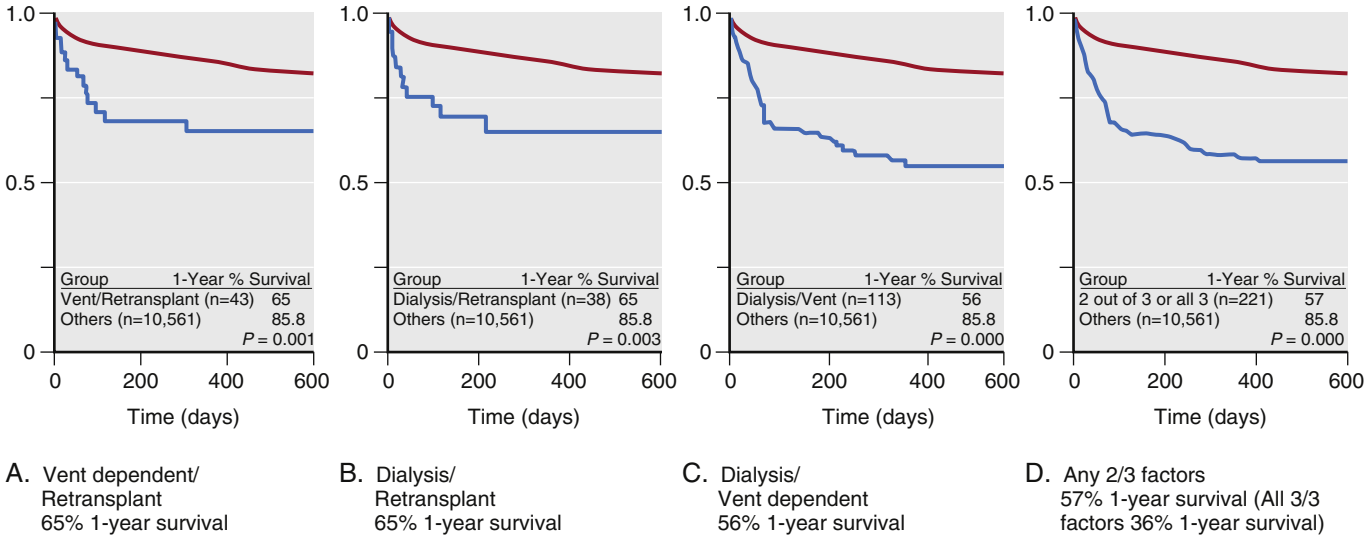

Figure 74-8. Risk factors for posttransplant survival. The four panels compare posttransplant survival between a reference group of 10,000 posttransplant patients (the uppermost Kaplan-Meier curve in all panels, 1-year post transplant survival 86%) and (**A**) patients undergoing retransplantation who are ventilator dependent (1-year posttransplant survival, 65%), (**B**) patients undergoing retransplantation who are undergoing dialysis (1-year posttransplant survival, 65%), (**C**) patients who are ventilator dependent and undergoing dialysis (1-year posttransplant survival, 56%), and (**D**) patients with any two or all three risk factors (1-year posttransplant survival, 57% with any two factors; 1-year posttransplant survival, 36% with three factors). *(From Desai NM, Mange KC, Crawford MD, et al: Predicting outcome after liver transplantation: utility of the model for end-stage liver disease and a newly derived discrimination function,* Transplantation *77:99-106, 2004.)*

SURGICAL PROCEDURE

Preoperative Considerations

In 2011, the median time to transplant in the United States was 12.6 months (interquartile range, 1.6 to 72 months).[76] As a result, a transplant candidate can be months removed from their initial evaluation when a suitable donor graft is identified. Therefore, the prospective recipient's evaluation should be reviewed while arrangements are made for donation. Candidates undergo an extensive preoperative assessment by multiple teams that typically include the surgical team, hepatologists, cardiologists, pulmonologists, psychiatrists, and social workers. In the event of unique comorbidities, additional consultants are involved as needed. Of particular interest to the anesthesiologist are interim changes in health status, hospitalizations (the possibility of infection should be considered with new-onset encephalopathy, variceal bleed, ascites, or hemodynamic deterioration), details of the initial and any subsequent cardiopulmonary evaluation (assess for the presence of coronary disease, heart failure, pulmonary hypertension, or arrhythmia), and renal status (acute kidney injury).

Patients predicted to have decreased survival 1-year after transplant represent a high-risk group and include patients undergoing retransplantation or those supported by mechanical ventilation, infusions of vasopressors, and renal replacement therapy (Fig. 74-8).[2] Patients with oliguria, acidemia, or dependent on renal replacement therapy may benefit from intraoperative renal replacement therapy.[130,131]

A protocol should be in place to notify the blood bank of the pending transplant, which results in the setup of red blood cells and plasma in a volume according to institutional protocol. If any delay is anticipated in the availability of blood products, for instance in the event of antibodies, the blood bank personnel should notify the transplant coordinator and anesthesiologist. In the presence of red cell antibodies, our institutional policy is to set up compatible red cells for the start and completion of the transplant, and to use compatibility-unknown red cells in the event of large transfusion requirements (see Chapter 61).

The surgical procedure is divided into three distinct stages. During the preanhepatic or dissection stage, the liver is mobilized and vascular structures (suprahepatic and infrahepatic vena cava, portal vein, and hepatic artery) are identified. The anhepatic phase begins with clamping of these vessels and hepatectomy of the native liver and continues during the implantation of graft. Reperfusion, usually via the portal vein, starts the neohepatic phase, which continues through completion of the remaining vascular anastomosis (usually the hepatic artery), anastomosis of the bile duct, hemostasis, and abdominal closure.

Intraoperative Management

Intraoperative personnel and monitoring vary among liver transplant services based on institutional practice, caseload, and resources. Most centers allocate two anesthesia providers to liver transplants; however, the qualifications of these providers vary. A typical arrangement in an academic setting consists of an attending anesthesiologist experienced in liver transplantation and a senior resident. In private practice settings, the second provider may be a second anesthesiologist, a certified nurse anesthetist, a licensed health care provider such as a perfusionist, or some combination of these.

Anesthesia typically begins with a rapid sequence induction because of the emergent nature of the surgery, preoperative administration of oral immunosuppressants/bowel decontamination antibiotics, and the presence of ascites. An arterial catheter is placed either before induction of anesthesia or, more commonly, immediately thereafter. Large-bore intravenous access is obtained. Either a triple-lumen 9-French introducer is placed centrally, or in the event of significant concern over blood loss (as is the case for retransplantation or in patients with extensive prior abdominal surgery) two double-lumen 9-French introducers are placed in a central vein. Sites designated for venovenous bypass are avoided, if possible. A pulmonary artery catheter is commonly used in adult patients; however, if the recipient has had a recent negative evaluation for pulmonary arterial hypertension, a pulmonary artery catheter may be avoided. Transesophageal echocardiography is increasingly used during the procedure. In a survey of high-volume liver transplant centers, more than 85% of respondent anesthesiologists (n = 217) reported using transesophageal echocardiography to some degree.[132] Most performed a limited-scope examination, and only 12% were board certified in echocardiography. Transesophageal echocardiography appears to be associated with a low likelihood of hemorrhagic complications, even in the presence of esophageal varices.[133] Some liver transplant centers avoid pulmonary artery catheter insertion in the event that transesophageal echocardiography is used, although a pulmonary artery catheter may be necessary when continuous intraoperative monitoring of pulmonary artery pressures is desired or for postoperative hemodynamic and fluid management in the ICU. New technologies, including arterial pressure waveform analysis and three-dimensional echocardiography, do not correlate with thermodilution-derived parameters and are not currently advocated for routine use intraoperatively.[134,135]

A rapid infusion system capable of high transfusion flow rates (>500 mL/min) is typically used. Such systems incorporate a reservoir, pump, filters, heat exchanger, and safety features designed to avoid and monitor for the presence of blood or air embolism, hypothermia, and line occlusion. Rapid infusion systems facilitate volume replacement and transfusion management.

The effects of the anesthetic technique on patient outcome are unknown. At the authors' center, a balanced anesthetic is used; this typically consists of a volatile anesthetic in low to moderate concentrations (0.5 to 1.0 minimum alveolar concentration, [MAC]) to ensure unconsciousness, whereas an opioid, usually fentanyl, is chosen to blunt the sympathetic response to stimulation and to provide a smooth transition for postoperative analgesia. In recipients with fulminant hepatic failure and cerebral edema, volatile anesthetics are avoided or used cautiously in low concentrations, in many cases with intracranial pressure monitoring (see later). In either case, periods of hypotension during the surgery may require temporary discontinuation of the volatile anesthetic. Midazolam, with minimal hemodynamic effects, can be used for its amnestic effects during these hypotensive periods. Historically, the volatile anesthetic of choice has been isoflurane, which preserves splanchnic blood flow better than previously used volatile drugs.[136] Studies in healthy humans have confirmed the vasodilator effects of isoflurane on the hepatic circulation, compared with the vasoconstrictor effects of halothane.[137] This beneficial effect on hepatic oxygen supply can be advantageous to the newly reperfused graft. The effects of desflurane on hepatic blood flow have been evaluated with conflicting results. In animals, desflurane decreased total hepatic blood flow in a dose-dependent fashion at concentrations up to 1.0 MAC; however, in a human study that excluded patients with liver disease, liver blood flow was slightly more rapid with desflurane than with isoflurane, although this effect was not statistically significant.[138] Another study compared the effects of sevoflurane and desflurane on hepatic blood flow and hepatocellular integrity in older patients[139] (see Chapter 80). Both anesthetics resulted in decreases in gastric mucosal pH and increases in cytosolic liver enzymes. The authors conclude that hepatocyte function is well preserved (lidocaine metabolism to monoethylglycinexylidide was unaffected by either agent), but disturbances of hepatocellular integrity and gastric tonometry suggest that splanchnic perfusion and oxygen delivery to the liver are decreased. Whether the increased metabolism of sevoflurane (100-fold that of desflurane) is detrimental to the liver is unknown, but it seems unlikely that the metabolites of sevoflurane cause liver damage.[140] Compound A, a breakdown product of sevoflurane found to be nephrotoxic in animals, has not been shown to cause renal toxicities in humans, even during low-flow sevoflurane administration[141] (see Chapter 26).

Cisatracurium is an attractive choice for neuromuscular blockade in patients undergoing liver transplantation because of its organ-independent elimination and diminished histamine release[142] (see Chapter 34). In patients with end-stage liver disease, the volume of distribution of cisatracurium is larger than that in healthy control patients. Hepatic clearance is also increased in patients with liver disease; this results in similar elimination half times and similar duration of action (time to 25% recovery). Other reports have suggested the use of rocuronium during liver transplantation, because the duration of the neuromuscular block appears to be a useful predictor of primary allograft function. All patients whose recovery time was longer than 150 minutes experienced primary graft dysfunction.[143]

Preanhepatic Stage

The preanhepatic stage begins with surgical incision and ends with vascular exclusion and hepatectomy of the native liver. Using conventional caval interposition technique, vascular exclusion of the liver is accomplished by cross-clamping the portal vein, the suprahepatic IVC, the infrahepatic IVC, and the hepatic artery (Fig. 74-9). If a piggyback technique is used, the native retrohepatic vena cava is preserved (Fig. 74-10).

The preanhepatic phase involves dissection and mobilization of the liver and identification of the porta hepatis. With abdominal incision and drainage of ascites, hypovolemia can occur. This should be treated in an anticipatory fashion with colloid-containing fluid to minimize changes in preload. In the presence of preexisting

coagulopathy, fresh frozen plasma is indicated soon after incision, although some authors have challenged the need for fresh frozen plasma during orthotopic liver transplantation (OLT).[144,145] In Europe, prothrombin complex concentrates (PCCs), which contain vitamin K–dependent factors (II, VII, IX, and X), are increasingly used as an alternative to plasma transfusion to avoid the risk of transfusion-related acute lung injury and transfusion-associated circulatory overload[146,147] (see Chapter 61). The so-called four-factor PCCs available in Europe contain therapeutic levels of factor VII in addition to Protein C and S, and differ from the three-factor PCCs available in the United States.[148] The primary concern related to PCC administration is thromboembolic complications, which vary according to the patient's underlying disease, dosing, and the constituents in each of the commercially available PCC products.[149] Another product, recombinant activated factor VII, was evaluated during liver transplantation and was found to improve coagulation study results, but did not result in a decrease in transfusion requirements.[150,151] Recombinant factor VIIa has been linked to an increased risk of arterial, but not venous, thromboembolic events.[152] Thromboelastography or standard laboratory tests (prothrombin time, fibrinogen, and platelet count) are used to guide the correction of coagulopathy.[153,154] Some authors disagree with the premise that coagulation monitoring is associated with blood product transfusion requirements during OLT.[155] However, in coagulopathic cardiac surgery patients, therapy guided by point-of-care testing using thromboelastometry resulted in fewer transfusions of red blood cells and plasma and improved 6-month survival.[156] Considerable institutional variation exists in transfusion practices for OLT, as do variations in patient acuity as evidenced by MELD scores. However, these differences in transfusion requirements might not be accounted for by variations in blood loss during the procedure.[157] Fibrinolysis is unusual during the preanhepatic phase of the surgery; therefore, cryoprecipitate administration is typically unnecessary. Hyponatremia should not be corrected rapidly. A perioperative increase of 21 to 32 mEq/L in the serum sodium level was associated with central pontine myelinolysis in one report, whereas an increase of less than 16 mEq/L was not.[117,158] Citrate intoxication (ionized hypocalcemia resulting from the infusion of citrate-rich blood products in the absence

of hepatic function) is avoided by the administration of calcium chloride (see Chapter 61). Ionized hypomagnesemia also results from citrate infusion, but values of ionized magnesium gradually return to normal after graft reperfusion.[159] The clinical significance of this remains speculative, but cardiovascular function may be affected. Aggressive treatment of hypokalemia is best avoided, particularly in preparation for reperfusion and the associated increase in serum potassium. Hyperkalemia should be avoided by the administration of diuretics and insulin accompanied by glucose or, in the event these are ineffective, by intraoperative dialysis. In the absence of insulin administration, supplemental glucose is usually not required except in pediatric patients or those with severe disease, such as fulminant hepatic failure. Hyperglycemia should be avoided, because glucose levels greater than 180 mg/dL are associated with an increase in surgical site infections in liver transplant recipients.[160] Blood gases, electrolytes, glucose, ionized calcium, and hemoglobin levels should be assessed regularly, and as frequently as hourly in the event of massive blood loss or preexisting abnormalities. Point-of-care testing facilitates rapid turnaround times for laboratory values. Coagulation studies are typically assessed at the beginning of the surgery, after correction of specific deficiencies, after reperfusion, and in the presence of microvascular bleeding.

The maintenance of urine output is desirable; however, the use of low-dose dopamine for this reason is unproven.[161,162] Hypothermia should be avoided. Core temperature control can be aided with heated venovenous bypass during the anhepatic phase. Regardless of whether bypass is used, forced-air warming blankets should be positioned beneath the patient and over the lower and upper body (see Chapter 54). Bleeding during this phase of surgery is related to the degree of preexisting coagulopathy, the presence and severity of portal hypertension, and the duration and complexity of the surgical procedure, which is adversely affected by prior abdominal surgery and adhesions.[163,164]

Anhepatic Stage

The anhepatic stage begins with the occlusion of vascular inflow to the liver, and it ends with graft reperfusion. Cross-clamping of the suprahepatic and infrahepatic IVC decreases venous return by as much as 50%. Venovenous bypass (VVB) diverts IVC and portal venous flow to the superior vena cava via the axillary vein, attenuates the decrease in preload, improves renal perfusion pressure, lessens splanchnic congestion, and can delay the development of metabolic acidosis.[165] However, the use of VVB is not without risk. Air embolism, thromboembolism, and inadvertent decannulation can be fatal or result in significant morbidity.[166] VVB is not uniformly used at all centers. A recent meta-analysis of three trials failed to reveal any difference in the incidence of renal failure or blood transfusion requirements between patients randomized to VVB compared with patients in whom the technique was not used.[167] The use of the "piggyback" technique, with IVC preservation, decreases the need for VVB.[168]

Hepatectomy is followed by hemostasis and vascular anastomoses of the suprahepatic and infrahepatic IVC and the portal vein. Despite the absence of hepatic clotting factor production during the anhepatic stage, blood loss is usually limited by vascular clamping of the inflow vessels to the liver. However, fibrinolysis may begin during this stage because of an absence of liver-produced plasminogen activator inhibitor, which results in the unopposed action of tissue plasminogen activator. The use of antifibrinolytics varies among centers (discussed later).

Neohepatic Stage

Reperfusion of the graft through the portal vein begins the neohepatic stage. Reperfusion is associated with abrupt increases in potassium and hydrogen ion concentrations, an increase in preload, and a decrease in systemic vascular resistance and blood pressure. Hypothermia, monitored through a centrally placed catheter, is a marker for the presence of graft outflow into the central circulation. Life-threatening hyperkalemia, clinically detectable by changes in the EKG, requires prompt treatment. Calcium chloride and sodium bicarbonate are the drugs of choice for the acute treatment of hyperkalemia. If time permits, albuterol and insulin are also effective. Intraoperative dialysis should be considered early in the procedure for patients with oliguria with elevated potassium levels.

The hallmark of the postreperfusion syndrome (PRS) is systemic hypotension and pulmonary hypertension occurring within the first 5 minutes after reperfusion of the graft. Approximately one in three patients undergoing OLT have profound hypotension after reperfusion. The cause is uncertain, but a number of factors have been implicated, such as hyperkalemia, acidosis, hypothermia, emboli (air or thrombotic), and vasoactive substances. Risk factors for hyperkalemia in the early postreperfusion period are elevated preanhepatic potassium levels and the use of donated-after-cardiac-death donor organs.[169] A retrospective study of 321 patients identified suboptimal grafts (higher degree of steatosis) and graft cold ischemia time as risk factors for PRS.[170] In this study all cases of PRS, defined as mean blood pressure less than 60 mm Hg, occurred in suboptimal donors with graft cold ischemia times longer than 6 hours. The authors defined suboptimal grafts as those from donors older than 50 years, those with a history of cardiac arrest, hypotension, need for high-dose inotropic drugs, ICU stay longer than 5 days, or elevated liver fat content. The PRS group had higher postreperfusion K^+ levels (at 1 and 5 minutes), and lower postreperfusion temperature (at 1 minute) than in the group without PRS.

In addition, other critical events such as severe, acute bleeding resulting in hemodynamic compromise and necessitating massive transfusion can occur at any point during the surgery. Arrhythmias and intracardiac thromboembolism can also occur at any time intraoperatively, but are more likely after reperfusion.[171,172]

Hepatic arterial anastomosis and biliary reconstruction are generally performed after venous reperfusion, although in pediatric patients the arterial anastomosis may be completed before reperfusion. Signs of graft function that might be observed in the operating room and early postoperative period include decreased calcium requirements, improvement in acidosis, increased urine

output, a rise in core temperature, and bile output from the graft.[71,173]

Antifibrinolytics

Fibrinolysis is most severe after reperfusion and is caused by abrupt increases in tissue plasminogen activator from graft endothelial cell release. Antifibrinolytic drugs and cryoprecipitate may be required. In studies before 1997, the benefits of antifibrinolytic drugs for OLT, typically defined as a decrease in blood loss or transfusion requirements, were not present in prospective, randomized, blinded studies. Nearly all these studies evaluated aprotinin. In contrast, tranexamic acid and ε-aminocaproic acid have not been studied extensively. In 2001, a randomized, blinded study from the Mayo Clinic showed a decrease in erythrocyte requirements (median of 5 units versus 7 units) with aprotinin compared with placebo.[174] The European Multicenter Study of Aprotinin in Liver Transplant (EMSALT) also showed a decrease in red blood cell usage with both large dose (2×10^6 kallikrein inhibiting units [KIU] loading dose followed by 1×10^6 KIU/h) and regular dose (2×10^6 KIU loading dose followed by 0.5×10^6 KIU/h) aprotinin compared with placebo (red blood cell requirements of 1500, 1750, and 2450 mL, respectively).[175] The authors report no difference in the prevalence of thromboembolic events in the aprotinin groups compared with control group. It was noted that the three patients who developed hepatic artery thromboses were in the control group. These three events may have been related to surgical technical issues, whereas the thrombotic events in the aprotinin group (pulmonary emboli, right coronary occlusion) were less likely attributable to the surgery. It is unclear whether antifibrinolytic drugs increase the risk of thrombotic events.[176] Fibrinolysis is an unpredictable event, and the risks of thrombosis are unknown. Aprotinin intensifies the likelihood of increases in creatinine levels in the first week after liver transplantation, but not with an increased need for renal replacement therapy.[177] Aprotinin was withdrawn from world markets in 2008 because of higher mortality in patients who received aminocaproic acid during cardiac surgery.[178]

Postoperative Care

The goals of the immediate postoperative period are to ensure a smooth transition from anesthesia and surgery (maintain hemodynamic stability, metabolic homeostasis, adequate analgesia), monitor graft function (transaminase levels, prothrombin time, bilirubin levels, bile and urine output, acid-base status), and maintain surveillance for known complications (bleeding, bile leaks, vascular thrombosis, primary nonfunction). The use of steroids leads to hyperglycemia, which can require insulin infusion. (See Chapters 95 and 102.)

The lack of bile output, accompanied by hemodynamic instability, suggests primary nonfunction of the graft, which may require urgent retransplantation. Conversely, a functioning liver graft facilitates early neurologic recovery, cardiovascular stability, and improved renal function, signs that can occur within hours of the completion of surgery.

Hepatic artery thrombosis can lead to graft necrosis, necessitating retransplantation. Within the first 2 to 3 postoperative days, markedly abnormal transaminase levels are common because of graft ischemia or injury during procurement, preservation, and reperfusion. After this period, hepatic enzyme and bilirubin levels that do not trend downward suggest the possibility of hepatic artery thrombosis, which should lead to prompt evaluation via Doppler ultrasonography.

Postoperative pain control is generally achieved with opioids, including patient-controlled analgesia (see Chapter 98). Analgesic requirements may be decreased compared with other major abdominal surgery.[179,180] Epidural analgesia is contraindicated because of coagulopathy, which usually preexists, or develops during the perioperative period.

The timing of tracheal extubation and termination of postoperative mechanical ventilation is not clear.[181,182] Early extubation of the trachea, including endotracheal tube removal in the operating room, is feasible in select patients. However, the benefits of immediate extubation appear limited to the potential of decreased resource utilization, which might not be fully realized in centers that direct posttransplant patients to ICUs regardless of their need for ventilatory support. As a result, many centers prefer to see clear signs of graft function before extubation.

ACUTE LIVER FAILURE

Acute liver failure (ALF; previously termed *fulminant hepatic failure*) is defined as the appearance of encephalopathy together with coagulopathy (international normalized ratio ≥ 1.5) in a patient without previous liver disease who has an illness of less than 26 weeks in duration. ALF is a rare entity with an incidence of approximately 2000 cases per year in the United States. Drug-related toxicity, primarily acetaminophen, accounts for more than half of the cases of ALF in the United States. Other causes include idiopathic, acute viral hepatitis, autoimmune, and ischemic. In the United States, approximately 45% of patients recover spontaneously, 25% undergo liver transplantation, and 30% die.[183] Etiology has a significant bearing on outcome; patients with acetaminophen toxicity, ischemic injury, or hepatitis A have the most favorable prognosis, whereas those with non-acetaminophen drug-induced liver injury, acute hepatitis B, Wilson's disease, or autoimmune hepatitis have poor prognoses in the absence of transplantation.[184]

Evidence of portal hypertension and cirrhosis is absent because of the rapid progression of disease. Acute decompensation of chronic liver disease, termed *acute on chronic liver disease,* is a separate condition with different etiologies, therapy, and prognostic indicators.

Although various etiologies of ALF exist, there are manifestations that are common to all patients with massive hepatic necrosis. The most serious, and lethal, is acute cerebral edema and intracranial hypertension. Effects on other organ systems include coagulopathy, circulatory dysfunction and hypotension, acute kidney injury, and metabolic derangements.

General measures to reduce cerebral edema include maintaining the patient in a 30-degree, head-up position, and making sure the head is in neutral position so as not to impede venous return. Once a patient is intubated, muscle relaxants should be considered to minimize rises in intracranial pressure from coughing, bucking, and shivering. Mannitol can be used to induce an osmotic diuresis, but may have limited utility in the patient with compromised renal function. Another option may be hypertonic saline, ideally targeting a serum sodium of 145 to 155 mEq/L. Current recommendations are to maintain normocarbia and to reserve hyperventilation for response to acute rises in intracranial pressure. Barbiturates can be used to decrease cerebral metabolism; however, their use may be limited by hypotension.

Monitoring techniques for cerebral edema and intracranial hypertension are controversial (also see Chapter 70). Serial head computed tomography (CT) images are not sensitive indicators of intracranial hypertension. CT can, however, provide information on structural abnormalities such as intracranial hemorrhage. Although many centers place an intracranial pressure (ICP) monitor to guide therapy in patients with stage III-IV coma, there are no randomized controlled studies to support this practice. Furthermore, ICP monitor placement is not a benign procedure, frequently entailing aggressive correction of coagulopathy and transport to and from the operating room for a critically ill, fragile patient. Nonetheless, ICP monitors are invaluable for guiding acute therapy, and for helping to determine who might no longer be a viable candidate for transplantation. In addition to measuring ICP, these monitors allow calculation of cerebral perfusion pressure ([CPP] = mean arterial pressure [MAP] – intracranial pressure [ICP]), which should be kept between 50 and 80 mm Hg. In one case series, a sustained CPP less than 40 mm Hg for greater than 2 hours was associated with a poor neurologic outcome. An effective protocol for managing intracranial hypertension in patients with stage III or IV encephalopathy has been described and resulted in a 95% response to treatment in episodes of ICP greater than 20 mm Hg. Furthermore, in this prospective series, ICP was monitored in all patients, and no patients died of isolated cerebral edema. The authors used a protocol that included activated recombinant factor VII (rFVIIa) to correct coagulopathy before ICP placement. Significant bleeding complications from ICP monitoring were not encountered.[185]

The decision regarding which patients should receive a transplant, based on who might recover spontaneously or who is unlikely to benefit from transplantation, is one of the most difficult decisions encountered during the management of patients with liver disease. The two most widely used prognostic models are the Clichy or Paul Brousse Hospital criteria and the King's College Hospital criteria. The Clichy criteria recommend transplantation for patients in stage III or IV coma, based on age and factor V levels.[186] There is no distinction made for etiology of ALF, which is considered a weakness of these criteria. The King's College Hospital criteria are superior for predicting outcomes in patients with ALF based on acetaminophen toxicity. However, the negative predictive value is less than 50% in patients who have not used acetaminophen.[187] Thus, patients who fail to fulfill these criteria include a number of patients who will die without proper consideration for transplantation.

In patients with ALF who are undergoing an invasive procedure, correction of thrombocytopenia to 50,000 platelets/mm^3 or greater and international normalized ratio (INR) to 1.5 or less is suggested.[184,188] Treatment thresholds are less clear for patients who are not bleeding, but prophylactic therapy is advised for severe abnormalities (e.g., platelet count ≤ 10,000/mm^3, INR > 7, and fibrinogen < 100 mg/dL.[184] Use of rFVIIa is reserved for rapid correction in patients who cannot tolerate a large volume of plasma. This agent may carry a thrombotic risk and is contraindicated in hypercoagulable conditions, which include pregnancy and Budd-Chiari syndrome.

Hypotensive patients with ALF should undergo intravascular volume status and cardiac function assessment before consideration of inotropes or vasopressors. Vasopressors can be used to treat either systemic hypotension or to maintain an adequate CPP. Based on recommendations for septic patients, norepinephrine should be used. The use of vasopressin is controversial because there is evidence that its use is associated with increases in ICP.[189] However, another study in which terlipressin was used did not reveal similar increases in ICP.[190]

LIVING DONOR LIVER TRANSPLANTATION

See Chapter 75.

PEDIATRIC LIVER TRANSPLANTATION

See Chapters 94 and 95.

ORGAN MATCHING AND ALLOCATION

The primary criteria used to match donor liver grafts with recipients are ABO blood type and graft size. ABO-incompatible transplantation (ILT) is generally limited to emergent situations, and as many as half of the adult recipients in early reports required retransplantation. Subsequent reports have identified patient populations with more favorable outcomes after ILT. Recipients with blood type O and pediatric patients tolerate ILT better than others.[191] Nonetheless, ILT remains a technique reserved for emergent situations.

In the United States, a national registry maintained by UNOS allocates organs to transplant candidates. In Europe, organs are allocated to transplant centers that subsequently identify the most suitable candidate from their waitlist. UNOS considers only disease severity, and no longer uses waiting time, when allocating deceased-donor liver grafts. Older systems used the Child-Turcotte-Pugh (CTP) score to determine disease severity (Table 74-3). Beginning in 2002, the MELD score replaced the CTP score. The MELD score is a mathematic formula that incorporates the serum bilirubin, creatinine level, and INR. It is considered more objective because there is no reliance on subjective physical examination to determine the presence and severity of findings, such as ascites or encephalopathy. The MELD score is a continuous scale,

TABLE 74-3 PUGH'S MODIFICATION OF THE CHILD-TURCOTTE CLASSIFICATION*

	Points		
Variable	**1**	**2**	**3**
Encephalopathy	None	1-2	3-4
Ascites	Absent	Slight	Moderate
Prothrombin time (sec prolonged)	<4	4-6	>6
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Bilirubin (mg/dL)	<2	2-3	>3

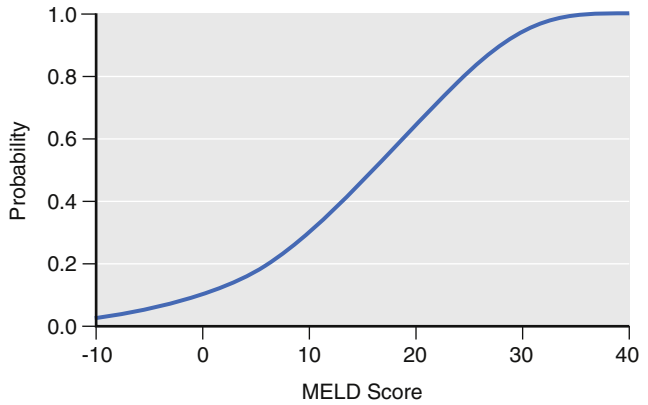

Figure 74-11. Relationship between Model for End-Stage Liver Disease (MELD) score and 3-month mortality in hospitalized (pretransplant) patients with cirrhosis. *(From Wiesner RH, McDiarmid SV, Kamath PS, et al: MELD and PELD: application of survival models to liver allocation,* Liver Transplant *7:567-580, 2001.)*

rather than categorical (found in the CTP score), which provides more discriminatory ability since disparate risks are not grouped within a single category. In addition, the inclusion of the creatinine level (not found in the CTP score) reflects the prognostic importance of renal dysfunction on advanced liver disease. The MELD score is an excellent predictor of 90-day pretransplant (waitlist) mortality (Fig. 74-11). The MELD score is regarded as a major advance in liver organ allocation, although it will undoubtedly continue to undergo refinement.

Hepatocellular carcinoma (HCC) can progress to inoperable status before manifesting changes in the MELD score, which disadvantages patients with HCC. As a result, UNOS policy grants exception points to patients with HCC to allocate organs equitably to patients with this condition.[192] Although there have been several adjustments to the MELD exception points awarded, patients with HCC appear to be advantaged compared with those without HCC; therefore, additional adjustments may be needed.[193] Waitlisted patients with HPS also receive exception points. UNOS policy does not specify the number of points allocated, but instead indicates that the exception should provide a chance of transplantation within 3 months. Evidence suggests that as a group, patients with HPS may have accrued a survival advantage compared with nonexception status candidates as a result of this policy; however, more analysis is needed before modifications are made.[194]

Most liver transplant candidates have MELD scores less than 25; only 2% of the waitlist has a MELD score greater than 25.[1] Candidates with MELD scores less than 15 have better survival without transplantation.[195] However, when the qualities of the donor graft are taken into account using the donor risk index, candidates with MELD scores of 12 to 14 benefit from liver transplant in the event that a favorable (low donor risk index) graft is transplanted.[196]

ANESTHESIA FOR PATIENTS AFTER LIVER TRANSPLANTATION

Liver transplant recipients with functioning grafts typically metabolize drugs in a normal fashion, but graft function must be assessed rather than assumed. The prothrombin time (or INR) is an excellent marker of synthetic function. In patients with grafts with impaired synthetic function, clotting abnormalities can be corrected with vitamin K or fresh frozen plasma; ascites managed with diuretics, albumin administration, or paracentesis; and the risk of encephalopathy minimized with lactulose administration and careful use of sedatives.

Careful adherence to sterile technique is required to prevent infectious complications in this immunosuppressed population. A stress dose of corticosteroids is required for patients receiving chronic supplementation. Renal function should be assessed and managed carefully to avoid an exacerbation of immunosuppressant-associated renal impairment. Hypertension is a common finding in patients whose condition is managed with calcineurin inhibitors such as cyclosporine. Drugs known to decrease hepatic blood flow, such as propranolol, should be avoided. Regional anesthesia is an option in patients with acceptable clotting status.

INTESTINAL TRANSPLANTATION

Intestinal transplantation is indicated in patients with irreversible intestinal failure and an inability to continue total parenteral nutrition.[197] Impending liver failure, lack of central vein access, frequent line infections or recurrent episodes of dehydration despite intravenous fluid supplementation can lead to intolerance to total parenteral nutrition. Intestinal failure is the inability to maintain adequate nutrition via the alimentary tract, commonly because of surgical removal or congenital absence of more than 70% of the small bowel (short-gut syndrome).

Approximately 130 intestinal transplants were performed in the United States in 2011.[1] The number of small bowel transplant candidates has declined since 2006, most likely because of improved medical management. In 2011, nearly 60% of waitlisted candidates were younger than 18 years (>40% were younger than 5 years). Almost half of intestinal grafts were transplanted with another organ in 2011; the remainder were transplanted as isolated intestinal transplants (Fig. 74-12). In the past, the most common accompanying organ was the liver; in 2011, it was the pancreas. The median time to transplant

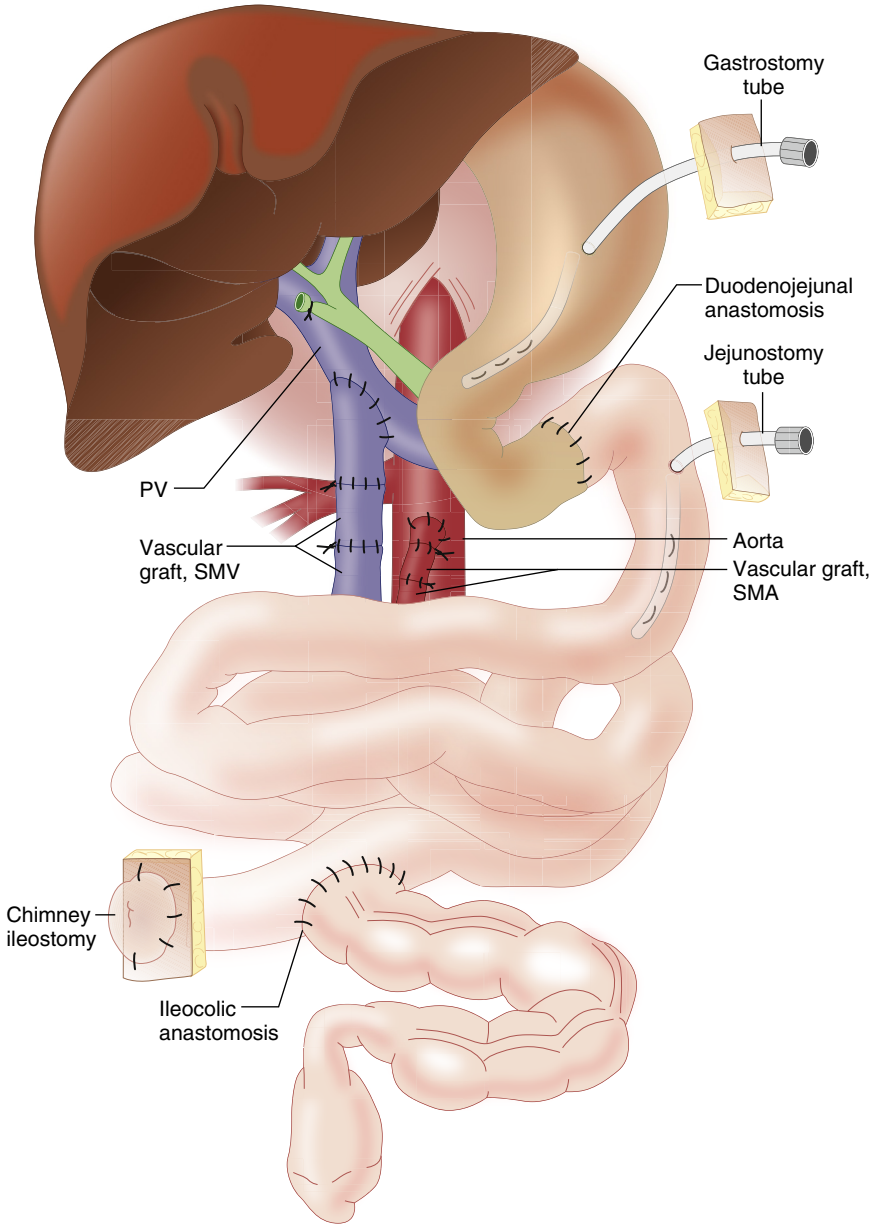

Figure 74-12. Intestinal transplantation. The implanted donor intestine is illustrated. *SMA,* Superior mesenteric artery; *SMV,* superior mesenteric vein. *(Modified from Abu-Elmagd K, Fung J, Bueno J, et al: Logistics and technique for procurement of intestinal, pancreatic and hepatic graft from the same donor,* Ann Surg *232:680-687, 2002.)*

in 2011 was 15 months for patients younger than 18 years of age, and 3 months for those aged 18 years or older. Patient survival after intestinal transplantation is improving. One-year survival is approximately 80%, and 5-year survival approaches 50%.

Intestinal transplant candidates should undergo an age-appropriate cardiovascular evaluation, with particular attention to vascular access. Because of the need for chronic indwelling vascular access, thrombosis and obstruction of central veins is common (vanishing vein syndrome) in patients presenting for intestinal transplantation. Doppler ultrasonography, contrast venography or magnetic resonance angiography, or all three, are indicated before surgery.[198]

Intraoperative blood loss varies based on whether other organs are transplanted simultaneously and on the extent of abdominal adhesions present from prior surgeries. Rapid infusion devices should be available. Patients are frequently hypercoagulable; care should be taken to avoid therapies that can increase the risk of thromboembolism.

Repeat hospitalization is common after transplantation, occurring in 85% by 6 months after transplant and in nearly all recipients by 4 years. Infection is responsible for 50% of mortality.[199] Other complications include acute rejection (fever, bloody stools), chronic rejection, graft-versus-host disease in 6%, and lymphoproliferative disease in 7% to 8%.[200]

MULTIVISCERAL TRANSPLANTATION

Multivisceral transplant includes the small intestine, stomach, liver, spleen, and the duodenopancreatic complex. Modified multivisceral transplant includes the visceral organs without the liver.[200] The indications for multivisceral transplant have been widened because of

the technically advantageous nature of the procedure, which involves a decreased number of anastomoses compared to combined liver-intestinal transplant. This is particularly favorable for infants. When the liver is included, the risk of stenosis or thrombosis of the portal anastomosis is avoided.[201]

POSTABDOMINAL TRANSPLANTATION COMPLICATIONS

Surgical Complications

Early postoperative surgical complications include postoperative bleeding, drainage leaks (bile, urine, pancreatic secretions), and vascular thrombosis. The risk of bleeding and thrombosis is lessened when a balance is maintained between procoagulants and anticoagulants (protein S and C, antithrombin). Because standard laboratory tests monitor only coagulation, this balance may be difficult to assess in the absence of viscoelastic tests, which evaluate whole blood clotting.

Complications vary based on donor graft qualities and recipient characteristics. For instance, hepatic artery thrombosis is more common in pediatric recipients because of the small caliber of the vessel, and bile leaks are more common after liver transplantation using grafts from cardiac death donors (see Chapter 75).[202]

Infection

After the immediate postoperative period, infection is the primary cause of death. Immunosuppressive medications, used to prevent rejection, are largely responsible for this risk. Bacterial infections predominate during the early postoperative period. Surgical site infections, intra-abdominal abscesses, and infected hematomas are common. In this immunosuppressed population, multidrug-resistant organisms are common. In liver transplant recipients, bacterial translocation or bile leaks can result in peritonitis, cholangitis, and perihepatic abscesses. In a recent study of liver transplant recipients, 47% of ICU patients had bloodstream infections, 35% had intra-abdominal abscesses, and 17% had ventilator-associated pneumonia.[203] Prompt diagnosis and treatment with minimally invasive drainage techniques should be considered over early laparotomy. When this approach fails, laparotomy is indicated.

Prolonged endotracheal intubation and indwelling central venous and urinary catheters are a common source of infection. These devices should be removed as early as possible in the postoperative period. In the meantime, strict aseptic technique is required when accessing indwelling catheters and tubes.

Comorbidities, such as diabetes and renal dysfunction, can increase the risk of infection. Viral and fungal infections are more likely after the first postoperative week. Risk factors for fungal infection in liver transplant patients include preexisting viral hepatitis, diabetes mellitus, multiple organ system failure, prolonged parenteral nutrition, long-term mechanical ventilation, and increased antibiotic use.[204] Common sites of fungal infection include oral, esophageal, pulmonary, and intracerebral. Invasive fungal infections, despite prolonged treatment with amphotericin or itraconazole, are associated with a poor prognosis.

Immunosuppression

Acute rejection is an important cause of graft dysfunction at 1 week and beyond, occurring in as many as one quarter of liver recipients.[205] The goals of immunosuppression are to prevent graft loss and to avoid the adverse consequences of antirejection regimens.[205] Immunosuppression for solid organ transplant is divided into initial (induction) and maintenance phases. Calcineurin inhibitors cyclosporine and tacrolimus (formerly FK506) are the foundation for the majority of induction and maintenance regimens. Both agents inhibit transcription of interleukin (IL)-2 and other cytokines, primarily in helper T lymphocytes. Both manifest renal toxicity, which is caused by afferent arteriolar vasoconstriction and a reduction in GFR. The resulting azotemia is reversible with a reduction of dosage. Hypertension is due to vasoconstriction and sodium retention, and typically appears within the first weeks of treatment. Neurologic toxicity includes tremors, headaches, seizures, and even focal neurologic abnormalities. Mycophenolate mofetil therapy is a beneficial adjunct by allowing a reduction in the doses of calcineurin inhibitors.

In addition to tacrolimus, the most widely used drug, there are many other drugs available.[206] Sirolimus, an inhibitor of the protein mTOR, is used for calcineurin-sparing effects and in patients transplanted for hepatocellular carcinoma to reduce recurrence.[207] Basiliximub, a monoclonal antibody to CD25, has been used as an alternative to steroids for the induction of immunosuppression in liver transplantation.[208]

New immunosuppressive drugs are typically introduced for use in renal transplantation before they are applied in liver transplantation. Of note, recipients of liver grafts require less immunosuppression than do recipients of other organs, and liver grafts confer protection on other organs transplanted from the same donor. This effect is an example of the privileged immune status of the liver.[205]

The diagnosis of rejection requires a biopsy. The threshold for performing a biopsy should be low, albeit with an awareness that other conditions can mimic the histologic changes seen with rejection. For instance, diffuse lymphocytic infiltration of the kidney can be seen with rejection or lymphoproliferative disorder, and recurrent hepatitis C in the liver can resemble rejection.

Malignancy

Immunosuppressant drugs increase the susceptibility of transplant recipients to malignancy.[209] This effect is primarily related to the level of immunosuppression, but production of transforming growth factor-β may also be responsible.

The spectrum of malignancy is wide ranging and includes cancers seen with HIV-infection, a condition also associated with immunosuppression. Lymphoma regression occurs if the immunosuppressive agent is discontinued early.

In a retrospective study of more than 250,000 solid organ transplant recipients, Hodgkin lymphoma risk factors included male sex, young age, and Epstein-Barr

virus (EBV) seronegativity at the time of transplant.[210] In a study of 175,000 solid organ recipients (primarily kidney and liver recipients), malignancy was identified in more than 10,000 patients, a standardized incidence ratio (SIR) of greater than 2 compared with the general population.[211] The cancer sites with the highest relative risk included Kaposi sarcoma (SIR = 61), lip (SIR = 17), skin, nonmelanoma (SIR = 14), liver (SIR = 12), vulva (SIR = 8), and non-Hodgkin lymphoma (SIR = 8).

Posttransplant lymphoproliferative disorder (PTLD) is associated with a proliferation of B cells after transplantation in response to infection with EBV. Clinical presentation varies from a mononucleosis-like syndrome to malignant lymphoma. Pediatric patients are at increased risk due to a lower likelihood of prior exposure to EBV. Diagnosis is made by biopsy of the affected area, which can include the graft. Treatment consists of a reduction of immunosuppression levels and antiviral therapy against EBV, primarily ganciclovir. Individuals at high risk, such as patients who are seronegative for EBV or who receive a graft from a seropositive donor, should be maintained on antiviral prophylaxis.

The mean latency period for all cancers is 3 to 5 years after transplant, although specific malignancies exhibited unique time intervals. Cancer sites vary depending on the organ transplanted; for example, renal transplant recipients have a 100-fold greater than expected risk of developing carcinoma in the native kidney.[212] The reasons are unclear, but prolonged dialysis before transplantation may be a risk factor.[213] The use of specific immunosuppressive drugs also affects the relative risk of various cancers. For example, OKT3, which contains antibodies directed against T lymphocytes, is associated with an increased incidence of PTLD. Antibodies directed against B lymphocytes (rituximab) can reduce the incidence of PTLD. Sirolimus is not associated with cancer risk, and in fact may have antitumor effects.

Long-Term Survival

Long-term survival is affected by common diseases, such as hypertension, hyperlipidemia, and diabetes mellitus.[214] Three years after liver transplantation, cardiovascular disease and de novo malignancy are the major causes of mortality.[215] Recurrent rejection and hepatitis C account for most of the hepatic causes of mortality.

CONCLUSIONS

Abdominal organ transplantation has matured over the past 30 years. From its beginning as an experimental procedure, it has become the best hope for survival in the case of liver transplantation, and the best option for an independent life without morbidity in the case of renal and pancreatic transplantation. Challenges for the future include a solution to the organ shortage, methods to minimize the likelihood of disease recurrence, and pharmacologic advances aimed at limiting the side effects of immunosuppression.

Chapter 75

Anesthesia for Organ Procurement

VICTOR W. XIA • RANDOLPH H. STEADMAN

Key Points

- The shortage of organs available for transplantation is a worldwide problem.
- The discrepancy between the number of patients waiting for organ transplantation and the available organs has widened.
- Most organs in the United States are donated after brain death, but organs from cardiac death and living organ donors are increasing.
- Brain-dead donors have physiologic alterations that must be actively managed to ensure that the organs are suitable for transplantation (also see Chapter 76).
- Determining brain death and cardiac death should follow national guidelines and local institutional protocols (also see Chapter 76).
- The anesthesiologist must have an awareness of the ethical and legal issues related to the declaration of death and organ donation.
- Expansion of the donor pool through the inclusion of extended criteria, such as high-risk donors, addresses the organ shortage and decreases waiting-list mortality.
- The use of extended criteria high-risk organs significantly impacts recipient outcomes and presents challenges to perioperative management.
- Ischemia-reperfusion injury in organ transplantation is unavoidable; however, management strategies can lessen the likelihood of postoperative graft failure.
- Goal-directed donor management can improve the number of organs transplanted per donor.
- Preclinical studies on the prevention or reduction of ischemia-reperfusion injury are promising, but they have not been widely implemented into clinical practice.
- Living organ donor kidney transplantation has increased, whereas the use of living donors for liver transplantation varies by country.

INTRODUCTION

Organ transplantation requires the donation and successful procurement of a human organ. The success of organ transplantation relies on a functioning donor graft. The majority of organs used for transplantation in the United States are from donors after the declaration of brain death (donation after brain death, [DBD]). Organs from donation after cardiac death (DCD) and living organ donation are in the minority but have increasingly been used in recent years[1] (also see Chapter 76). Organs procured from these sources have different characteristics and present varying challenges in management. For instance, DBD donors often have significant physiologic alterations and hemodynamic instability that is associated with brain death. These alterations and instability, if not treated, will lead to organ deterioration and may prevent the organ from being suitable for transplantation. In contrast, DCD donors have an obligatory period of hypotension of varying duration before cardiac arrest. The resulting compromise in perfusion can exacerbate reperfusion injury and can lead to an increased incidence of posttransplant biliary dysfunction.

The shortage of organs is a worldwide problem and is the most important obstacle in organ transplantation. The gap between the number of patients waiting for transplant and the available organs has widened (Fig. 75-1). In September 2012, more than 114,000 transplant candidates were wait-listed in the United States through the United Network for Organ Sharing (UNOS). Of these, 74,000 were active candidates; however, less than 30,000 candidates were expected to undergo transplant surgery in 2012.[2] The majority of candidates were awaiting kidney grafts, with a smaller number awaiting liver, heart, and lung grafts. Many strategies were implemented to decrease the gap between the demand and supply, including public awareness campaigns and updates to the organ allocation system. Organ donation rates and the number of organs transplanted per donor vary substantially across geographic regions. Per 100 eligible deaths in the United States in 2009, the organ

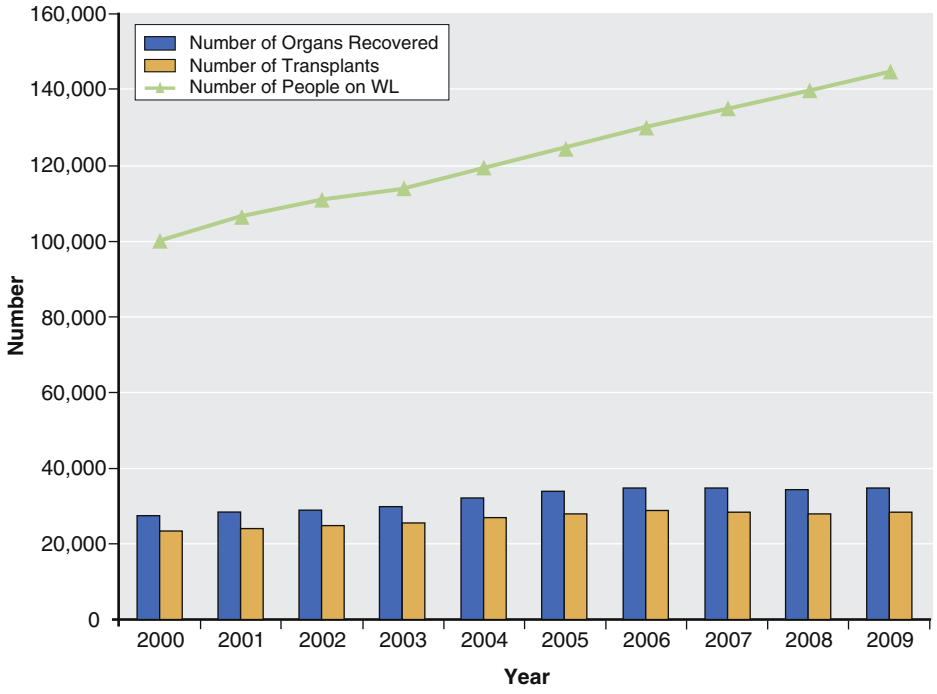

Figure 75-1. The gap between the number of patients on the waiting list (WL) for transplantation and the number of transplants performed each year in the United States is increasing every year. A significant number of procured organs are not used for transplantation. *(Data available at http://optn.transplant.hrsa.gov. Accessed June 30, 2012.)*

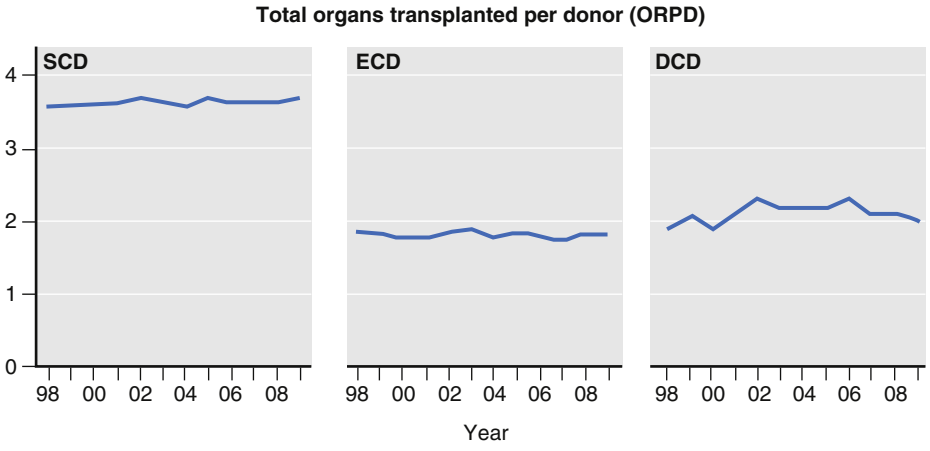

Figure 75-2. Total organs transplanted per donor based on donor type. *DCD,* Donation after cardiac death; *ECD,* extended criteria donor; *SCD,* standard criteria donor.

donation rate varied from a low of 51 to a high of 91.[3] To increase the number of organs for transplant, many programs have expanded the donor pool by using extended criteria donors (ECDs). Not surprisingly, the number of organs transplanted per donor varies according to donor category: ECD, DCD, or standard criteria donor (SCD). The number of organs transplanted from DCD donors is similar to ECDs, primarily attributable to the ability of the kidney to tolerate the longer periods of ischemia associated with organ procurement after DCD (Fig. 75-2). The use of living-related and living-unrelated donors is widespread in countries with moral or legal objections to brain death and is an important worldwide donor source. Many policies have been proposed to promote the best practices in organ donation.[1,4]

Organ transplantation is a complex process that requires close coordination among many specialized teams. The procurement organizations, transplant coordinators, social workers, nurses, surgeons, internists, intensivists, and anesthesiologists are involved in the process. To maximize the number of organs transplanted (Fig. 75-3) and to preserve the best possible function of donated organs, anesthesiologists need to understand the pathophysiologic derangements associated with donation and ischemia-reperfusion injury. In addition, anesthesiologists must be aware of the ethical and legal issues related to the declaration of death and organ donation.

MANAGEMENT OF ORGAN DONORS AFTER DECLARATION OF BRAIN (NEUROLOGIC) DEATH

DBD provides approximately 80% of donated organs in the United States. Organ procurement from DBD donors can only occur after the declaration of death. The concept of brain death emerged in the 1950s when clinicians encountered patients whose brain function had ceased, but the function of other organs was maintained by preserved cardiac perfusion in the presence of mechanical ventilation. In

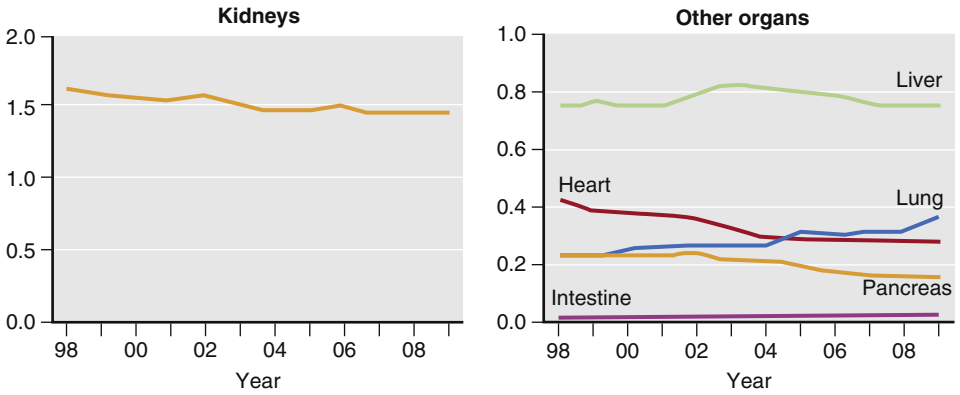

Figure 75-3. Organs transplanted per deceased organ donor. *(Data from the Organ Procurement and Transplantation Network (OPTN) and Scientific Registry of Transplant Recipients (SRTR):* OPTN/SRTR 2010 annual data report, *Rockville, Md, 2011, Department of Health and Human Services, Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation, p. 127.)*

1968, a Harvard Ad Hoc Committee on Irreversible Coma established a set of criteria that has been widely used today for the determination of brain death[5] (also see Chapter 76). In the United States, the Uniform Determination of Death Act was approved in 1981 by the National Conference of Commissioners on Uniform State Laws, in cooperation with the American Medical Association, the American Bar Association, and the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research. Although the criteria for the declaration of brain death were based on ethical principles established several decades ago, the criteria remain valid today.[6]

Although the concept of brain death has been widely accepted in Western cultures, minor variations in definition and implementation exist in different countries. Despite these differences, the clinical criteria are similar.[7] A larger difference exists among different cultures in accepting and implementing the brain death criteria. In fact, brain death has not reached a legal status in some countries, such as China.

DIAGNOSIS AND DETERMINATION OF BRAIN DEATH

In 1995 and updated in 2010, the American Academy of Neurology published practice parameters for the determination of brain death (also see Chapter 76).[6] To determine brain death, physicians must confirm the presence of the following three findings: irreversible coma, absence of brainstem reflexes, and absence of respiratory drive after a carbon dioxide (CO_2) challenge. Reversible cerebral dysfunction caused by hypothermia, hypotension, or residual drug effects must be excluded. A lack of brainstem activities is confirmed by the lack of a pupillary response to light, corneal reflex, gag and cough reflexes, ocular movements, and facial motor response. The absence of respiratory drive is assessed with an apnea test (CO_2 challenge) in patients without a history of CO_2 retention. During the apnea test, the patient is mechanically ventilated with 100% oxygen for at least 10 minutes to attain partial arterial pressure of oxygen (PaO_2) greater than 200 mm Hg in the presence of a normal partial arterial pressure of carbon dioxide ($Paco_2$) (35 to 45 mm Hg). The patient is then disconnected from the ventilator while oxygenation is preserved via an insufflation catheter or a T-piece connected to the endotracheal tube. The apnea test is positive if no respiratory movements are observed for 8 to 10 minutes and the $Paco_2$ is at or greater than 60 mm Hg. A positive apnea test confirms the lack of brainstem control of ventilation. If the test is inconclusive but the patient is hemodynamically stable and adequately oxygenated, then the test may be continued for a longer period (10 to 15 minutes). In clinical practice, ancillary tests can be used when the neurologic examination is indeterminate or the apnea test cannot be performed. The tests that have been used for this purpose include electroencephalography, cerebral angiogram, computed tomographic angiography, magnetic resonance angiography, somatosensory-evoked potentials, and transcranial Doppler imaging[6] (also see Chapter 49).

PATHOPHYSIOLOGIC CHANGES WITH BRAIN DEATH

A variety of pathophysiologic changes are associated with brain death. The pathophysiologic mechanisms of brain death have profound effects at the molecular, cellular, and tissue levels. The clinical presentations associated with brain death may be complex and vary from patient to patient. They can be further complicated by prior pathologic abnormalities, disease, and therapy. The typical pathophysiologic changes associated with brain death are further described in Table 75-1.

CARDIOVASCULAR RESPONSES TO BRAIN DEATH

The cardiovascular system is closely regulated by the central neural system. Cardiovascular responses to brain death usually consist of two phases. The first phase is characterized by sympathetic discharge (catecholamine storm), which causes intense vasoconstriction or elevated systemic vascular resistance (hypertensive crisis), tachycardia, and a redistribution of blood volume with visceral ischemia. Acute myocardial injury can occur in brain-dead donors without a history of coronary artery disease.[8] Echocardiographic evidence of myocardial dysfunction is observed in 40% of brain-dead donors under consideration for heart donation.[9] At times, parasympathetic activation can result in bradycardia. After the sympathetic discharge of the first phase, the loss of sympathetic tone, decreased cardiac output, blunted hemostatic responses, and severe peripheral vasodilatation (vasoplegia) characterize the second phase. In addition to neurohormonal disturbances, other contributing factors include

TABLE 75-1 **PATHOPHYSIOLOGIC CHANGES ASSOCIATED WITH BRAIN DEATH**

Signs and Symptoms	Pathophysiologic Changes	Incidence
Hypertension	Catecholamine storm	80%-90%
Hypotension	Vasoplegia, hypovolemia, reduced coronary blood flow, myocardial dysfunction	80%-90%
Bradycardia and other arrhythmias	Catecholamine storm, myocardial damage, reduced coronary blood flow	25%-30%
Pulmonary edema	Acute blood volume diversion, capillary damage	10%-20%
Diabetes insipidus	Posterior pituitary damage	45%-80%
Disseminated intravascular coagulation	Tissue factor release, coagulopathy	30%-55%
Hypothermia	Hypothalamic damage, reduced metabolic rate, vasodilation and heat loss	Varied
Hyperglycemia	Decreased insulin concentration, increased insulin resistance	Common

blood loss, intravascular depletion attributable to capillary leakage, osmotic therapy for rising intracranial pressure (ICP), and diabetes insipidus.

The first phase is correlated with ischemia in various parts of the brain and is attributable to an increase of ICP, and the second phase is caused by cerebral herniation and spinal cord ischemia. Although the first hypertensive phase generally represents a transient period in the progression to brain death, the second hypotensive phase is profound and sustained. Failure to correct these cardiovascular derangements results in poor organ perfusion and inadequate tissue oxygenation, which will threaten the viability of the donated organs.

RESPIRATORY RESPONSES TO BRAIN DEATH

An increase in systemic vascular resistance after brain death results in blood shifting from the systemic circulation to the more compliant pulmonary circulation. The resulting increase in hydrostatic pressure in the pulmonary circulation causes pulmonary capillary leakage and pulmonary edema. Sympathetic activity triggers a sterile systemic inflammatory response, initiating infiltration of neutrophils and increasing pulmonary endothelial permeability, which further contributes to lung injury. Proinflammatory cytokines are released at the alveoli and are associated with early graft failure and mortality after lung transplantation. The inflammatory response in brain-dead donors is associated with the deterioration in cardiac function and a shift to anaerobic metabolism. Hormonal instability can reduce alveolar fluid clearance, resulting in significant accumulation of extravascular lung water. If ventilation is not supported, then respiratory arrhythmia progresses to apnea and cardiac arrest.[10,11]

ENDOCRINE, METABOLIC, AND STRESS RESPONSES TO BRAIN DEATH

Brain death is frequently associated with pituitary failure and disturbances of cortisol, thyroid hormones, antidiuretic hormone, and insulin. Posterior pituitary function in brain-dead donors is frequently lost. The development of central diabetes insipidus results in severe fluid and electrolyte derangements and can be observed in up to 90% of brain-dead donors.[10] Anterior pituitary function in brain death can also be affected, resulting in a deficiency in triiodothyronine (T_3) and thyroxine (T_4), adrenocorticotropic hormone, thyroid-stimulating hormone, and human growth hormone. Thyroid hormonal deficiency may be similar to the euthyroid sick syndrome commonly observed in the non–brain injured patient with multisystem organ failure. Hyperglycemia is commonly encountered in brain-dead donors because of decreased insulin concentrations and increased insulin resistance. Hypothalamic function and control of body temperature are lost. Although hyperpyrexia may initially occur, hypothermia follows, which is caused by a reduction in metabolic rate and muscle activity, in combination with peripheral vasodilation. Disseminated intravascular coagulation is present in up to one-third of isolated patients with head injuries and is believed to be caused by the release of tissue thromboplastin from brain tissue.[11]

DONATION AFTER CARDIAC (CIRCULATORY) DEATH

Before the acceptance of brain death, all organs procured were from donors who suffered a cardiac demise (DCD, previously known as donation from a non–heart-beating donor). After the establishment of the Harvard criteria for brain death, DBD quickly became the principal source of organ donation. However, an interest in the use of DCD organs has been renewed in recent years, driven by the persistent shortage of DBD donors and the lack of acceptance of brain death in some countries. Policies and protocols developed by health care organizations now encourage DCD organs, and their use is increasing in the United States and other countries. In the United States over the 5-year period from 2004 to 2009, the number of DCD donors more than doubled and accounted for over 10% of donors in 2009[12] (Fig. 75-4). During the same period, the number of living donors dropped slightly from 7000 to 6600.[3] Kidney grafts accounted for over 95% of the organs transplanted from living donors during this period. The American Society of Anesthesiologists established a Sample Policy for Organ Donation after Cardiac Death, with the recommendation that its members actively participate in the development of institutional DCD protocols.

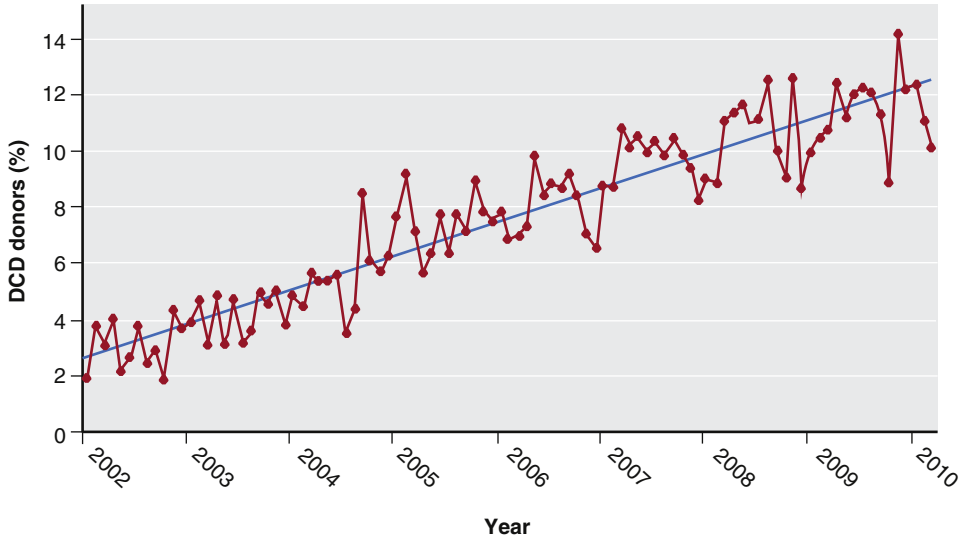

Figure 75-4. Percent of donations after cardiac death (DCDs) by year. *(Redrawn from Wynn JJ, Alexander CE: Increasing organ donation and transplantation: the U.S. experience over the past decade,* Transpl Int *24:324, 2011.)*

DCD donors are divided into five categories: I, patients dead on arrival at the hospital arrival; II, unsuccessfully resuscitated patients; III, patients in whom cardiac arrest is imminent; IV, cardiac arrest in brain-dead donors; V, unexpected arrest in the intensive care unit (ICU). Categories III and IV are considered as controlled DCDs, whereas the remaining categories are considered uncontrolled DCDs. Controlled DCD implies that life-support withdrawal can be planned and the transplant team is awaiting the cardiac arrest and is ready for rapid organ recovery. In contrast, uncontrolled DCD implies the patient has experienced an unanticipated cardiac arrest, and organ donation is considered only after an unsuccessful resuscitation. Warm ischemia time is significantly longer in uncontrolled DCDs. Currently, most DCD donors for organ transplantation are controlled DCD donors. Successful use of the uncontrolled DCD grafts has been reported in several studies.[13]

DCD donors usually suffer from irreversible brain or spinal injury but do not meet the brain death criteria. The prognosis for a meaningful quality of life is poor. Withdrawal of therapy must be based on a clinical decision of futility and conform to the wishes of the patient and family. The consideration of the withdrawal of life-sustaining therapies must be independent from any discussion related to transplantation. The transplantation team cannot be involved in this decision. Drugs can be used to relieve pain and anxiety and to provide comfort for the patient during withdrawal. Therapies designed to improve graft quality, but without benefit to the patient, are controversial; however, therapies with minimal impact on the patient that improve organ survival are allowed in some protocols.

Declaration of cardiac death should follow procedures proposed by national organizations and policies adopted by the local institution.[14,15] After a decision has been made to withdraw support, the trachea is extubated and life support is stopped. A physician who is not involved with organ transplantation declares cessation of cardiac function. Declaration of cardiac death is not different from clinical practice, which requires a clinical examination to confirm pulselessness or the absence of an arterial waveform. The duration between cessation of cardiovascular activities and the declaration of cardiac death is usually 2 to 5 minutes to ensure irreversibility. Organ procurement starts after death is declared.

Although organs procured from DCD donors are not exposed to the physiologic derangements of brain death, they are at greater risk for ischemia-reperfusion injury than organs from DBD donors. This potential results from hypoxemia and ischemia in a warm environment, which is unique during DCD procurement. The time elapsed from extubation to cardiac death is an important factor for determining the suitability of organ donation. If spontaneous breathing and/or heart function continues for a prolonged period after life support withdrawal, then the organs may not be suitable for transplantation, particularly in donors with comorbidities. To assist physicians in predicting how long a patient will sustain life after the withdrawal of life support, a 6-variable score was developed by the University of Wisconsin (Table 75-2). A low score (8 to 12) means that breathing and/or cardiac function will continue for some time. A high score (19 to 24) means that apnea and cardiac arrest are imminent.[16]

The two separate definitions and procedures used for DBD and DCD have led to a new debate about the definition and determination of death. A uniform concept of death, which combines all previous criteria for death, is emerging. A growing consensus is that all criteria used to diagnose human death rely on the demonstration of the irreversible loss of the capacity to breath, combined with the irreversible loss of the capacity for consciousness. The irreversible loss of these two functions equates to human death.[17]

Category III (impending cardiac arrest) DCD is the ideal source for organ transplant. Kidneys from DCD donors are frequently used. Several studies have showed that, despite a higher incidence of delayed graft function (DGF), kidneys from DCD donors have comparable short- and long-term graft survival.[13] Livers from DCD donors have a higher likelihood of postoperative biliary complications such as diffuse ischemic cholangiopathy with intrahepatic biliary stricture and may also have a higher incidence of primary

TABLE 75-2 UNIVERSITY OF WISCONSIN CRITERIA FOR DONATION AFTER CARDIAC DEATH EVALUATION TOOL

Variables	Points
Spontaneous respiration after 10 minutes	
Respiratory rate >12 breaths/min	1
Respiratory rate <12 breaths/min	3

graft nonfunction (PNF) and DGF compared to grafts from DBD donors.[18] Ischemic cholangiopathy occurs more frequently if the donor is older, is overweight, and has a prolonged ischemic period. Heart and lungs are susceptible to ischemia and only a few cases of the successful use of such grafts from DCD donors have been reported.[16]

ISCHEMIA-REPERFUSION INJURY AND ORGAN PRESERVATION

Ischemia-reperfusion injury of transplanted grafts is unavoidable. It is easy to understand that an interruption of the blood supply during the ischemic period results in metabolic and pathophysiologic changes. Surprisingly, restoration of blood flow and reoxygenation can also cause tissue injury, as well as profound immune and inflammatory responses.[19,20]

Ischemia-reperfusion injury results from a wide range of pathologic processes. During ischemia, a lack of oxygen supply leads to a depletion of adenosine triphosphate (ATP) and glycogen. Without ATP, sodium-potassium (Na-K) pumps cannot maintain ion gradients across the cellular membrane. As a result, extracellular sodium ions move into cells, causing swelling. Vascular permeability is increased since intracellular cyclic adenosine monophosphate (cAMP) levels and adenylate cyclase activity is decreased.[19] The restoration of the blood supply causes a series of pathophysiologic changes that lead to tissue injury. Reperfusion-related injuries include necrosis, apoptosis (programmed death), and autophagy-associated cell death. Reperfusion also activates autoimmune responses including natural antibody recognition of neoantigens, activation of the complement system, activation of innate and adaptive immune responses, and cell migration to the affected area.

After procurement, organs are routinely stored in a cold (4° C) preservation solution to slow the metabolic rate. Various cold-storage solutions are used worldwide with the University of Wisconsin (UW) solution one of the most widely used. The UW solution contains high potassium and adenosine to supply ATP during cold storage. Recently, histidine-tryptophan-ketoglutarate (HTK) solution, originally developed for cardioplegia and subsequently applied to organ preservation in Europe, has gained popularity in the United States.[21] The potential for hyperkalemia during organ reperfusion (particularly with the liver) increases when the UW solution is used, compared with the HTK solution. However, the graft is typically flushed with colloid before reperfusion, regardless of the solution used, which decreases the likelihood of severe hyperkalemia. Recent data suggest that the HTK solution may be associated with poor graft function in abdominal organ transplantation.[22,23] Organ-specific solutions, such as Perfadex solution (manufactured by Vitrolife in Göteborg, Sweden) for the lung and Celsior solution (manufactured by Genzyme in Cambridge, MA) for the heart, are available. Although cold ischemia time should be minimized, the various storage times vary by organ. Generally accepted cold ischemia times are 24 hours for the kidney, 12 hours for the liver, 6 hours for the heart, and 4 hours for the lung. Even within these time windows, however, shorter storage times are preferred. In one study, reperfusion syndrome was avoided during liver transplantation when the cold ischemia time was less than 6 hours.[24] However, longer storage times allow transportation of the graft to the highest acuity patient.

In addition to the preservation solution, various techniques have been used to minimize the effects of storage, including continuous perfusion (as opposed to flushing) with a hypothermic or normothermic solution.[25] The potential advantage for perfusion techniques is a reduction in proinflammatory cytokine expression, as well as less activation of adhesion molecules and migration of leukocytes.[25] Recent reviews of data from the Scientific Registry of Transplant Recipient (SRTR) suggest an association between machine perfusion and a reduction in DGF, particularly in high-risk donors.[26] In addition, the function of procured organs can be assessed during normothermic perfusion preservation, which is particularly useful for heart grafts. However, normothermic continuous perfusion uses red blood cells and costly equipment, making it less practical.[27] Nonetheless, oxygen can be added into the perfusion

solution, which may restore cellular levels of ATP.[28] Several pharmacologic and biologic agents have been tested in animal models and preclinical trials; some, including recombinant agents that block leukocyte adhesion, have shown promise.[29,30] Preconditioning with volatile anesthetics has been shown to protect tissue from ischemia-reperfusion injury in animal models.[31] In human trials, volatile anesthetics have some beneficial effects in the setting of myocardial infarction, minimizing ischemia-reperfusion injury, although the data remain inconclusive.[32]

EXTENDED CRITERIA DONOR

Traditionally, DBD organ donors are young and otherwise healthy until stricken by an isolated cerebral event or head injury (SCDs). As the numbers of patients waiting for transplant increase, many centers have extended donor criteria to minimize waiting-list mortality. Many terms, including suboptimal donor, marginal donor, inferior donor, nonstandard donor, and high-risk donor, have been used.[33] The criteria that make up the ECD group are more elusive and evolving. Donor characteristics of ECDs vary from organ to organ but generally include advanced age, prolonged cold ischemia time, inferior organ function, and other comorbidities.[33,34] In kidney transplantation, SRTR defines ECD kidneys as those whose relative risk of graft failure is greater than 1.7 when compared with normotensive donors aged 10 to 39 years who exhibit normal renal function and who did not die as a result of a cerebrovascular accident. These include grafts from donors 60 years of age or older, as well as donors aged 50 to 59 years who have two of the following characteristics: history of hypertension, death caused by cerebrovascular accident, or preterminal serum creatinine level greater than 1.5 mg/dL[12] (Box 75-1). In liver transplantation, important ECD variables include advanced age, prolonged hospital stay, prolonged ischemia time, and macrosteatosis[35] (Box 75-2). In lung transplant, low PaO_2 values (<300 mm Hg) at the time of harvest, purulent secretions confirmed by bronchoscopy, and smoking more than 20 pack-years are significant factors for early- and long-term adverse outcomes.[36]

Recently, a donor risk index (DRI) has been defined for liver grafts. DRI is a quantitative assessment of the risk of graft failure associated with the donor. Liver DRI is calculated from several donor characteristics including increasing age, decreasing height, DCD graft (yes or no), split or partial grafts (yes or no), African-American race (yes or no), cause of death other than anoxia or cerebrovascular accident, national (versus regional) sharing, and cold ischemia time longer than 8 hours.[37] Despite an increased risk of graft failure, moderate-to-high acuity transplant candidates who receive a high DRI graft have a survival benefit compared with those remaining on the wait-list.[38] Calculation of the DRI can help physicians make a decision to accept or reject a donor offer; however, the calculation requires a projected cold ischemia time. Machine perfusion and dual kidney transplantation have been shown to reduce DGF in ECD kidney transplantation.[26]

The use of ECD or high-risk DRI grafts has implications on intraoperative management. In a study of liver transplantation, several donor characteristics are associated with a high incidence of intraoperative hyperkalemia in adults: DCD grafts, prolonged ischemia time, and prolonged donor hospital stay before procurements.[39] ECD liver grafts are also associated with postreperfusion syndrome, intraoperative bleeding, and postoperative reoperation.[40]

BOX 75-1 ***Extended Donor Criteria for Kidney Donors***

Donors >60 years of age
Donors 50 to 59 years of age with two of the following three characteristics:
- History of hypertension
- Death caused by cerebrovascular accident
- Preterminal serum creatinine level >1.5 mg/dL

MANAGEMENT OF ORGAN DONORS BEFORE PROCUREMENT

As previously discussed, various physiologic derangements are common in DBD donors. If not treated, these derangements can lead to graft deterioration, resulting in organs unsuitable for transplantation. A discussion of treatment strategies follows.

CARDIOVASCULAR MANAGEMENT

Although both hypertension and hypotension are associated with brain death and can result in poor perfusion to the organs, hypotension is more profound and difficult to treat. Maintaining adequate intravascular volume is probably the most effective therapy for vasoplegia. No evidence demonstrates that a specific crystalloid solution is superior to another. Adequate resuscitation, as evidenced by a mean arterial pressure of 60 to 100 mm Hg, may decrease cytokine levels and increase the number of organs available for transplantation.[41] Large doses of starch-based colloids should be avoided because they may be associated with DGF[42] (also see Chapter 61).

When hemodynamic stabilization is not achieved with fluid resuscitation, vasoactive drugs should be considered. Dopamine is most commonly used in this setting. If a large dose of dopamine is required, then a second vasoactive agent can be added. Dopamine and other catecholamines have beneficial antiinflammatory and immunomodulatory effects. Vasopressin is recommended as the initial therapy of choice for potential heart donors by the American College of Cardiology.[43] Vasopressin reduces catecholamine requirements and is an effective treatment for diabetes insipidus.

For a potential heart donor, cardiac function should be assessed, with early interventions to improve the donor procurement rate. Echocardiography is useful since it can identify both functional and structural abnormalities (also see Chapter 46). Functional abnormalities identified in the early stage can be managed before heart transplantation, whereas structural abnormalities may preclude transplantation. Coronary angiography is useful in older donors with suspected or known coronary artery disease. Myocardial damage caused by catecholamine storm may be prevented or attenuated by controlling cardiovascular responses, which may increase the number of heart transplants.[11] However, large doses of norepinephrine are associated with increased cardiac graft dysfunction and increased recipient mortality.[44]

Excessive intravascular fluid therapy may have detrimental effects and should be avoided in lung donors. Fluid restriction increases the number of lung grafts available for transplantation.[10] Because this practice creates a conflict of interest on the basis of which organs will be procured, particularly between the lungs and kidneys, fluid management should be balanced to optimize overall donation potential.[10] The goal is to maintain a euvolemic state and to maintain arterial blood pressure and cardiac output with the least amount of vasoactive support possible. Invasive hemodynamic monitoring may be used to guide intravascular fluid therapy (also see Chapter 59).

PULMONARY MANAGEMENT

The lungs are vulnerable to injury and, consequently, are one of the most difficult organs to preserve. Only 15% to 25% of donated lungs are used in transplantation. Current pulmonary management for potential lung donors favors small tidal volume ventilation. The focus of pulmonary management is to recruit and retain lung units while limiting tidal volume and inspiratory pressure. This strategy is extrapolated from studies in acute respiratory distress syndrome. Specific approaches to ventilator management for the donor are variable, but a common approach is a low tidal volume (6 to 8 mL/kg), low fraction of inspired oxygen concentration (FiO_2), and relatively high positive end-expiratory pressure (PEEP).[45] Pulmonary recruitment maneuvers, using pressure-controlled ventilation and high PEEP (15 cm water [H_2O]), followed by a return to conventional volume-controlled ventilation with a lower PEEP, are recommended by others. The administration of aerosolized terbutaline increases alveolar fluid clearance via β-adrenergic stimulation.[46] As previously discussed, a large amount of intravascular fluid and/or large-dose vasopressors are associated with impaired graft function in potential lung donors.[10]

Adequate gas exchange and good oxygenation are the most important indicators of the functional quality of the lung. However, an initial PaO_2/FiO_2 ratio less than 300 mm Hg should not be used as grounds for exclusion. Reversible processes such as secretions, pulmonary edema, and atelectasis can affect the PaO_2/FiO_2 ratio. Bronchoscopy is generally performed to remove mucous plugs that are present.

TEMPERATURE

Donor management should include active warming to maintain a body temperature above 35° C before and during organ procurement (also see Chapter 54).

HORMONES, STEROIDS, AND ELECTROLYTES

Hormonal deficiency is common in brain-dead donors and hormonal replacement is beneficial.[8,10] Exogenous replacement of antidiuretic hormone in brain-dead donors improves graft function in kidney, liver, and cardiac recipients.[10] Thyroid hormone replacement improves the number of organs transplanted per donor.[41] However, most studies showing advantages to hormone supplement are retrospective; adequately powered randomized trials are lacking.

The systemic inflammatory response associated with brain death leads to pulmonary infiltration of neutrophils and the elevation of interleukins. The systemic inflammatory response of the donor is associated with graft failure and recipient mortality. Methylprednisolone administration can moderate the inflammatory response and may improve oxygenation, reduce lung water, and increase lung yield. Methylprednisolone administration can also decrease inflammation in the liver, heart, and kidney.

Intravascular volume replacement is essential in the management of diabetes insipidus. After administering initial fluid to correct hypovolemia, hypernatremia should be treated by giving a hypotonic solution.[10] Studies have demonstrated that donor hypernatremia (>155 mmol/L) is associated with poor post–liver transplant outcomes.[47] Analysis of heart donors in Europe showed increased recipient mortality when donor sodium was less than 130 or greater than 170 mmol/L.[48] Correction of severe hypernatremia before organ procurement appears to attenuate post–transplant liver dysfunction.[10] Hyperglycemia in the donor is common and exacerbated

by steroid therapy. Poor glucose control adversely affects donor renal function.[49] Insulin management should target a glucose level between 120 and 180 mg/dL.

DONOR MANAGEMENT GOALS

Recent recommendations stress the use of standardized donor management with specific preprocurement goals designed to increase the number of organs transplanted per donor. The objective of donor management goals (DMGs) is to maintain cardiovascular, pulmonary, renal, and endocrine homeostasis. However, goals typically vary from center to center and in published reports (Table 75-3). In 2009, a study examined six preset clinical DMGs and found that compliance with all six goals significantly improved the number of organs transplanted. However, the benefit was more obvious in SCDs than in ECDs for unclear reasons.[50]

TABLE 75-3 DONOR MANAGEMENT GOALS (DMGS), AS REPORTED BY VARIOUS AUTHORS

Preset Clinical End Points	Six DMGs*	Eight DMGs†	Ten DMGs‡
Mean arterial pressure (mm Hg)	≥60	60-120	60-100
Central venous pressure (mm Hg)	≤10 (or serum osmolality 285-295 mmol/L)	4-12	4-10
Final sodium (mmol/L)	≤155	≤155	135-160
Pressors	≤1 (1 plus vasopressin to treat DI is acceptable)	≤1 or low dose	≤1 and low dose
PaO_2 (mm Hg) or PaO_2/FiO_2 ratio	PaO_2 ≥300 while on 100% oxygen (or $Paco_2/FiO_2$ ratio >3)	Final PaO_2 >100	PaO_2/FiO_2 ratio: >300 on PEEP = 5 cm H_2O
Arterial blood gas: pH	7.25-7.50	7.30-7.50	7.30-7.45
Glucose (mg/dL)		≤150	<150
Urine output (mL/kg/h) in 4 hours before procurement		0.5-3.0	1-3
Ejection fraction of left ventricle			>50%
Hemoglobin (mg/dL)			>10

‡Malinoski DJ, Daly MC, Patel MS, et al: Achieving donor management goals before deceased donor procurement is associated with more organs transplanted per donor, J Trauma *71(4):990-995,* 2011, discussion, p 996.

A prospective study examined eight common DMGs and confirmed that meeting or exceeding seven out of eight DMGs increased organ recovery and transplantation rates. Some goals are more important than others. An analysis of individual goals showed terminal PaO_2 (>100 mm Hg or >80 mm Hg on FiO_2 ≤40%), low pressor use (≤1 pressor dose and low dose), and glucose concentration of or less than 150 mg/dL were independent predictors of the high-organ yield. Lungs were 10 times more likely to be transplanted when the PaO_2 was maintained above 100 mm Hg. Tight glucose control was a significant predictor for pancreas and lung transplantation. Thoracic organs were the most affected organs by the achievement of DMGs.[51]

Another study used 10 predefined DMGs, and compliance with 8 or more out of 10 goals increased the likelihood of providing more than 4 organs per donor. Among the 10 preset goals, 4 individual goals were highly significant for organ yield: (1) central venous pressure (CVP) between 4 to 10 mm Hg, (2) ejection fraction greater than 50%, (3) PaO_2/FiO_2 ratio greater than 300 mm Hg, and (4) serum sodium less than 150 mmol/L. Other variables (e.g., age, serum creatinine concentration, thyroid hormone therapy) were also important predictors of the number of organs recovered.[41] Early achievement of DMGs is important. Donors with four or more organs transplanted per donor have significantly more individual DMGs met at the time of consent. Efforts should focus on early management in patients with catastrophic brain injury until the intent to donate is known[52] (also see Chapter 76). One study showed that only 15% of donors met DMGs at the time of consent, although the rate was higher immediately before organ procurement.

MANAGEMENT OF DONORS AFTER CARDIAC DEATH

The majority of DCD donors are patients awaiting cardiac arrest in the ICU (category III). To minimize warm ischemia time, life support is usually withdrawn in the surgical unit. However, the family's desire to be present has led some institutions to withdraw life support in other nearby locations. The procurement team should not take part in patient management before a determination of irreversible death, which includes the period during which withdrawal of support and declaration of death occur. The administration of pharmacologic drugs for the purpose of maximizing donation potential, particularly therapies capable of hastening death, is controversial. However, narcotics and benzodiazepines are commonly continued and can be titrated to blunt sympathetic responses. Premortem administration of heparin can facilitate organ procurement but, because of the bleeding risk, is omitted in some institutional policies. Most protocols require specific consent for premortem donor therapy.

Invasive premortem techniques for reducing warm ischemia time have been described. These include cannulation of the femoral artery and vein before the withdrawal of life support, which allows rapid infusion of cold preservation solution after the declaration of death. These cannulas can also be used for extracorporeal membrane oxygenation (ECMO) after death. However, the

postmortem use of ECMO to restore the blood flow to vital organs generates vigorous debate, which highlights the ongoing ethical questions in donor management—the need to protect the best interest of the dying patient, while facilitating his or her wish to donate.[10]

MANAGEMENT OF ORGAN DONOR DURING PROCUREMENT SURGERY

Anesthesia care for organ procurement is required only in the case of brain-dead donors. The majority of organ procurement occurs at community hospitals, not tertiary medical centers. As a result, the logistics of organ procurement, the social circumstances, and the unusual sequence of intraoperative events may seem intimidating to the anesthesiologist.

Surgical techniques may vary, depending on whether single or multiple organs are procured. Generally, wide exposure of the surgical field is established via a midline laparotomy extended by sternotomy. A cannula is placed in the aorta to flush the organs with the cold preservation solution. Ice is applied to the surgical field to further protect the organs. The organs are removed with their vascular structures after isolation in an order according to their susceptibility to ischemia, with the heart first and the kidney last.

Most donors arrive in the surgical unit already tracheally intubated and supported by the intravenous administration of vasoactive drugs. During procurement surgery, patients can have movements resulting from spinal reflexes; therefore, neuromuscular blockers are desirable. Spontaneous spinal reflex or surgical stimulation can cause catecholamine release and hypertension. Hypertension can be managed by a number of drugs including vasodilators, opiates, and anesthetics; however, volatile anesthetics are commonly preferred. As previously mentioned, volatile anesthetics may provide additional benefits that include ischemic preconditioning and the reduction of ischemia-reperfusion injury.[53]

The intravascular administration of fluids and vasoactive drugs can treat blood loss and cardiovascular instability caused by surgical manipulation. Maintaining hemodynamic stability allows surgeons to procure the organs without further damage to the organs. Vasodilators such as phentolamine or alprostadil (for lung recovery) may be administered during cross-clamping with the goal of decreasing systemic vascular resistance and allowing an even distribution of the preservation solution. Clinically significant bradycardia in brain-dead donors does not respond to atropine; therefore, a direct-acting chronotrope such as isoproterenol should be readily available (also see Chapter 76). Heparin is usually administered before cross-clamping the aorta. If recovery of the heart or lung is anticipated, then pulmonary artery catheters and/or CVP catheters need to be withdrawn before cross-clamping. If lung recovery is anticipated, then the lungs are ventilated well beyond cross-clamping. Communication between the surgical team and the anesthesiologist is crucial to ensure optimal organ quality. As soon as the organs are perfused with the cold solution, mechanical ventilation and anesthesia care can be stopped.

MANAGEMENT OF LIVING ORGAN DONORS

Living donor organ transplantation has been successfully used as an alternative to deceased donor transplantation. In the United States the number of living donor organ transplants is increasing, primarily attributable to living donor kidney transplantation. In some Asian countries such as Japan and Korea, living donor transplantation is a standard procedure since donation after brain death is unusual because of cultural beliefs in these countries. Living donor organ transplantation has some advantages. The procedure can be scheduled as elective surgery at the same facility, which allows donor and recipient surgeries to be coordinated and the cold ischemia time to be minimized. Additionally, the graft is not exposed to the physiologic alterations associated with DBD or DCD donors. Living donors direct their donation to a specific recipient; therefore, the timing of the transplant can be optimized for the recipient, and prolonged waiting times associated with deceased donor transplantation are typically avoided. As a result, the recipient is generally in better overall condition. Although living organ transplantation has its advantages, it exposes healthy donors to medical risks. Additional concerns are potential decreased quality of life and an adverse financial impact after donation. The ethical aspect of living organ donation, particularly liver donation, continues to be vigorously scrutinized.[54,55]

Living donation should be preceded by a thorough medical, psychologic, and social evaluation that confirms the absence of contraindications and the lack of coercion. The informed consent includes full disclosure of possible complications and is facilitated by a patient advocate in many institutions with no relationship to the recipient. In the past, donors were typically related to the prospective recipient. Although the total number of living related donors is not increasing, the numbers of living unrelated (mostly kidney) donors has significantly increased in the last 10 years. Living unrelated donors now account for 28% of all living kidney donors in the United States.[56,57] Recently, paired or chain donation for kidney transplantation has been widely publicized. Paired donation allows two recipients with incompatible living donors to exchange donors, improving the graft match for both recipients. In chain donation, more than two donor-recipient pairs are involved. Similar to the expansion of deceased donor criteria, living donor criteria have been extended to include donors of advanced age and those with obesity.[58]

LIVING KIDNEY DONOR

Because the kidney is a paired organ, the kidney is a natural choice for living donation. The first successful kidney transplant was a living organ transplant performed between identical twins in 1954. Now, living donors account for approximately 40% of kidney transplants in the United States.[59] Living donor kidney transplantation provides the optimized timing for transplant and can avoid pretransplant dialysis, which is associated with improved survival.[56] In addition, living donor grafts provide better function and last longer than grafts from deceased donors.[60] A wide range of medical

and nonmedical factors need to be considered to ensure donor safety. To ensure a sufficient reserve after donation, many transplant centers use a glomerular filtration rate (GFR) greater than 80 mL/min/1.73 m^2 as a cutoff for donation. GFR is typically estimated by the measurement of urine creatinine clearance. If the estimated GFR is marginal, then radioactive and nonradioactive tracers can provide additional information.[61] Some centers allow a lower GFR.[62]

Traditionally, living kidney donor surgery was performed via open nephrectomy via a subcostal lateral incision. Now, it is commonly performed via laparoscopy. With this approach, donors experience less postoperative pain, a faster recovery, and a shorter hospital stay.[62] Either the left or the right kidney can be used for transplant; however, the left kidney is usually preferred because of the easier surgical exposure and longer vascular supply. The right kidney has a short vein, and its artery courses posterior to the inferior vena cava.

The patient is placed in a lateral position with the table flexed and the kidney rest elevated (also see Chapter 41). The surgical procedure begins with mobilization of the kidney with subsequent identification and dissection of the ureter, renal vein, and artery, and separation of the adrenal vein. When the right donor nephrectomy is performed, additional steps include duodenal mobilization and separation of the kidney from the liver. After mobilization of the kidney and clamping of the vascular structures, the kidney is retrieved through a small incision by either a hand-assisted or non–hand-assisted technique. Donor nephrectomy can be performed via a transabdominal route but is increasingly accomplished via a retroperitoneal approach using minimally invasive techniques. The advantage of a retroperitoneal approach is less manipulation of intraabdominal viscera. Single-incision donor nephrectomy has been described using uniquely designed devices. Recently, robotic-assisted laparoscopic living donor nephrectomy has been reported.[62,63] This technique may further decrease the trauma and discomfort to the donor (also see Chapter 87).

Anesthetic management of elective laparoscopic donor surgery on a healthy patient is similar to that used for elective laparoscopic nephrectomy. Standard noninvasive monitors are usually sufficient. One or two large-bore peripheral intravenous lines are usually placed. Transfusion of red blood cells is rare; however, type and screen, or type and cross for 1 to 2 units of blood, is routine practice in some centers in case of injury to major vessels. General anesthesia is required for laparoscopic nephrectomy and general anesthesia combined with epidural anesthesia is often used if open nephrectomy is planned.

Although laparoscopic nephrectomy on a healthy patient may be routine, some concerns in addition to potential blood loss exist. High intraabdominal pressure reduces venous return and has been associated with postoperative renal dysfunction. Lower insufflation pressure may prevent compression of the renal veins and parenchyma.[64] Adequate intravascular fluid administration appears to be the best strategy to preserve kidney function. Some advocate liberal fluid administration (10 to 20 mL/kg/hr), although laparoscopic nephrectomy is typically associated with minimal blood loss. Others use urinary output as an indicator for fluid management. To ensure that the urinary output is greater than 2 mL/kg/hr, fluid is usually given in excess of the physiologic need throughout the procedure. The surgeon may request the administration of furosemide and/or mannitol during the surgery for the purpose of increasing urine output. The preferred type of fluid for intravascular volume expansion during donor nephrectomy is not known. In the absence of evidence, most centers use an isotonic crystalloid solution. Nitrous oxide is best avoided because of a concern over bowel distention and poor surgical exposure. Intravenous heparin (3000 to 5000 international units [IU]) is often administered immediately before the renal vessels are clamped. Protocols may vary among institutions, and close communication with the transplant surgeon is essential. If hypotension occurs after adequate fluid replacement, then dopamine and ephedrine are preferable to direct-acting vasopressors to minimize vasoconstriction in the graft. After the kidney is retrieved, anesthesiologists should be prepared for a quick closure and ensure that neuromuscular blockade is reversed (also see Chapter 35).

Mild or moderate pain after laparoscopic nephrectomy originates from the port insertion, the abdominal incision, pelvic organ manipulation, diaphragmatic irritation, and/or ureteral colic. Postoperative pain can be easily managed in most patients with supplemental intravenous opioids in the early postoperative period and later with oral opioids and acetaminophen. Nonsteroidal antiinflammatory drugs should be used with caution because of their potential prostaglandin-mediated adverse renal effects. Pain after open nephrectomy with subcostal lateral incision is severe and can last several days, which can limit the patient's efforts to breathe, cough, and move, leading to atelectasis and postoperative infection. Postoperative epidural analgesia should be considered for pain relief in these patients (also see Chapter 98).

Postdonation complications reported to the Organ Procurement and Transplantation Network (OPTN) within 6 weeks of surgery include the need for blood transfusion (0.4%), readmission (2.1%), interventional procedures (0.9%), and reoperation (0.5%).[59] A study of more than 80,000 living kidney donors showed a 90-day mortality of 3.1 per 10,000 donors (0.03%) and remains unchanged in the last 15 years.[65] Pulmonary embolism occurred in 0.1% of donors and is the main cause of mortality.[59] Kidney donors are at moderate risk for developing venous thromboembolism; therefore, intermittent pneumatic compression devices and prophylactic heparinization are recommended until ambulation. A decrease of approximately 30% in GFR can be expected after donation, and most donors will maintain a GFR greater than 60 mL/minute at 3 months.[62] Donor nephrectomy does not appear to increase long-term mortality or end-stage renal disease. Within the donor population, the likelihood of postdonation chronic kidney disease, hypertension, and diabetes is relatively higher among certain subgroups, such as African-American and obese donors, but the impact of unilateral nephrectomy on the lifetime risks of adverse events in these subgroups is unknown because the risks without nephrectomy have not been defined.[59]

LIVING LIVER DONOR

Living donor liver transplantation (LDLT) was first introduced in 1988 for pediatric recipients[66] and later expanded to adult recipients. Although LDLT is commonly performed in some Asian countries, it only consists of a small portion (<5%) of overall liver transplants performed in the United States.[1] The primary concern, that of harm to a healthy, altruistic donor, is greater in LDLT, compared with kidney donation.

The liver's remarkable reserve, coupled with its unique capacity to regenerate, forms the basis for LDLT. After resection of as much as two thirds of the liver, the donor's liver regains its original size in 2 to 3 weeks.[67] A portion of the adult liver (typically the left lobe or left lateral segment) transplanted to a pediatric recipient will grow with the recipient. Most LDLTs are electively performed in patients with chronic liver disease. Emergent LDLT is uncommon but is occasionally performed for acute liver failure. LDLT performed in patients with very advanced disease generates considerable debate.

The determination of donor liver volume and anticipated graft size is unique to LDLT. Formulas using demographics, including body weight, height, age, and sex, have been developed. Methods using radiologic or ultrasonic measurements also have been proposed.[68] Accurate estimation of donor liver volume and intended liver graft volume is critical to avoid small-for-size syndrome in the recipient and to preserve adequate remnant liver volume in the donor.[69] For pediatric LDLTs, the left lateral segment (segments II and III) or a total left hepatic lobectomy (segments II, III, and IV) is generally enough to provide sufficient liver mass (Fig. 75-5) (also see Chapter 93). From a surgical point of view, a left hepatectomy is less complex, and the duration of surgery is shorter. Since the first report in 2002, more living donor left lobectomies are performed using laparoscopy.[70] For adult-to-adult LDLT, right hepatic lobectomy is usually required. The surgical technique for right hepatectomy involves separation of the right hepatic lobes (segments V, VI, VII, and VIII) from the left (see Fig. 75-5). Compared with left hepatectomy, right hepatectomy is technically more challenging and associated with more perioperative risk. Right hepatectomy results in a graft weighing 500 to 1000 grams, which leaves the donor with approximately one third of the original liver mass. If one donor cannot provide sufficient liver mass, then a technique using two donors to one recipient has been reported.[71] For a small recipient, the left lobe of a large donor organ may suffice.

Anesthetic management starts with a preoperative discussion with the donor patient and family that addresses the risks and concerns associated with the procedure. Most transplant programs provide extensive educational materials, discussion, and support, beginning well before the day of surgery. General anesthesia with neuromuscular blockade is required for living liver donation surgery (also see Chapter 34). The patient is placed in a supine

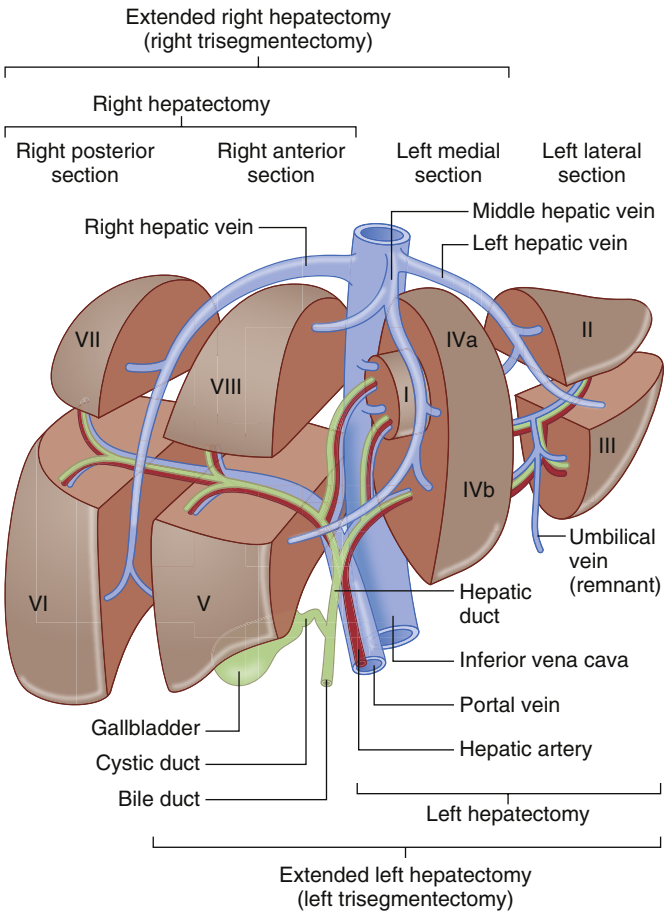

Figure 75-5. Segmental liver anatomy illustrates the segments resected during various partial hepatectomies. *(Redrawn from Steadman RH, Braunfeld M, Park H: Liver and gastrointestinal physiology. In Hemmings HC, Egan T, editors:* Pharmacology and physiology in anesthesia: foundations and clinical applications. *Philadelphia, 2013, Saunders, p 475-486.)*

position and intraoperatively uses the reverse Trendelenburg position to facilitate the exposure of the liver (also see Chapter 41). Two large-bore intravenous catheters are placed. Standard noninvasive monitors and arterial blood pressure monitoring are typically used. A nasogastric tube is placed for decompression of the stomach and surgical exposure.

An L-shaped or standard bilateral subcostal incision with a midline extension is frequently used in living donor surgery. During mobilization of the liver and its vasculature, manipulation of the liver occasionally results in decreased venous return to the heart with episodes of hypotension. The return of the liver to its orthotopic position will relieve the venous obstruction; alternatively, administering short-acting vasoactive agents and/or a fluid bolus will generally treat the problem. Most blood loss occurs during transection of the liver parenchyma. With surgical devices specifically designed for hepatectomy, blood loss during living donor hepatectomy is significantly reduced. After the vasculature of the donor lobe is clamped and divided, the graft is removed, and the vasculature and bile duct are oversewn. The abdomen is closed after hemostasis is achieved.

Blood loss during hepatectomy is a major concern and is associated with adverse outcomes. Placement of the CVP catheter and the use of low CVP (<5 cm H_2O) technique are advocated in some centers to reduce blood loss and transfusion requirements.[72] Low CVP reduces blood loss by increasing venous drainage from the hepatic sinusoids and decreasing blood backflow.[72] In addition, low CVP may reduce graft edema and improve postoperative graft function.[64] Low CVP is most often achieved by intravascular fluid restriction and sometimes by drugs, including diuretics and vasodilators.[72] Others consider the placement of a CVP catheter and low CVP technique unnecessary during hepatic resection surgery because of the inability to demonstrate a relationship between CVP and blood loss.[73] Other factors, including steatosis, body weight, and sex, may be more important than CVP in influencing blood loss during living donor hepatectomy.[74] Potential drawbacks of the low CVP technique are the risk of CVP catheter placement and difficulty reversing hemodynamic disturbances in the event of massive bleeding. Others point out that the use of low CVP originates from early experience with hepatectomy several decades ago, when blood loss was significant. With improved surgical techniques and equipment, blood loss during hepatectomy has been dramatically reduced, making CVP placement and monitoring unnecessary.[73,74] At the authors' institution, CVP placement is rarely used. Peripheral venous pressure measurements in the arm may be measured as an alternative to conventional CVP measurements.[75]

Several other blood-saving strategies have been used in living donor hepatectomy. These include cell salvage techniques and preoperative donation of 1 to 2 units of autologous blood, which reduces the chance of allogeneic blood transfusion (also see Chapter 63). Intraoperative isovolemic hemodilution with retrieval of 1 to 2 units of blood in the surgical unit can minimize the likelihood of blood transfusion.[76] The application of one or more of the blood-saving strategies previously listed is usually sufficient in the vast majority of patients.[73] After the graft is removed, excessive intravascular volume should be avoided because it may impede venous return and result in congestion of the remnant liver.[64]

Most living liver donors can be extubated at the end of the procedure in the surgical unit and transferred to the postoperative care unit. Discontinuation of mechanical ventilation reduces intrathoracic pressure, which reduces congestion in the remnant liver. Admission to the ICU is generally unnecessary but preferred in some institutions. Caution is required with the use of intravenous analgesics and opioids in the immediate postoperative period. The remnant liver is assumed to have some degree of insufficiency, although this assumption has not been thoroughly investigated.[64] Optimal perfusion of the remnant liver is achieved by the maintenance of adequate cardiac output and an avoidance of hypovolemia, anemia, and hypothermia-induced coagulopathy.[64]

The use of epidural anesthesia for postoperative pain control in living donor surgery remains controversial (also see Chapter 98). Similar to other upper abdominal surgery, postoperative epidural analgesia provides excellent pain control with less sedation, compared with intravenous patient-controlled analgesia.[77] By facilitating pulmonary toilet, epidural analgesia reduces the risk of respiratory infections. Despite these advantages, preoperative placement of a thoracic epidural catheter is routinely performed in some transplant centers and is entirely avoided in others. The difference of practice originates from the development of postoperative coagulopathy in patients after donor hepatectomy. Postoperatively, thrombocytopenia occurs while the prothrombin and activated partial thrombin times are prolonged. These changes peak on postoperative day 2 to 3, followed by a steady trend toward normalization in the following days.[78] Thus concern over the potential development of an epidural hematoma is the basis for avoiding epidural catheter placement. Several studies examining the use of the epidural catheter in this population report no adverse effects. In a study of 755 donors who received an epidural catheter for postoperative pain management, no complications associated with the epidural catheter were reported.[79] Another study including 242 living liver donors also showed that epidural analgesia seems to be a safe option when carefully used.[78] Another piece of evidence supporting epidural placement is that hypercoagulability, not hypocoagulability measured by thromboelastography (TEG), can develop in the majority of patients after hepatectomy.[80] Despite the low overall incidence of epidural hematoma, these studies are criticized for a lack of power to assess the risk of this rare event. If the epidural catheter is placed, then the catheter should not be removed until satisfactory coagulation parameters have been retained, which usually takes 3 to 5 days.[64] If the epidural catheter is not placed, then patient-controlled analgesia is used. The choice of pain-control strategy is influenced by the patient's expectations, surgical preferences, institutional consensus, postoperative monitoring capabilities, and nursing staff familiarity with the various techniques.

Worldwide, a number of LDLT-related donor complications, including mortality, have been reported.[81,82]

A recent multicenter observational study of 760 adult-to-adult LDLTs with up to 12 years of follow-up revealed that 40% of donors had complications (Table 75-4).[83] A total of 19% of donors had more than one complication. Although most of the complications were not associated with residual disability, some were severe. Infection is the most common complication and biliary complications such as bile leaks or stricture can be difficult to treat and can lead to prolonged hospital stays with the possibility of further surgery. Higher preoperative creatinine levels, intraoperative hypotension, and intraoperative transfusion are associated with donor complications. Increased institutional experience is not associated with decreased complications.[81] One report of 1263 living donor hepatectomies found that donors who had a right hepatectomy had higher complication rates than donors who underwent left hepatectomy surgery.[64,82]

LIVING LUNG DONOR

Living lung transplantation is an alternative to deceased lung transplantation. Typically, two donors are used for one recipient in living lung transplantation, although the use of a single living donor has been reported.[84] If two donors are involved, then careful coordination and timing of the anesthetic induction of the two donors and recipient are required. The right lower lobe of one donor and the left lower lobe of the second donor are implanted in the recipient in place of the whole right and left lungs. Donor lobectomy requires sufficient bronchial, arterial, and vein cuffs to permit successful anastomoses. A bronchial air leak can result in a prolonged need for chest tube drainage, which lengthens hospital stay.

After the induction of general anesthesia, a single-lumen endotracheal tube is usually placed initially to facilitate fiberoptic bronchoscopic examination before incision. Once a decision is made to proceed, a left-sided double-lumen endotracheal tube later replaces the single-lumen endotracheal tube. Standard noninvasive monitors, intraarterial blood pressure monitoring, and capnography may be sufficient. After placing the donor in the lateral decubitus position and rechecking the double-lumen tube position by fiberoptic bronchoscope, a thoracotomy is performed. Intraoperative cardiorespiratory and metabolic homeostasis minimizes the risk of postoperative complications. Prostaglandin E_1 is usually intravenously administered to dilate the pulmonary vessels with titration according to systemic blood pressure (hypotension needs to be avoided). After mobilization is complete, the lung is reinflated for 5 to 10 minutes, followed by the administration of heparin and a steroid. Transection of the lung is performed after the lung is recollapsed.

Thoracic epidural analgesia is a useful adjunct for perioperative care. The epidural catheter may be placed hours before surgery.[64] Although this approach may be questionable in patients undergoing heparinization, the superiority of postoperative analgesia and the avoidance of atelectasis and infection appear to justify the risk of donor epidural catheterization.[85]

TABLE 75-4 **TYPE AND FREQUENCY OF COMPLICATIONS OF LIVING LIVER DONORS**

Complications	Frequency (%)
Infections	13.2
Pleural effusion	11.0
Bile leak or biloma	8.1
Incisional hernia	6.6
Psychologic difficulty	5.6
Neuropraxia	3.4
Ascites	2.8
Unplanned reexploration	2.7
Pulmonary edema	2.1
Bowel obstruction	1.6
Intraabdominal abscesses	1.2
Pulmonary embolism	1.0
Pneumothorax	0.8
Deep vein thrombosis	0.8
Biliary stricture	0.7
Portal vein thrombosis	0.5
Inferior vena cava thrombosis	0.4
Total	**40**

Chapter 76

Brain Death

KOH SHINGU • SHINICHI NAKAO

Acknowledgment: The editors and publisher would like to thank Dr. Kenjiro Mori for his contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The first description of cessation of brain functions using a concept similar to the modern definition of brain death appeared in 1959, although the subject became more controversial after the development of organ transplantation. Criteria for brain death were first published in 1968, a year after the first heart transplantation. Although cultural and religious diversity may lead to great differences in attitudes toward brain death and no global consensus in diagnostic criteria exists, the concept of brain death as defining the death of the individual is widely accepted and many countries have published recommendations or legal requirements for the diagnosis of brain death, particularly as a necessary prerequisite for organ donation.
- The traditional concept of death has used the cessation of cardiac and respiratory functions as its basis because of the acceptance of simple and nonmedical concepts: that life begins with the first inspiration after birth, that death comes with the last expiration, and that cardiac activity ceases within a few minutes of the last expiration. In contrast, the modern concept of brain death adopts the conclusions of modern biologic science (central integrator theory of the brain): that the central nervous system (CNS), including the brainstem, is the control center for the living organism; that cessation of CNS functions represents cessation of the harmony of life; and that without CNS control, the living organism is nothing more than an aggregation of living cells. However, this notion has become controversial, because not all brain-dead patients inevitably deteriorate to cardiovascular collapse in a short time and they can assimilate nutrients, fight infections, heal wounds, and carry out a pregnancy.
- Trauma to the brain or cerebrovascular injury produces brain edema. Because the brain is covered by a rigid bony skull, edema is accompanied by an increase in intracranial pressure, which, if sufficiently high, exceeds arterial blood pressure. When cerebral circulation ceases, aseptic necrosis of the brain ensues. Within 3 to 5 days, the brain becomes a liquefied mass. Such increased intracranial pressure compresses the entire brain, including the brainstem, and total brain infarction follows.
- Clinical studies indicate that hypothalamic and anterior pituitary functions are preserved to some degree for a certain period after the onset of brain death. The response of the immune system to stimulation is modified considerably after total and irreversible loss of CNS functions. Hormonal changes and inflammatory responses after brain death are the theoretical and scientific basis of hormonal therapy for hemodynamic stabilization of brain-dead organ donors.
- During the process of brain death after head injury or intracranial bleeding, intracranial pressure increases and compression of the brainstem leads to marked hypertension and bradycardia (i.e., Cushing phenomenon). At the onset of brain death by tonsillar herniation, sudden decrease of arterial blood pressure occurs, but the arterial pressure gradually returns to normal with the spinal cord gaining automaticity.
- Determination of brain death confirms the irreversible cessation of all functions of the entire brain, including the brainstem. Irreversibility means that no treatment may be reasonably expected to change the condition. Although testing all functions of the brain is conceptually impossible, the cessation of all functions of the brain is practically determined by loss of consciousness, loss of brainstem responses, apnea, and confirmatory tests.

KEY POINTS—cont'd

- Cerebral death, the so-called persistent vegetative state, refers to cessation of the functions of the cerebral cortices. It is not the equivalent of death.
- It is true that cultural and religious diversities may affect the notion of death, but there is a significant variability in policies and practices for determining brain death internationally and even among states and hospitals.
- Tests to confirm brain death include an electroencephalogram, evoked responses, and measurement of blood flow.
- The concept of brain death has been developed with the development of organ transplantation. The "dead-donor rule," which requires that patients must be declared dead before the removal of any life-sustaining organs and the retrieval of organs for transplantation should not cause the death of a donor, is the ethical and legal axiom.
- Because of a critical shortage of organs for transplantation, not only donation after brain death but also donation after circulatory death has been increasing.
- Because of their intact spinal cord and the presence of somatic and visceral reflexes, brain-dead patients require special anesthetic management, including use of muscle relaxants, vasodilators, and perhaps sedation and analgesia. Anesthesiologists should understand the medical and legal definitions of death and the ethical concepts behind them.

INTRODUCTION

Because advancements in medicine have changed the definition and concept of death, legislation also must change accordingly. This issue results from progress in organ transplantation and the increasing number of patients who have a living body but nonfunctioning brain, which is a consequence of discoveries in resuscitative and life support techniques. Such refinements in critical care medicine mean that neurologists, neurosurgeons, and anesthesiologists must be able to make an appropriate diagnosis of death. Although cultural and religious diversity may lead to great differences in attitudes toward brain death and no global consensus exists on diagnostic criteria, the concept of brain death as defining the death of the individual is widely accepted[1,2] and many countries have published recommendations or legal requirements for the diagnosis of brain death as a necessary prerequisite for organ donation.[3,4]

HISTORY

In 1902, Cushing[5] first reported cessation of cerebral circulation when intracranial pressure exceeded arterial blood pressure in monkeys. He also described the use of artificial ventilation to prolong cardiac function for 23 hours after cessation of spontaneous respiration in a patient with a brain tumor. In 1959, Bertrand and colleagues[6] reported the maintenance of respiration by mechanical means for 3 days after death of a patient with otitis media who had circulatory collapse. Repeated seizures had preceded a deep coma. Autopsy revealed extensive brain necrosis of the cerebral and cerebellar cortices, basal ganglia, and brainstem nuclei, which was attributed to cessation of cerebral circulation during artificial ventilation. Wertheimer and colleagues[7] proposed criteria for new clinical states, "death of the nervous system." Also in 1959 appeared the first description of cessation of brain functions using a concept similar to the modern definition of brain death (i.e., *le coma dépassé* or irretrievable coma) by Mollaret and co-workers.[8] Mollaret and Goulon[8] differentiated coma depasse from other coma states, such as vegetative state.

These historical reports support the argument that the concept of brain death is independent of and was established before the start of organ transplantation from brain-dead patients. The heated discussion on brain death started after the first heart implantation by Barnard in 1967, in which the heart was procured after circulatory-determined death in a patient who satisfied criteria for coma depasse. One year later, the ad hoc Committee of the Harvard Medical School to Examine the Definition of Brain Death published its criteria for brain death and defined "irreversible coma as a new criterion for death."[9] The committee deliberations focused on a whole-brain formulation to define brain death. The criteria of "irreversible coma" include (1) unreceptivity and unresponsitivity, (2) no movements or breathing, (3) no reflex, (4) flat electroencephalogram (EEG), and (a) all of these tests shall be repeated at least 24 hours with no change, and (b) exclusion of hypothermia (below 90° F [32.2° C]) or central nervous system (CNS) depressants. In 1981, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research[10] defined the brain as the "primary organ" and justified the application of a whole-brain definition for brain death in the United States. The whole-brain formulation of brain death was acknowledged by statute in the *Uniform Determination of Death Act* (UDDA)[11] by stating that "an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards." This formulation is the one most commonly applied worldwide and forms the foundation for legal codification in many

Western nations. Numerous criteria on brain death have been offered by institutions, state agencies, expert groups, and governments.[1,2,4,12,13] The American Academy of Neurology (ANN) published guidelines for determining brain death in adults in 1995.[12] Guidelines for pediatric patients were published in 1987 by a multisociety task force.[14]

After the publication of UDDA by the President's Commission, there remains considerable controversy whether "brain death" can be defined as the death of a human being, because procurement of organs for transplantation is permitted from the brain-dead patients and medical interventions for brain-dead patients should (can) be withdrawn for medical futility and considering the dignity of the patients' end of life. In 2008, the President's Council on Bioethics published a white paper ("Controversies in the Determination of Death")[15] addressing the issues regarding brain death. The white paper proposed a new term, *total brain failure,* instead of *whole brain death.* Critics have argued that the whole brain is not dead in patients who satisfied the criteria of brain death. One example is the possible presence of integrated neuroendocrine function; such as the persistent release of pituitary hormones like prolactin, growth hormone, luteinizing hormone, and thyroid-stimulating hormone. Second is existence of cases showing remaining electroencephalographic activity, uptake of radioactive material on cerebral blood flow studies, or blood flow in the cerebral angiograms. The white paper also abandoned the concept of "the somatic integration" and the assumption that the brain is the "integrator" of somatic function. The brain has been considered as an integrator of the body, and the brain is necessary for the functioning of the organism as a whole. Therefore, "a patient on a ventilator with a totally destroyed brain is merely a group of artificially maintained subsystems since the organism as a whole has ceased to function." However, this rationale was criticized by Shewmon[16-18] with presentation of cases of persistent homeostasis of liver, kidneys, cardiovascular and endocrine systems, maintenance of body temperature, wound healing, defense functions against infections and foreign bodies (immune system), development of a febrile response to infection, cardiovascular and hormonal stress responses to unanesthetized incision for organ retrieval, successful gestation of a fetus in a brain-dead pregnant woman, sexual maturation of a brain-dead child, and proportional growth of a brain-dead child. The white paper developed a new account of wholeness of a living organism as fundamental work. "Determining whether an organism remains a whole depends on recognizing the persistence or cessation of the fundamental vital work of a living organism—the work of self-preservation, achieved through the organism's need-driven commerce with the surrounding world."[15]

The guidelines for determining brain death in adults and in pediatrics were updated in 2010[19] (Box 76-1) and 2011[20] (Boxes 76-2 and 76-3), respectively.

BOX 76-1 ***Checklist for Determination of Brain Death***

Prerequisites (All Must be Checked)

1. Coma, irreversible and cause known
2. Neuroimaging explains coma
3. Central nervous system depressant drug effect absent (if indicated, toxicology screen; if barbiturates given, serum level <10 μg/mL)
4. No evidence of residual paralytics (electrical stimulation if paralytics used)
5. Absence of severe acid-base, electrolyte, endocrine abnormality
6. Normothermia or mild hypothermia (core temperature >36° C)
7. Systolic blood pressure >100 mm Hg
8. No spontaneous respirations

Examination (All Must be Checked)

1. Pupils nonreactive to bright light
2. Cornea reflex absent
3. Oculocephalic reflex absent (tested only if C-spine integrity ensured)
4. Oculovestibular reflex absent
5. No facial movement to noxious stimuli at supraorbital nerve or temporomandibular joint
6. Gag reflex absent
7. Cough reflex absent to tracheal suctioning
8. Absence of motor response to noxious stimuli in all four limbs (spinally mediated reflexes are permissible)

Apnea Testing (All Must be Checked)

1. Patient is hemodynamically stable
2. Ventilator adjusted to provide normocarbia ($Paco_2$ 34 to 45 mm Hg)
3. Patient preoxygenated with 100% FiO_2 for >10 minutes to PaO_2 >200 mm Hg
4. Patient well-oxygenated with a PEEP of 5 cm H_2O
5. Provide oxygen via a suction catheter to the level of the carina at 6 L/min or attach T-piece with CPAP at 10 cm H_2O
6. Disconnect ventilator
7. Spontaneous respirations absent
8. Arterial blood gas drawn at 8 to 10 minutes, patient reconnected to ventilator
9. Pco_2 >60 mm Hg or 20–mm Hg rise from normal baseline value

OR

10. Apnea test aborted

Ancillary Testing (Only One To Be Performed; To Be Ordered Only If Clinical Examination Cannot Be Fully Performed Because of Patient Factors or If Apnea Testing Inconclusive or Aborted)

1. Cerebral angiogram
2. HMPAO SPECT
3. EEG
4. TCD

Time of death (DD/MM/YY): _____
Name of physician and signature: _____
_____

Wijdicks EFM, Valelas PN, Gronseth GS, Greer DM: Evidence-based guideline update: determining brain death in adults—report of the Quality Standards Subcommittee of the American Academy of Neurology. Neurology *74:1911, 2010.*

EEG, Electroencephalogram; *HMPAO,* hexamethylpropyleneamine-oxime; *SPECT,* single photon emission computed tomography; *TCD,* transcranial Doppler ultrasonography.

BOX 76-2 ***Summary Recommendations for the Diagnosis of Brain Death in Neonates, Infants, and Children***

1. Determination of brain death in neonates, infants, and children relies on a clinical diagnosis based on absence of neurologic function with a known irreversible cause of coma. Coma and apnea must coexist to diagnose brain death. This diagnosis should be made by physicians who have evaluated the history and completed the neurologic examinations.
2. Prerequisites for initiating a brain death evaluation are as follows:
   a. Hypotension, hypothermia, and metabolic disturbances that could affect the neurologic examination must be corrected before examination for brain death.
   b. Sedatives, analgesics, neuromuscular blockers, and anticonvulsant agents should be discontinued for a reasonable period based on elimination half-life of the pharmacologic agent to ensure they do not affect the neurologic examination. Knowledge of the total amount of each agent (milligram per kilogram) administered, because hospital admission may provide useful information concerning the risk for continued medication effects. Blood or plasma levels to confirm high or supratherapeutic levels of anticonvulsants with sedative effects that are not present should be obtained (if available) and repeated as needed or until the levels are in the low to midtherapeutic range.
   c. The diagnosis of brain death based on neurologic examination alone should not be made if supratherapeutic or high therapeutic levels of sedative agents are present. When levels are in the low or in the midtherapeutic range, medication effects sufficient to affect the results of the neurologic examination are unlikely. If uncertainty remains, an ancillary study should be performed.
   d. Assessment of neurologic function may be unreliable immediately after cardiopulmonary resuscitation or other severe acute brain injuries, and evaluation for brain death should be deferred for 24 to 48 hours or longer if concerns exist or inconsistencies are found in the examination.
3. Number of examinations, examiners, and observation periods:
   a. Two examinations, including apnea testing with each examination separated by an observation period, are required.
   b. The examinations should be performed by different attending physicians involved in the care of the child. The apnea test may be performed by the same physician, preferably the attending physician who is managing ventilator care of the child.
   c. Recommended observation periods are as follows:
      (1) 24 Hours for neonates (37 weeks of gestation to term infants 30 days of age)
      (2) Twelve hours for infants and children (>30 days to 18 years)
   d. The first examination determines the child has met neurologic examination criteria for brain death. The second examination, performed by a different attending physician, confirms that the child has fulfilled criteria for brain death.
   e. Assessment of neurologic function may be unreliable immediately after cardiopulmonary resuscitation or other severe acute brain injuries and evaluation for brain death should be deferred for 24 to 48 hours if concerns exist or inconsistencies are found in the examination.
4. Apnea testing:
   a. Apnea testing must be performed safely and requires documentation of an arterial $Paco_2$ 20 mm Hg above the baseline $Paco_2$ and 60 mm Hg or greater with no respiratory effort during the testing period to support the diagnosis of brain death. Some infants and children with chronic respiratory disease or insufficiency may be responsive only to supranormal $Paco_2$ levels. In this instance, the $Paco_2$ level should increase to 20 mm Hg or greater above the baseline $Paco_2$ level.
   b. If the apnea test cannot be performed because of a medical contraindication or cannot be completed because of hemodynamic instability, desaturation to less than 85%, or an inability to reach a $Paco_2$ of 60 mm Hg or greater, an ancillary study should be performed.
5. Ancillary studies:
   a. Ancillary studies (electroencephalography and radionuclide cerebral blood flow) are not required to establish brain death unless the clinical examination or apnea test cannot be completed.
   b. Ancillary studies are not a substitute for the neurologic examination.
   c. For all age groups, ancillary studies can be used to assist the clinician in making the diagnosis of brain death, to reduce the observation period, or when (1) components of the examination or apnea testing cannot be completed safely as a result of the underlying medical condition of the patient; (2) uncertainty exists about the results of the neurologic examination; or (3) if a medication effect may interfere with evaluation of the patient. If the ancillary study supports the diagnosis, the second examination and apnea testing can then be performed. When an ancillary study is used to reduce the observation period, all aspects of the examination and apnea testing should be completed and documented.
   d. When an ancillary study is used because there are inherent examination limitations (i.e., points 1 to 3 in 5c), components of the examination done initially should be completed and documented.
   e. If the ancillary study is equivocal or concern exists about the validity of the ancillary study, the patient cannot be pronounced dead. The patient should continue to be observed until brain death can be declared on clinical examination criteria and apnea testing or a follow-up ancillary study can be performed to assist with determination of brain death. A waiting period of 24 hours is recommended before further clinical reevaluation or repeat ancillary study is performed. Supportive patient care should continue during this period.
6. Declaration of death:
   a. Death is declared after confirmation and completion of the second clinical examination and apnea test.
   b. When ancillary studies are used, documentation of components from the second clinical examination that can be completed must remain consistent with brain death. All aspects of the clinical examination, including the apnea test, or ancillary studies must be appropriately documented.
   c. The clinical examination should be carried out by experienced clinicians who are familiar with infants and children and have specific training in neurocritical care.

BOX 76-3 ***Neurologic Examination Components to Assess for Brain Death in Neonates, Infants, and Children, Including Apnea Testing***

Reversible conditions or conditions that can interfere with the neurologic examination must be excluded before brain death testing.

1. Coma. The patient must exhibit complete loss of consciousness, vocalization, and volitional activity.
   a. Patients must lack all evidence of responsiveness. Eye opening or eye movement to noxious stimuli is absent.
   b. Noxious stimuli should not produce a motor response other than spinally mediated reflexes. The clinical differentiation of spinal responses from retained motor responses associated with brain activity requires expertise.
2. Loss of all brainstem reflexes, including:
   a. Midposition or fully dilated pupils that do not respond to light. Absence of pupillary response to a bright light is documented in both eyes. Usually the pupils are fixed in a midsize or dilated position (4 to 9 mm). When uncertainty exists, a magnifying glass should be used.
   b. Absence of movement of bulbar musculature, including facial and oropharyngeal muscles. Deep pressure on the condyles at the level of the temporomandibular joints and deep pressure at the supraorbital ridge should produce no grimacing or facial muscle movement.
   c. Absent gag, cough, sucking, and rooting reflex. The pharyngeal or gag reflex is tested after stimulation of the posterior pharynx with a tongue blade or suction device. The tracheal reflex is most reliably tested by examining the cough response to tracheal suctioning. The catheter should be inserted into the trachea and advanced to the level of the carina, followed by one or two suctioning passes.
   d. Absent corneal reflexes. Absent corneal reflex is demonstrated by touching the cornea with a piece of tissue paper, a cotton swab, or squirts of water. No eyelid movement should be seen. Care should be taken not to damage the cornea during testing.
   e. Absent oculovestibular reflexes. The oculovestibular reflex is tested by irrigating each ear with ice water (caloric testing) after the patency of the external auditory canal is confirmed. The head is elevated to 30 degrees. Each external auditory canal is irrigated (one ear at a time) with approximately 10 to 50 mL of ice water. Movement of the eyes should be absent during 1 minute of observation. Both sides are tested with an interval of several minutes.
3. Apnea. The patient must have the complete absence of documented respiratory effort (if feasible) by formal apnea testing demonstrating a $Paco_2$ 60 mm Hg or greater and 20 mm Hg or greater increase above baseline.
   a. Normalization of the pH and $Paco_2$ measured by arterial blood gas analysis, maintenance of core temperature above 35° C, normalization of blood pressure appropriate for the age of the child, and correcting for factors that could affect respiratory effort are a prerequisite to testing.
   b. The patient should be preoxygenated using 100% oxygen for 5 to 10 minutes before initiating this test.
   c. Intermittent mandatory mechanical ventilation should be discontinued once the patient is well oxygenated and a normal $Paco_2$ has been achieved.
   d. The patient's heart rate, blood pressure, and O_2 saturation should be continuously monitored while observing for spontaneous respiration effort throughout the entire procedure.
   e. Follow-up blood gases should be obtained to monitor the rise in $Paco_2$ while the patient remains disconnected from mechanical ventilation.
   f. If no respiratory effort is observed from the initiation of the apnea test to the time the of measured $Paco_2$ 60 mm Hg or greater and 20 mm Hg or greater above the baseline level, the apnea test is consistent with brain death.
   g. The patient should be placed back on mechanical ventilator support, and medical management should continue until the second neurologic examination and apnea test confirming brain death is completed.
   h. If oxygen saturations fall below 85%, hemodynamic instability limits completion of apnea testing, or a $Paco_2$ level of 60 mm Hg or greater cannot be achieved, the infant or child should be placed back on ventilator support with appropriate treatment to restore normal O_2 saturations, normocarbia, and hemodynamic parameters. Another attempt to test for apnea may be performed at a later time, or an ancillary study may be pursued to assist with determination of brain death.
   i. Evidence of any respiratory effort is inconsistent with brain death, and the apnea test should be terminated.
4. Flaccid tone and absence of spontaneous or induced movements, excluding spinal cord events such as reflex withdrawal or spinal myoclonus.
   a. The patient's extremities should be examined to evaluate tone by passive range of motion, assuming that no limitations exist to performing such an examination (e.g., previous trauma) and the patient is observed for any spontaneous or induced movements.
   b. If abnormal movements are present, clinical assessment to determine whether these are spinal cord reflexes should be done.

From Nakagawa TA, Ashwqal S, Mathur M, et al; Society of Critical Care Medicine; Section on Critical Care and Section on Neurology of the American Academy of Pediatrics; Child Neurology Society: Guidelines for the determination of brain death in infants and children: an update of the 1987 Task Force recommendations. Crit Care Med *39:2139–2155, 2011.*

In contrast, brainstem definition for brain death was first pronounced in 1976 by the Conference of Medical Royal Colleges and their Faculties in the United Kingdom.[21] The document in 1995 entitled "Criteria for the Diagnosis of Brain Stem Death"[22] encouraged the use of the more correct term *brainstem death* rather than *brain death* and gave a definition of death, stating that "death is defined as the irreversible loss of the capacity for consciousness, combined with the irreversible loss of the capacity to breathe."

In Japan, brain death can be determined only for organ transplantation donor candidates in law, and death of individuals can be diagnosed with the traditional criteria in other situations.

TRADITIONAL CONCEPT OF DEATH OF AN ORGANISM

In Greek antiquity, two concepts existed regarding the body cavity, where "the principle of life," now known as "function of the brain," was housed. One is that of Plato, and another is Aristotle's. Plato first postulated the tripartite soul in the *Republic* and *Timaeus*. The first part is the

reason, the second is emotion, and the third is appetite or desire. Reason, which we might today call consciousness, is the reappearance of the God's soul (the divine), housed in the ideally shaped vessel, in which all distances from the center are the same (i.e., the head). The second soul, emotion, is located in the heart. It affects circulation, and its manifestations—such as pulse rate—are functions that correlate with what we think of as the autonomic nervous system. The neck is constructed as a kind of isthmus or boundary between the head and the chest to ensure that reason is not affected by emotion. The third part of the soul—that is, the appetite for food and drink or sexual desire—is the least noble part. It is housed in the stomach, separated from the heart by the diaphragm and thought to be punished by the bitterness of bile. However, we cannot interpret this too literally, because it was meant to be a sort of analogy for consumption by the ordinary citizen. Plato considered death to be the separation of reason from the mortal body, whereas Socrates, in his *Apology,* confessed that he did not know the fate of reason after death. The vegetative state in today's neurophysiology, is, according to Plato, the equivalent of death.

Unlike Plato, Aristotle, who is known as the founding father of genetics, stressed experience, or empirical knowledge, rather than abstract thinking. Aristotle postulated that all functions of the brain were housed in the heart, which he considered the most important organ of the body—the seat of the intelligence and the origin of motion and sensation. Other organs surrounding it, such as the brain and lungs, existed simply to cool the heart. Aristotle dissected dogs, horses, grasshoppers, crickets, and other living creatures to understand the reasons why, for instance, dogs cannot give birth to horses. He thought that animals "cook" foods in their digestive tracts and that blood transports nutrients to each organ from the heart. This transport corresponds to the electrical signals in the nerves in today's neurophysiology. According to Aristotle, the lungs cool the heart and the cranium serves as a cooling apparatus for liquefying a transmitter, a kind of "pneuma."

In Aristotle's system, the vehicle that conveys commands from the control center to the peripheral organs and tissues, roughly equivalent to the electrical signals of the nervous system in today's neurophysiology, was assumed to be something like vapor or gas. This concept is the basis from which the idea of "pneuma" (breath or spirit) originates. God created man (Adam) out of the dust of the earth and inspired the breath of life into his nostrils, and a man became a living soul. Later, Eve was created from Adam's rib and, with God's breath, became a living soul as well. This story might call to mind the first cry of the neonate, which is the first activity of life caused by the God's "inspiration." This creative breathing, or inspiration, is the subject of Botticelli's painting *The Birth of Venus,* in which Zephyr, the west wind, puffs vigorously as his wife Chloris gently blows her warm breath on Venus, who stands on a shell. Aristotle's idea postulating the heart as the principal seat of the spirit had a profound influence on Western scientific thought for a long period. William Harvey's discovery, described in his *Circulation of Blood* (1628) is considered as the final scientific development of Aristotle's ideas, and Aristotle is the thinker most cited in Harvey's book.

All living organisms take in oxygen by respiration, distribute the O_2 to peripheral tissues through circulation, and then excrete metabolites by means of the circulation and through respiration. Respiration and circulation are vital to the living organism. Respiration is the functional expression of the brainstem, and cessation of brainstem functions leads to the cessation of respiration. Because the brainstem maintains its function through its supply of O_2 and nutrients, cessation of circulation ultimately leads to cessation of respiration. The functions of the brain, heart, and lungs are mutually dependent and share the basic role of maintaining life. An organism dies when one of these life-sustaining organ systems ceases to function. The traditional concept of death of an organism emphasized the cessation of respiration or circulation, without consideration of the role of the brain. This occurred because assessment of brain function was not easy to accomplish. When mechanical ventilation was not widely used, cessation of brain functions related directly to cessation of respiration and assessment of brainstem functions was unnecessary.

THE CONCEPT OF BRAIN DEATH

Brain death represents death of the organism and not merely death or necrosis of the brain in a living body. The organism is an aggregation of living cells, although an aggregation of living cells does not necessarily constitute an organism. An organism exists only when the cell aggregation is under the control of modulating systems such as the CNS, the endocrine system, and the immune system. After any one of these systems ceases to function, death is inevitable unless artificial measures can be taken. The physiologic significance of brain death and cardiac death is essentially equal, and both represent an irreversible loss of communication between the control center and peripheral cells and tissues, as well as loss of modulation of an aggregation of cells. Without these systems, harmonious functioning of individual cells as constituents of the whole organism ceases. Because total and irreversible elimination of immune or endocrine function is not of practical significance, the concept of endocrine or immune death has not developed.

Brain-oriented death can have three forms, defined by the structures (1) whole-brain death, (2) brainstem death, and (3) neocortical death.[23] Whole-brain death and brainstem death are different in their anatomic interpretation, but both are defined as the irreversible cessation of the organism as a whole. Critical roles of brainstem to maintain "life" are well known.[24] Brainstem is (1) the through-station for almost all hemispheric input and output, (2) the center that generates arousal (which is essential for consciousness), and (3) the center of respiration. Further, brain lesion (caused by massive traumatic injury, intracranial hemorrhage, or anoxia) mostly progresses from thalami to the brainstem with increased intracranial pressure. The brainstem is often the last structure to be injured in brain damage. Therefore, brainstem death, which is diagnosed with irreversible (1) loss of consciousness, (2) loss of brainstem reflexes, and (3) apnea, can be defined as death of a human being. Possibly, most of

the brain functions vital to life could be replaced with computers and drugs and the circulatory functions maintained for months or years. The only function advanced technology cannot provide is that constituting humanity or personality, both of which are possibly products of the telencephalon. Therefore, "loss of personality" can be defined with irreversible coma and loss of the capacities for thought, reason, and feeling (irreversible loss of critical cerebral function, or neocortical death). However, it is impossible to ascertain scientifically the inward state of an individual. A case was reported in which functional magnetic resonance imaging (fMRI) revealed retaining the ability to understand spoken commands and to respond to them through brain activity in a patient fulfilling the clinical criteria for a diagnosis of vegetative state.[25] Neocortical death should and can be clearly differentiated from brain death, and it should not be regarded as death of a human being.

MECHANISM OF BRAIN DEATH

Brain injury has a number of sources, such as traumatic or cerebrovascular injury and generalized hypoxia, all of which produce brain edema. Based on the pathologic mechanisms involved, brain edema is classified as vasogenic or cytotoxic.[26] Because it is rare that only one mechanism operates exclusively, the label of vasogenic or cytotoxic is only relative. Vasogenic edema is induced by an increase in cerebrovascular permeability after leaking of serum proteins into the brain parenchyma (i.e., after destruction of the blood-brain barrier). Chemical mediators such as histamine, serotonin, angiotensin, bradykinin, and prostaglandins can disrupt blood-brain barrier function.[27] Cytotoxic brain edema occurs in hypoxic and ischemic conditions and results from disturbance of cellular osmoregulation, a process that depends primarily on energy-dependent functioning of ionic pumps. The disturbance of osmoregulation increases entry of water into brain parenchyma. Although in a pure form of cytotoxic edema the blood-brain barrier would remain basically intact, cytotoxic edema would nevertheless disturb blood flow and induce hypoxia and vasogenic edema. Recent studies have revealed that water channels, aquaporins (AQPs), play important roles in the brain edema formation and resolution after brain injury. AQP4, the most abundant AQP in the CNS, may have dual effects on the brain edema formation and resolution. In the early stage it may facilitate edema formation, but at later points it may be important for the clearance of water from the brain into blood vessels.[28]

Brain edema may be focal at first, but it then spreads throughout the whole brain in a predictable sequence. Because the brain is covered by a rigid bony skull, its edema is accompanied by an increase in intracranial pressure. The critical cerebral perfusion pressures (CPPs) are in the range of 10 to 20 mm Hg (CPP = mean arterial pressure [MAP] – intracranial pressure). Cerebral blood perfusion is lost with less than these critical CPPs (see also Chapters 17 and 70). When cerebral circulation ceases, aseptic necrosis of the brain ensues. Within 3 to 5 days, the brain becomes a liquefied mass, a condition known as respirator brain.[29] Such increased intracranial pressure compresses the entire brain, including the brainstem, and uncal and tonsillar herniation and total brain infarction follow.[30] Brain damage mostly progresses from the thalami to the lower medulla, although not necessarily in a gradual fashion. The medulla oblongata has the longest survival time, and that important finding places emphasis on damage to the lower centers to determine brain death.[31] On the other hand, aside from the usual first pattern of brain death, in which CPP fell to the critical level, Palmer and Bader[32] found the second pattern, in which the intracranial pressure did not exceed the MAP with maintenance of CPP, using brain tissue oxygenation ($Pbto_2$). They suggested that the mechanism for fall in $Pbto_2$ to 0—that is, brain death—might have been primary metabolic failure of the brain.

Brainstem lesion that spares the thalami and cerebral cortex can exist with a hemorrhagic origin. In that case, brainstem death in the absence of clinical brainstem functions despite intact intracranial circulation can be declared by the U.K. criteria. However, such cases with absence of all brainstem functions with apnea but some residual functions of arousal (ascending reticular activating system [RAS]), which is clinically undetected, have never been reported.[23]

NEUROPHYSIOLOGIC BASIS OF BRAIN DEATH

AREAS OF THE BRAIN INVOLVED IN BRAIN DEATH

By definition, brain death is a total irreversible cessation of functioning of the brain. However, "the whole brain" does not require the irreversible cessation of functioning of every brain neuron. Rather, it requires only the irreversible cessation of all clinical functions of the brain, namely, those measurable at the bedside by clinical examination.[2] The brain includes all the CNS structures except the spinal cord. It is generally agreed that brain death does not include lower portions of the spinal cord (caudal from C2), because their location outside the skull spares them from compression during brain edema. Histologic studies of human spinal cord in cases of brain death revealed divergent pathologic findings ranging from histologically intact tissues to complete destruction.[29]

The United Kingdom[21,22,33] and some other countries[3,4] supported a rather exceptional criterion for brain death, one that excludes involvement of the bilateral cerebral cortices. This state, known as brainstem death, does not require recording of an EEG for its diagnosis. In the United Kingdom, no confirmatory test (including an EEG) is required.[34] Grigg and colleagues[35] reported that 11 of 56 clinically brainstem-dead patients (19.6%) had electroencephalographic activity and 2 patients (3.6%) even demonstrated sleeplike cortical electroencephalographic activity for as long as 168 hours, although none of the patients recovered.[35] The rationale for excluding the cerebral cortices is based on the facts that the brainstem, not the cerebral cortices, plays the major role in controlling whole-body vital activities such as respiration,

circulation, and other homeostatic functions and that the reticular formation forms the basis of consciousness. However, some investigators strongly recommend confirmatory tests (EEG, transcranial Doppler, or brainstem auditory evoked potential) in supporting the diagnosis of brainstem death, especially when it is not possible to carry out all of the brainstem tests (e.g., in the presence of high spinal cord injury[36] or if the residual effect of sedative agents cannot be excluded[37]).

AROUSAL AND CONSCIOUSNESS

Moruzzi and Magoun[38] demonstrated the essential role of the brainstem reticular core in activating the cortical EEG. Segundo and associates[39] showed that destruction of the brainstem reticular core leads to a loss of consciousness in laboratory animals. These observations gave birth to the concept of the ascending reticular activating system (ARAS). Although the central insight of this concept—that structures in the brainstem regulate the state of consciousness—still holds true, the ARAS is no longer regarded as a monolithic unit, nor is it restricted to the classically defined reticular nuclei of the brainstem. Maintenance of wakefulness or control of the sleep-wake cycle does not depend exclusively and unalterably on any single region of the brain.[40] With the advance of anatomic and physiologic techniques, neurochemically specific wake-promoting cell groups within the ARAS were identified.[41] These wake-promoting cell groups are (1) noradrenergic cells in the locus coeruleus, (2) serotoninergic cells in the raphe nuclei, (3) acetylcholinergic cells in the pedunculopontine tegmentum and laterodorsal tegmentum, (4) glutamatergic cells in the midbrain, and (5) dopaminergic cells in the substantia nigra compacta and ventral tegmental area. Projections from these pontine and midbrain wake-promoting cells travel dorsally to activate the thalamocortical systems and ventrally to activate the hypothalamocortical and basalocortical systems. Cell groups in the forebrain also promote wakefulness in addition to these ARAS wake-promoting cell groups, such as histaminergic cells in the tuberomammillary nuclei of the posterior hypothalamus, hypocretin (orexin)-containing cells in the lateral hypothalamus, cholinergic cells in the basal forebrain, neuropeptide Y–containing cells in the suprachiasmatic nucleus, and glutamatergic cells in the ventromedial prefrontal cortex. Functions of the neocortex, which play major roles in consciousness, depend on these arousal systems.

In brain death, the patient is believed to have no consciousness, no intellectual activity, and therefore no true humanity. This state is defined as deep coma and is the basis for the concept of brainstem death.

RESPIRATION

The primary respiratory center, consisting of the inspiratory and expiratory neurons, is located in the reticular core of the medulla oblongata. Various abnormal patterns of respiration (e.g., gasping, apneusis, irregular and shallow respirations) are observed in laboratory animals and humans with brainstem lesions. In brain death, spontaneous respiration does not occur in patients even when $Paco_2$ reaches 55 to 60 mm Hg. Confirming apnea is one of the keys for determining brain death. Mechanical stimulation of the carina to induce the cough reflex may be helpful in detecting residual functioning of the medullary respiratory neurons.

Development of neurogenic pulmonary edema caused by brain insult is well known. Catecholamine surge with enhanced sympathetic discharges and release of neuropeptide Y cause pulmonary vasoconstriction and increase in pulmonary capillary hydrostatic pressure. The lungs are also damaged by loss of vasomotor tone, hypotension, and development of systemic inflammatory responses.[42]

CARDIOVASCULAR FUNCTIONS

The central neurons that control the circulatory system distribute diffusely in the pontine and medullary reticular core. Of these neurons, the vasomotor and cardioaccelerating neurons undergo negative-feedback control through the carotid and aortic sinus nerves, which relay at the nucleus tractus solitarius. Activation of these cells induces sympathetic nervous outflow, thereby increasing the heart rate and arterial blood pressure. Hypertension then suppresses these cells through the feedback mechanism, and circulation returns to preactivation levels.

During the process of brain death after head injury or intracranial bleeding, intracranial pressure increases, and compression of the brainstem leads to marked hypertension and bradycardia (i.e., the Cushing phenomenon). In an animal model of brain death, a precise mechanism of cardiovascular responses by the progression of CNS ischemia as a result of an expanding supratentorial mass was studied. When the entire cerebrum was ischemic, vagal activation with resultant decrease in heart rate, mean arterial pressure, and cardiac output was observed. As ischemia progressed rostrally to approach the pons, sympathetic stimulation was added to vagal stimulation, leading to bradycardia and hypertension (the Cushing phenomenon). When the entire brainstem became ischemic, the vagal cardiomotor nucleus became ischemic, with unopposed sympathetic stimulation, leading to tachycardia, hypertension, and high blood levels of catecholamine (i.e., autonomic storm or catecholamine surge).[43,44] Some authorities think that myocardial damage may occur at this stage of autonomic storm, which may contribute to the early failure of some transplants and obscure or complicate the histologic manifestations of rejection in others.[42] However, in humans, this stage of tachycardia and hypertension may be brief, and attempts to reduce blood pressure may not be necessary or even recommended.[44]

When intracranial pressure is elevated, arterial blood pressure suddenly decreases (Fig. 76-1). This sudden decrease is the sign of tonsillar herniation (i.e., herniation of the cerebellar tonsils) through the foramen magnum on the cervical spinal cord, in which outflow of the cardioaccelerating and vasomotor neurons to the spinal cord suddenly ceases. This is one typical onset for brain death. Such dramatic changes in arterial blood pressure are not observed in other types of brain death, such as that induced by hypoxia or those involving other

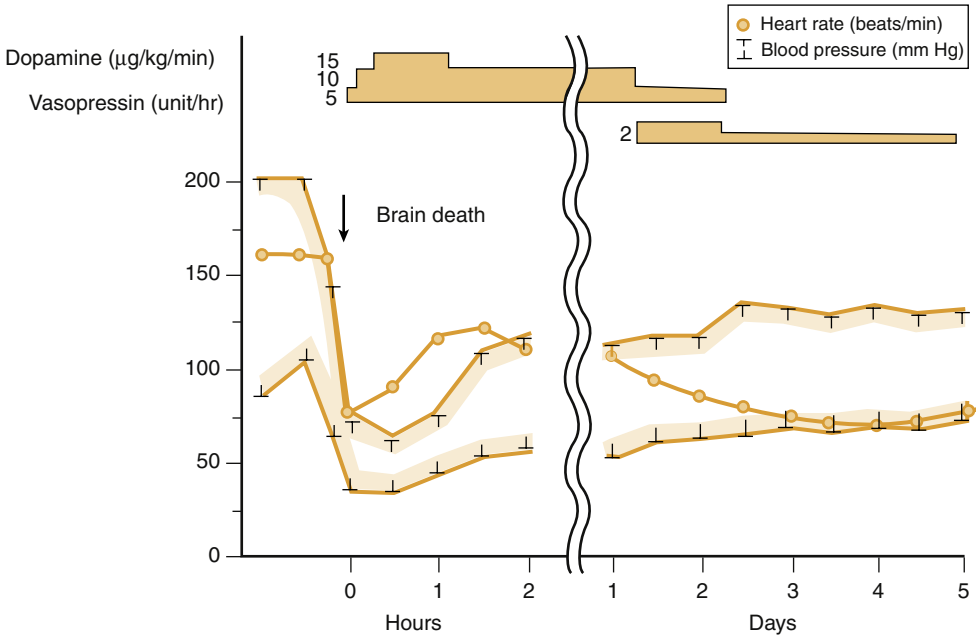

Figure 76-1. The representative time course of arterial blood pressure and heart rate before and after brain death. The 18-year-old male patient was involved in a traffic accident. Sustained hypertension was followed by a sudden and marked decrease in blood pressure. Dopamine was administered to increase blood pressure, which gradually became stable. Doses of dopamine were tapered and finally became unnecessary.

intricate factors. Adequate volume replacement with balanced salt solution or colloid solution and, in some cases, blood transfusion is required. Inotropic agents, such as dopamine, epinephrine, and norepinephrine, are sometimes required to maintain an adequate blood pressure. The vasomotor and cardioaccelerating neurons of the spinal cord (located in the lateral horn) obtain automaticity within several days of disconnection from the supraspinal structures, and arterial blood pressure returns to normal without supplementation with vasopressors.[45] This situation is familiar to anesthesiologists because background arterial blood pressure is usually normal in tetraplegic patients.

After the establishment of brain death, different types of autonomic spinal cord reflexes develop, such as elevation of arterial blood pressure because of bladder distention. Surgical stimulation–induced hypertension and tachycardia are well known by anesthesiologists in tetraplegic patients. A similar phenomenon has been observed in brain-dead patients.[46] Vasodilators or general anesthesia, or both, should be used during the donation operation.[47] Although the cardioaccelerating and vasomotor neurons are located in the brainstem, changes in arterial blood pressure are not used as an index of brainstem function.

REGULATION OF BODY TEMPERATURE

Rodbard[48] suggested that the neural mechanisms governing homeostatic temperature control developed in the hypothalamus from circulatory control neurons in the course of evolution from reptile to mammal. Body temperature is regulated when changes in blood temperature stimulate heat-sensitive receptors in the hypothalamus. Nerve impulses from cold receptors in the skin also can activate heat-producing neurons. The most important heat producers are the skeletal muscles, brain, liver, and heart. The greatest heat radiator is the skin, especially that on the hands. Local electrical stimulation of the heat-producing center induces shivering and constriction of blood vessels in the skin, activating vasomotor nerves and decreasing blood flow. Warming of the heat-loss center suppresses vasomotor nerve activity and in this way increases blood flow through the skin.

In brain death, the neural connection between the temperature-regulating center and peripheral body tissues is lost and the patient becomes poikilothermic. When criteria from the National Institute of Neurological Diseases and Stroke were applied to establish brain death, such patients showed only a "tendency for the temperatures to be subnormal."[29] In contrast, when brain death was established using the criterion of cessation of all brainstem functions, "poikilothermia was found in all patients later than 24 hours after brain death."[49] Even if infection occurs, fever should not develop in cases of brain death, because the temperature-regulating centers no longer function. After brain death, body temperature tends to be hypothermic, even with vigorous application of external heat.

HYPOTHALAMIC-PITUITARY ENDOCRINE FUNCTIONS

No criteria used to establish brain death attempt to determine whether functions of the hypothalamus are preserved. Clinical studies have indicated that hypothalamic and anterior pituitary functions are preserved to a certain degree for a certain period after the onset of brain death. Schrader and co-workers[50] reported normal levels of anterior pituitary hormones, the half-lives of which are less than 1 hour, such as thyroid-stimulating hormone, prolactin, growth hormone, and luteinizing hormone, as well as positive test results for the hypothalamic hormone, luteinizing hormone–releasing hormone, and thyrotropin-releasing hormone, for 2 to 24 hours after determination of brain death. Sugimoto and associates[51]

confirmed that concentrations of these hormones were normal for more than 1 week.

In contrast, the level of vasopressin, a hormone produced in the hypothalamus and stored in the posterior pituitary, decreased sharply after brain death.[51] However, the occurrence of diabetes insipidus is variable. In one study, many patients did not have diabetes insipidus after brain death.[52] Another study found that 24 (77%) of 31 patients with brain death had clinical diabetes insipidus.[53] When arginine vasopressin is added to the infusion in cases of brain death with diabetes insipidus, the heart beat can be maintained for several months.[54] It was reported that plasma levels of the thyroid hormones triiodothyronine (T_3) and thyroxin (T_4) were decreased markedly after brain death.[55] However, the decline in T_3 plasma levels is not uniform in brain-dead patients. Frequently the decline in T_3 is accompanied by a parallel increase in reverse T_3. This condition is similar to euthyroid sick syndrome.

The diaphragma sellae protects the pituitary gland from compression caused by swelling of the brain. Blood supply to the pituitary gland comes mostly from the superior, middle, and inferior nine arteries and the capsular arteries. The portal venous system is another source of blood supply to the anterior lobe. In brain death, blood supply through the superior hypophyseal artery and the portal vein can easily be blocked. However, blood supply through the cavernous portion of the internal carotid artery and its branches, such as the inferior hypophyseal artery and the capsular artery, may be spared.[56] Morphologic studies of brain death indicate that damage to the anterior lobe is incomplete but severe, whereas the posterior lobe is relatively preserved.[51] However, because vasopressin is synthesized in the hypothalamus and transferred to the posterior lobe of the pituitary through axoplasmic flow along the long axon, depletion of this hormone may be greater than would be expected from the slight morphologic damage seen in the posterior lobe.

In studies on brain death, the hypothalamic hormones, such as growth hormone–releasing hormone, corticotropin-releasing hormone, thyroxine-releasing hormone, and luteinizing hormone–releasing hormone were found in trace to subnormal levels.[51,57] Schrader and co-workers[50] reported a normal growth hormone response to hypoglycemic stimulation. Arita and associates[58] also demonstrated that insulin and arginine increased growth hormone levels in brain-dead patients. Hypoglycemia affects glucoreceptors in the ventromedial nucleus to stimulate growth hormone–releasing hormone and corticotropin-releasing hormone release and stimulates growth hormone or adrenocorticotropic hormone release, indicating that some hypothalamic function may be preserved. However, the origin of the hypothalamic hormones released in brain death cannot be identified. Results from morphologic studies on the hypothalamus are controversial. Walker and colleagues[29] reported that the neurons with lytic changes were intermingled with relatively normal cells, a result that may account for the sustained secretion of hypothalamic hormones. In contrast, Sugimoto and co-workers[51] observed extensive necrosis of the hypothalamus after the sixth day of brain death and postulated a nonbrain supply of these hormones, such as the pancreas, intestine, or adrenal gland. The hypothalamus receives its blood supply through the branches of the superior hypophyseal and posterior communicating arteries; therefore, blood flow to the hypothalamus, at least its basal part, may be preserved in relatively mild instances of intracranial hypertension.

Hormonal therapy for hemodynamic stabilization of brain-dead organ donors has been developed and recommended. The Cardiac Work Group of the Crystal City Conference led by United Network for Organ Sharing (UNOS) recommended a heart donor management algorithm that included four-drug hormonal resuscitation (T_3, vasopressin, methylprednisolone, and insulin) for donors with a left ventricular ejection fraction less than 45% or with unstable hemodynamics,[59] and Organ Procurement and Transplantation Network (OPTN)/UNOS multivariate studies on hormonal treatment of brain-dead donors (T_3/T_4, methylprednisolone, and arginine vasopressin) revealed significant increases in the number of organs transplanted and in 1-year survival of kidneys and hearts.[60] However, some investigators failed to observe any hemodynamic or metabolic benefit of the use of T_3 in adult cadaveric organ donors,[61] and it was also reported that not T_4 administration but rather steroid administration and desmopressin and diuretic usage were associated with organ yield.[62] It is suggested that thyroid hormones have some beneficial role only in unusual cases of prolonged donor management—that is, longer than 24 to 48 hours.[63]

THE IMMUNE SYSTEM AND INFLAMMATION

The CNS exerts significant influence over the immune system. Even if the immune system is intact, its response to stimulation is modified considerably after total and irreversible loss of CNS functions. Increased levels of inflammatory mediators, such as cytokines (interleukin-1β[IL-1β], IL-6, tumor necrosis factor–α [TNF-α])[64,65] and adhesion molecules (E-selectin, intercellular adhesion molecule–1 [ICAM-1], vascular cell adhesion molecule [VCAM-1])[66,67] in blood and organs are observed in brain-dead patients, and it is thought that these cytokines are responsible for some of the endocrine and acute-phase reactant abnormalities found in these patients and for the low success rates after organ transplantation. Brain death also may induce a systemic inflammation. The possible mechanisms are (1) inflammatory mediators are released from the ischemic brain; (2) the catecholamine surge causes anerobic metabolism, which induces nuclear factor–κB (NF-κB) activation or flow-induced shear stress of the endothelial cells or induces ischemia in the gut; (3) metabolic changes after brain death modulate the inflammatory response; and (4) neuropeptides are released from the nervous system and play a role in inflammation.[68]

BRAINSTEM REFLEXES

Various brainstem reflexes are used to diagnose brain death, such as pupillary, oculocephalic, oculovestibular, and cough reflexes. Preservation of the cough reflex indicates preservation of the brainstem respiratory center. All the brainstem reflexes (except those of the respiratory

centers) need not be present for the organism to be said to be alive, but they are tested to confirm preservation of brainstem functions.

CRITERIA AND TESTS FOR DETERMINING BRAIN DEATH

Determination of brain death confirms the irreversible cessation of all functions of the entire brain, including the brainstem.[12] Irreversibility means that no treatment may be reasonably expected to change the condition. The responsible disorder may be thought of as structural, and it does not result from functional and potentially reversible causes such as drug intoxication, hypothermia, or metabolic or endocrine disturbance. The passage of time is also an essential component in determining that a lesion is irremediable. Although testing all functions of the brain is conceptually impossible, the cessation of all functions of the brain is practically determined by loss of consciousness, loss of brainstem responses, apnea, and confirmatory tests, including the lack of electroencephalographic activity.

LOSS OF CONSCIOUSNESS AND UNRESPONSIVENESS

The patient should be in coma and scored as 3 on the Glasgow Coma Scale. Motor responses of the limbs or facial muscles to painful supraorbital pressure should be absent. Motor responses (i.e., the Lazarus sign) may occur spontaneously during apnea testing[69] and are considered to have a spinal origin. This sign is often observed during hypoxic or hypotensive episodes. Other spontaneous movements from spinal origin are observed.

PUPILS

The shape of the pupils can be round, oval, or irregular. The size of the pupils may vary from 4 to 9 mm, but in most cases is 4 to 6 mm.[12,70] Sympathetic cervical pathways can be intact in the state of brain death, connect with the radially arranged fibers of the dilator muscle, and dilate the pupils.

BRAINSTEM RESPONSES

The tests for brainstem responses vary in different countries. The criteria of the American Academy of Neurology[19] include light reflex, oculocephalic reflex, caloric (vestibular) test, corneal reflex, facial muscle movement to a noxious stimulus, pharyngeal (gag) reflex, and tracheal (cough) reflex.

APNEA TEST

Apnea testing is mandatory for the determination of brain death and considered the most important testing, but controversies have existed about it. Its safety is a major issue. During the apnea test, marked hypotension or severe cardiac arrhythmias,[70] or both, and pneumothorax may occur[71] and the intracranial pressure can increase markedly. The apnea test should be performed as the last test after the other tests fulfill the criteria of brain death. Goudreau and associates[72] reported that during the apnea test complications such as a marked blood pressure decrease or the development of ventricular arrhythmia developed in 27 (39%) of 70 patients with pretest unfavorable factors but developed in only 11 (15%) of 74 patients without them. They pointed out that inadequate preoxygenation and acid-base or electrolyte abnormalities were the major unfavorable pretest factors. Preparation before the apnea test is required. Prerequisites are (1) normotension (systolic blood pressure ≥100 mm Hg), (2) normothermia (core temperature >36° C), (3) euvolemia, (4) eucapnia ($Paco_2$ 35 to 45 mm Hg), and (6) no prior evidence of carbon dioxide retention. Preoxygenation with 100% O_2 for at least 10 minutes is required before apnea testing to PaO_2 greater than 200 mm Hg. Ventilator requirements should be evaluated, and the patient should be well-oxygenated with low positive end-expiratory pressure (5 cm H_2O). During apnea testing, 100% O_2 is delivered at 6 L/min through a catheter placed at the level of the carina or attached T-piece with continuous positive airway pressure at 10 cm H_2O.[12,19,70] Apnea testing should be aborted if systolic blood pressure decreases to less than 90 mm Hg or O_2 saturation (SpO_2) decreases to less than 85% for longer than 30 seconds. A bolus of intravenous phenylephrine 100 μg is recommended in the case of hypotension.

Another issue is the appropriate level of $Paco_2$ to be achieved. After equipment for analyzing blood gases became widespread, the importance of the value of $Paco_2$ rather than the time for observation of apnea was confirmed. An increase in $Paco_2$ decreases pH in the cerebrospinal fluid, which stimulates the medullary respiratory chemical center. The normal ventilatory response to the increase in $Paco_2$ rises linearly to 80 mm Hg, and then the slope becomes less steep and peaks at approximately 150 mm Hg in dogs.[73] Damage in the medullary respiratory center may affect the level of $Paco_2$ for development of spontaneous respiration. The level of $Paco_2$ at which spontaneous respiration resumes is also modified by PaO_2. Wijdicks[4] reported that although most of all brain death guidelines in the world required apnea tests (71 of 80 nations), only 41 of 71 guidelines defined a definite $Paco_2$ target value, and he concluded that if the premise of documenting apnea using hypercarbia to maximally stimulate the respiratory centers was accepted, it could be concluded that in half of the countries the apnea test was not performed adequately. The exact level of $Paco_2$ to be achieved is still unknown, but the American Academy of Neurology criteria define various prerequisites and the procedure of apnea testing and adopt the level of $Paco_2$ 60 mm Hg or greater[12,19,70] and the U.K. criteria requires a $Paco_2$ target of 6.65 kPa (50 mm Hg).[34]

PREREQUISITES FOR DIAGNOSING BRAIN DEATH

Several disorders mimic brain death and can lead to an erroneous diagnosis. The absence of these conditions must be confirmed and the following factors considered before the criteria for brain death are applied.

DEEP COMA

The patient must be in a deep coma, and the cause of the coma must be identified. Organic brain damage must be confirmed as a prerequisite for diagnosing brain death. Drug intoxication, severe electrolyte, acid-base or endocrine disturbance, hypothermia, and other common treatable disorders should be ruled out.

BODY TEMPERATURE

After cessation of brainstem and hypothalamic functions and after complete disconnection of the spinal cord from supraspinal brain structures, the patient becomes poikilothermic and body temperature tends to be hypothermic, even with vigorous warming. Because hypothermia suppresses CNS function and can lead to misdiagnosis of brain death, body temperature must be within normal range (i.e., hypothermia must be corrected) before the criteria for brain death are applied.

ABSENCE OF CARDIOVASCULAR COLLAPSE

When intracranial pressure increases, systemic hypertension occurs as a result of the Cushing phenomenon. This is followed by a sudden decrease in blood pressure because of sudden interruption of vasomotor output from the brainstem and hypothalamus to the spinal cord. Hypotension usually resolves spontaneously within several days because of restoration of spontaneous activity of the spinal cord's vasomotor neurons. Hypotension may result in compromised cerebral perfusion leading to loss of electroencephalographic activity, thus causing a spurious diagnosis. Therefore, administration of a vasopressor to achieve relative normotension should be considered; vasopressor therapy will occasionally restore electroencephalographic activity in the determination of brain death.

CLINICAL DIAGNOSIS OF BRAIN DEATH

The guidelines and clinical diagnosis for determining brain death differ in various countries[3,4] and among institutions in the United States and Canada. However, the principle seems similar,[1,3,4,12] and clinical diagnosis of brain death should be performed in the following three steps:

1. Establishing the cause of disease
2. Excluding certain potentially reversible syndromes that may produce signs similar to brain death
3. Demonstrating clinical signs of brain death: coma, brainstem areflexia, and apnea

Confirmatory tests in the determination of brain death are not always mandatory, but they are desirable, especially when the clinical picture is confusing. In general, two examinations separated by at least 6 hours are required to establish the diagnosis of brain death. Most codes mandate that the clinical diagnosis be confirmed by two or three physicians who are independent of the transplantation team, and at least one of the physicians is required to be a specialist in neurology, neurosurgery, or anesthesiology.

SPECIAL CONSIDERATIONS

SPINAL CORD REFLEXES AND SURGERY

The CNS structures essential to the definition of brain death do not include the spinal cord. Histologic studies have shown that the spinal cord is the best preserved part of the CNS in cases of brain death, and results have ranged from grossly normal histology to edema, neuronal loss, neurolysis, and, rarely, infarction.[29]

Spontaneous and reflex movements are found in brain-dead patients. Spontaneous body movements may be observed during the apnea test, while the body is being prepared for transport, at the time of a skin incision for the retrieval of organs, or in synchrony with the respirations produced by mechanical ventilation.[1] In 5 of 60 cases of brain death after terminally turning off the ventilator or during apnea tests, Ropper[69] reported bizarre, seemingly purposeful movements of the upper extremities, termed the Lazarus sign, in which the arms flexed quickly to the chest from the patient's side, the shoulders adducted, and in some patients, the hands crossed or opposed just below the chin. Saposnik and associates[74] reported that 15 (39%) of 38 patients who fulfilled criteria for brain death showed spontaneous or reflex movements; the most common movement was finger jerks, and the undulating toe flexion sign, triple flexion response, Lazarus sign, pronation-extension reflex, and facial myokymia also were seen. Health care staff should remember that a patient may move in response to noxious stimulation and that full curarization is required for surgical procedures involving brain death.

CONSIDERATIONS REGARDING CHILDREN

The child's brain is a developing organ, and it is believed that the anatomic neurodevelopment continues by 2 years of age or beyond the first decade of life (see also Chapters 93 and 95). During this time, changing patterns of vulnerability to injury and different responses to the injury itself occur.[75] Furthermore, the presence of open fontanelles and open sutures in young children makes the skull an expandable chamber. Intracranial pressure may not exceed mean arterial blood pressure, and cerebral blood flow continues. It is generally assumed that the child's brain is more resistant to insults leading to death, although this issue is controversial and lacks convincing clinical documentation.[14]

The need for facilitation of end-of-life decision and organ procurement in infants and children has increased. In 1987, the Task Force for the Determination of Brain Death in Children endorsed the *Determination of Death Act* and offered the Guidelines for the Determination of Brain Death in Children.[14] The multisociety task force revised the 1987 guidelines after reviewing literature published from 1987 with clarifying the grade of recommendations (see Boxes 76-2 and 76-3).[20] Although 1987 guidelines excluded neonates younger than 7 days of age, in the revised guidelines the exclusion of recommendations was restricted to preterm infants younger than 37 weeks of gestational age, because insufficient data were available, some of the brainstem reflexes may not

be completely developed, and assessment of the level of consciousness in critically ill, sedated, and intubated neonates is difficult. Although an ancillary study (EEG) was mandatory in infants younger than 1 year of age in the 1987 guidelines, in the revised guidelines, ancillary studies (EEG and cerebral blood flow) were changed to be optional. Further, unspecified values of several subjects in the 1987 guidelines were specified in the revised guidelines. In the United Kingdom, where brainstem death criteria are adopted, the brain death criteria for children are as follows: after 2 months of age, criteria should be the same as in adults; between 37 weeks of gestation and 2 months of age, it is rarely possible to diagnose brain death confidently; and before 37 weeks of gestation, the criteria for brain death cannot be applied.[76,77] In Japan, organ donation from a brain-dead child younger than 15 years has been legal from 2009 with family consent, and the most rigid criteria in the world are applied to declare brain death in children younger than 6 years (Table 76-1). Computed tomography (CT) or MRI examination is mandatory in children as a prerequisite to clarify the causes of brain insults. Further, a possibility of child abuse should be excluded if the child is younger than 18 years of age.

VARIABILITY IN POLICIES AND PRACTICES FOR DETERMINING BRAIN DEATH

Although the concept of brain death as defining the death of the individual is widely accepted, significant variability exists in policies and practices for determining brain death among nations and even within a nation—that is, among states and hospitals. Wijdicks[4] reported that of 80 countries examined, legal standards on organ transplantation were present in 55 countries (69%) and practice guidelines for brain death for adults were present in 70 countries (88%). All guidelines specified exclusion of confounders, irreversible coma, absent motor response, and absent brainstem reflexes. Although apnea testing is one of the most important tests for determining brain death, a few guidelines do not require apnea

TABLE 76-1 **COMPARISON OF PEDIATRIC BRAIN DEATH GUIDELINES BETWEEN THE UNITED STATES AND JAPAN**

	United States (Updated Guidelines)	Japan
1. Age-related exclusion	Preterm infants <37 wk gestational age	Preterm infants <12 wk in corrected age
2. Core body temperature	>35° C (95° F)	<6 yr: ≥35° C (95° F), ≥6 yr: 32° C (89.6 ° F)
3. Arterial blood pressure	Age-dependent Above normal value for the age – 2 SD	Age-dependent <1 yr ≥65 mm Hg 1 year ≤13 yr: ≥65 + (age × 2) mm Hg ≥13 years: ≥90 mm Hg
4. Number of examinations	Two examinations	Two examinations
5. Number of examiners	Two (different attending physicians must perform the first and second examinations)	Two (neurosurgeon, neurologist, anesthesiologist, intensive care physician, emergency medicine physician, or pediatrician: board-certified)
6. Observation interval between neurologic examinations	Age-dependent Term newborn (37 wk gestation) to 30 days of age: 24 hr 31 days to 18 yr: 12 hr	Age-dependent <6 yr: 24 hr ≥6 yr: 6 hr
7. Reduction of observation period between examinations	Permitted for both age groups if EEG or CBF consistent with brain death	Not permitted
8. Apnea testing	Two apnea tests required unless clinically contraindicated	Two apnea tests required
9. Final P_{CO_2} threshold for apnea testing	≥60 mm Hg and ≥20 mm Hg above the baseline Pa_{CO_2}	≥60 mm Hg
10. Ancillary study	Not required except in cases in which the clinical examination and apnea test cannot be completed Term newborn (37 wk gestation) to 30 days of age: EEG or CBF are less sensitive in this age group; CBF may be preferred >30 days to 18 yr: EEG and CBF have equal sensitivity	EEG is mandatory
11. Time of death	Time of the second examination and apnea test (or completion of ancillary study and the components of the second examination that can be safely completed)	Time of second examination and apnea test
12. Others		CT or MRI is mandatory to identify the cause of brain insults A child having a possibility of abuse is excluded

testing. Further, significant differences exist in the area of the brain (whole brain versus brainstem), in requirement of confirmatory tests (EEG, brainstem evoked potentials, cerebral angiogram), number of examinations (and time interval between examinations), method of apnea testing (baseline $Paco_2$, target value of $Paco_2$, time of disconnection from the ventilator, oxygenation method during the test), time of observation from the insults, number and required expertise of examining physicians, critical thresholds of temperature and arterial blood pressure, and legal time of death. Furthermore, because brain death practices are largely determined by individual hospitals in the United States and Canada, significant variabilities among hospital policies and guidelines for brain death were found. Wijdicks[4] and other investigators stressed the need to standardize the practice of neurologic determination of death.[78,79] Wide variation in practices was also reported in the pediatric population[80,81] and in the brainstem death criteria in the United Kingdom,[37] despite the existence of clear guidelines for performing the test.[82-84]

Jeffe and colleagues[85] surveyed understanding of the concept and diagnostic tests of brain death in American board-certified neurologists in 2010. They sent a questionnaire to 500 neurologists and analyzed 192 returned forms. The most common (48%) justification for understanding brain death as an individual death was "a high brain concept (irreversible loss of consciousness)," followed by "loss of integrative unity (27%)" and "the irreversible lack of vital work of an organism (12%)." Although criteria for determining brain death in the United States do not require lack of some remaining functions of the brain, many neurologists responded that certain brain functions remaining are not compatible with diagnosis of brain death, including EEG activity (70%), evoked potential activity (56%), hypothalamic neuroendocrine function (9%), brain blood flow (52%), and normal brainstem pathology (19%). This survey indicates that American neurologists have neither a consistent rationale for accepting brain death as death nor diagnostic tests for brain death.

ANCILLARY TESTS FOR BRAIN DEATH

Tests that confirm the loss of bioelectrical activity of the brain or the cerebral circulatory arrest are not always mandatory for adults (Box 76-4). In several European, Central American, South American, and Asian countries, ancillary testing is required by law.[1,2,4] In the United States, the choice of tests is left to the discretion of the physician. Ancillary tests can reduce the time of observation and are strongly recommended when uncertainties exist about the reliability of certain aspects of the clinical examinations and in situations in which the apnea testing cannot be completed. Young and associates[86] proposed criteria for ideal confirmatory ancillary tests:

1. No instances of false positive findings should occur—that is, when the test confirms "brain death," none should have recovered or have the potential to recover.
2. The test should be independently sufficient to establish that brain death is or is not present.
3. The test should not be susceptible to confounders, such as drug effects or metabolic disturbances.
4. The test should be standardized in technology, technique, and classification of results.
5. The test should be available, safe, and readily applied. Testing should not be restricted to only a few research centers; ideally it could be applied within any intensive care unit (ICU) and the technique should be reliable and mastered without difficulty.

BOX 76-4 ***Methods of Ancillary Testing for the Determination of Brain Death***

1. Cerebral angiography
   a. The contrast medium should be injected in the aortic arch under high pressure and reach both anterior and posterior circulations.
   b. No intracerebral filling should be detected at the level of entry of the carotid or vertebral artery to the skull.
   c. The external carotid circulation should be patent.
   d. The filling of the superior longitudinal sinus may be delayed.
2. Electroencephalography
   a. A minimum of eight scalp electrodes should be used.
   b. Interelectrode impedance should be between 100 and 10,000 Ω.
   c. The integrity of the entire recording system should be tested.
   d. The distance between electrodes should be at least 10 cm.
   e. The sensitivity should be increased to at least 2 μV for 30 minutes with inclusion of appropriate calibrations.
   f. The high-frequency setting should not be set below 30 Hz, and the low-frequency setting should not be above 1 Hz.
   g. Electroencephalography should demonstrate a lack of reactivity to intense somatosensory or audiovisual stimuli.
3. Transcranial Doppler (TCD) ultrasonography
   a. TCD is useful only if a reliable signal is found. The abnormalities should include either reverberating flow or small systolic peaks in early systole. A finding of a complete absence of flow may not be reliable owing to inadequate transtemporal windows for insonation. There should be bilateral insonation and anterior and posterior insonation. The probe should be placed at the temporal bone, above the zygomatic arch and the vertebrobasilar arteries, through the suboccipital transcranial window.
   b. Insonation through the orbital window can be considered to obtain a reliable signal. TCD may be less reliable in patients with a prior craniotomy.
4. Cerebral scintigraphy (technetium-99m exametazime [HMPAO])
   a. The isotope should be injected within 30 minutes after its reconstitution.
   b. Anterior and both lateral planar image counts (500,000) of the head should be obtained at several time points: immediately, between 30 and 60 minutes later, and at 2 hours.
   c. A correct intravenous injection may be confirmed with additional images of the liver demonstrating uptake (optional).
   d. No radionuclide localization in the middle cerebral artery, anterior cerebral artery, or basilar artery territories of the cerebral hemispheres (hollow skull phenomenon).
   e. No tracer in superior sagittal sinus (minimal tracer can come from the scalp).

Wijdicks EFM, Valelas PN, Gronseth GS, Greer DM: Evidence-based guideline update: determining brain death in adults: report of the Quality Standards Subcommittee of the American Academy of Neurology. Neurology *74:1911, 2010.*

In all cases, ancillary tests should be used in conjunction with appropriate clinical judgment.

ELECTROENCEPHALOGRAPHIC RECORDING

The EEG is the most widely available neurophysiologic test and is used in many countries and institutions as a confirmatory test for brain death (whole-brain death) (see also Chapters 49 and 50).[1,4] Loss of bioelectrical brain activity as shown on the EEG (i.e., isoelectric EEG) is a reliable confirmatory test for brain death. However, several problems must be considered. An isoelectric EEG can be found after drug intoxication (false positive), such as occurs with barbiturates,[87] and, conversely, residual electrical activity may persist after brainstem death or even in some patients who met clinical criteria for brain death (false negative).[35,88]

Electrocerebral inactivity (ECI) or electrocerebral silence (ECS) is defined as no electroencephalographic activity above 2 μV/mm when recording from scalp electrode pairs placed 10 cm or more apart and with interelectrode impedances less than 10,000 Ω but more than 100 Ω. Ten guidelines for electroencephalographic recordings are as follows[89]:

1. A minimum of eight scalp electrodes should be used.
2. Interelectrode impedances should be less than 10,000 but more than 100 Ω.
3. The integrity of the entire recording system should be tested.
4. Interelectrode distances should be at least 10 cm.
5. Sensitivity must be increased from 7 μV/mm to at least 2 μV/mm for at least 30 minutes of the recording, with inclusion of appropriate calibrations.
6. Filter settings should be appropriate for the assessment of ECS.
7. Additional monitoring techniques should be employed when necessary.
8. No electroencephalographic reactivity should occur to intense somatosensory, auditory, or visual stimuli.
9. Recordings should be made only by a qualified technologist.
10. A repeat EEG should be performed if doubt about ECS exists.

EVOKED RESPONSES

Brainstem auditory evoked potentials (BAEPs) and median nerve somatosensory evoked potentials (SSEPs) are used for the diagnosis of brain death. Unlike EEG signals, the early components of BAEPs and SSEPs are minimally affected by sedative drugs and anesthetics. However, drugs and metabolic derangements affect middle and late BAEPs and SSEPs.[86] BAEPs are signals generated in the auditory nerves and brainstem after an acoustic stimulus. BAEPs consist of five identifiable waves generated from specific brainstem structures along the auditory pathways. Wave I represents the eighth nerve compound action potential; wave II, the eighth nerve and cochlear nerves; wave III, the lower pons, including the superior olive; and waves IV and V, the upper pons and the midbrain, as high as the inferior colliculus.[90] Brainstem abnormalities can be detected with BAEPs. The loss of waves III to V or II to V or no reproducible BAEP on both sides is usually regarded as brain death,[88] although wave I sometimes remains. Preexisting deafness or severe peripheral auditory system damage may lead to a false-positive diagnosis.

After electrical stimulation of a peripheral nerve, waves of SSEPs are generated from the neural structures along the afferent somatosensory pathways: the brachial plexus, the upper cervical cord, the dorsal column nuclei, the ventroposterior thalamus, and the sensory cortex.[90] "Practice Parameters for Determining Brain Death in Adults," published in *Neurology,* recommended bilateral absence of N20-P22 responses with median nerve stimulation as a confirmatory laboratory test.[12] Facco and coworkers[91] reported that the absence of components later than N13, which represents postsynaptic activity in the central gray matter of the cervical cord, or N13 and P13 dissociation, was reliable to confirm brain death. These investigators also recommended the combined use of BAEPs and SSEPs for determining brain death. Sonoo[92] considered a loss of N18 potential, which is supposedly generated at the cuneate nucleus in the medulla oblongata, as reliable for the diagnosis of brain death.[92]

CEREBRAL PERFUSION AND METABOLISM

Possible mechanisms for brain death include an obstruction of circulation by cerebral swelling, and thus the demonstration of absent intracranial circulation indicates irreversible cerebral damage (see also Chapter 17). However, because in some situations, cerebral perfusion may be maintained despite documented brain death,[32] Heran and associates[93] state that it is important to understand the situation in which these false negative results may arise, to assess the results in context and consider other options for confirmation of brain death. Table 76-2 shows the advantages and disadvantages of ancillary tests for determination of cerebral blood flow in the setting of brain death.[93]

ANGIOGRAPHY

Contrast Catheter Angiography

Four-vessel cerebral angiography is a traditional gold standard modality among ancillary tests for brain death. This method is primarily an anatomic and not a physiologic demonstration of perfusion, although nonquantitative inferences about perfusion rates may be made. The greatest advantage of catheter angiography for the determination of brain death is that it is not influenced by CNS depressant drugs or hypothermia. This method has been widely recommended to confirm brain death.[88,94,95] "Practice Parameters for Determining Brain Death in Adults" recommended conventional angiography as a confirmatory test, and the following criteria were identified[12]: no intracerebral filling should be seen at the level of the carotid bifurcation or circle of Willis; the external carotid circulation is patent; and filling of the superior longitudinal sinus may be delayed. Drawbacks of this method are that the patients need to be transported to the radiology suite and it is an invasive examination that needs an experienced neuroradiologist and may

TABLE 76-2 COMPARISON OF ANCILLARY TESTS FOR DETERMINATION OF CEREBRAL BLOOD FLOW IN THE SETTING OF BRAIN DEATH

Test	Definition	Minimum Flow Limit (mL/100 g/min)	Advantages	Disadvantages	Consensus
DSA	Digital subtraction angiography	0	Direct visualization of CBF	Invasive Exposure to iodinated contrast Not readily available Not portable Expensive	Reference standard for NDD assessment Not preferred test because of invasiveness
SPECT	Single-photon emission computed tomography	5	Widely available Portable Low cost Whole brain coverage	Not quantitative Poor spatial resolution	Reference standard for NDD assessment
PET	Positron emission tomography	0	Quantitative Can assess multiple factors, including oxygen consumption, by using different radioligands Repeated measurements possible Whole brain coverage	Impractical for daily use Not portable Expensive	Reference standard for CBF assessment Not useful in NDD
Xe-CT	Xenon computed tomography	0	Quantitative Allows simultaneous CT-based imaging techniques Can be repeated within 10 min	Available in only a few academic centers because not FDA approved Not portable Limited brain coverage (6 cm) Delivery of Xe gas may present challenges	Reference standard for CBF assessment Not useful in NDD because of limited availability
MRA	Magnetic resonance angiography	Depends on technique of acquisition, but considered very low (<10)	No contrast necessary Can be combined with other MR-based techniques	Not readily available Scanning time lengthy Not portable Expensive	Limited data but promising
MRP	Magnetic resonance perfusion	8	Whole brain coverage Can be combined with other MR-based techniques Repeatable	Not quantitative for CBF Not readily available Not portable	Likely not useful because not quantitative
CTA	Computed tomography angiography	Unknown but likely very low (<10)	Readily available Rapid acquisition	Exposure to iodinated contrast Not portable	Limited data but most promising as ubiquitous technology
CTP	Computed tomography perfusion	0	Readily available Rapid acquisition Quantitative*	Exposure to iodinated contrast and ionizing radiation Limited anatomic coverage (2-4 cm) Requires postprocessing of data Relies on intact blood-brain barrier Not portable	Limited data but holds promise, especially if anatomic coverage extended
TCD	Transcranial Doppler ultrasound	Unknown	Rapid Noninvasive Portable	Does not quantify CBF Difficult to perform One measurement for each hemisphere	Not deemed useful in NDD

*Controversy exists regarding its true quantitative abilities.

yield severe complications, such as vasospasm, subintimal injection, arterial dissection, and thromboembolism, leading to a false image of absent flow and cerebral ischemia. Intraarterial (aortic arch) or intravenous (vena cava) digital subtraction angiography has been shown to be as effective as conventional four-vessel angiography, is less invasive, and is easier to perform.[96]

Radionuclide Angiography

Confirmation of brain death using conventional dynamic radionuclide angiography with blood pool agents has been used for a long time.[97] Such investigations are less invasive than others and may be carried out at the bedside using a mobile scintillation camera, but they cannot image the posterior fossa well. Radioligands such as technetium-99m hexamethylpropyleneamine-oxime (HMPAO), which cross the blood-brain barrier and are picked up and held by viable cells for several hours, are recommended to confirm brain death.[98] The lack of uptake of isotope in brain parenchyma (i.e., the hollow skull phenomenon) is characteristic for brain death.[12] ^{99m}Tc-HMPAO single-photon emission computed tomography (SPECT) provides much more precise regional information and has been proved effective in the diagnosis of brain death both in children and adults.[99,100] The lack of signal from the intracranial compartment and the normal uptake in other parts of the head produces the "empty light bulb" and "hot nose" signs.[99,100] Munari and coworkers confirmed the reliability of SPECT in the diagnosis of brain death and recommended that it should be a good candidate for the standard diagnostic modality.[101]

Computed Tomography

CT angiography has been useful as a noninvasive test to confirm brain death.[102] After intravenous injection of contrast media, time-density analysis of a specific area can be performed with a CT scanner equipped with a software program that can evaluate blood flow. CT angiography has several advantages[102]: (1) it is easily accessible around the clock and present in almost all hospitals with an ICU, (2) it is fairly inexpensive, (3) imaging requires only minutes, (4) it delivers conventional CT images at the same imaging session and can also be combined with CT perfusion imaging, (5) it is noninvasive except for intravenous injection of the contrast agent, and (6) the images are easy to interpret. However, significant divergence with catheter angiography was observed; CT angiography demonstrated some opacified proximal anterior cerebral artery segments, although absence of intracranial flow was noted with catheter angiography,[103] which may relate to contrast stasis with CT angiography.

The xenon-CT cerebral blood flow method has been applied to the confirmation of brain death.[92] This technique is quantitative and allows coregistration of flow data with CT anatomy. Pistoria and associates[104] suggested that an average global flow of less than 5 mL/100 g/min confirms brain death.

MAGNETIC RESONANCE

Magnetic resonance (MR) imaging (MRI) and MR angiography have been used for the confirmation of brain death with the advent of MRI-compatible ventilators.[105,106] MRI allows an assessment of intracranial contents and is particularly helpful in defining abnormalities in the posterior fossa, which may be obscured by bone artifact inherent in CT. Although currently experimental and limited in spatial resolution, phosphorus and proton MR spectroscopy (MRS) has been proposed for the determination of brain death.[107,108] MRS can demonstrate the total absence of high-energy phosphorus compound (including adenosine triphosphate, leaving only one single peak of inorganic phosphate in ^{31}P MRS and massive lactate concentration in ^{1}H MRS. Diffusion-weighted MRI, which detects the molecular diffusion of water, has been proposed as an adjunct in the diagnosis of brain death, because it can identify widespread cerebral ischemia.[109]

TRANSCRANIAL DOPPLER ULTRASONOGRAPHY

Transcranial Doppler ultrasonography (TCD) is a safe, noninvasive, and inexpensive method that can be performed at the bedside. However, the test requires skill and knowledge in its application to insonate the major intracranial arteries. The Neurosonology Research Group of the World Federation of Neurology created a task force group to evaluate the role of TCD as a confirmatory test for determining brain death and offered the criteria for the diagnosis of cerebral circulatory arrest.[110] According to the criteria, cerebral circulatory arrest can be confirmed if the following extracranial and intracranial Doppler sonographic findings have been recorded and documented both intracranially and extracranially and bilaterally on two examinations at an interval of at least 30 minutes:

1. Systolic spikes or oscillating flow in any cerebral artery can be recorded by bilateral transcranial insonation of the internal carotid artery (ICA) and middle cerebral artery (MCA), respectively, or any branch or other artery that can be recorded (anterior and posterior circulation).
2. The diagnosis established by the intracranial examination must be confirmed by the extracranial bilateral recording of the common carotid artery, ICA, and vertebral arteries.
3. The lack of a signal during transcranial insonation of the basal cerebral arteries is not a reliable finding because this can be due to transmission problems.
4. Ventricular drains or large openings of the skull as in decompressive craniotomy possibly interfering with the development of the intracranial pressure are not present.

According to the report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology, the sensitivity of TCD for diagnosis of brain death ranges from 91% to 100%.[111] In a meta-analysis of 10 studies concerning TCD examination, two high-quality studies showed a sensitivity of 95% and a specificity of 99% to detect brain death, and all 10 studies showed a sensitivity of 89% and a specificity of 99%.[112] Poularas and co-workers[113] reported that when they examined 40 clinically brain-dead patients by TCD and angiography the agreement between the TCD and angiography

to confirm brain death was 100%. Young and associates,[86] however, strongly recommend that because of numerous caveats and lack of precise guidelines, TCD should not be, at this time, recommended as the sole test of brain perfusion in the case of suspected brain death.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) imaging involves intravenous injection of radiotracers labeled with positron-emitting nuclides (e.g., O-15, carbon-11, nitrogen-13). These radionuclides are incorporated into organic compounds chemically similar to those present in the body, and several physiologic parameters can be measured. A few of the reports about the use of PET in the setting of brain death indicated the utility of PET in the confirmation of brain death. No detectable glucose metabolism was reported using fluorine-18 fluorodeoxyglucose (^{18}F-FDG) in brain-dead patients.[114] On the other hand, Medlock and colleagues[115] reported a clinically brain-dead 2-month-old infant with no cerebral electrical activity who demonstrated the persistence of glucose metabolism by PET. These investigators speculated that the preservation of glucose metabolism was partly caused by glial cells, which are more resilient than neurons. The use of PET in the investigation of comatose or brain-dead patients is still in an early stage of development and limited by its high cost and need for special facilities. Laureys and associates[116] suggested that functional neuroimaging is providing new insights into cerebral activity in patients with severe brain damage and that measurements of cerebral metabolism and brain activations in response to sensory stimuli with PET, functional MRI, and electrophysiologic methods can provide information on the presence, degree, and location of any residual brain function.

ORGAN DONATION

The concept of brain death has been developed with the development of organ transplantation, and the main purpose of diagnosis of brain death is that it permits multiple vital organ procurement for transplantation (see also Chapter 75). In 2010, the World Health Assembly led by World Health Organization (WHO) endorsed revised Guiding Principles on Human Cell, Tissue and Organ Transplantation, referring to both living and deceased donations, to provide an orderly, ethical and acceptable framework for the acquisition and transplantation of human cells, tissues, and organs for therapeutic purposes. In guiding principles, it is stated that tissues and organs may be removed from the bodies of deceased persons for the purpose of transplantation if (1) any consent required by law is obtained and (2) there is no reason to believe that the deceased person objected to such removal.[117] The dead-donor rule[118] is the ethical and legal axiom. Because of a critical shortage of organs for transplantation, various measures have been proposed to improve the rate of organ donation from brain-dead patients, such as "required request" and "presumed consent."[117,118] Furthermore, "non–heart beating organ donor,"—that is, "donation after circulatory death (DCD)" protocols, in which life-sustaining therapy is withheld for an imminently dying patient with the removal of the transplantable organs after the patient's cardiac arrest, have been introduced. Such protocols have gained popularity, especially after a qualified endorsement by the Institute of Medicine.[121,122] However, the protocols are not new and special, because before the acceptance of donation after brain death (DBD), cadaveric donations were from patients who had been declared dead by cardiorespiratory criteria and many of the renal transplantations performed have used organs retrieved after determination of cardiac arrest. Although warm ischemic injuries limit the potential for DCD, not only kidney but also liver, pancreas, and lungs, which are rather vulnerable to ischemia, are now being retrieved by DCD and successfully transplanted.[123] The warm ischemia time (WIT) in DCD begins at the withdrawal of life-sustaining cardiorespiratory support and ends at the end of cardiopulmonary function when cold perfusion is established, and a number of attempts to reduce the length and degree of WIT have been performed to improve the outcomes of transplants from DCD to reduce ischemic injury. Although DBD, unlike DCD, has an opportunity to maintain or even improve the condition of organs before retrieval by optimal donor management and minimizing WIT, various risk factors exist to aggravate injury to donor's organs and consequently increase propensity to rejection, such as cardiovascular instability and generalized inflammatory and hormonal changes.[122] Therefore, many therapeutic goals and treatment guidelines have been proposed to maximize use of organs procured from cadaver donors.[59,60,124,125]

DCD is classified into five categories by the modified Maastricht classification: category I (dead on arrival), II (unsuccessful resuscitation), and V (unexpected arrest in patients in the ICU) belong to uncontrolled DCD, whereas category III (anticipated cardiac arrest) and IV (cardiac arrest in a brain-dead donor) belong to controlled DCD, in which organ retrieval is performed after death resulting from the planned withdrawal of life-sustaining cardiorespiratory support.[126] The DCD may be used when the donor does not fulfill brain death criteria. Although the controlled DCD is the most common form of DCD, logistical and ethical difficulties remain: the robust diagnosis and reason for medical futility to justify treatment withdrawal is mandatory.[127] It is also necessary that the decision to withdraw or withhold life-sustaining cardiorespiratory support should be independent and made before any consideration of organ donation.[123] In addition, diagnosis of death requires the determination of *irreversibility,* but some cases of autoresuscitation (spontaneous return of the circulation after circulatory arrest) after cardiac arrest have been reported. Most criteria allow death to be confirmed (and therefore organ retrieval to begin) after 5 minutes of continuous cardiorespiratory arrest, which is empirically believed to be sufficient interval to ensure that both consciousness and respiration have ceased and autoresuscitation should not occur. However, the Institute of Medicine acknowledges the uncertainty and lack of scientific evidence for irreversibility for the 5-minute interval.[122,127-129] As in adults, DCD has been applied for children in the past decade as a result of the chronic

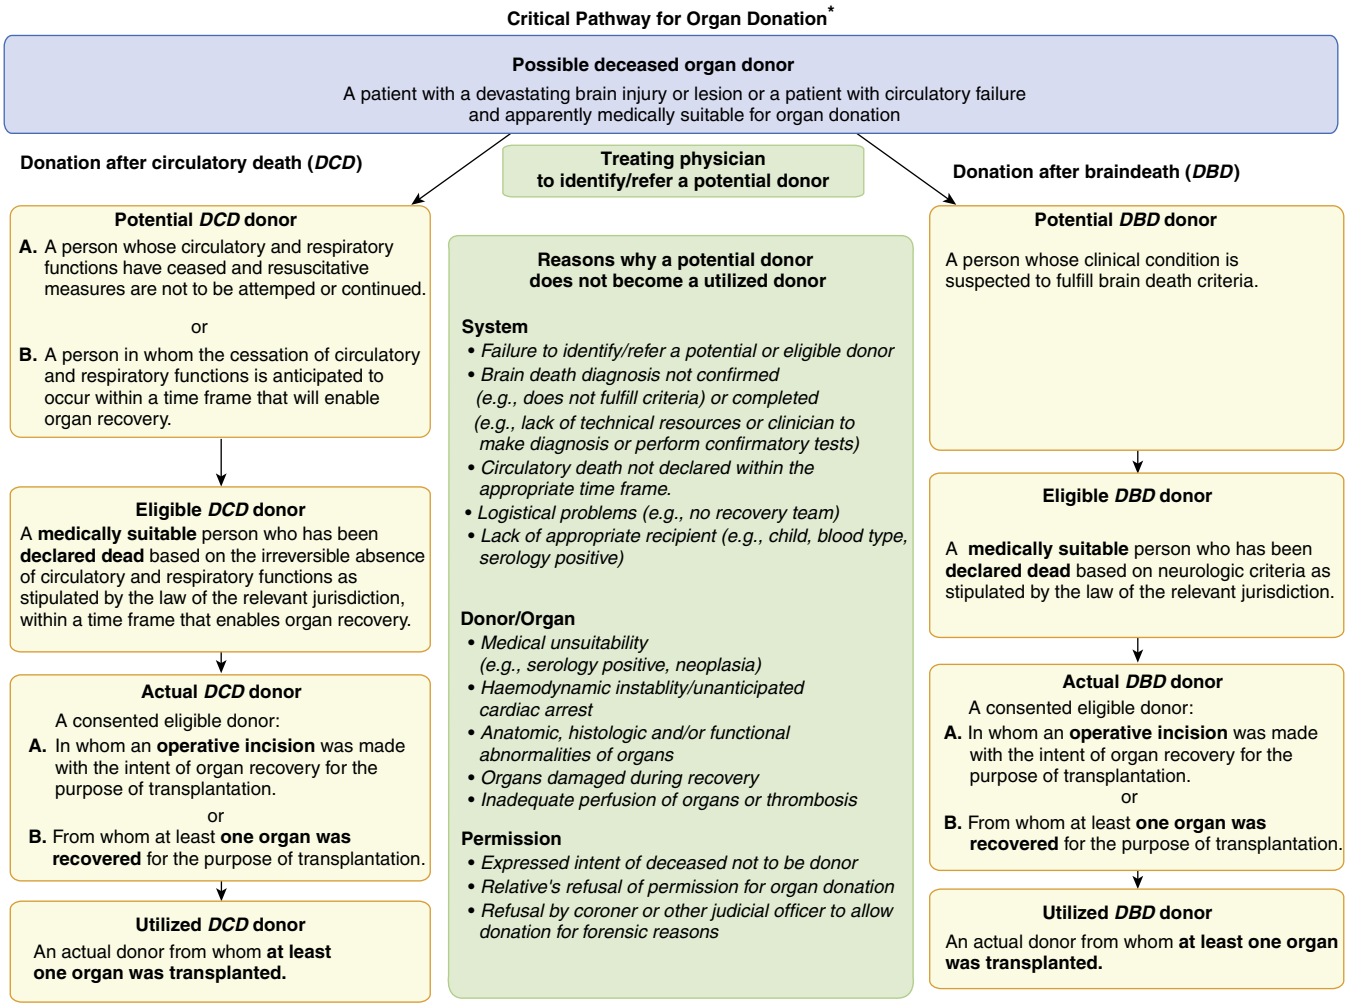

Figure 76-2. The critical pathways for donation after brain death and donation after circulatory death, as published by the World Health Organization. *(From Dominguez-Gil B, Delmonico FL, Shaheen FAM, et al: The critical pathway for deceased donation: reportable uniformity in the approach to deceased donation.* Transplant Int *24:373, 2011.)*

shortage of organs for transplantation and death is confirmed after 5 minutes of continuous circulatory arrest.[77]

Organ donation and transplant rates vary widely across the globe. A number of countries, such as Spain, Portugal, France, Italy, and the United States, have deceased donation rates over 20 per million of population, whereas the rates were less than 20 per million of population in the United Kingdom, the Netherlands, and Australia in 2009.[130] The contribution of DCD to overall donor numbers varies internationally, too. Whereas DCD accounts for a substantial proportion of overall deceased organ donors in the Netherlands and the United Kingdom, DCD is virtually nonexistent in Germany and Portugal.[123] The WHO recently issued the critical pathway for both DCD and DBD, a tool that can be applicable to every country and every area of specific hospitals, regardless of the level of development of the related health care system or its baseline experience on deceased organ donation (1) to provide a common systematic approach to the deceased organ donation process, considering both DBD and DCD; (2) to provide a useful and common tool for assessing the potential of deceased donation, evaluation performance in the deceased donation process and identifying areas for improvement; and (3) to create a common scenario or trigger in which the prospective identification and referral of a possible deceased organ donor can be undertaken (Fig. 76-2).[131]

Anesthesiologists should have ample knowledge about brain death and organ donation, because they would be involved not only in anesthetic management of a brain-dead patient for organ procurement but also in brain death diagnosis. In brain-dead patients, brainstem function with or without cortical functions is absent, and theoretically the patients are unconscious. However, because the spinal cord is intact and somatic and visceral reflexes remain,[1,69] special care is required for anesthesia management. Muscle relaxants are necessary to suppress motor activity mediated by spinal reflexes. Vasodilators usually are employed to suppress hypertension and tachycardia by noxious stimuli. However, some have the opinion that sedation and analgesia should be given with muscle relaxation for organ donation, especially in cases of brainstem brain death,[47] although analgesic and anesthetic agents are theoretically unnecessary. Van Norman[119] stressed

that anesthesiologists must have specific knowledge about the medical and legal definitions of death, as well as the ethical concepts behind them, and when anesthesiologists face anesthetic management for organ donation, they should consider the conditions of brain-dead patients and furthermore determine whether they really are brain dead.

Chapter 77

Anesthesia for Obstetrics

PAMELA FLOOD • MARK D. ROLLINS

Acknowledgment: The editors and the publisher would like to thank Drs. David J. Birnbach and Ingrid M. Browne, who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The normal physiologic changes of pregnancy begin in the first trimester, affect all organ systems, and alter pharmacokinetic and pharmacodynamic responses to many drugs commonly used in anesthesia.
- All women in labor are considered to have a full stomach and an increased risk for pulmonary aspiration of gastric contents during induction of anesthesia. Drugs and clinical approaches for aspiration prophylaxis should be considered before all surgical procedures during pregnancy.
- Uterine blood flow increases progressively during pregnancy from approximately 100 mL/minute in the nonpregnant state to 700 mL/minute (~10% of cardiac output) at term gestation. Consequently, hemorrhage during pregnancy carries significant morbidity and is a leading cause of maternal death in the United States and worldwide. Early recognition with timely intervention, optimal team performance, and appropriate blood transfusions are all essential to improving patient outcome.
- Uterine and placental blood flow depend on maternal cardiac output and are directly related to uterine perfusion pressure and inversely related to uterine vascular resistance. Decreased perfusion pressure can result from maternal hypotension secondary to hypovolemia, aortocaval compression, sympathetic blockade, and decreased systemic resistance from either general or neuraxial anesthesia. Phenylephrine in boluses or as an infusion is not only effective in reducing hypotension but also has less transfer to the fetus and results in less fetal acidosis than ephedrine.
- The fetal oxyhemoglobin dissociation curve is left-shifted and the maternal oxyhemoglobin dissociation curve is right-shifted, facilitating oxygen transfer to the fetus. Fetal O_2 saturation does not exceed 60% even with 100% O_2 delivery to the mother. Maternal $Paco_2$ decreases from 40 mm Hg to approximately 30 mm Hg during the first trimester. This reduction facilitates carbon dioxide transfer across the placenta, which is primarily limited by blood flow and not diffusion.
- Maternal-fetal exchange of most drugs and other substances occurs primarily by diffusion. The rate of diffusion and peak levels in the fetus depend on maternal-to-fetal concentration gradients, maternal protein binding, molecular weight of the substance, lipid solubility, and the degree of ionization of that substance.
- Labor is a continuous process separated into first, second, and third stages. The first stage of labor includes the change of the uterine cervix from a thick closed tube to an opening of approximately 10 cm through which the fetus can be expelled. This stage is further divided into latent and active phases.
- Neuraxial anesthesia does not affect the duration of the first stage of labor or increase the risk for cesarean delivery. Also, epidural analgesia inserted early in labor does not increase the risk for cesarean delivery.
- Neuraxial analgesia is the most reliable and effective method of reducing pain during labor. Adequate analgesia is achieved with blockade of T10 to L1 during the first stage of labor and requires extension to include T10 to S4 during the second stage of labor.
- Hypertensive disorders of pregnancy complicate 5% to 10% of worldwide pregnancies and lead to more frequent rates of maternal and fetal mortality. Patients with preeclampsia have an increased risk for cerebral hemorrhage, pulmonary edema, and coagulopathy. Systolic and diastolic blood pressure higher than 160/110 mm Hg should be treated to prevent intracerebral hemorrhage.

PHYSIOLOGIC CHANGES DURING PREGNANCY AND DELIVERY

During pregnancy and the peripartum period, substantial changes in maternal anatomy and physiology occur secondary to (1) changes in hormone activity, (2) increased maternal metabolic demands and biochemical alterations induced by the fetoplacental unit, and (3) mechanical effects of an enlarging uterus.[1,2] These physiologic changes have a significant impact on anesthetic physiology, pharmacology, and management techniques required during pregnancy and present even greater implications for patients with comorbidities.

CARDIOVASCULAR CHANGES

Changes in the cardiovascular system occur throughout gestation and include (1) an increase in intravascular volumes and changes in hematology, (2) an increase in cardiac output, (3) a decrease in vascular resistance, and (4) the presence of supine hypotension. Table 77-1 and the following sections provide additional details of these changes.

Intravascular Volumes and Hematology

Maternal intravascular fluid volume begins to increase in the first trimester secondary to changes in the renin-angiotensin-aldosterone system promoting sodium absorption and water retention. These changes are likely induced by rising progesterone from the gestational sac. Plasma protein concentrations accordingly decrease with a 25% decrease in albumin and 10% decrease in total protein at term compared with nonpregnant levels.[3] Consequently, colloid osmotic pressure decreases from 27 to 22 mm Hg over the time of gestation.[4] At term, the plasma volume has increased approximately 50% above prepregnancy values and the red cell volume has increased only approximately 25%. The greater increase in plasma volume creates a physiologic anemia of pregnancy. The hemoglobin (Hb) normally remains at 11 g/dL or greater even at term, and smaller values at any time during pregnancy are concerning for anemia.[1] Overall oxygen delivery is not reduced by this anemia because of the subsequent increase in cardiac output. The additional intravascular fluid volume of approximately 1000 to 1500 mL at term helps compensate for the estimated blood loss of 300 to 500 mL typically associated with vaginal delivery and the estimated blood loss of 800 to 1000 mL that accompanies a standard cesarean section. After delivery, uterine contraction creates an autotransfusion of blood often in excess of 500 mL that offsets the blood loss from delivery. Leukocytosis is common in pregnancy unrelated to infection. Leukocytosis is defined as a white blood cell (WBC) count greater than 10,000 WBCs/mm^3 of blood. In pregnancy, the normal range can extend to 13,000 WBCs/mm^3. Neutrophilia increases at term and is exacerbated in labor, often to 34,000 WBCs/mm^3. These changes revert to normal over 4 to 5 days after delivery.[5]

Pregnancy is a hypercoagulable state with a marked increase in factor I (fibrinogen) and factor VII and lesser increases in other coagulation factors (see Table 77-1). Factors XI and XIII and antithrombin III are decreased, and factors II and V typically remain unchanged. These changes result in an approximately 20% decrease in prothrombin time (PT) and partial thromboplastin time (PTT) in normal pregnancy. Platelet count may remain normal or slightly decreased (10%) at term as a result of dilution. However, 8% of otherwise healthy women have a platelet count less than 150,000/mm^3.[6] In the absence of other hematologic abnormalities, the cause is usually gestational thrombocytopenia, during which time the platelet count does not

TABLE 77-1 CHANGES IN THE CARDIOVASCULAR SYSTEM DURING PREGNANCY

Cardiovascular Parameter	Value at Term Compared With Nonpregnant Value
Intravascular fluid volume	Increased 35%-45%
Plasma volume	Increased 45%-55%
Erythrocyte volume	Increased 20%-30%
Cardiac output	Increased 40%-50%
Stroke volume	Increased 25%-30%
Heart rate	Increased 15%-25%
Systemic vascular resistance	Decreased 20%
Pulmonary vascular resistance	Decreased 35%
Central venous pressure	No change
Pulmonary capillary wedge pressure	No change
Femoral venous pressure	Increased 15%
Coagulation System	
Increased factors	I, VII, VIII, IX, X, XII, and von Willebrand factor
Decreased factors	XI, XIII, antithrombin III, and tPA
Platelets	Decreased 0%-10%
Clinical Studies	
Electrocardiography	Heart rate dependent decrease in PR and QT intervals Small QRS axis shift to right (first TM) or left (third TM) ST depression (1 mm) in left precordial and limb leads Isoelectric T-waves in left precordial and limb leads Small Q-wave and inverted T-wave in lead III
Echocardiography	Heart is displaced anteriorly and leftward Right-sided chambers increase in size by 20% Left-sided chambers increase in size by 10%-12% Left ventricular eccentric hypertrophy Ejection fraction increases Mitral, tricuspid and pulmonic valve annuli increase Aortic annulus not dilated Tricuspid and pulmonic valve regurgitation common Occasional mitral regurgitation (27%) Small insignificant pericardial effusions may be present

TM, Trimester.
Data from references 1, 2, 283.

usually decrease to less than 70,000/mm^3. However, this syndrome is not associated with abnormal bleeding. Gestational thrombocytopenia is due to a combination of hemodilution and more rapid platelet turnover and is a diagnosis of exclusion. Other more consequential diagnoses such as idiopathic thrombocytopenic purpura and HELLP syndrome (hemolysis, elevated liver enzyme levels, and low platelet count) must be excluded (see section on maternal comorbidities and coagulopathies).

Thromboelastography (TEG) is a test of blood coagulation that examines the end result of coagulation and can provide information about clotting variables, including platelet function and the role of other coagulation factors (see also Chapter 61). At term gestation, TEG analysis reflects the hypercoagulable state with decreased time to start of clot formation (R), decreased time to specified clot strength (K), increased rate of clot formation (α), and increased clot strength (MA).[7] Although the timing and degree of change in TEG analysis varies with each parameter, many of the changes begin to occur within the first trimester.[8]

Cardiac Output

By the end of the first trimester, maternal cardiac output typically increases approximately 35% above prepregnancy values and continues to increase 40% to 50% above nonpregnant values by the end of the second trimester, where it remains throughout the third trimester. This increased cardiac output is secondary to increases in both stroke volume (25% to 30%) and heart rate (15% to 25%). Labor further increases cardiac output, which fluctuates with each uterine contraction. Increases above prelabor values of 10% to 25% occur during the first stage and 40% in the second stage. The largest increase in cardiac output occurs immediately after delivery, when cardiac output can increase by 80% to 100% more than prelabor values. This abrupt increase is secondary to the autotransfusion from the final uterine contraction, reduced vascular capacitance from loss of the intervillous space, and decreased lower extremity venous pressure from release of the aortocaval compression. This large fluctuation in cardiac output presents a unique postpartum risk for patients with cardiac disease, especially those with fixed valvular stenosis and pulmonary hypertension. Cardiac output returns toward prelabor values approximately 24 hours postpartum and decreases substantially toward prepregnant values by 2 weeks postpartum, with complete return to nonpregnant levels between 12 and 24 weeks after delivery.

Systemic Vascular Resistance

Although cardiac output and plasma volume increase, systemic blood pressure decreases in an uncomplicated pregnancy secondary to a reduction in systemic vascular resistance. Although affected by positioning and parity, systolic, diastolic, and mean blood pressure may all decrease 5% to 20% by 20 weeks gestational age and then gradually increase toward nonpregnant values as the pregnancy progresses.[9] Diastolic arterial blood pressure decreases more than systolic arterial blood pressure. Central venous and pulmonary capillary wedge pressures do not change during pregnancy, despite the increased plasma volume, because venous capacitance increases.

Aortocaval Compression

Aortocaval compression by the gravid uterus as a result of supine positioning is associated with a decrease in systemic blood pressure. Supine hypotension is experienced by nearly 15% of women at term (defined as a decrease in mean arterial pressure > 15 mm Hg with an increase in HR > 20 beats/minute)[10] and is often associated with diaphoresis, nausea, vomiting, and changes in mentation. This group of symptoms is known as supine hypotension syndrome. At term, the inferior vena cava is almost completely occluded in the supine position with the return of blood from the lower extremities through the epidural, azygos, and vertebral veins that become engorged (Fig. 77-1, *A*). Also, significant aortoiliac artery compression occurs in 15% to 20% of pregnant women. Vena caval compression in the supine position causes a decrease in both stroke volume and cardiac output of 10% to 20% (see Fig. 77-1, *B*), and may exacerbate venous stasis in the legs and thereby result in ankle edema, varices, and increased risk for venous thrombosis.

Most pregnant women have compensatory adaptations that reduce the supine hypotension despite aortocaval compression. One compensatory response is a reflexive increase in peripheral sympathetic nervous system activity. This increase in sympathetic activity results in increased systemic vascular resistance and permits arterial blood pressure to be maintained despite the reduced cardiac output. Consequently, the reduced sympathetic tone from neuraxial or general anesthetic techniques impairs the compensatory increase in vascular resistance and exacerbates the impact of hypotension from supine positioning. Compression of the lower abdominal aorta by the gravid uterus reduces arterial pressure in the lower extremities; however, decreases in systemic blood pressure as measured in the maternal arms are not reflective of this change.[11] Consequently, even without maternal symptoms, uterine and placental blood flow may be substantially decreased from supine aortocaval compression. Even with a healthy term pregnancy, prolonged maternal hypotension can significantly decrease uterine blood flow and lead to progressive fetal acidosis.[12]

Therefore, supine positioning is avoided during use of neuraxial techniques for labor analgesia and cesarean deliveries. Reducing the compression of the inferior vena cava and abdominal aorta with left tilt mitigates the degree of hypotension and helps maintain uterine and fetal blood flow. This is accomplished by positioning the patient laterally or by elevating the right hip 10 to 15 cm with a blanket, wedge, or table tilt.

Increased venous pressure below the level of compression of the inferior vena cava diverts venous blood return from the lower half of the body via the paravertebral venous plexuses to the azygos vein. Flow from the azygos vein enters the superior vena cava to bypass the obstruction and maintain venous return to the heart. Dilation of the epidural veins in pregnancy may make unintentional placement of the epidural catheter more likely. An unintended intravascular bolus of local anesthetic solution could result. An unintended intravenous bolus of local anesthetic can have significant

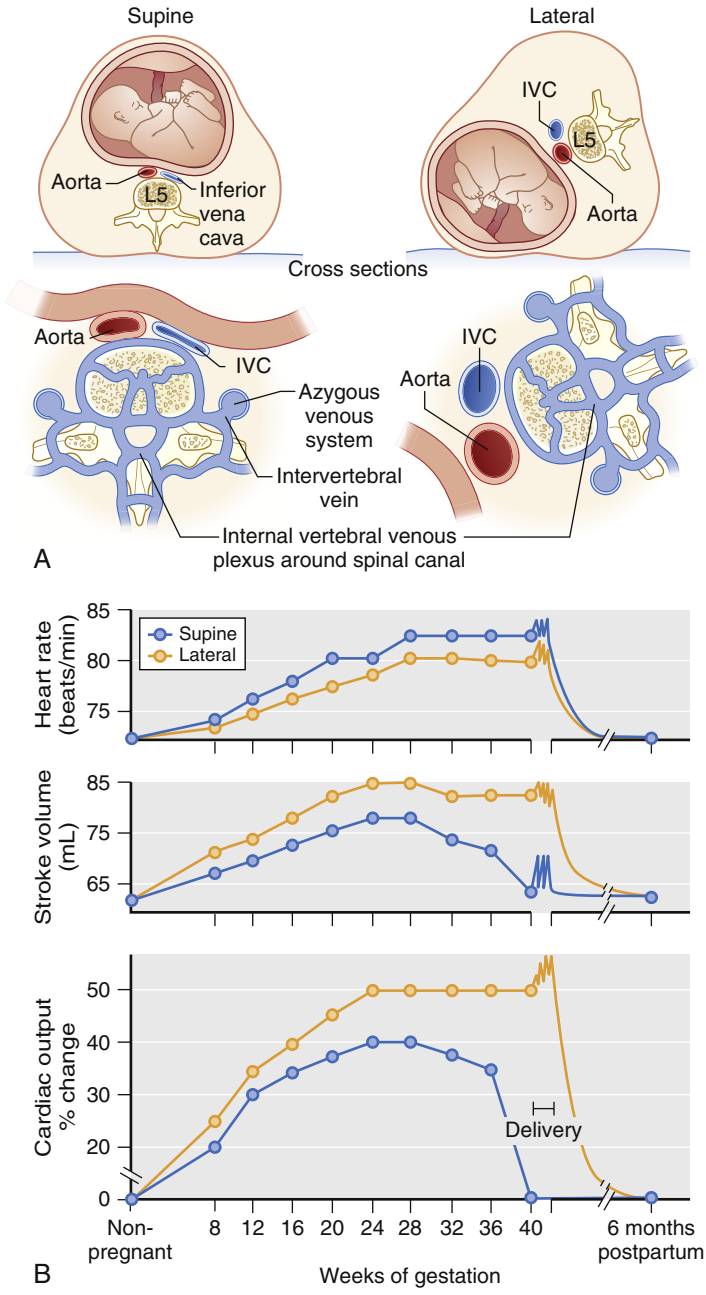

Figure 77-1. Cross-sectional views of aortocaval compression from the gravid uterus in the supine position with loss of compression in the lateral position (**A**). Alterations in heart rate, stroke volume, and cardiac output for both supine and lateral positioning with increasing gestation of pregnancy (**B**). *IVC,* Inferior vena cava. (Reprinted with permission from Bonica JJ, editor: *Obstetric analgesia and anesthesia,* Amsterdam, 1980, World Federation of Societies of Anaesthesiologists.)

consequences on the cardiovascular and central nervous systems with the possibility of complete hemodynamic collapse, seizures, and death. A small, nontoxic test dose is thus employed to decrease the likelihood of unrealized intravascular placement with initiation of neuraxial blockade. This technique is described in the section on epidural analgesia.

The cardiovascular changes of a normal pregnancy are significant. In cardiac auscultation an accentuated first heart sound (S_1) can be heard, with an increased splitting noted from dissociated closure of the tricuspid and mitral valves. A third heart sound (S_3) is often heard in the final trimester, and a fourth heart sound (S_4) can also be heard in a few pregnant patients as a result of increased volume and turbulent flow. Neither the S_3 nor S_4 has clinical significance. In addition, a benign grade 2/6 systolic ejection murmur is typically heard over the left sternal border and is secondary to mild regurgitation at the tricuspid valve from the annular dilation associated with the increased cardiac volume. Table 77-1 details the effects of pregnancy on the electrocardiogram and echocardiography. Women who present with chest pain, syncope, high-grade flow murmurs, and clinically significant shortness of breath or severe arrhythmias should undergo appropriate diagnostic investigation and referral.

RESPIRATORY SYSTEM CHANGES

Pregnancy results in significant alterations in (1) the upper airway, (2) lung volumes and minute ventilation, and (3) O_2 consumption and metabolic rate (Table 77-2).

TABLE 77-2 **CHANGES IN THE RESPIRATORY SYSTEM AT TERM**

Pulmonary Parameter	Value Near Term Compared With Nonpregnant Value (%)
Minute ventilation	Increased 45-50
Tidal volume	Increased 40-45
Respiratory rate	Increased 0 to 15
Lung Capacities and Associated Volumes	
Total lung capacity	Decreased 0-5
Vital capacity	No change
Inspiratory capacity	Increased 5-15
Inspiratory reserve volume	Increased 0-5
Tidal volume	Increased 40-45
Functional residual capacity	Decreased 20
Expiratory reserve volume	Decreased 20-25
Residual volume	Decreased 15-20
Oxygen Consumption	
Term	Increased 20
Labor (first stage)	Increased 40 above prelabor value
Labor (second stage)	Increased 75 above prelabor value
Respiratory Measures	
FEV_1	No change
FEV_1/FVC	No change
Closing capacity	No change

The Upper Airway

During pregnancy, capillary engorgement occurs with increased tissue friability and edema of the mucosal lining of the oropharynx, larynx, and trachea. As a result, an increased risk for bleeding exists during manipulation of the upper airway, in addition to an increased risk of difficult ventilation and intubation of the trachea. Suctioning of the airway and placement of devices (nasal instrumentation should be avoided) should be performed gently to prevent bleeding. Furthermore, there is increased risk for airway obstruction during ventilation and both laryngoscopy and tracheal intubation are more difficult. Also, after extubation, the airway may be compromised as a result of edema, with subsequent risk for airway obstruction in the immediate recovery period.

Consequently, attempts at laryngoscopy should be minimized and a smaller size cuffed endotracheal tube (6.0 to 6.5 mm internal diameter) used to minimize the chances of difficult placement secondary to airway edema. Airway edema can be more severe in patients with coexisting preeclampsia, in upper respiratory tract infections, and after active pushing as a result of associated increased venous pressure.[13] In addition, pregnancy-associated weight gain, particularly in women of short stature or with coexisting obesity, can create a difficult laryngoscopy because of a shorter neck and increased breast tissue. In all cases, a patient's position should be optimized and all airway instrumentation should be available before attempts are made at intubation of the trachea.

Minute Ventilation and Oxygenation

The increased O_2 demand and carbon dioxide production of the growing placenta and fetus cause minute ventilation to be increased 45% to 50% more than nonpregnant values in the first trimester and for the remainder of the pregnancy. This larger minute ventilation is attained primarily as a result of a larger tidal volume and a slight increase in respiratory frequency. Maternal $Paco_2$ decreases from 40 mm Hg to approximately 30 mm Hg during the first trimester as a reflection of the increased minute ventilation. Arterial pH, however, remains only mildly alkalotic (typically 7.42 to 7.44) because of metabolic compensation with increased renal excretion of bicarbonate ions (HCO_3^- is typically 20 or 21 mEq/L at term). Early in gestation, maternal room air PaO_2 is more than 100 mm Hg because of the presence of hyperventilation and the associated decrease in alveolar CO_2. Later, PaO_2 becomes normal or even slightly decreased, most likely reflecting small airway closure with normal tidal volume ventilation and intrapulmonary shunt. Arterial oxygenation can be significantly improved by moving the patient from the supine to the lateral position. Maternal Hb is right shifted, with the P50 (partial pressure of O_2 at which Hb is 50% saturated with oxygen) increasing from 27 to approximately 30 mm Hg. The higher P50 in the mother and lower P50 in the fetus mean that the fetal blood has higher affinity for O_2 and offloading of O_2 across the placenta is facilitated.

At term, O_2 consumption is increased by 20%. During the first stage of labor, O_2 consumption increases above prelabor values by 40% and during the second stage it is increased by 75%. The pain of labor can result in severe hyperventilation causing $Paco_2$ to occasionally decrease below 20 mm Hg.

Lung Volumes

During pregnancy, the expanding uterus forces the diaphragm cephalad and creates a 20% decrease in functional residual capacity (FRC) by term (see Table 77-2). This reduction is made up of nearly equal reductions in both the expiratory reserve volume (ERV) and residual lung volume (RV). However, closing capacity (CC) remains unchanged and creates a reduced FRC/CC ratio. This creates more rapid small airway closure with reduced lung volumes, and in the supine position FRC can be less than CC for many small airways, giving rise to atelectasis. Vital capacity does not change with pregnancy. The combination of increased minute ventilation and decreased FRC results in a more rapid rate at which changes in the alveolar concentration of inhaled anesthetics can be achieved.

During induction of general anesthesia, desaturation, and subsequent hypoxemia occur more rapidly than in a nonpregnant patient because of decreased O_2 reserve (secondary to decreased FRC) combined with increased O_2 uptake (resulting from increased metabolic rate). Preoxygenation before general anesthesia is critical for patient safety to mitigate these physiologic changes. Inhalation of either 100% O_2 for 3 minutes before induction of anesthesia, or four vital capacity breaths of 100% O_2 over the 30 seconds immediately before emergent induction is required to prevent hypoxia while intubating the trachea. The increased airway edema makes both ventilation and tracheal

intubation more difficult and further increases the potential for complications and morbidity of general anesthesia in pregnancy.

GASTROINTESTINAL CHANGES

After midgestation, the induction of general anesthesia places pregnant women at increased risk for regurgitation, aspirating gastric contents, and developing acid pneumonitis. The stomach and pylorus are moved cephalad by the gravid uterus. This repositions the intraabdominal portion of the esophagus intrathoracic and decreases the competence of the lower esophageal sphincter muscle. Higher progesterone and estrogen levels of pregnancy further reduce lower esophageal sphincter tone. Gastrin, secreted by the placenta, increases gastric hydrogen ion secretion and lowers the gastric pH in pregnant women. These changes in combination with the increased gastric pressure from the enlarged uterus increase the risk for acid reflux in pregnancy. Maternal gastric reflux with subsequent esophagitis (heartburn) increases with the pregnancy duration and is common in pregnant women.[14] In addition, gastric emptying is decreased with the onset of labor, pain, anxiety, or administration of opioids, and increased gastric contents can further increase the risk for aspiration. However, gastric emptying is not prolonged in pregnancy before labor.[15] Epidural analgesia using local anesthetics alone does not further delay gastric emptying. In contrast, epidural boluses of fentanyl do delay gastric emptying.[16]

All women in labor are considered to have a full stomach and an increased risk for pulmonary aspiration of gastric contents during induction of anesthesia. To reduce this risk, a nonparticulate antacid, a rapid sequence induction of anesthesia technique including cricoid pressure, and endotracheal intubation are considered routine parts of general anesthesia in a pregnant woman past midgestation. Reducing the production and severity of acid pneumonitis is the basis for the administration of antacids to pregnant women before induction of anesthesia. In addition to a nonparticulate antacid such as sodium citrate (30 mL) before induction of general anesthesia, metoclopramide can be useful for decreasing the gastric fluid volume of pregnant women in active labor who require general anesthesia. It can significantly decrease gastric volume in 15 minutes, although prior opioid administration reduces the effectiveness of metoclopramide.[17] Histamine-2 (H_2)-receptor antagonists increase gastric fluid pH in pregnant women approximately 1 hour after administration. A recent Cochrane review notes that a combination of antacids plus H_2 antagonists is more effective than no pharmacologic intervention and better than antacids alone in decreasing gastric acidity.[18] Current American Society of Anesthesiologists (ASA) guidelines for obstetric anesthesia state, "Before surgical procedures (i.e., cesarean delivery, postpartum tubal ligation), practitioners should consider the timely administration of non-particulate antacids, H2 receptor antagonists and/or metoclopramide for aspiration prophylaxis."[19]

HEPATIC AND BILIARY CHANGES

Blood flow to the liver does not change significantly with pregnancy. The markers of liver function, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin, increase to the upper limits of normal with pregnancy. Plasma protein concentrations are reduced during pregnancy, and the decreased serum albumin levels can result in elevated free blood levels of highly protein-bound drugs. Plasma cholinesterase (pseudocholinesterase) activity is decreased approximately 25% to 30% from the 10th week of gestation up to 6 weeks postpartum.[20-22] Although neuromuscular transmission should be analyzed before extubation, the clinical consequence of the reduced cholinesterase activity is unlikely to be associated with more marked prolongation of the neuromuscular block resulting from succinylcholine or mivacurium. Alkaline phosphatase levels more than double secondary to placental production. The risk for gallbladder disease is increased during pregnancy with incomplete gallbladder emptying and changes in bile composition. Cholecystectomy during pregnancy is required in between 1 in 1600 to 1 in 5000 pregnancies.[23]

Renal Changes

Renal blood flow and the glomerular filtration rate are increased 50% to 60% by the third month of pregnancy and remain elevated until 3 months postpartum. Therefore, the clearance of creatinine, urea, and uric acid are increased in pregnancy, and the upper laboratory limits for blood urea nitrogen and serum creatinine concentrations are decreased approximately 50% in pregnant women. Levels of urine protein and glucose are commonly increased as a result of decreased renal tubular resorption capacity. The upper limits of normal in pregnancy in a 24-hour urine collection are 300 mg protein and 10 g glucose.

Neurologic Changes

Pregnant patients are considered more sensitive to both inhaled and local anesthetics. They have a reduced minimum alveolar concentration (MAC) for inhaled anesthetics.[1,2] The MAC of a volatile anesthetic is reduced by 40% in animals[24,25] and 28% in humans during the first trimester of pregnancy.[26] However, MAC or immobility in response to volatile anesthetics occurs at the level of the spinal cord. An electroencephalographic based study suggests that anesthetic effects of sevoflurane on the brain are similar in the pregnant and nonpregnant state.[27] The underlying mechanism of reduced MAC in pregnancy remains unclear; it is likely multifactorial, and many postulate progesterone may have a role.

Pregnant women are more sensitive to local anesthetics. The same level of either spinal or epidural neuraxial blockade is achieved with a smaller dose of local anesthetic compared with that in nonpregnant individuals. At term the epidural veins are engorged, which decreases the size of the epidural space and volume of cerebrospinal fluid (CSF) in the subarachnoid space. However, CSF pressure does not increase with pregnancy until labor, when it increases in a pulsatile manner with both uterine contractions and pushing.[28] Although the decreased volume of these spaces facilitates the spread of local anesthetics, the local anesthetic dose requirement is decreased for neuraxial block as early as the first trimester, before

significant aortocaval compression or other mechanical- or pressure-related changes occur.[29] Consequently, the increased nerve sensitivity and decrease in local anesthetic dose requirements are likely biochemical in origin.

UTEROPLACENTAL PHYSIOLOGY

The placenta is composed of both maternal and fetal tissues and is the interface of maternal and fetal circulation systems. It provides a substrate for physiologic exchange between the two systems. The placenta is made up of a basal and a chorionic plate that are separated by the intervillous space. Maternal blood is delivered to the placenta by the uterine arteries and enters the intervillous space via the spiral arteries. The fetal blood arrives at the placenta via two umbilical arteries that form umbilical capillaries that cross the chorionic villi. After placental exchange, nutrient-rich and waste-free blood is returned from the placenta to the fetus through a single umbilical vein.

UTERINE BLOOD FLOW

An understanding of uteroplacental blood flow is critical for appropriate clinical care. Uterine blood flow increases progressively during pregnancy from about 100 mL/minute in the nonpregnant state to 700 mL/minute (~10% of cardiac output) at term gestation. Approximately 80% of the uterine blood flow perfuses the intervillous space (placenta) and the remainder perfuses the myometrium. Uterine blood flow has minimal autoregulation, and the vasculature remains essentially fully dilated during pregnancy. Uterine and placental blood flow depend on maternal cardiac output and are directly related to uterine perfusion pressure and inversely related to uterine vascular resistance. Decreased perfusion pressure can result from maternal hypotension secondary to hypovolemia, aortocaval compression, or sympathetic blockade and decreased systemic resistance from either general or neuraxial anesthesia. Increased uterine venous pressure also can decrease uterine perfusion. This can occur from supine positioning with vena caval compression, frequent or prolonged uterine contractions, or significant prolonged abdominal musculature contraction (Valsalva) during pushing. Additionally, extreme hypocapnia ($Paco_2$ < 20 mm Hg) occasionally associated with hyperventilation secondary to labor pain can reduce uterine blood flow with resultant fetal hypoxemia and acidosis.

Neuraxial blockade does not alter uterine blood flow as long as maternal hypotension is avoided, but decreases in maternal blood pressure during neuraxial or general anesthesia should be immediately corrected.

Endogenous maternal catecholamines and exogenous vasopressors may cause increasing uterine arterial resistance and decreasing uterine blood flow depending on the class and amount given. In a pregnant ewe model, use of α-adrenergic vasopressors—methoxamine and metaraminol—increases uterine vascular resistance and decreases uterine blood flow, whereas administration of ephedrine did not reduce uterine blood flow despite drug-induced increases in maternal arterial blood pressure.[30] As a result, ephedrine was previously considered the vasopressor of choice for the treatment of hypotension caused by the administration of neuraxial anesthesia to pregnant women. In complete contrast, more recent human trials demonstrate the use of phenylephrine (α-adrenergic agonist) for treatment of neuraxial-induced hypotension or use of phenylephrine as a prophylactic infusion at the time of spinal placement is not only effective in preventing hypotension, but also is associated with less fetal acidosis and base deficit than use of ephedrine.[31-34] Other methods to reduce maternal hypotension with induction of regional or general anesthesia are discussed in the section on anesthesia for cesarean delivery.

PLACENTAL EXCHANGE

Oxygen Transfer

The delivery of O_2 from the mother to the fetus depends on a variety of factors, including the ratio of maternal to fetal placental blood flow, the O_2 partial pressure gradient between the two circulations, the diffusion capacity of the placenta, the respective maternal and fetal Hb concentrations and O_2 affinities, and the acid-base status of the fetal and maternal blood (Bohr effect). O_2 delivery to the fetus is facilitated primarily because the fetal oxyhemoglobin dissociation curve is left-shifted (greater O_2 affinity) while the maternal oxyhemoglobin dissociation curve is right-shifted (decreased O_2 affinity). Fetal PaO_2 is normally 40 mm Hg and never more than 60 mm Hg, even if the mother is breathing 100% O_2.[35] This is because significant O_2 has been extracted before arrival at the fetoplacental unit. Animal studies note that in the face of decreased O_2 delivery, fetal O_2 consumption can be maintained with increased O_2 extraction until the maternal O_2 delivery is approximately 50% of its normal state.[36,37] CO_2 easily crosses the placenta and is limited by blood flow and not diffusion.

Drug Transfer

Maternal-fetal exchange of most drugs and other substances less than 1000 Daltons occurs primarily by diffusion. The rate of diffusion and peak levels in the fetus depend on maternal-to-fetal concentration gradients, maternal protein binding, molecular weight of the substance, lipid solubility, and the degree of ionization of that substance. The maternal blood concentration of a drug is typically the primary determinant of how much drug will ultimately reach the fetus. The high molecular weight and poor lipid solubility of nondepolarizing neuromuscular blocking drugs result in limited ability of these drugs to cross the placenta (see also Chapter 34). Succinylcholine has a low molecular weight but is highly ionized and therefore does not readily cross the placenta unless given in large nonclinical doses. Thus, during administration of a general anesthetic for cesarean delivery, the fetus or neonate is not paralyzed. Both heparin and glycopyrrolate have minimal placental transfer because they are highly charged. In contrast, placental transfer of volatile anesthetics, benzodiazepines, local anesthetics, and opioids is facilitated by the relatively low molecular weights of these drugs. As a general consideration, drugs that readily cross the blood-brain barrier also readily cross the placenta.

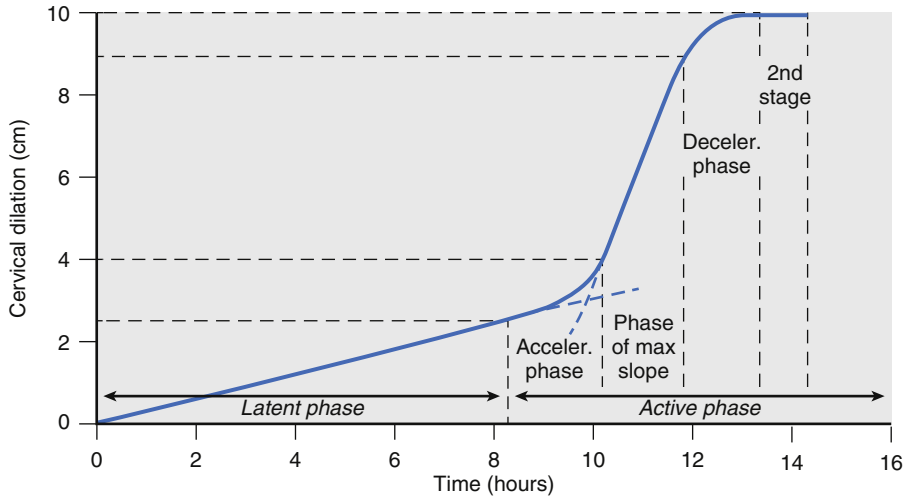

Figure 77-2. Friedman's original sigmoid model of the progress of cervical dilation over time based on an analysis of 500 nulliparas at term. Since the model's development, the existence of a deceleration (*Deceler.*) phase has been discounted and the actual time frame has expanded, likely as a result of physiognomic and treatment-related changes. *Acceler,* Acceleration. (Reproduced with permission from Friedman E: Primigravid labor: a graphicostatistical analysis, *Obstet Gynecol* 6:567-589, 1955.)

Fetal blood is more acidic than maternal blood, and the lower pH creates an environment in which weakly basic drugs, such as local anesthetics and opioids, cross the placenta as nonionized molecules and become ionized in the fetal circulation. Because this newly ionized molecule has more resistance to diffusion back across the placenta, the drug may accumulate in the fetal circulation and reach levels higher than the maternal blood. This process is referred to as ion trapping. During fetal distress (lower pH in the fetal circulation), higher concentrations of these weakly basic drugs can be trapped.[38] High amounts of local anesthetics in the fetal circulation decrease neonatal neuromuscular tone. Extremely high levels, such as those associated with unintended maternal intravascular local anesthetic injection, result in a variety of fetal effects, including bradycardia, ventricular arrhythmias, acidosis, and severe cardiac depression. Placental transfer and fetal uptake of specific analgesic and anesthetic drugs are detailed later in the sections on methods of labor analgesia and anesthesia for cesarean delivery.

FETAL CIRCULATION AND PHYSIOLOGY

The fetal blood volume increases throughout gestation. Approximately two thirds of the fetal-placental blood volume is contained within the placenta.[39] During the second and third trimester, the fetal blood volume has been estimated to be approximately 120 to 160 mL/kg of fetal body weight.[40] Thus, the total blood volume of a term normal fetus is approximately 0.5 L. Although fetal liver function is not yet mature, coagulation factors are synthesized independent of the maternal circulation. The serum concentrations of these factors increase with gestational age and do not cross the placenta. However, fetal clot formation in response to tissue injury is decreased in comparison to that in adults. The anatomy of the fetal circulation helps decrease fetal exposure to potentially high concentrations of drugs in umbilical venous blood. Approximately 75% of umbilical venous blood initially passes through the fetal liver, which may result in significant drug metabolism before the drug reaches the fetal heart and brain (first-pass metabolism). Fetal and neonatal enzyme system activities are lower than those of adults, but most drugs can be metabolized. In addition, drugs entering the fetal inferior vena cava via the ductus venosus are initially diluted by drug-free blood returning from the fetal lower extremities and pelvic viscera. These anatomic characteristics of the fetal circulation markedly decrease fetal plasma drug concentrations compared to maternal concentrations.

LABOR PROGRESS

Labor begins with the onset of repetitive uterine contractions that result in the dilation of the cervix. In reality, however, preparation for labor may begin several hours or days before active labor with an inflammatory process mediated by cellular infiltration and release of local cytokines that result in softening of the cervix. The signals that orchestrate the onset of spontaneous labor are not precisely known. Organized, regular uterine contractions result in progressive cervical dilation and effacement. When spontaneous labor does not occur at an appropriate time, labor may be induced for fetal or maternal indications with various pharmacologic and physical methods.[41]

Labor is a continuous process separated into first, second, and third stages. The first stage of labor includes the change of the uterine cervix from a thick, closed tube to an opening of approximately 10 cm through which the fetus can be expelled. This stage is further divided into a latent phase and an active phase. The second stage of labor begins when the cervix is fully dilated and ends with the expulsion or birth of the fetus. The third stage of labor is the delivery of the placenta. The time course of the first stage of labor was first studied by Emanuel Friedman who described a sigmoidal relationship between cervical dilation and time (Fig. 77-2). The sigmoidal nature of the relationship has since been challenged in that little evidence

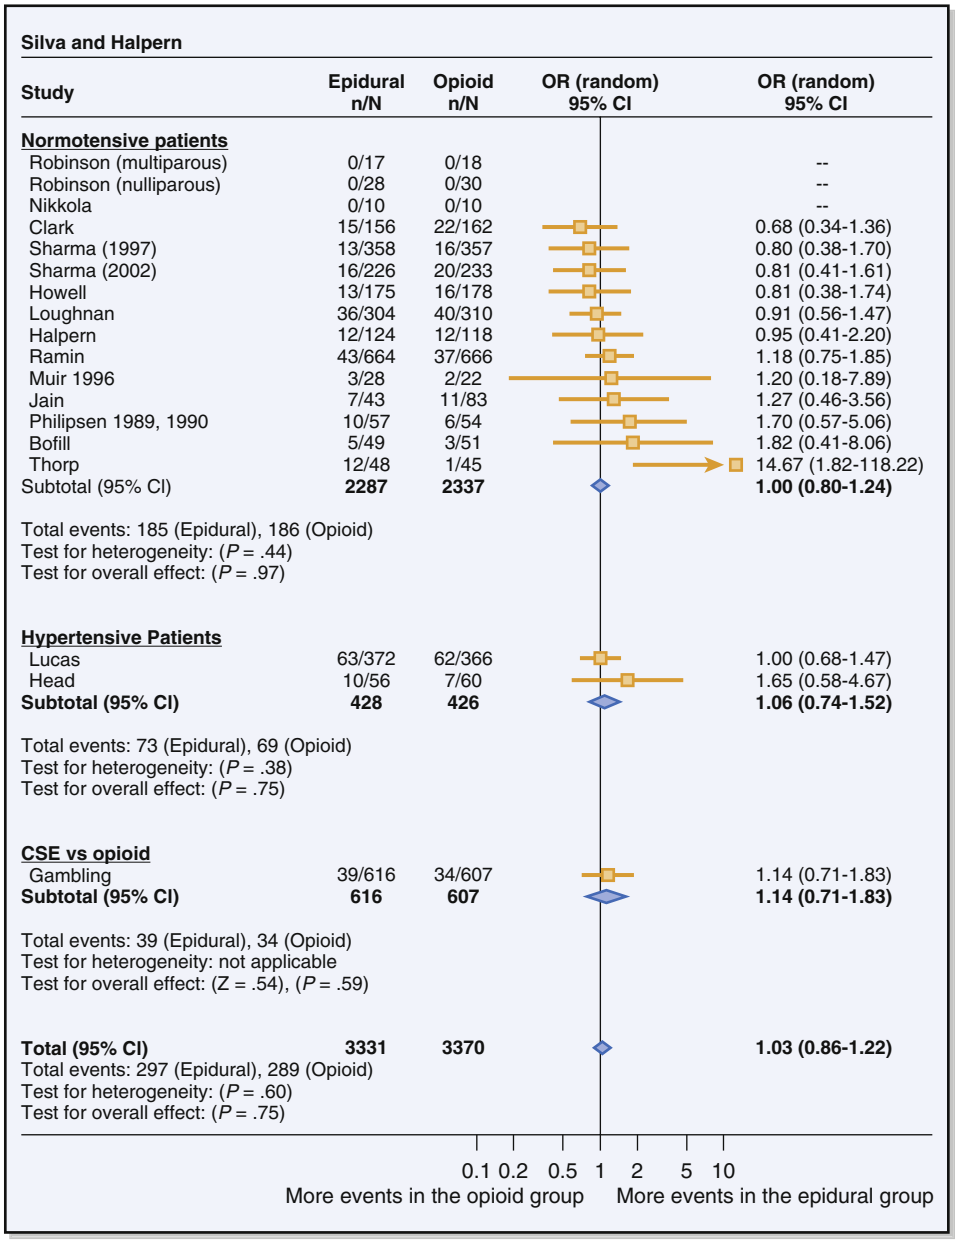

Figure 77-3. The number of patients who had a cesarean section, the odds ratio (*OR*), and 95% confidence interval (*CI*) are shown for each study. The size of the box is proportional to the weight of the study in the meta-analysis. The scale is logarithmic. *N*, Total number of patients in the analysis; *n*, number of events (Reproduced with permission from Leighton, BL, Halperhn SH: Epidural analgesia and the progress of labor. In Halpern SH, Douglas MJ, editors: *Evidence-based obstetric anesthesia,* Oxford, 2005, Blackwell.)

exists for a deceleration phase as the cervix approaches complete dilation (10 cm). However, the separation of the first stage of labor into an early slow phase termed *latent labor* and a more rapid phase of active labor has stood the test of time and advances in modeling techniques.[42,43]

Labor may be referred to as abnormal on the basis of having abnormally slow latent labor, arrest in the active phase, or arrest of descent (failure of stage 2). Dystocia is defined as abnormal labor and may be a result of inadequate uterine contractions, mismatch of fetal and pelvic size, or abnormal fetal position. The Montevideo unit is traditionally used by obstetricians to assess the adequacy of uterine contractions. The Montevideo unit is defined as the intensity of contractions (in millimeters of mercury, as measured with an intrauterine pressure catheter) multiplied by the number of contractions that occur in 10 minutes. The diagnosis of dystocia is based on deviation from normal values derived from populations; however, significant variability exists among individual laboring women. Multiparity has been consistently associated with faster labor. Various demographic and genetic factors contribute to the variability in labor progress.[42-47] Greater maternal weight, older age, and larger fetal size have been associated with slower labor.[42,45,48] Evidence also indicates a hereditary role in labor progress from epidemiologic studies.[49] Specifically, β_2-adrenergic and oxytocin receptor polymorphisms have been implicated in mediating variability in labor progress.[44-46] Abnormally poor response to intrinsic or extrinsic oxytocin may result in abnormal contractility, as would abnormally strong response to β_2-adrenergic agonists and native catecholamines, which inhibit contractility.

Many observational studies have suggested that epidural analgesia is associated with slower labor progress.[45,50] This association has been repeatedly noted in observational trials but has not been replicated in prospective randomized trials (Fig. 77-3). It is not clear that

epidural analgesia *causes* slower labor progress. Rather, various confounding variables could result in this association. Clearly, patients with more exposure to severe pain would be more likely to request analgesia and more likely to request it earlier. Large prospective studies in which patients were randomly assigned to early or late neuraxial anesthesia have invariably concluded that neuraxial anesthesia does not affect the length of the first stage of labor or increase the risk for cesarean delivery and that epidural analgesia placed early in labor does not increase the risk for cesarean delivery.[51-55] Some have hypothesized that the difference between the findings of earlier observational trials and more recent randomized controlled trials might be due to a change to lower concentrations of local anesthetics in regional anesthesia regimens. This is not the case, because a comparison with an older regimen that used 0.25% bupivacaine and a lower dose regimen using 0.1% bupivacaine found no difference in the rate of cesarean delivery.[56] The lack of association makes physiologic sense because uterine smooth muscle is not innervated by motor nerves and thus not affected by local anesthetics. No physiologic mechanism is known by which blockade of sensory transduction or local anesthetic activity would impede uterine contractility. In contrast, several prospective trials suggest that neuraxial anesthesia may cause a modest prolongation of the second stage of labor of approximately 15 minutes.[57,58] This may occur because maternal delivery of the fetus normally requires the participation of abdominal and pelvic skeletal muscle, and diminution of motor nerve transmission and lack of sensory feedback could impede coordinated pushing. Local anesthetic dose can be reduced in the second stage if the blockade is too dense to allow for coordinated expulsion efforts. When the labor is comfortable for the pregnant patient, tolerance for a longer second stage may allow uterine contractions to lower the fetal station before active efforts for vaginal delivery begin.[59]

LABOR AND FETAL MONITORING

Intrapartum fetal monitoring was created in an effort to evaluate fetal well-being and detect fetal distress earlier in labor to allow intervention before any permanent fetal injury. Electronic fetal monitoring (EFM) combines interpretation of fetal heart rate (FHR) monitoring and uterine contraction monitoring. FHR monitoring was developed in the 1960s and has been used increasingly, with 85% of laboring women monitored in 2002.[60] Practitioner variability is frequent in interpretation of the FHR tracings.[61,62] A meta-analysis comparing EFM to intermittent FHR auscultation noted the use of EFM reduced the risk for neonatal seizures (relative risk: .50), but not the risks for perinatal mortality or cerebral palsy.[63] The use of this monitoring increased rates of both operative and cesarean deliveries.[63,64]

FHR monitoring is most commonly accomplished with a surface Doppler ultrasound transducer (external monitoring), but it may be necessary to apply a fetal scalp electrode to obtain accurate continuous FHR monitoring (internal monitoring). For internal monitoring, a peak or threshold voltage of the fetal R wave from the scalp electrode is used to measure FHR. Of note, a fetal scalp electrode can be placed only if the cervix is minimally dilated and the membranes are ruptured. The fetal brain and heart rate respond to fetal asphyxia from activation of peripheral and central chemoreceptors and baroreceptors, as well as a result of various fetal CNS metabolic changes.[65] The changes in FHR produce specific patterns and characteristics that provide an evaluation of the fetal state. The nomenclature, interpretation, and management principles for FHR monitoring were updated in 2009 by the American Congress of Obstetricians and Gynecologists (ACOG).[64] These current guidelines are detailed later, and related terminology is presented in Boxes 77-1 and 77-2. An understanding of the specific uterine contraction and FHR monitoring terminology

BOX 77-1 *Fetal Heart Rate Monitoring Pattern Definitions*

Baseline

The mean FHR rounded to increments of 5 bpm during a 10-minute segment, excluding:
- Periodic or episodic changes
- Periods of marked FHR variability
- Segments of baseline that differ by more than 25 bpm

The baseline must be for a minimum of 2 minutes in any 10-minute segment, or the baseline for that period is indeterminate. In this case, one may refer to the prior 10-minute window for determination of baseline.
- Normal FHR baseline: Rate is 110 to 160 bpm.
- Tachycardia: FHR baseline is greater than 160 bpm.
- Bradycardia: FHR baseline is less than 110 bpm.

Baseline Variability

Fluctuations occur in the baseline FHR that are irregular in amplitude and frequency.

Variability is visually quantitated as the amplitude of peak-to-trough in beats per minute.
- Absent: Amplitude range is undetectable.
- Minimal: Amplitude range is detectable but 5 bpm or fewer.
- Moderate (normal): Amplitude range is 6 to 25 bpm.
- Marked: Amplitude range is greater than 25 bpm.

Acceleration

A visually apparent abrupt increase (onset to peak in < 30 seconds) occurs in the FHR.

At 32 weeks gestation and beyond, an acceleration has a peak of 15 or more bpm above baseline, with a duration of 15 seconds or more but less than 2 minutes from onset to return.

Before 32 weeks gestation, an acceleration has a peak of 10 or more bpm above baseline, with a duration of 10 seconds or more but less than 2 minutes from onset to return.

Prolonged acceleration lasts 2 minutes or more but less than 10 minutes.

If an acceleration lasts 10 minutes or longer, it is a baseline change.

Sinusoidal Pattern

Visually apparent, smooth, sine wave–like, undulating pattern occurring in FHR baseline, with a cycle frequency of 3 to 5 cycles per minute that persists for 20 minutes or longer.

Data from Macones GA, Hankins GD, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, *J Obstet Gynecol Neonatal Nurs* 37:510-515, 2008.
bpm, Beats per minute; *FHR,* fetal heart rate.

BOX 77-2 ***Fetal Heart Rate Monitoring Deceleration Definitions***

Characteristics of Early Deceleration

Visually apparent, usually symmetric gradual decrease and return of the FHR occurs, associated with a uterine contraction.
A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or more.
The decrease in FHR is calculated from the onset to the nadir of the deceleration.
The nadir of the deceleration occurs at the same time as the peak of the contraction.
In most cases, the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively.

Characteristics of Late Deceleration

Visually apparent, usually symmetric gradual decrease and return of the FHR occurs, associated with a uterine contraction.
A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or greater.
The decrease in FHR is calculated from the onset to the nadir of the deceleration.
The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction.
In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively.

Characteristics of Variable Deceleration

Visually apparent abrupt decrease in FHR occurs.
Abrupt FHR decrease is defined as from the onset of the deceleration to the beginning of the FHR nadir of less than 30 seconds.
The decrease in FHR of 15 bpm or greater occurs, lasting 15 seconds or longer and less than 2 minutes in duration.
When the variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive uterine contractions.

Characteristics of Prolonged Deceleration

Visually apparent decrease occurs in the FHR below the baseline.
Decrease in FHR from the baseline that is 15 bpm or more lasting 2 minutes or more but less than 10 minutes.
If a deceleration lasts 10 minutes or longer, it is a baseline change.

Data from Macones GA, Hankins GD, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, *J Obstet Gynecol Neonatal Nurs* 37:510-515, 2008.
FHR, Fetal heart rate.

and clinical implications is critical for optimal communication during emergent situations among anesthesiologists, obstetricians, midwives, and labor nurses.

CONTRACTION MONITORING

Uterine contractions can be monitored externally or with an intrauterine pressure transducer. External monitors allow determination only of contraction frequency, whereas internal monitors also allow quantitative measurement of intrauterine pressure. Uterine contractions are quantified over a 10-minute window that is averaged over a 30-minute window with recent guidelines provided by the ACOG.[64] Normal contractions are defined as five or fewer contractions in 10 minutes, averaged over a 30-minute window. Tachysystole is defined as uterine activity greater than five contractions in 10 minutes, averaged over a 30-minute window. Tachysystole applies to both spontaneous and augmented labor and should always be qualified as to the presence or absence of associated FHR decelerations. The terms *hyperstimulation* and *hypercontractility* are no longer defined and should be abandoned. Treatment of tachysystole during labor may differ depending on the clinical situation, but may include sublingual or intravenous (IV) nitroglycerin[66] to briefly relax the uterus, as well as the use of β_2-adrenergic drugs such as terbutaline.

FETAL HEART RATE TRACING

The FHR tracing is used as a nonspecific reflection of fetal acidosis. It should be interpreted over a time course in relation to the clinical context and other known maternal and fetal comorbidities, because multiple factors other than fetal acidosis can influence the FHR tracing. Box 77-1 defines FHR baseline, variability, and accelerations. Box 77-2 details FHR tracing deceleration characteristics. Late decelerations are a result of uteroplacental insufficiency causing relative fetal brain hypoxia during a contraction. The resulting sympathetic outflow elevates the fetal blood pressure and activates the fetal baroreceptors and an associated slowing in the FHR. A second type of late deceleration is from myocardial depression in the presence of increasing hypoxia.[67] Early decelerations tend to mirror the uterine contraction and are believed to be in response to a vagal stimulus, which may or may not be the result of fetal head compression. However, other sources note these may be a benign variant of the "reflex" late deceleration that rather mirrors the uterine contraction and might evolve into a more typical late deceleration.[68] Variable decelerations are associated with umbilical cord compression. A sinusoidal FHR pattern is associated with placental abruption and is ominous.[69] In general, minimal-to-undetectable FHR variability in the presence of decelerations is associated with fetal acidosis.[70] Severe decelerations (<70 beats/minute for >60 seconds) are associated with fetal acidemia and are extremely ominous, particularly with the absence of variability.[71] These patterns and characteristics are used to define the FHR categories in the following section.

FETAL HEART RATE CATEGORIES

A three-tiered FHR category classification system is currently recommended for fetal assessment.[64] This system evaluates the fetus for a given moment of the assessment, and it must be recognized the fetal condition may move back and forth from one category to another over time. Specific terminology used for categorization is defined in Boxes 77-1 and 77-2.

Category I FHR tracings are considered normal and are predictive of a normal fetal acid-base state at the time of observation, and no specific management is required. All of the following criteria must be present: (1) baseline FHR of 110 to 160 beats/minute, (2) moderate baseline FHR variability, (3) no late or variable decelerations, (4) early decelerations may be present or absent, and (5) accelerations may be present or absent.

Category II FHR tracings are considered indeterminate and include all tracings not in categories I or III. Examples include but are not limited to fetal tachycardia, absence of induced accelerations after fetal stimulation, prolonged decelerations more than 2 minutes but less than 10 minutes, and recurrent late decelerations with moderate baseline variability. Category II tracings are not predictive of abnormal fetal acid-base status and require continued monitoring and reevaluation in light of the entire clinical picture. In some cases, additional tests may be obtained or intrauterine resuscitative measures taken to improve the fetal condition.

Category III FHR tracings are considered abnormal and are associated with an abnormal fetal acid-base state at the time of observation. Category III tracings include either a sinusoidal FHR pattern or absent FHR variability with recurrent late decelerations, recurrent variable decelerations, or bradycardia. These tracings require prompt patient evaluation and efforts to improve the fetal condition. These interventions may include intrauterine resuscitation with change in maternal position, discontinuation of labor augmentation, treatment of maternal hypotension, use of supplemental O_2, and treatment of tachysystole if present. If the FHR tracing does not improve, expeditious delivery should proceed.

LABOR ANALGESIA

Childbirth is a pinnacle event in a family's life that is surrounded by many beliefs and traditions, some of which are founded in science and others more historical. In this context, several nonpharmacologic techniques have been used to relieve the pain of childbirth throughout history, including acupuncture,[72] massage,[73,74] and hypnosis.[75] Drugs were not used in Western medicine to relieve pain in childbirth until the mid-1800s, most famously when the English Queen Victoria chose to inhale chloroform for analgesia during the birth of Prince Leopold.

For most women, labor is intensely painful. However, the time course of pain intensity is highly variable, dynamic, and unpredictable. Some women will experience severe pain only just before the second stage of labor, whereas others will report severe pain from their first contraction. Rarely do women not experience any pain in labor and give birth unexpectedly under inopportune conditions.[76] The source of these differences in labor pain is not completely known but may be in part genetic. In one study, Asian women reported more pain in labor than women of other ethnic backgrounds.[42,45] This association was also found with a single nucleotide polymorphism in the β_2-adrenergic gene.[45] Other factors may include pelvic size and shape, fetal presentation, and whether the contractions are augmented.

NONPHARMACOLOGIC LABOR PAIN MANAGEMENT

Many patients prefer to use nonpharmacologic methods of pain management during all or part of labor. Acupuncture can be effective in treating postoperative pain after cesarean section,[77] but it is not as effective for analgesia during labor. In a recent meta-analysis, labor pain was compared between patients who received acupuncture and those who reviewed sham acupuncture (superficial needling lateral to an actual acupuncture point). The patients reported a small but statistically significant effect of acupuncture (4% to 6%) that lasted for only 30 minutes.[78] Unfortunately, most of the trials were not properly blinded, increasing the likelihood of bias.

Several trials have found a reduction in pain and anxiety during the first stage of labor with the use of massage. A Cochrane review on massage in labor identified seven randomized trials of massage, six of which were judged to have low or unclear risk for bias.[74] During the first stage of labor, pain was reduced in the massage group by –0.98/10 (confidence interval [CI], 1.17 to 0.47). No difference was found in the use of pharmacologic pain relief between groups or in pain report during the second and third stages of labor. One study of 60 women found that massage decreased anxiety.[79]

Hypnosis has been used both as a relaxation technique and for management of pain during labor. When hypnosis was compared with standard care, no evidence was found that pain was less after hypnosis, nor was evidence found for a difference in satisfaction with pain relief.[74]

Other nonpharmacologic techniques include the breathing techniques described by Lamaze, the LeBoyer technique, transcutaneous nerve stimulation, hydrotherapy, presence of a support person, intradermal water injections, and biofeedback. A retrospective national survey of women's childbearing experiences found that although neuraxial methods of pain relief were considered the most helpful and effective, nonpharmacologic methods of tub immersion and massage were rated more or equally helpful in relieving pain compared with the use of opioids.[80] Although many nonpharmacologic techniques seem to reduce the perception of labor pain, most published studies lack the rigorous scientific methodology for useful comparison of these techniques to pharmacologic methods.

CONSIDERATIONS FOR PHARMACOLOGIC TREATMENT OF PAIN IN LABOR

Preprocedural assessment is required for any patient who is a potential candidate for neuraxial analgesia and should be considered as a preparation for potential obstetric emergency. Assessment of all laboring women for risk factors for neuraxial analgesia and general anesthesia is recommended, because in the event an emergency decision is made to proceed with either procedure, sufficient time may not be available for adequate, safe evaluation and discussion with the patient. In otherwise healthy women, routine laboratory testing is not required.[19] Although any laboring woman has the potential to require cesarean section, labor takes many hours and requires adequate nutrition and hydration. While balancing these two considerations, the ASA has recommended that moderate amounts of clear liquids be allowed during the administration of neuraxial analgesia and throughout labor and, furthermore, a period of abstention from solids before the placement of neuraxial analgesia is not required.[19]

SYSTEMIC MEDICATIONS

The first systemic medications used for labor analgesia were herbal and plant preparations. Plant extracts used for labor analgesia include motherwort and rice bran syrup,[81] but these treatments have not been prospectively studied, and it is unknown whether these treatments provide analgesic benefit. Extracts of the poppy plant that contain opium have analgesic properties that are clearly a result of their activation of the μ-opioid receptor. Many other natural and synthetic drugs that also act via activation of the μ-opioid receptor provide statistically and clinically significant labor analgesia. Opioids are used commonly for labor analgesia because they are mostly inexpensive and widely available. They can be administered intramuscularly without the need for IV access. In current practice, long-acting opioids used for labor analgesia include morphine, hydromorphone, and meperidine. Worldwide, meperidine is the most commonly used long-acting opioid in obstetric practice[82] but, unfortunately, the most likely to result in side effects. It is typically administered intravenously in doses of up to 25 mg or intramuscularly in doses up to 50 mg. Maternal half-life is 2 to 3 hours, and fetal and newborn half-life is significantly longer (13 to 23 hours) with an active, potentially neurotoxic metabolite (normeperidine) that can accumulate with repeated doses. With increased dosing and shorter intervals between doses and delivery, risk to the newborn is increased, including lower Apgar scores and prolonged time to sustained neonatal respiration.[83]

Morphine is rarely used for labor pain. Like meperidine it has an active metabolite (morphine-6-glucuronide) with a half-life that is longer in neonates than in adults, and it produces significant maternal sedation. Obstetricians may use intramuscular morphine combined with phenergan for analgesia, sedation, and rest termed "morphine sleep." This combination produces analgesia and sedation for approximately 2.5 to 4 hours, with an onset of 10 to 20 minutes and is used most commonly in latent labor.

More recently, the shorter acting fentanyl and ultra–short-acting remifentanil have entered clinical practice. Fentanyl has a short duration and no active metabolites. When given in small IV doses of 50 to 100 μg/hr, no significant differences are seen in neonatal Apgar scores and respiratory effort compared with those in newborns of mothers not receiving fentanyl.[84]

Remifentanil has entered clinical practice as an alternative to neuraxial analgesia for patients with contraindications and in some settings as an alternative for patients who simply do not desire neuraxial anesthesia. Overall, short-acting and long-acting opioids do not show a significant difference in pain relief. One exception is that remifentanil may offer some advantage over other opioids in efficacy.[73] In addition, remifentanil offers an important safety advantage when used in active labor in that it is an ultra short acting opioid highly metabolized by placental esterase and thus the fetal-to-maternal ratio is small. The metabolism of remifentanil depends completely on tissue tissue and plasma esterases, which are fully mature in the fetus. Thus, remifentanil does not depend on the maturity of any organ for its degradation and is more rapidly metabolized in the fetoplacental unit than in the maternal plasma. In the pregnant ewe model, the maternal-to-fetal ratio of remifentanil is approximately tenfold,[85] and the ratio was similar in human studies.[86] Because of these characteristics, more remifentanil can be administered to the mother at times close to delivery than would be considered safe for longer acting opioids that rely on slower metabolism by the liver. Remifentanil is more effective than long-acting opioids[73]; however, the improvement in pain relief may be because larger doses of remifentanil were given compared with doses of meperidine.[87] Another study comparing remifentanil to meperidine and fentanyl noted improved analgesia with remifentanil in the first hour, with return to no difference between opioids after 3 hours.[88] A randomized controlled trial comparing epidural analgesia to use of a remifentanil patient-controlled analgesia noted lower pain scores in the epidural group.[89] Although there was higher maternal sedation in the remifentanil group, there were no differences in fetal outcome measures. The major risk of remifentanil in labor is maternal respiratory depression. Careful surveillance is required to ensure adequate oxygenation throughout treatment.

INHALED ANALGESIA

Inhaled anesthetics were the first treatments for labor analgesia used in modern times. The first woman anesthetized for childbirth in the United States was Fanny Longfellow, the wife of the poet, Henry Wadsworth Longfellow. Longfellow acted as anesthesiologist to his wife who was highly criticized for her decision to accept anesthesia. In the United Kingdom, Emma Darwin, wife of Charles Darwin, was anesthetized with chloroform for the last two of her eight births, also with her famous husband acting as anesthesiologist. Six years later, British Queen Victoria was administered chloroform for analgesia by Dr. John Snow during the birth of Prince Leopold.[90] Despite disapproval from religious authorities, pregnant women in the United States and Britain voted with their swollen feet and began requesting anesthesia for childbirth. However, as volatile anesthetics became more commonly used in childbirth, side effects were more commonly encountered. Neonatal depression and maternal gastric aspiration were reported as volatile techniques became more commonly used for operative delivery.[91-93] Delivery was complicated by aspiration of gastric contents in 66 women from 44,016 deliveries (0.15%) between 1932 and 1945. The preventive fasting measures recommended by Mendelsohn became cornerstones of obstetric anesthesia practice. Reduction of stomach contents by restricting intake, provision of nonparticulate antacids, and improvement of anesthetic-induction technique have improved the safety of volatile anesthetics in pregnancy, which are in modern times almost exclusively used as general anesthetics for cesarean section rather than for pain relief during vaginal delivery. Volatile anesthetics are no longer used for labor analgesia. Nitrous oxide, however, is still commonly used worldwide and is welcomed by many parturients as a less invasive approach to pain relief in labor.

In 1881, Stanislav Klikovitch described the use of N_2O for labor in Russia.[94] Klikovitch recommended mixing N_2O with O_2 and intermittent use of the gas with contractions. N_2O is currently used commonly in this manner

for labor analgesia in Europe, Scandinavia, and Australia, but only uncommonly in the United States. Typically it is blended with O_2 in a 50:50 ratio or slightly greater for patient-inhaled self-administration. N_2O provides significant pain relief with a median reduction of pain score of 14/100 (95% CI −4 to −24) in a meta-analysis that included data from three studies.[95] Compared with placebo or no treatment, N_2O is associated with a median reduction in pain score of 3.5 in 10 (95% CI 3.3 to 3.8) in one study of 509 parturients.[95] Some studies have demonstrated moderate analgesia in response to inhaled N_2O (8 in 10 to 6 in 10),[96] whereas others have shown no difference in visual analogue pain scores.[97] Paradoxically, many of the women who were enrolled in the previously mentioned negative study by Carstoniu and colleagues[97] wished to continue its use after the study period. Women in other studies have reported significant "benefit" to its use, and the majority who used it during labor stated that they would choose it as a form of pain relief for subsequent labors.[98,99] The analgesic effect of N_2O may be confounded by sedative or relaxing effects that offer benefit to the parturient apart from or in addition to analgesia. Without the coadministration of opioids, use of 50% N_2O in O_2 is safe and does not result in hypoxia, unconsciousness, or loss of protective airway reflexes.[100] In addition, no decrease in uterine contractility or neonatal depression occurs regardless of duration of use.

NEURAXIAL ANALGESIA

Neuraxial analgesia is the most reliable and effective method of reducing pain during labor.[80] However, it is encumbered by small but real and predictable risks.

Timing of Placement

The optimal timing for the placement of a neuraxial anesthetic has been extensively studied. In a 2011 updated Cochrane review of 38 trials including 9658 parturients, epidural analgesia offered better pain relief compared with placebo (median reduction 3.4 in 10 (95% CI 1.3 to 5.4) and reduced the need for additional pain medication.[101] However in these trials, the use of neuraxial analgesia was associated with an increased risk of requirement for assisted vaginal birth (relative risk [RR] 1.4, 95% CI 1.3 to 1.6), motor blockade (RR 32, 95% CI 4 to 232), urinary retention (RR 17, 95% CI 5 to 60), longer second stage of labor (mean diiference [MD] 13.7 minutes, 95% CI 6.7 to 20.7 minutes), and risk for cesarean section for fetal distress (RR 1.4, 95% CI 1.03 to 1.97). However, the rate of cesarean section and neonatal Apgar scores were not different. Therefore, epidural analgesia can provide superior analgesia, but at the cost of an increased likelihood of instrument delivery and a prolonged second stage of labor (see earlier discussion of labor progress). Does the stage of labor at which the neuraxial analgesic was placed influence the ensuing time course of labor? As discussed previously, older studies in which larger doses of local anesthetic were used that did not use random allocation of treatment found that early initiation of epidural analgesia is associated with a longer first stage of labor. Blinding of patient and investigator in studies of a complex intervention, such as neuraxial analgesia, is difficult, but inadequate blinding and random allocation leaves the results of the trial subject to concerns for bias. In 2011, a meta-analysis including prospective, well-randomized trials was conducted to test the hypothesis that neuraxial analgesia placement during the early first stage of labor is associated with prolonged first stage of labor.[102] Six studies of 15,399 parturients compared placement of neuraxial analgesia at 3-cm cervical dilation or less to placement only in active labor. No increase was found in the incidence of cesarean section, and the first stage of labor was not prolonged. Thus, if a parturient chooses neuraxial analgesia despite the increased risk for a prolonged second stage and maternal fever, no evidence indicates that any point in the first stage of labor is "too early" to initiate analgesia. Current ASA guidelines note that maternal request for labor pain relief is sufficient justification for intervention and the decision should not depend on an arbitrary cervical dilation.[19]

Epidural Analgesia

Epidural analgesia is most commonly initiated after placement of a catheter into the epidural space between L2-3 and L4-5. Initial dosing of local anesthetic through the needle within the epidural space is not recommended because of potential unintended intravascular placement and rapid onset of local anesthetic toxicity, including seizures, arrhythmias, and cardiovascular collapse. Analgesia should be initiated with a test dose consisting of a dose of local anesthetic that would not be harmful if injected intravascularly but that would induce an altered sensorium, most commonly described as dizziness or a sensation of buzzing in the ears or numbness in the lips. This dose should be sufficient to cause numbness and motor block in the lower extremities if inadvertently injected into the spinal fluid but would not cause significant sensory effects if injected into the epidural space. Thus, the "test dose" tests for inadvertent intravascular or intrathecal placement of the catheter.[103] Some clinicians favor inclusion of a small dose of epinephrine in the test dose so that if the placement were intravascular, a slight tachycardia would ensue. However, the utility of the inclusion of epinephrine has been debated in the setting of pregnancy because the sensitivity and specificity of small changes in heart rate in the setting of uterine contractions may not be adequate. A prospective blinded randomized study of 59 laboring women administered an IV injection of 0, 1, 2, or 3 mL of 1.5% lidocaine with 1:200,00 epinephrine to mimic an epidural test dose, measured the sensitivity and specificity for this intervention with a blinded observer.[104] In all cases, the total volume injected was diluted with normal saline for a final volume of 3 mL. For women receiving either the 2- or 3-mL test dose (lidocaine with epinephrine), the sensitivity was 100% (100% negative predictive value), but examination of the women who received only saline noted the specificity was only 79% with 11 of 15 true negative results. Although the 100% sensitivity will indeed prevent unrecognized intravascular catheter placement, a 21% false-positive rate is problematic because these catheters would be inappropriately removed. The risk for adverse effects from intravascular injection of local anesthetic is mitigated by the use of slow and low concentrations of local

anesthetic infusions rather than repeated bolus doses of concentrated local anesthesia.

Intrathecal and Combined Spinal Epidural Analgesia

Intrathecal analgesia for labor can be used independently of epidural analgesia, or more commonly combined with the placement of an epidural catheter so that when the analgesic effect of the intrathecal dose dissipates, analgesia can be maintained with an epidural infusion. However, intrathecal analgesia alone is useful when the duration of labor can be reasonably estimated. For example, what should be done if a multiparous parturient in the second stage of labor requests analgesia? Opioid combined with a small dose of local anesthetic is quick to perform, provides rapid analgesia, and dissipates when no longer needed. When an epidural catheter is placed in addition to the intrathecal dose, no loading dose is required because the parturient will have analgesia from the spinal dose that will normally last until an epidural infusion can reach a steady state. In this setting, identification of an intrathecal catheter may be less reliable because the patient already has analgesia. However, typical doses of local anesthetic in combined spinal epidural placements provide analgesia without motor block, and the detection of an intravascular catheter as discussed previously may have value.[104]

Neuraxial Analgesic Medications

Any preservative-free local anesthetic can be used in an epidural catheter. Most commonly, bupivacaine and ropivacaine are used because the ratio of sensory to motor blockade is greater than that for lidocaine or 2-chloroprocaine. Epidural lidocaine and 2-chloroprocaine are usually reserved for surgical anesthesia, rather than labor analgesia, in which preserved motor function during the procedure is not desirable.

During the 1990s, intrathecal lidocaine and 2-chloroprocaine were associated with multiple case reports of transient neurologic symptoms and longer lasting cauda equine syndrome.[105,106] Notably, most but not all cases were associated with high concentration—that is, hyperbaric preparations. In vitro, high concentrations of all local anesthetics cause neuronal necrosis or apoptosis; this is likely to be the cause of cauda equina syndrome, but the cause of transient neurologic symptoms is at present not clear.[107] Transient neurologic symptoms and cauda equina syndrome also have been reported with intrathecal bupivacaine[108]; however, the risk for transient neurologic symptoms is greater with lidocaine than bupivacaine (RR 5.1; 95% CI 2.5 to 10.2).[109]

Epidural analgesia for labor began in 1909 when Stoeckel reported 141 cases of caudal epidural anesthesia.[110] Since that time, lumbar epidural analgesia has replaced caudal anesthesia for labor. A search is ongoing for the perfect analgesic recipe that would provide excellent analgesia with no motor blockade or other maternal or fetal effects. This combination has yet to be described. In more recent years, lower concentrations of local anesthetic have been used alone or combined with opioids and multiple other analgesic adjuvants to reduce motor blockade and improve sensory blockade. All local anesthetics cause dose-dependent sympathetic blockade. At higher concentrations, maternal hypotension can result in fetal asphyxia. Epidural bupivacaine (0.625% to 0.125%) or ropivacaine (0.625% to 0.2%) are most commonly used for obstetric analgesia because of the reduced motor block. Ropivacaine and levobupivacaine were synthesized to reduce cardiotoxicity that occurs with inadvertent intravascular bolus doses of bupivacaine. However, with the small doses of local anesthetic currently used for labor analgesia, cardiotoxicity is uncommon.

The addition of lipid-soluble opioids, fentanyl 1 to 3 μg/mL or sufentanil 0.1 to 0.5 μg/mL allowed the reduction of local anesthetic dose with associated decreased motor blockade, preserved analgesia, and enhanced maternal satisfaction.[111] Unfortunately, no epidural opioid only regimen provides adequate analgesia without unacceptable side effects. The most troublesome complication that limits the dose of epidural fentanyl is itching. Patient-controlled epidural analgesia allows the patient to dose the epidural catheter with the use of a pump that has a maximum amount of drug per hour to prevent toxicity. In one study, patients who self-administered local anesthetic as needed in labor used less drug and had similar pain relief.[112]

The search for the perfect labor epidural drug combination has led to the use of other adjuvant drugs that can reduce the dose of local anesthetic that is required. Most of these drugs act through activation of adrenergic receptors. Epinephrine is a nonselective adrenergic agonist activating α_1-, α_2-, β_1-, and β_2-adrenergic receptors. Activation of α_1-receptors in the epidural vasculature causes vasoconstriction that delays the vascular uptake of local anesthetic and opioid.[113] Additional analgesia is likely provided by epinephrine through activation of α_2-adrenergic receptors.[114] The dose of epidural epinephrine is typically dilute (1:400,000 to 1:800,000) secondary to concern for uterine artery vasoconstriction by systemic effects of higher doses. Neostigmine reduces the degradation of synaptic epinephrine and has effects similar to those of low-dose epinephrine.[115-117] Intrathecal neostigmine causes an unacceptable incidence of nausea and vomiting,[115] and epidural neostigmine does not seem to offer any advantage over epinephrine (see also Chapter 97). Clonidine is a relatively selective α_2-adrenergic antagonist that when added to dilute local anesthetic solution provides adjuvant analgesia.[118,119] Although clearly effective for labor analgesia, within the United States epidural clonidine carries a U.S. Food and Drug Administration (FDA) warning that states it is "not recommended for obstetrical, postpartum or perioperative pain management as the risk of hemodynamic instability (e.g., hypotension, bradycardia) may be unacceptable in this population." Monitoring recommendations related to this statement declare that in "a rare obstetrical, postpartum, or perioperative patient, potential benefits may outweigh possible risks." Dexmedetomidine is a significantly more selective α_2-adrenergic receptor agonist that is not approved for epidural use in the United States.[120] However, one randomized controlled trial found that it was efficacious combined with epidural bupivacaine.[121]

Neuraxial Complications

In addition to the neuraxial drug–related complications noted previously, administration of epidural analgesia can

result in rare but severe toxicity. The earliest experiments with spinal cocaine resulted in severe post–dural puncture headache. Leakage of spinal fluid is thought to result in vascular hyperemia, migraine physiology and traction on pain-sensitive fibers may contribute. The incidence, severity, and duration of post–dural puncture headaches are related to the size of the needle and the shape of the tip. Spinal needles used for combined spinal epidural technique range from 25 to 29 gauge and result in an incidence of post–dural puncture headache of less than 1%.[122,123] Epidural catheters are most commonly placed through a 17- or 18-gauge blunt-tipped needle, and thus the incidence of post–dural puncture headache is reported at 30% to 80%.[122] Given the similarity of symptoms to those of migraine headache and the related physiology, post–dural puncture headaches have been treated with drugs that are useful in migraine with variable success. Caffeine is effective to treat the pain of a post–dural puncture headache in the short term likely because of its vasoconstrictive effects,[124] but the duration of the headache is likely related to healing of the rent in the dura. In the setting of dural puncture with an epidural needle, the needle may be replaced at a different interspace or an intrathecal catheter may be placed. If an intrathecal catheter is placed, unintentional injection of an epidural anesthetic dose must be carefully avoided. After an unintended dural puncture, placement of a spinal catheter can provide excellent analgesia and alleviates the need for multiple repeat epidural attempts with the potential of a second accidental dural puncture.[125] The incidence of post–dural puncture headache after a wet tap may or may not be reduced with this technique in comparison to epidural replacement, but labor analgesia is more quickly established with a spinal catheter.[125] When strict aseptic technique is used, infection is uncommon with spinal and epidural anesthesia.[126,127]

The epidural space is highly vascular, and vessels are likely punctured, often in epidural needle placement. However, with normal platelets and coagulation factors, epidural hematoma is extremely uncommon, with an estimated upper limit of 4.6×10^{-5} in the obstetric population.[128] Although rare, back pain and persistent motor blockade are potential signs of epidural hematoma and should be thoroughly evaluated. All parturients should be monitored postpartum until complete resolution of epidural blockade. Direct nerve damage from an epidural or spinal needle placed for labor is exceedingly rare because they are placed below the level of the conus medularis. Damage attributed to direct neurologic injury has been estimated at 0.6 in 100,000 with epidural and 3 in 100,00 with spinal analgesia.[129-131] Postpartum back pain is common regardless of whether neuraxial analgesia has been used after childbirth. However, no evidence indicates that it is more common when neuraxial analgesia is used for labor. Several trials have identified an association between increased maternal temperature and epidural use as a secondary outcome.[132] Attribution of causality is difficult in this setting because temperature increases with advancing labor likely as a result thermogenic cytokines.[132,133] Epidurals are also more likely to be placed later in labor and thus may be associated with higher temperature that results from the intense metabolic activity of labor (also see Chapters 56 and 98 for related information regarding epidural anesthesia and analgesia).

OTHER REGIONAL NERVE BLOCKS

Local anesthetic nerve blocks have been used for many years to relieve labor pain, mostly by obstetricians.[134] For a paracervical block, local anesthetic is injected lateral to the cervix at 4 o'clock and 10 o'clock, taking care to avoid vascular structures. The paracervical block is effective to relieve pain of cervical dilation but does not affect cramping pain from contraction of the uterine corpus. However, paracervical block does reduce pain in the second stage of labor. Paracervical block is more effective for relief of labor pain in contrast to placebo or intramuscular meperidine.[135] No difference was found in pain relief comparing paracervical block to patient controlled analgesia with IV fentanyl.[136] Paracervical block can be complicated by injection of local anesthetic into the presenting fetal head, which can have devastating consequences. Intense fetal monitoring is warranted for a time after the procedure. More commonly, side effects of transient fetal bradycardia and maternal local anesthetic toxicity have been reported.[137-139] The technique of paracervical block has become safer with more superficial injection ensured by a needle guide and more dilute solutions of local anesthetic.

The pudendal nerve is derived from sacral nerve roots and can be blocked with local anesthetic using a transvaginal or transperineal approach to treat pain during the second stage of labor and for episiotomy repair. A pudendal nerve block can be helpful but is not as effective as a subarachnoid block with fentanyl and bupivacaine.[140] Pudendal block can impede the urge to push during the second stage of labor.[141] Other complications include a high rate of block failure; systemic local anesthetic toxicity; ischiorectal or vaginal hematoma; and, rarely, fetal injection of local anesthetic (see also Chapters 56 to 58 regarding regional anesthesia).

ANESTHESIA CONSIDERATIONS FOR OPERATIVE DELIVERY

Low-dose epidural analgesia can be inadequate for assisted vaginal delivery with forceps or vacuum. In this setting, higher concentration local anesthetic can be administered through an indwelling epidural catheter or a "second-stage spinal" can provide excellent perineal analgesia. Supplementation of an indwelling epidural catheter with 5 to 10 mL of 1% to 2% lidocaine or 2% to 3% 2-chloroprocaine is usually adequate, depending on whether vacuum or forceps are being used. Pudendal nerve block also can be considered for operative delivery.

ANESTHESIA FOR CESAREAN DELIVERY

MATERNAL RISKS AND CONSIDERATIONS

Cesarean delivery rates in the United States increased by 50% between 1998 and 2008, rising from 22% to 33% of all births.[142] Although maternal mortality has substantially

decreased during the first half of the twentieth century, the rate of maternal mortality is 10 times higher with cesarean delivery than vaginal delivery, based on a retrospective study of 1.5 million deliveries between 2000 and 2006.[143] Perhaps some of the women who died were in an emergent situation and required general anesthesia rather than a neuroaxial technique. Pregnant women who undergo general anesthesia for cesarean delivery are at increased risk for mortality from pulmonary aspiration of gastric contents and failed intubation of the trachea, inadequate ventilation, or both compared with those under neuraxial blockade, particularly in emergent situations. However, the RR has decreased over time. Data in the United States from 1979 to 1990 noted a 16.7 increased mortality risk with use of general anesthesia for cesarean delivery compared with neuraxial blockade[144]; between 1997 to 2002, the risk ratio was only 1.7 with general anesthesia.[145] In addition to improved maternal safety, use of epidural or spinal anesthesia for cesarean delivery minimizes neonatal anesthetic exposure and allows the mother to see the child almost immediately after birth. Although a variety of anesthetic considerations for cesarean delivery exist, the following discussion is a general summary and other sources can provide additional information.[146,147]

All pregnant women should undergo a preoperative evaluation, regardless of planned delivery mode or type of anesthetic technique, with appropriate risk and benefit counseling. The current status of the fetus and obstetric management plan also should be determined in conjunction with the anesthetic plan. In addition, appropriate equipment and medications should always remain readily available to safely provide general anesthesia for an emergent or unanticipated situation. Although the rates of significant maternal aspiration of gastric contents with induction of general anesthesia are difficult to determine, the mortality from such an event is estimated at 5% to 15% based on retrospective data.[148,149] As mentioned previously, ASA guidelines recommend, "timely administration of nonparticulate antacids, H_2 receptor antagonists, and/or metoclopramide for aspiration prophylaxis" before obstetric surgical procedures.[19] The decision to use general anesthesia or neuraxial block for cesarean delivery is determined by a variety of factors that include the fetal condition and urgency of delivery, maternal comorbidities, presence of a previously placed epidural for labor analgesia, surgical considerations, and maternal wishes. At present, most cesarean deliveries in developed countries are performed with neuraxial techniques.

SPINAL ANESTHESIA

If an epidural catheter is not already placed, spinal anesthesia is typically used for nonemergent cesarean deliveries. Compared with an epidural, this type of neuraxial block is quicker and easier to place, allows adequate operating conditions in a shorter time, provides a denser block, is more cost effective, and is less likely to fail (failure rate < 1%).[150,151] The chance of significant maternal hypotension is greater with spinal anesthesia than with epidural anesthesia. Left uterine displacement with appropriate administration of fluids and use of vasopressors can minimize the associated hypotension. Although IV administration of crystalloid or colloid can reduce the degree of hypotension after spinal anesthesia for cesarean delivery,[152] a randomized controlled trial comparing colloid versus crystalloid noted that use of colloid was superior to crystalloid preload.[153] Another study noted that giving colloid with spinal placement is equally beneficial in reducing hypotension compared with use of prior administration of a colloid.[154] However, concern exists regarding the safety of synthetic colloids as part of intraoperative and critical care resuscitation (see also Chapter 61).

Previously ephedrine was considered the vasopressor of choice to manage hypotension caused by neuraxial anesthesia in pregnancy; however, phenylephrine in boluses or as an infusion is not only effective in reducing hypotension but also has less transfer to the fetus and results in less fetal acidosis than ephedrine.[31,34,155] Lastly, despite the concerns of hypotension, spinal anesthesia is safe to administer in preeclamptic patients.[156,157]

Although various local anesthetics could be used for spinal blockade, hyperbaric bupivacaine 10 to 15 mg is frequently used to achieve an adequate (T4) block level. Neither patient height nor weight affect block extension,[158] although dosing may require adjustment at extremes of the height spectrum. Adjuncts, such as fentanyl, sufentanil, and epinephrine, may be added to improve the quality of the block. Preservative-free morphine 0.10 to 0.25 mg is frequently administered with spinal to reduce postoperative pain for 18 to 24 hours after the anesthetic has dissipated.

EPIDURAL ANESTHESIA

If an epidural catheter has already been inserted for labor analgesia, it provides an excellent method to provide surgical anesthesia for cesarean delivery. A catheter-based technique allows for the ability to titrate the local anesthetic to the proper block height and provide additional local anesthetic administration during the case. For patients who do not already have a catheter in place, this technique may be chosen if the cesarean procedure is anticipated to take additional time, or if maternal comorbidities would favor a more gradual, controlled onset of epidural anesthesia. Achieving surgical block conditions takes longer with an epidural than spinal technique, but can be rapid enough for use in many urgent situations if already in place and used for maternal analgesia. Although use of a rapid-onset local anesthetic such as 3% 2-chloroprocaine to attain a T4 level in a newly placed catheter may take 10 minutes,[159] extension of a T10 level with a density for labor analgesia to a T4 level for surgical anesthesia can be obtained in approximately 5 minutes using 3% 2-chloroprocaine or alkalinized 2% lidocaine.[160] Several local anesthetics may be used if rapid onset is not needed, and typical local anesthetic volumes required range between 10 and 20 mL, depending on whether the epidural is already in use. The administration of epidural local anesthetic should occur in divided doses to ensure that the catheter has not migrated into the intravascular or intrathecal space. Block quality can be improved with addition of epinephrine 1:200,000, fentanyl 50 to 100 μg, or

sufentanil 10 to 20 μg. Epidural clonidine 50 to 100 μg can be useful in patients with preexisting chronic pain or severe hypertension if the benefit is judged to outweigh the risk for hypotension and bradycardia. Epidural morphine 3 to 5 mg is frequently administered to improve postoperative pain.

COMBINED SPINAL EPIDURAL ANESTHESIA

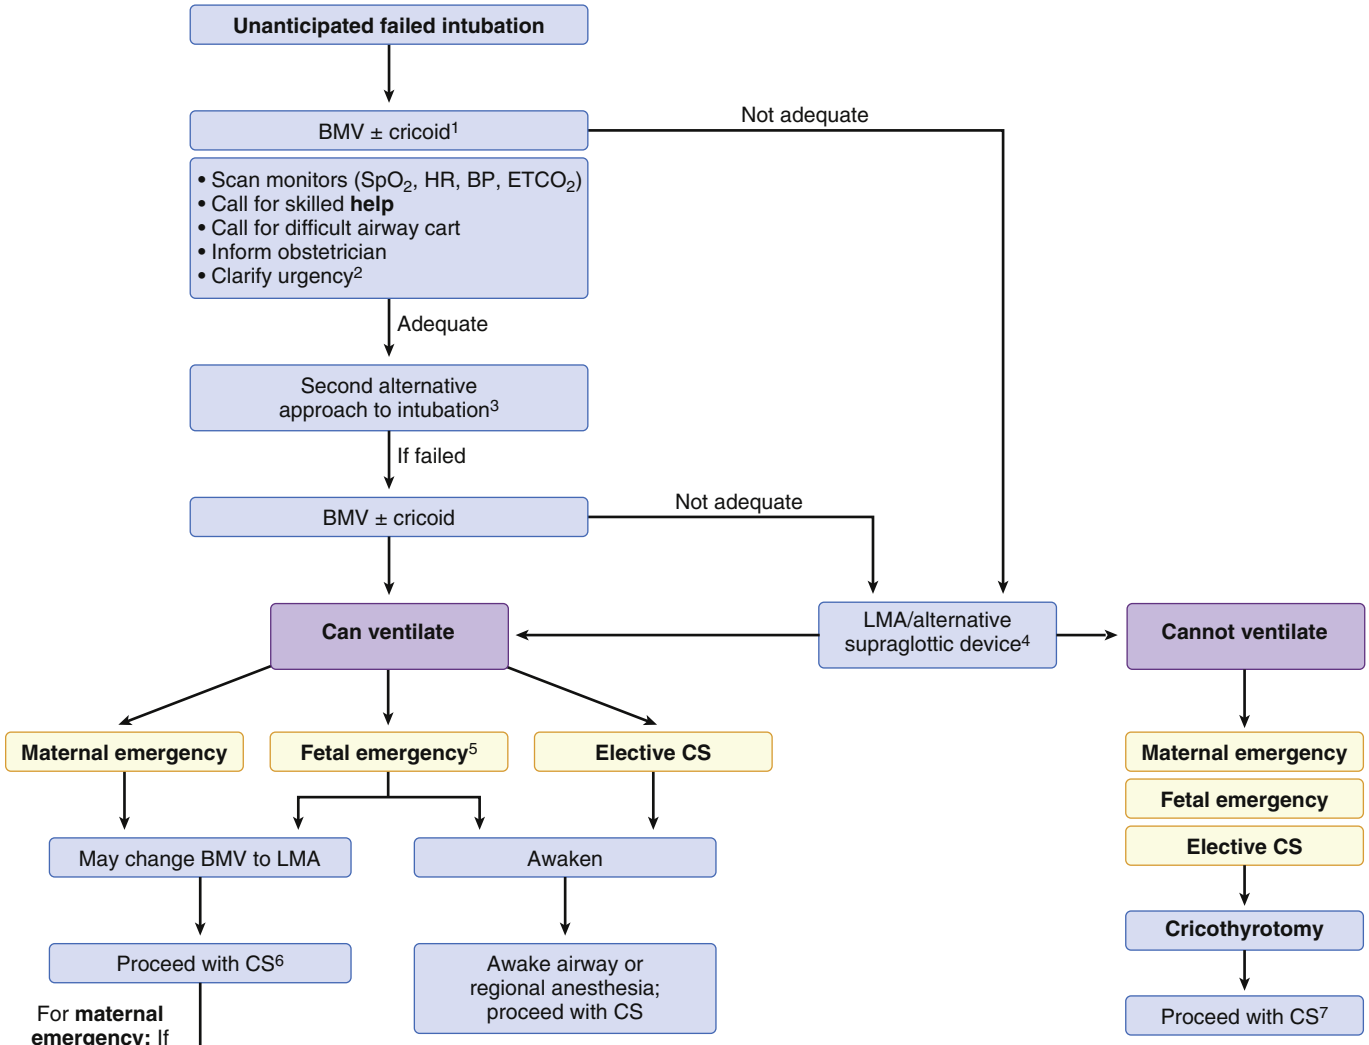
Use of a combined spinal epidural for cesarean delivery may be optimal in some situations because it combines the benefits of the spinal and epidural techniques. This technique allows the rapid onset of a dense reliable block while allowing the block time or height to be extended with use of the epidural catheter. Possible disadvantages include the presence of an untested catheter and the possibility of a misplaced or nonfunctioning epidural. More details of this type of neuraxial block are discussed in the previous section on labor analgesia.

GENERAL ANESTHESIA

In certain emergent situations (e.g., fetal bradycardia, maternal hemorrhage or coagulopathy, uterine rupture, maternal trauma) general anesthesia may be needed for cesarean delivery because of its rapid and reliable characteristics. In addition, it allows for a controlled airway, controlled ventilation, and improved hemodynamic stability in comparison to neuraxial anesthesia.

Appropriate equipment preparation, knowledge of patient comorbidities, airway examination, and familiarity with the difficult airway algorithm are necessary preparation for delivering a safe anesthetic whether general or neuraxial. The ASA difficult airway algorithm[161] has been modified slightly by some authors for use in the setting of cesarean delivery, and a previously published example is provided in Figure 77-4. In addition, a suggested approach for cesarean delivery with general anesthesia is detailed in Box 77-3. Clear concise communication among all members of the perioperative team is especially critical in urgent or emergent situations to maximize patient safety and minimize procedural complications. Open lines of communication are essential around the time of induction of anesthesia, airway management, and surgical incision. If endotracheal intubation fails, surgical incision should commence only when the patient can be reliably ventilated with a facemask or laryngeal mask airway (LMA).[19] The LMA has a high success rate for placement in obstetric patients; it does not protect against aspiration of gastric contents and should be used primarily for rescue of a failed intubation. The LMA has been used without observed aspiration or presence of hypoxia in a prospective study of over 1000 patients having elective cesarean section.[162,163] Anesthesia-related mortality from airway difficulties may occur during emergence and in the recovery period, as well as during induction. Improper monitoring, provider inexperience, emergent situations, and patient obesity all increase patient risk.[164] Emergent cesarean delivery is an uncommon but predictable emergency that can be practiced by teams using simulation.

Induction of Anesthesia: Intravenously Administered Drugs



Sodium thiopental 4 to 6 mg/kg intravenously is still used in many countries for induction of anesthesia and was previously the most commonly used drug for induction of anesthesia within the United States (see also Chapter 30). At present, propofol is the most commonly used for induction of general anesthesia for cesarean delivery and is able to induce unconsciousness in approximately 45 seconds. Like sodium thiopental, it can result in significant hypotension and has an umbilical artery (UA) to umbilical vein (UV) ratio of 0.7.[165] Propofol administration does not affect neonatal Apgar scores with typical intravenous induction doses (2.5 mg/kg), but repeated or larger cumulative doses (9 mg/kg) are associated with significant newborn depression.[166] The exact reason for the lack of effects on the newborn is unclear, but is likely the result of a combination of rapid redistribution into the maternal tissues, first-pass metabolism in the neonatal liver, further dilution with blood from the lower extremities with an anesthetic that traverses the ductus venosus into the lower vena cava, and higher fetal brain water content that reduces its central effect.

Etomidate is quick acting and its rapid hydrolysis results in a relatively short duration of action. Unlike thiopental and propofol, etomidate has minimal effects on maternal hemodynamics, but has higher rates of nausea and vomiting and can increase risk for seizures in patients with decreased seizure threshold. At typical induction doses (0.3 mg/kg), decreased neonatal cortisol production for less than 6 hours was noted with unclear clinical significance.[167]

Ketamine inhibits the *N*-methyl-D-aspartate receptor and has analgesic, amnestic, and hypnotic properties while having only minimal respiratory depression effects. At typical induction doses (1 to 1.5 mg/kg), ketamine causes central stimulation of the sympathetic nervous system and inhibits the reuptake of norepinephrine. This helps maintain arterial pressure, heart rate, and cardiac output. It is an ideal choice for a pregnant woman in hemodynamic compromise resulting from bleeding. No neonatal depression is observed with standard induction dosing.[168] Larger doses can increase uterine tone, reduce uterine arterial perfusion, and lower maternal seizure threshold. In certain situations, ketamine may be used in smaller intravenous doses (<0.25 mg/kg) as a profound analgesic, but often causes unwanted hallucinations, which can be reduced with coadministration of benzodiazepines. Care should be taken if it is used for analgesia and conscious sedation that repeated dosing does not result in loss of consciousness with an unprotected airway that would increase the risk for pulmonary aspiration.

Muscle Relaxants

Uterine muscle tone is not affected by skeletal muscle relaxants, and in standard doses all classes of muscle relaxants are poorly transferred to the fetus (see also Chapter 34). Succinylcholine 1 to 1.5 mg/kg intravenously has rapid onset (30 to 45 seconds) and short duration of action. After administration, it is hydrolyzed in the plasma by pseudocholinesterase and only small amounts cross to the fetus because it is highly ionized and poorly lipid

1 ***Cricoid pressure*** should be released if thought to be impairing visualization of the larynx or impeding ventilation by bag and mask (BMV) or with LMA.
2 All cases, including ***semiurgent***, must be classified as urgent or elective type cases for the purposes of subsequent management decisions.
3 Canadian Airway Focus Group (1998) ***recommends only 2 attempts*** at intubation in the pregnant patient (***vs. 3 or 4 attempts*** in other recommended algorithms). However, if the airway has not been traumatized, good oxygenation is being well maintained, and there is a high likelihood of success at a third attempt, then a third attempt may be reasonable. It should be noted, ***any successive attempts*** should be done after optimizing head position ***and*** that ***different*** techniques/equipment (bougie, intubating LMA, glidescope, fiberoptic intubation, etc.) are tried for ***each*** of the successive attempts.
4 ***If initial BMV is inadequate but ventilation by LMA (classic or proseal) or alternative supraglottic device is adequate,*** might consider proceeding with CS directly if absolute emergency ***or*** only make second or third attempt at intubation ***if*** mother is at higher risk for aspiration and/or slow difficult CS is anticipated.
5 In the event of a ***fetal emergency only*** and a situation in which mother can be ventilated, there are ***two options:*** one may proceed with unprotected airway for sake of fetus or if mother is at higher risk than usual for aspiration, desaturation, or subsequent failure to ventilate or loss of airway (recent large meal, morbidly obese, airway significantly traumatized in failed intubation attempts, etc.), one may choose to awaken the mother and proceed to regional anesthesia or awake airway. This latter course of action may clearly put the fetus at great risk but follows the principle of "Mother comes first."
6 ***Anesthesia management details*** should be at the ***discretion*** of the anesthesiologist, bearing in mind his or her own practice and preference and any patient or obstetric issues unique to each case: (1) additional doses of succinylcholine or return to spontaneous ventilation, (2) choice of maintenance anesthetic agents, and (3) elective change to LMA or other supraglottic devices even if BMV remains easy and effective.
7 ***In the three cannot-ventilate situations,*** maternal and fetal ***emergencies*** should proceed to CS immediately after ***transtracheal airway***. Arguably in ***elective*** CS, the fetus will be stressed by now and hence CS should also be seriously considered at this point.

Figure 77-4. Algorithm for management of unanticipated difficult airway in obstetric patients. *BMV,* Bag-mask ventilation; *BP,* blood pressure; *CS,* cesarean section; *$ETCO_2$,* end-tidal carbon dioxide; *HR,* heart rate; *LMA,* laryngeal mask airway; *SpO_2,* oxygen saturation. (Redrawn from Balki M, Cooke M, Dunington S, et al: Unanticipated difficult airway in obstetric patients: development of a new algorithm for formative assessment in high-fidelity simulation, *Anesthesiology* 117:883-897, 2012, with permission.)

soluble. It is undetectable in umbilical cord samples unless larger maternal doses are administered (2 to 3 mg/kg), and exceedingly high maternal doses (10 mg/kg) are needed to inadvertently create neonatal neuromuscular blockade.[169] After succinylcholine administration, maternal muscle strength should always be monitored because prolonged weakness can occur if the hydrolytic enzyme has a reduced plasma concentration or has an atypical form or if muscle weakness is exacerbated by prior administration of magnesium sulfate.

BOX 77-3 ***Suggested Sequence for General Anesthesia for Cesarean Section***

1. Administer a nonparticulate oral antacid (sodium citrate) before induction of anesthesia with consideration for metoclopramide or a histamine-2 blocker
2. Place standard monitors, maintain left uterine displacement, and ensure suction, airway equipment, and appropriate drugs are readily available.
3. Ensure the patient has a working intravenous catheter and start an infusion of crystalloid solution.
4. If time permits (nonemergent), administer prophylactic antibiotics and participate in time-out checklist.
5. Preoxygenate/denitrogenate patient for more than 3 minutes or 4 maximal (vital capacity) breaths over 30 seconds with 100% oxygen.
6. When the surgeon is ready and patient prepared, an assistant should apply cricoid pressure (and maintain until the position of the endotracheal tube is verified).*
7. Notify and confirm with the surgeon that the patient is ready for induction of anesthesia.
8. Administer induction agent and muscle relaxant in rapid sequence, wait 30 to 60 seconds, and then initiate direct laryngoscopy for tracheal intubation. Consider using etomidate or ketamine if concern for hypotension exists.
9. After confirming endotracheal tube placement, communicate to surgeon to proceed with incision.
10. Administer 50% nitrous oxide in oxygen with 0.5 to 0.75 minimum alveolar concentration of a halogenated anesthetic.
11. Adjust minute ventilation to maintain normocarbia (end-tidal carbon dioxide 30 to 32 mm Hg).
12. After delivery, anesthesia may be augmented by administering opioids, barbiturates, or propofol while continuing the volatile anesthetic. Additional muscle relaxant may be considered if necessary.
13. Administer oxytocin and assess uterine tone.
14. Extubate the trachea when the patient is awake and following commands and neuromuscular blockade is fully reversed.

*Not all agree that cricoid pressure is efficacious or required in every patient.

Modified from Lucero JM, Rollins MD: Obstetrics. In Miller RD, Pardo MC, editors: *Basics of anesthesia,* ed 6. Philadelphia, 2011, Elsevier, p 531.

Rocuronium may be considered as an alternative to succinylcholine for muscle relaxation. It allows adequate relaxation for endotracheal intubation in less than 60 seconds at intravenous doses of 0.9 to 1.2 mg/kg.[170,171] This is an attractive alternative to succinylcholine in clinical settings outside the United States in which sugammadex is available for reversal, because even after an intravenous intubating dose of 0.9 to 1.2 mg/kg body weight, the neuromuscular blocking effect can rapidly be reversed by a large intravenous dose of sugammadex (12 to 16 mg/kg body weight), which makes the total duration of action shorter than after an equipotent dose of succinylcholine (also see Chapter 35). Like succinylcholine, nondepolarizing muscle relaxants do not cross to the fetal circulation in amounts that would cause neonatal weakness.[172] However, if large doses of nondepolarizing neuromuscular blockers are given over long periods, significant neonatal neuromuscular weakness can occur. Although cholinesterase inhibitors may be administered to the neonate, treatment is primarily respiratory support until the drug is eliminated. Neonatal elimination of muscle relaxants may be significantly longer than adult elimination.

In the case of administration of magnesium sulfate, a distinct potentiation occurs of the effect of any nondepolarizing agents, with subsequently prolonged recovery time. The choice and dosing of neuromuscular blocking agents should therefore take into account the interaction with magnesium sulfate and the potential risk for muscle weakness resulting from residual neuromuscular block in the recovery room or postanesthesia care unit. As a consequence, neuromuscular monitoring based on an objective monitoring technique (see also Chapter 53) should be used to assess neuromuscular function in these patients.

Maintenance of General Anesthesia

After induction, general anesthesia is most frequently maintained with a volatile anesthetic agent with or without N_2O. Volatile anesthetics help reduce the incidence of maternal recall. Although the MAC to prevent movement in response to a painful stimulus is reduced in pregnancy, electroencephalographic evidence suggests that anesthetic effects of halogenated agent on the brain are similar in the pregnant and nonpregnant state.[27] Volatile anesthetics are highly lipid soluble, have a low molecular weight, and are readily transferred to the fetus. Fetal concentrations depend on both the maternal plasma concentrations and duration of the anesthetic before delivery. After delivery, opioids, propofol, benzodiazepines, or a combination are administered and a halogenated anesthetic typically provided at 0.5 MAC. These additional drugs are administered only after the cord is clamped to prevent any transfer to the neonate and associated respiratory depression. Use of only volatile anesthetics at higher concentrations is associated with increased blood loss secondary to uterine atony because all volatile anesthetics are uterine muscle relaxants.[173]

General anesthesia for cesarean delivery is frequently used in cases of fetal distress because it is so rapid and reliable. Clearly, a fetus depressed before delivery often becomes a depressed neonate. A Cochrane review of studies of uncomplicated cesarean deliveries that compared regional blockade and general anesthesia concluded that "No significant difference was seen in terms of neonatal Apgar scores of six or less and of four or less at one and five minutes and need for neonatal resuscitation."[174] The study noted neither method of anesthesia was superior for neonatal outcome.

If large concentrations of volatile anesthetics are administered for a prolonged time, neonatal flaccidity, cardiorespiratory depression, and decreased tone may be anticipated. If neonatal depression is due to volatile anesthetics, the infant should respond to assisted ventilation to facilitate exhalation of the anesthetics. Consequently, physicians able to assist neonatal ventilation should be present at all cesarean deliveries performed with the patient under general anesthesia. In addition, communication to all perioperative physicians is critical if extended anesthetic time is anticipated before delivery.

MATERNAL COMORBIDITIES

HYPERTENSIVE DISORDERS

Hypertensive disorders of pregnancy are among the most common causes of maternal morbidity and are associated with more frequent rates of maternal and fetal mortality.[175] Hypertensive disorders of pregnancy complicate 5% to 10% of pregnancies worldwide and preeclampsia is diagnosed in 3% of pregnancies.[175] The World Health Organization (WHO) has identified hypertension as the leading cause of maternal death, accounting for 16% of mortality associated with pregnancy.[176] Chronic hypertension may precede pregnancy and may or may not be complicated by superimposed preeclampsia.

Although some variations exist in hypertensive definitions worldwide, the following are used in the United States by the ACOG based on a working group in 2013.[177]

Gestational hypertension is defined as the onset of hypertension (systolic blood pressure [SBP] > 140 mm Hg or diastolic blood pressure [DBP] > 90 mm Hg) after 20 weeks gestation in a previously normotensive parturient without proteinuria.

Preeclampsia is defined as hypertension (SBP > 140 mm Hg or DBP > 90 mm Hg) after 20 weeks gestation associated with proteinuria. Preeclampsia is diagnosed when urine protein is greater than 300 mg/day or, alternatively, there is a protein/creatinine ratio of at least 0.3. In 2013, massive proteinuria (> 5g in 24 hours) and fetal growth restriction were eliminated as considerations of severe preeclampsia. In addition, the term *mild preeclampsia* is no longer used. Now only *preeclampsia* or *preeclampsia with severe features* are defined. Severe features of preeclampsia include an SBP of 160 mm Hg or greater or DBP of 110 mm Hg or greater on two separate occasions at least 4 hours apart while on bed rest; thrombocytopenia; impaired liver function with twice normal concentrations of liver enzymes; right upper quadrant pain; progressive renal insufficiency with serum creatinine greater than 1.1 mg/dL or a doubling of serum creatinine without other known renal disease; pulmonary edema; and new onset cerebral or visual abnormalities. In the absence of proteinuria, preeclampsia can be diagnosed with new onset hypertension as previously defined and presence of a severe feature.[177]

Hemolysis, increased liver enzymes, and low platelet count syndrome (HELLP) is defined as preeclampsia associated with hemolysis, elevated liver enzymes, and low platelet count. Eclampsia is preeclampsia complicated by seizure activity. The incidence of preeclampsia has increased likely as a result of increases in maternal age and obesity, whereas the risk for eclampsia has decreased because of more widespread prenatal care and the use of prophylactic magnesium.[175,178] The cause of preeclampsia is not known, but hypotheses include maladaptation of the placental circulation, immunologic rejection of paternal antigens, and maternal genetic and environmental factors. Constitutional, genetic, and hemodynamic factors have been proposed for the causes of early preeclampsia.[179,180] Pregnant women who develop preeclampsia before 34 weeks gestation have lower cardiac output and higher vascular resistance than those who develop later, less severe disease when measured at 20 weeks gestation before the onset of signs.[181]

Patients with preeclampsia have an elevated risk for cerebral hemorrhage, pulmonary edema, and coagulopathy. Current guidelines recommend treating SBP more than 160 mmHg for prevention of intracerebral hemorrhage.[177] Initial treatment typically includes labetalol and hydralazine. Other considerations are increased airway edema with associated difficulty of intubation and increased rates of postpartum atony related to the use of magnesium sulfate. Methylergonovine (methergine) should be used cautiously in patients with preeclampsia because it may lead to hypertensive crisis.

Women with a diagnosis of preeclampsia should have their platelet count checked before initiation of regional anesthesia or removal of an epidural catheter. Patients with severe preeclampsia should have additional coagulation studies, including prothrombin time (PT) with international normalized ratio (INR) and activated partial thromboplastin time, before neuraxial anesthesia. Coagulopathy is a contraindication to regional anesthesia. Although the risk for spinal hematoma is lower in pregnant women than in the elderly,[130] in one study 68% of patients who had spinal hematomas after neuraxial blockade had preexisting coagulopathy.[182]

COAGULOPATHIES

Thrombocytopenia complicates 10% of pregnancies as a result of several etiologic factors.[183,184] Thrombocytopenia may be preexisting or can develop as a result of the pregnancy. As discussed earlier, thrombocytopenia that develops after 20 weeks gestation may be a sign of preeclampsia. However, most thrombocytopenia in pregnancy is benign, gestational thrombocytopenia. Platelet count is expected to decrease by approximately 10% in normal pregnancy.[185] Autoimmune thrombocytopenia, antiphospholipid syndrome, and liver disease are less common.[184] Glucocorticoids and IV immunoglobulin can be used to elevate platelet counts in certain types of severe disease but require several days to be effective.[186] No platelet count is universally accepted as safe for epidural placement. Most anesthesiologists agree that placement of an epidural in the setting of a platelet count greater than 100,000/mm^3 is safe and epidural placement with platelets less than 50,000/mm^3 is unsafe. Disagreement exists about the safety of epidural placement at platelet counts between 50 and 100,000/mm^3.[187] Ironically, disagreement regarding threshold for platelet transfusion often occurs around similar values during surgical procedures (see also Chapters 61 and 62).

Women with von Willebrand disease are at increased risk for bleeding intrapartum and postpartum.[188] Prophylactic treatment is recommended for women with von Willebrand factor (VWF) less than 50 international units/dL. Because of the multiple types and subtypes of von Willebrand disease that have different responses to therapy, it is imperative that hematologic studies be part of the management to help guide the most appropriate therapy. In type I von Willebrand disease, a partial reduction in the quantity of VWF is seen. Women with type I von Willebrand disease usually do not need prophylactic treatment because their VWF typically rises in the third trimester of pregnancy to greater than 50 international units/dL. Desmopressin can

be used in women with type 1 von Willebrand disease to release VWF. Type 2 Willebrand disease is characterized by a defect in the function of VWF, and facilitation of release is not helpful. Parturients with type 3 von Willebrand disease almost always require replacement of VWF before delivery, because they have almost no intrinsic VWF. Although concern should be elevated for epidural hematoma, women with normal factor levels can have regional anesthesia in the setting of a normal platelet count.[189]

Factor V Leiden is an abnormal variant of factor V that acts as a cofactor that allows activation of thrombin by factor Xa. The factor V Leiden variant cannot be easily degraded by activated protein C and thus leads to hypercoagulability. Patients with factor V Leiden abnormality do not intrinsically have an increased risk for epidural hematoma, but they may be maintained on anticoagulants for prophylaxis or treatment of deep venous thrombosis (DVT).[190]

OBESITY

Increasing rates of maternal obesity (prepregnancy body mass index ≥ 30 kg/m^2) and metabolic syndrome in pregnancy are thought to be causes for the increased rate of preeclampsia (see also Chapter 71).[175] The immunologic abnormalities associated with metabolic syndrome may have commonality with those implicated in preeclampsia.[175] Obese parturients are at increased risk for larger babies, prolonged labor, and caesarean section.[48,191] Cesarean section for these women is also at greater risk with increased rates of failed tracheal intubation, increased wound infections, thromboembolism, and increased mortality.[192,193] Sleep apnea is more common in obesity and is a risk factor for hypoventilation after treatment with systemic opioids and difficult tracheal intubation when general anesthesia is required. Epidural anesthesia is more difficult in obese parturients and the risk for inadvertent epidural venous catheter insertion and dural puncture is higher.[194] An early anesthesia consultation is advised for morbidly obese women regardless of planned delivery mode.

CARDIAC DISEASE

Women with cardiac anomalies were often advised not to attempt pregnancy (see also Chapter 39). Before advances in cardiopulmonary bypass, only the mildest congenital cardiac anomalies were compatible with normal survival to adulthood. Children who benefited from palliative and curative surgeries often ignored this advice and provided evidence that most women with congenital heart disease can have successful pregnancies with the proper surveillance. However, the normal physiologic changes of pregnancy including an increase in cardiac output, decrease in peripheral vascular resistance, and increase in pulmonary blood flow can be challenging in the setting of some congenital lesions. Regurgitant valvular lesions and left-to-right shunts are tolerated better than stenotic lesions because the increased volume and decreased systemic vascular resistance favor forward flow.[195] In mitral stenosis, the combination of increased heart rate and increased volume lead to increased left atrial pressure and risk for atrial fibrillation and left heart failure.[195] The most common cyanotic congenital cardiac lesion is tetralogy of Fallot. This lesion consists of a large ventricular septal defect, overriding aorta, pulmonic stenosis, and right ventricular hypertrophy. Tetralogy of Fallot is normally repaired in infancy with a patch to close the ventricular septal defect and widening of the pulmonic outflow tract. Most patients do well with a successful repair; however, the increased intravascular volume in pregnancy can bring out insufficient widening of the pulmonic outflow tract. Consultation of a cardiologist specializing in obstetrics and an echocardiographic evaluation are recommended during pregnancy. These patients are also at risk for heart block because of abnormalities in ventricular conduction as a result of the condition or of surgery.[196] Epidural analgesia is recommended for women with congenital heart disease to obviate the portion of the increased cardiac output tachycardia attributable to labor pain. In women with aortic stenosis, the decrease in afterload that occurs with epidural analgesia may need to be countered with a carefully titrated α-adrenergic agonist to prevent tachycardia and ischemia.

Anticoagulation is required for women with artificial heart valves, some congenital heart disease, pulmonary hypertension, and cardiomyopathy. It is necessary to carefully time stopping anticoagulation to allow for epidural placement and birth while restarting before a clot can form. For this reason, women are usually maintained on heparin at the end of pregnancy, pending delivery, because of its quick offset. If IV heparin was used, it should be stopped 2 to 4 hours before the procedure and normal coagulation status (PTT or activated clotting time [ACT]) documented before neuraxial instrumentation or removal of an epidural catheter.[197] If conversion to intravenous heparin cannot take place before labor, warfarin should be stopped and neuraxial analgesia deferred until the PT is within normal limits and the INR is documented at less than 1.5. Low-molecular-weight heparin (LMWH) has been used frequently for prophylaxis of DVT in pregnancy. Unlike unfractionated heparin, the anticoagulant effects of LMWH cannot be reliably measured, and it is not reversible with protamine. Epidural analgesia should not be placed within 24 hours of therapeutic dose and 12 hours of prophylactic dose LMWH. The epidural catheter should be removed 2 hours before the next dose, but at least 24 hours should pass before the next dose if blood is found in the needle or catheter.[197] Prophylactic dosing of unfractionated heparin or LMWH is often increased in later trimesters, and care should be taken that the patient is being given dosing that is within guidelines.[197] Nonsteroidal antiinflammatory drugs do not in themselves increase risk for spinal hematoma, but can increase risk in combination with other anticoagulants.[197] If labor begins before neuraxial analgesia can safely be given, IV remifentanil and N_2O are alternatives in some settings.[198,199]

PULMONARY DISEASE

As previously detailed in the section on pulmonary changes, adaptations in the respiratory system are required to meet the metabolic demands of the mother and fetus with increases in minute ventilation, decreased O_2 reserve, and increased airway edema most notable (see also Chapter 39).

Community-acquired pneumonia is the most common nonobstetric infectious complication that results in maternal death.[200] Aspiration of gastric contents is also

more common during endotracheal intubation in pregnant than in nonpregnant patients because of laxity of the gastroesophageal junction combined with anatomic changes from the expanding uterus.[201] Strict fasting recommendations, rapid-sequence tracheal intubation, and antacids are used before general anesthesia in pregnancy.

DVT and pulmonary embolism are more common in pregnancy as a result of hormonal changes. Significant risk factors are factor V Leiden, prothrombin G20210A, protein S, protein C and antithrombin deficiency, and antiphospholipid antibodies.[202] Patients diagnosed with DVT or pulmonary embolism in pregnancy will need prolonged anticoagulation and will require delivery planning with a brief hiatus for regional anesthesia and delivery.

Cystic fibrosis is a common autosomal dominant disorder in women of northern European origin. With improved medical care, women with cystic fibrosis are living to reproductive years and beyond. Pregnancy is uncommon in women with cystic fibrosis (216 pregnancies in 24,000 women), but when it occurs, careful multidisciplinary care is required.[203] The disease is caused by a mutation in the cystic fibrous membrane conductance regulator in epithelial cells, which causes abnormalities in the lungs, pancreas, intestines, and hepatobiliary systems. The major issues in pregnancy are restrictive lung disease and diabetes.

NEUROLOGIC DISORDERS

Multiple sclerosis is a neuroinflammatory disorder that disproportionately affects young women (also see Chapter 39). Pregnancy is associated with a decrease in the incidence of relapse, although a postpartum increase does occur. Multiple sclerosis is a disease of demyelination, and thus theoretic concern exists that local anesthetic toxicity may be enhanced. Cases of worsening symptoms after regional anesthesia have been reported; however, it is hard to impute causality in a relapsing and remitting disease. Nevertheless, the lowest effective concentration possible should be given and vasoconstrictive agents should not be given.

Neurofibromatosis is an autosomal dominant disorder that occurs in 1 in 3000 individuals, with variable manifestations. It is characterized by café-au-lait lesions on the skin, cutaneous neurofibromas, Lisch nodules of the iris, bone abnormalities, and tumors of the spinal cord and cranial nerves.[203] Neurofibromas often grow in pregnancy. Disagreement exists as to whether neuraxial anesthesia is contraindicated in women with neurofibromatosis because of the incidence of vascular spinal tumors. Epidural hematoma has been reported in a woman with neurofibromatosis in the setting of a spinal tumor.[204] The hormonal changes of pregnancy may cause tumor growth, and a knowledge of lesion location and current clinical symptoms is needed to avoid instrumentation of tumors and safely deliver neuraxial anesthesia.[205]

ANESTHESIA FOR ABNORMAL PRESENTATIONS

Higher order multiple births are frequently delivered by cesarean section because of the likelihood of cord entanglement and possibility of head entrapment. Twin pregnancy can be delivered vaginally but may present difficulties at delivery. If the second twin is not in the vertex position, epidural anesthesia can provide abdominal muscle relaxation and analgesia to allow for version or manual extraction.[206-208] In addition, it provides analgesia and perineal relaxation for instrumented delivery if needed, and the ability for conversion to cesarean delivery if the second twin becomes distressed or is unable to be delivered vaginally. The same considerations apply for external cephalic version of a singleton breech presentation. Anesthetic rather than analgesic concentrations are required for appropriate conditions. External cephalic version has an overall success rate (all gestational ages) of approximately 60%, with risks for abruption, fetal bradycardia, rupture of membranes, and need for emergent delivery. For these reasons, anesthesiologists should be immediately available in case need for emergent delivery occurs.

Shoulder dystocia occurs when after the delivery of the head, the shoulders cannot be delivered secondary to impaction on the maternal pelvis. This is an obstetric emergency. It is associated with prolonged gestation, labor induction, obesity, high fetal weight, prolonged dilation from 8 to 10 cm, and epidural analgesia.[209,210] Prolonged gestation and slow difficult delivery make epidural analgesia more desirable, so the association between epidural analgesia and shoulder dystocia is not likely to be causal. However, epidural analgesia provides good conditions for rescue of the infant in the case of shoulder dystocia. Recommended procedures for the management of shoulder dystocia include the McRoberts maneuver, in which the mother's legs are flexed and pushed tightly to her abdomen with application of suprapubic pressure.[211] The muscle relaxation and pain relief offered by epidural analgesia facilitate this process. However, the Gaskin maneuver requires placing the mother on her hands and knees, which may not be possible to sustain with the use of higher dose epidural local anesthetic because of inadequate motor strength. If these maneuvers are unsuccessful, pushing the fetus back into the pelvis and emergent cesarean delivery may be required. Deliveries with shoulder dystocia have an increased risk for postpartum hemorrhage and fourth-degree lacerations.[212]

OBSTETRIC EMERGENCIES

A variety of emergent conditions may manifest during the care of obstetric patients. These urgent situations frequently involve maternal hemorrhage, fetal distress, or both. To optimize the clinical outcome, prior preparation and excellent communication among all members of the peripartum care team are essential.

OBSTETRIC HEMORRHAGE

Hemorrhage during pregnancy carries significant morbidity and is a leading cause of maternal death worldwide.[213,214] In addition, the need for blood transfusion is the most common indicator of severe maternal morbidity based on 2008 to 2009 U.S. peripartum hospitalization data.[215] Most of these hemorrhage-related deaths are preventable, and appropriate training, simulation, team

communication, and education are all essential elements needed to improve patient outcome.[216,217] Common difficulties with hemorrhage management include inaccurate determination of blood loss, unrecognized hemorrhage risk factors, delayed intervention, and improper or inadequate transfusion of blood products. Various causes of peripartum hemorrhage and management of obstetric hemorrhage are discussed in greater detail in the following section.

Placenta Previa and Accreta

Placenta previa is diagnosed when the placenta is located low in the uterus and in front of the presenting fetus, either covering or encroaching on the cervical os. The incidence is approximately 0.5% of all pregnancies. Associated risk factors include advanced maternal age, assisted pregnancy, multiparity, prior placenta previa, and uterine scarring from infection or prior surgery. Placenta previa normally manifests as painless vaginal bleeding, with the first occurrence being self-limited. The diagnosis is confirmed or determined by ultrasonography. Cesarean delivery is required with placenta previa unless the placenta significantly changes position during gestation to 2 cm or more away from the cervical os before the time of delivery.

The term *placenta accreta* is often used to include the three subtypes of accreta vera, increta, and percreta. Placenta accreta vera is an abnormal adherence to the myometrium with an absent decidual line of separation. Placenta increta is abnormal implantation and growth of the placenta into the myometrium, and placenta percreta is growth of the placenta through the uterine wall with placental implantation onto surrounding tissue that might include bladder, bowel, ovaries, or other organs surrounding the uterus. Presence of accreta occurs in approximately 0.04% of pregnancies in developed countries; however, the rate is increasing and a recent study in Utah noted a rate of 0.12% based on 2002 to 2006 data.[218] In a multiinstitutional cohort study, the sensitivity for detecting placenta accreta using ultrasound or magnetic resonance imaging was 93% and 80% with specificities of 71% and 65%, respectively.[219] Rates of accreta are significantly affected by the presence of placenta previa and the number of prior hysterotomies. In patients with a known placenta previa, the rates of accreta are 3%, 11%, 40%, and more than 60% with zero, one, two, and three or more prior uterine incisions, respectively.[220] Unfortunately, the diagnosis of accreta is not certain until the time of hysterotomy, and in patients with significant risk factors, massive hemorrhage could occur, regardless of imaging study result.[19,217] If the diagnosis of placenta accreta or percreta is likely before delivery, preoperative interventions such as bilateral common iliac artery balloon catheter insertion or selective embolization of uterine vessels near the time of delivery could be considered, but efficacy remains unclear.[221-223]

Vasa Previa

Vasa previa is a rare condition in which velamentous insertion of umbilical vessels occurs so that these fetal vessels traverse the fetal membranes and are positioned over the cervical os.[224,225] The incidence is between 0.04% and 0.02% of pregnancies and carries significant fetal morbidity and mortality if not diagnosed antenatally. In a study of 155 women, neonatal survival was 97% with antenatal diagnosis and only 44% without diagnosis before delivery.[226] If undiagnosed, vaginal bleeding may be noted at the time of membrane rupture and represents fetal blood loss rather than maternal. Previously undiagnosed vasa previa represents an obstetric emergency requiring immediate cesarean delivery, typically done under general anesthesia because of its rapidity. In cases in which the diagnosis is known antenatally, cesarean delivery is performed before labor. The optimal gestational age for delivery is not definitively established, but delivery by cesarean at approximately 36 weeks of gestation is suggested with consideration for administration of steroids for fetal lung maturity and consideration of maternal hospitalization between 28 and 32 weeks gestation in the case of the need for urgent preterm delivery.[224,225]

Placental Abruption

Placental abruption is defined as partial or complete separation of the placenta from the uterine wall after 20 weeks gestation but before delivery. The incidence is approximately 1% of pregnancies, and risk factors include advanced maternal age, chorioamnionitis, cocaine use, excessive alcohol use, hypertension, premature rupture of membranes, history of abruption, smoking, and trauma. Abruption often manifests with vaginal bleeding and uterine tenderness with examination. However, a significant volume of blood can be trapped behind the placenta and remain in the uterus. As for any situation with massive bleeding in pregnancy, coagulopathy resulting from massive blood loss can frequently occur. Therefore, appropriate laboratory panels should be obtained and preparation for massive transfusion and administration of additional coagulation factors initiated, taking into account the need for close collaboration with transfusion medicine or blood bank expertise (see later discussion of management of massive obstetric hemorrhage).

Uterine Rupture

Uterine rupture can be a life-threatening emergency for both mother and fetus. The occurrence rate for women undergoing a trial of labor after cesarean delivery ranges between 0.4% and 1% and includes a range of pathologic processes from cases of scar dehiscence to complete uterine wall rupture.[227] Other risk factors for uterine rupture include fetal malposition, instrumented delivery, macrosomia, excessive oxytocin administration, rapid delivery, trauma, and tumor. Typical clinical presentation includes fetal bradycardia, cessation of uterine contractions, abdominal pain, vaginal bleeding, and loss of station. A nonreassuring FHR tracing is the most reliable and sensitive clinical sign, and breakthrough pain may be present in only a minority of patients and unrelated to epidural use.[228-230] If trial of labor after cesarean delivery is the planned method of delivery, the American College of Gynecology recommends that an obstetrician, anesthesiologist, and nursing staff be immediately available to the laboring patient so that an emergent cesarean delivery and possible hemorrhage management can be started immediately if a rupture occurs.[231]

Uterine Atony

Postpartum uterine atony and associated hemorrhage is the leading cause of maternal death worldwide and is increasing in incidence.[232,233] Risk factors include chorioamnionitis; excessive use of oxytocin during labor, high parity, long labor, macrosomia, multiple births, prolonged labor, retained products of conception, and use of volatile anesthetics, magnesium sulfate, or terbutaline. After bimanual massage, oxytocin should be administered as the initial treatment and prophylactic drug for uterine atony. Specific dosing of oxytocin varies across institutions and countries.[234] Although the WHO recommends 20 international units of oxytocin administered in 1 L of crystalloid after uncomplicated cesarean delivery, it may be that somewhat less is needed in most situations.[235] Although a dilute oxytocin solution administered over a long time has minimal hemodynamic effects and is typically well tolerated, larger doses and bolus infusion can result in significant hypotension, tachycardia, nausea, and headache. If oxytocin is not sufficient in controlling postpartum hemorrhage, methylergonovine 0.2 mg intramuscularly, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) 0.25 mg intramuscularly, or prostaglandin E_1 (PGE_1) 600 μg orally, sublingually, vaginally, or rectally should be considered. These drugs can have a variety of side effects.[236] Side effects of methylergonovine, an ergot derivative, include nausea, hypertension (systemic and pulmonary), and coronary artery spasm, and it is relatively contraindicated in patients with preeclampsia and those with cardiac disease. $PGF_{2\alpha}$ is associated with pulmonary hypertension, bronchospasm, desaturation, nausea, and tachycardia and is contraindicated in patients with asthma. PGE_1 does not have significant cardiovascular effects but may result in mild hyperthermia. If postpartum hemorrhage is not controlled with drugs, invasive and surgical techniques described in the following section should be considered.

Management of Massive Obstetric Hemorrhage

Successful management of a massive obstetric hemorrhage requires excellent communication and coordination of all perioperative disciplines, including anesthesiologists, obstetricians, labor and operating room nurses, neonatologists, interventional radiologists, gynecologic surgeons, and blood bank staff. A list of general considerations for management of a massive obstetric hemorrhage and resuscitation is provided in Box 77-4. Early diagnosis of hemorrhage and timely intervention are key to minimizing patient morbidity and mortality. Although few studies regarding hemorrhage in obstetrics exist, many studies have been published from the military and trauma hospitals regarding transfusion ratios and transfusion triggers (see also Chapters 61 and 81). Specific ratios of fresh frozen plasma (FFP) and platelets with or without packed red blood cells (PRBCs) for management of massive obstetric hemorrhage have been recommended.[217,237,238] These ratios approach 1 unit of PRBCs to 1 unit of FFP, with 1 platelet plasmapheresis unit transfused for each 4 to 6 units of PRBCs. These higher ratios are recommended to decrease the incidence of coagulopathy and acidosis. Although frequent laboratory studies with use of point-of-care testing if available is optimal, transfusion of blood products should initially be guided by the clinical situation and patient assessment rather than waiting for laboratory values to return. In addition, cryoprecipitate should be considered if decreased fibrinogen is present or likely and only on rare occasions should recombinant activated factor VII be used. Although doses of 70 to 90 μg/kg reduce obstetric hemorrhage, multiple adverse events have been reported to the FDA with the off-label use of treating massive hemorrhage with factor VIIa.[239-241] Cell salvage has been used successfully in numerous published cases of obstetric

BOX 77-4 ***Considerations in the Management of Massive Obstetric Hemorrhage***

- If massive hemorrhage is anticipated, have a multidisciplinary meeting for planning and consider arranging for use of blood salvage, placement of iliac balloon catheters, arterial embolization, or a combination of these in advance.
- Call for additional personnel (anesthesiologists, obstetricians, nurses, gynecologic surgeons, and interventional radiologists).
- Obtain a brief medical history and perform a clinical assessment of the patient.
- Perform short time-out procedure (as defined by the World Health Organization) with all present personnel.
- Place large-bore intravenous catheters (16 to 14 gauge).
- Place invasive monitoring lines (arterial and central venous lines).
- Repeat laboratory tests frequently and use point-of-care testing if available (complete blood count, arterial blood gases, electrolytes, ionized calcium, and coagulation studies).
- Use fluid warmers and forced air warmer.
- Place bladder catheter to measure urine output.
- Place lower extremity compression devices to minimize chance of thromboembolism.
- Prime rapid infusion blood delivery system.
- Bring equipment in case of cardiac arrest (e.g., ACLS cart) into operating room.
- Designate a person for recording and tallying blood products and blood loss.
- Obtain direct communication with blood bank and central laboratory and request prioritization of workflow to your location.
- Request blood products as needed in "packs" of correct ratio (PRBCs/FFP/platelets).
- During significant hemorrhage, transfuse products based on clinical situation rather than waiting for laboratory results.
- Prepare for general anesthesia.
- Ensure vasopressors and uterotonics are immediately available.
- Administer calcium appropriately during rapid transfusion of blood products to prevent low ionized calcium levels.
- Reserve intensive care unit bed for postoperative care.
- Consider use of blood salvage.
- Consider cryoprecipitate (fibrinogen < 100 mg/dL).
- Consider factor VIIa (off-label hemostatic use) only after approximately 10 units PRBCs and factor replacement using FFP and cryoprecipitate.
- Consider use of interventional radiology for arterial embolization if patient is stable for transport.
- Consider other surgical options, including uterine balloon tamponade, compression sutures, and hysterectomy
- Make time to debrief after event with all disciplines

Based on management suggestions from the California Maternal Quality Care Collaborative (CMQCC) Hemorrhage Task Force <*http://www.cmqcc.org*>; and Gallos G, Redai I, Smiley RM: The role of the anesthesiologist in management of obstetric hemorrhage, *Semin Perinatol* 33:116-123, 2009.

FFP, Fresh frozen plasma; *PRBC,* packed red blood cells.

hemorrhage despite the theoretic concern of amniotic fluid embolism.[242,243] The use of a salvage device with a leukocyte reduction filter has been demonstrated to remove tissue factor, α-fetoprotein, fetal squamous cells, bacteria, and other undesirable contaminants.[243,244] Although two reports of hypotension related to the use of cell salvage exist,[245] the technique is appropriate for use in massive obstetric hemorrhage. In parturients who are Rh negative, anti-D immunoglobulin should be used as soon as possible in coordination with Kleihauer-Betke testing to prevent alloimmunization because variable amounts of fetal RBCs will be transfused to the mother with use of cell salvage. When standard resuscitation methods are not adequate to control the obstetric hemorrhage, the peripartum obstetric team should consider use of invasive options, including compression sutures, uterine balloon tamponade, ligation of uterine vessels, and use of interventional radiology for arterial embolization if stable for transport. Based on a 2007 systematic review of the literature, no single invasive option is significantly better than another, and all have success rates of approximately 85% to 90%.[246] If these options fail or are not feasible, a hysterectomy should be performed.

AMNIOTIC FLUID EMBOLISM

The rate of amniotic fluid embolism (AFE) is between 1:20,000 and 1:83,000 live births, with a 1999 database rate of 1:20,646 singleton pregnancies.[247,248] Signs and symptoms of AFE include hypotension, respiratory distress, hypoxia, disseminated intravascular coagulation (DIC), altered mental status, and hemodynamic collapse. This constellation of clinical features must be differentiated from other more common conditions that mimic AFE (i.e., venous air embolism, pulmonary embolism, cardiac dysfunction, massive hemorrhage, and pulmonary aspiration). The mechanism of AFE remains unclear, but it is no longer believed to be embolic, but rather an anaphylactoid reaction.[247,249] Previously, it was clinical practice to diagnose AFE based on the presence of fetal squamous cells in the maternal pulmonary circulation at autopsy, but the presence of these cells is frequently noted in the pulmonary circulation of otherwise unremarkable pregnant women around the time of labor and delivery. Consequently, determining the occurrence of an AFE is a clinical diagnosis of exclusion and no diagnostic laboratory test for AFE currently exists, even postmortem. AFE is managed with supportive care, frequently focused on intubation, ventilation, cardiopulmonary resuscitation, inotropic support, management of DIC, and correction of arterial hypoxemia.

OTHER OBSTETRIC EMERGENCIES

Certain urgent situations may occur around the time of labor and delivery that require tailored anesthetic care to optimize both the maternal and fetal outcome. Cord prolapse through the cervical os can result in abrupt fetal bradycardia. Rates of umbilical cord prolapse range between 0.1% and 0.6%.[250] The risk is significantly increased with the presence of transverse lie, breech presentation, multiple gestations, and an abnormally long umbilical cord. In addition, cord prolapse may occur around the time the membranes are ruptured if an abnormal fetal presentation is present or the mother has polyhydramnios. Diagnosis is confirmed with visualization or palpation of the cord in the vaginal canal below the presenting fetal part. Intervention typically consists of elevating the compressing fetal part back into the pelvis off of the cord until an urgent cesarean delivery can be performed. Use of an in situ epidural catheter or spinal technique can be considered as long as the FHR tracing is reassuring, but general anesthesia is frequently used in the event of fetal compromise.

Uterine inversion occurs in approximately 0.04% of deliveries[251] and is usually associated with hypotension, pain, and significant blood loss. Risk factors include excessive cord traction before placental separation, location of the placenta at the fundus, and presence of placenta accreta. Treatment goals include relaxation of the uterus to aid replacement, maternal fluid resuscitation, and increased uterine tone after replacement to reduce postpartum hemorrhage. Uterine relaxation can be quickly and reliably achieved using either intravenous nitroglycerine or volatile anesthetics.[252-254] The mother's hemodynamic condition may guide the choice of therapy. If the initial uterine intervention and replacement is not successful with nitroglycerine because of lack of relaxation, maternal pain, hemodynamic instability, or other logistics, transfer to the operating room should occur. A rapid sequence intubation with standard precautions for recent pregnancy followed by use of volatile anesthetic administration will allow needed uterine relaxation, pain control, and procedural conditions for uterine replacement. Only on rare occasion are vaginal maneuvers unsuccessful and laparotomy required. After uterine replacement, the uterine cavity should be explored for perforation, laceration, or retained products. Afterward, appropriate examination uterotonic drugs can be started.

Lacerations of the vagina, cervix, and perineum are the most common injuries associated with vaginal birth. Significant bleeding can be concealed in hematomas, and maternal hypotension and tachycardia may be the first signs of the injury. Retroperitoneal hematomas are rare but can represent substantial life-threatening blood loss that requires exploratory surgery. Anesthetic management to allow surgical repair or exploration depends on the hemodynamic state of the mother and can include use of local anesthetic at the site, neuraxial blockade, or—in severe hemodynamic compromise—use of general endotracheal anesthesia. Equally important is the hemodynamic assessment and initiation of resuscitation efforts for the mother. Even small unrecognized lacerations can result in significant blood loss.

NONOBSTETRIC SURGERY DURING PREGNANCY

PERIOPERATIVE CONSIDERATIONS

Although elective surgery is not performed during pregnancy, the requirement of surgery during pregnancy is

not uncommon; between 0.75% and 2% of pregnant women will require surgery. The most common indications are acute appendicitis and cholecystitis, maternal trauma, and cancer.[255]

ANESTHETIC TOXICITY

All general anesthetic drugs cross the placenta. Although no clear evidence exists for toxicity of specific anesthetic drugs in humans, data in rodents and primates suggest that exposure to general anesthetic drugs, including volatile anesthetics, propofol, and ketamine, induce inappropriate neuronal apoptosis that is associated with long-lasting behavioral abnormalities.[256-258] These preclinical results are concerning, but whether these drugs cause toxicity in humans is not known. The critical period of rapid synaptic development is extended in humans from the prenatal period through 2 years of postnatal life.[259] Analyses of existing human data have found conflicting evidence. In a population-based cohort evaluating the effect of general anesthesia before birth, evidence suggested that multiple exposures increase the risk for learning disability in language, mathematics, or reading.[259] The results of these types of studies are difficult to interpret because the reason for the anesthesia cannot be separated from the impact of the anesthesia. Also, current studies have not included data on the timing, type, or duration of anesthesia. No studies found an excess of birth defects in women who underwent general anesthesia during pregnancy, but most found a small increase in the risk for preterm delivery or miscarriage.[260-262] In general, the second trimester is preferred for surgical intervention because this is a period after much organogenesis has taken place and yet it minimizes the risk for preterm labor associated with the third trimester. Monitoring for contractions is recommended, and in some situations suppression with magnesium sulfate or indomethacin is recommended after surgery. Because the long-term impact of general anesthesia on the fetus is unknown, regional anesthesia is favored when possible for the surgical procedure, but should not be undertaken unless both the anesthesiologist and surgeon are experienced in using the technique for a given procedure.

PERIOPERATIVE FETAL HEART RATE MONITORING

After 18 weeks, FHR monitoring is practical; after 25 weeks, FHR variability is a reliable sign of fetal well-being. The ACOG states, "although there are no data to support specific recommendations regarding non-obstetric surgery and anesthesia in pregnancy, it is important for non-obstetric physicians to obtain obstetric consultation before performing non-obstetric surgery. The decision to use fetal monitoring should be individualized and each case warrants a team approach for optimal safety of the woman and her baby."[263] Under general anesthesia the loss of FHR variability may not be indicative of fetal academia but may be a result of anesthetic alteration of autonomic tone. Fetal bradycardia is more concerning and can be affected by hypothermia, maternal acidosis, or the maternal administration of drugs such as β-blockers that cross the placenta and reduce FHR.

ANESTHETIC MANAGEMENT

As mentioned earlier, for theoretic fetal considerations, regional anesthesia is preferred when possible to general anesthesia for nonobstetric surgery in pregnancy. Very practical maternal considerations also favor regional anesthesia. The increase in peripheral blood flow induced by pregnancy results in airway edema and friability. These changes can be present from the second trimester. Mallampati classification is more predictive of difficult intubation in pregnancy. Increased difficulty of intubation in pregnancy should be considered, and equipment for advanced airway should be readily available before intubation is attempted. Equally important to anesthetic technique is avoidance of decreased uterine blood flow and oxygen delivery to the fetus. Considerations similar to those discussed in the section on anesthesia for cesarean delivery should be undertaken for any nonobstetric surgery during pregnancy. The anesthetic plan should optimize the maternal and fetal condition. Perioperative team planning should include consultation with an obstetrician and perinatologist regarding plans for unexpected events, including need for emergent cesarean section or possible maternal arrest.

POSTOPERATIVE PAIN CONTROL

Maternal pain control after nonobstetric surgery is of paramount importance to maternal well-being (see also Chapter 98). When surgery is conducted under regional anesthesia, the epidural can be continued for postoperative analgesia. Postoperative systemic opioids including those used in patient-controlled analgesia, cross the placenta and may reduce FHR variability. However, no evidence has shown that this is detrimental to the fetus. If the fetus is born prematurely shortly after exposure to maternal systemic opioids, respiratory support may be necessary. Nonsteroidal antiinflammatory drugs, though useful adjuvant analgesics outside of pregnancy, should be used with caution in pregnancy. They are associated with an increased risk for miscarriage and fetal malformation when used in early pregnancy and premature closure of the ductus arteriosus and oligohydramnios when used after 30 weeks gestation.[264] Acetaminophen is generally accepted as safe in pregnancy.

After surgery, both the FHR and uterine activity should be monitored. Preterm labor can be managed with appropriate tocolytic drugs. Postoperative pain relief medications may make it difficult for the patient to note early contractions and patient perception should not be considered a substitute for standard monitoring. In addition, thrombosis prophylaxis should be instituted unless surgically contraindicated.

ADVANCED CARDIAC LIFE SUPPORT IN PREGNANCY

The protocol for advanced cardiac life support (ACLS) in pregnancy is similar to that recommended for other

BOX 77-5 *Factors Important in Maternal Laparoscopy*

Use an open technique to enter the abdomen.
Monitor maternal end-tidal P_{CO_2} (4- to 4.6-kPa range) with or without arterial blood gas to avoid fetal hypercarbia and acidosis.
Maintain low pneumoperitoneal pressure (1.1 to 1.6 kPa) or use a gasless technique.
Limit the extent of Trendelenburg or reverse Trendelenburg position and initiate any position slowly.
Monitor fetal heart rate and uterine tone when feasible.

Modified from Reitman E, Flood P: Anesthetic considerations for non-obstetric surgery in pregnancy, *Br J Anaesth* 107(suppl 1):i72-i78, 2011.

adult cardiac arrest situations, except that compression of the maternal great vessels by the pregnant uterus greatly impedes the success of external cardiac massage (see also Chapter 108). Cesarean delivery should be performed not later than 4 minutes after maternal cardiac arrest.[265] Although potentially beneficial for the fetus if viable, its primary goal is to improve ACLS effectiveness and improve maternal survival by increasing venous return to the heart with ACLS maneuvers and improving thoracic compliance and maternal ventilation.[266] In addition, if the maternal cardiac arrest may have been caused by local anesthetic toxicity, lipid rescue should be initiated.[267]

SPECIFIC SURGICAL TECHNIQUES

Laparoscopy

Surgery for appendicitis and cholecystitis are common in pregnancy. These surgeries are most commonly performed with a laparoscopic technique outside of pregnancy and are being done more commonly with laparoscopy because of reduced morbidity for the mother and potentially a decreased incidence of preterm labor as a result of reduced manipulation of the uterus.[268] Open appendectomy may have a slightly less frequent rate of fetal mortality compared with laparoscopic appendectomy, although maternal morbidity is more frequent.[269] However, a comparison of laparoscopy and laparotomy has considered over 2 million pregnancies in Sweden and no difference in fetal outcome was identified between the two techniques.[270] Left uterine displacement must be maintained after the second trimester to facilitate uterine perfusion and ventilation maximized to prevent maternal CO_2 retention and acidosis. With increased abdominal pressure from insufflation, maternal cardiac output and uteroplacental perfusion may decrease. Thus, the smallest possible intraabdominal pressure should be used. According to the guidelines issued by the Society of American Gastrointestinal Endoscopic Surgeons regarding laparoscopic surgery during pregnancy,[271] whenever possible, surgery should be deferred to the second trimester and indications for the use of laparoscopic techniques are the same as in nonpregnant patients. Specific considerations for these types of procedures are listed in Box 77-5. Fetal and uterine status should be monitored, and careful attention should be paid to maternal end-tidal P_{CO_2}. During laparoscopic surgery, gradients between end-tidal CO_2 and arterial CO_2 are typically less than 3 mm Hg, and arterial blood gas monitoring is not needed unless otherwise indicated.[272] An open technique is preferred to enter the abdomen. Aortocaval compression should be avoided. Finally, low pneumoperitoneal pressure (<1.6 kPa) should be used. A systematic review of laparoscopic surgery for appendicitis during pregnancy noted that trimester timing did not influence the complication rate, the need for conversion to open was less than 1%, and a lower rate of preterm delivery was found with laparoscopic approach in contrast to open.[269]

Trauma

The most common cause of maternal death in the United States is trauma. Initial primary and secondary survey should be directed toward maternal well-being, with consideration of the physiologic changes induced by pregnancy (see also Chapter 81). Gestational age is an important variable in trauma evaluation. During the first trimester, the fetus is protected by the bony pelvis and damage is unlikely in the absence of severe hypoperfusion. However, as pregnancy progresses, the uterus is not only exposed but also causes pressure on the maternal inferior vena cava and aorta, potentially compromising perfusion and resuscitation. After 20 weeks gestation, left uterine displacement should be implemented as the initial step. Blunt trauma carries a risk for intrauterine fetal demise, fetal injury, placental abruption, and uterine rupture. These dangers should be evaluated with fetal heart monitoring ultrasonography, computed tomography, or exploratory laparotomy when indicated.[273] The consequences for ACLS are discussed earlier in the chapter.

Cardiac Surgery

The physiologic changes induced by pregnancy can put inordinate strain on patients with preexisting heart disease (see also Chapter 67). In particular, patients with severe mitral or aortic valvular obstruction are at risk from the increased intravascular volume and cardiac output required to support an ongoing pregnancy. New techniques in percutaneous balloon valvuloplasty can obviate open cardiac intervention in pregnancy and have been associated with reduced fetal and neonatal mortality.[274,275] Cardiopulmonary bypass increases risk to the fetus as a result of nonpulsatile perfusion, low perfusion pressures, emboli to the uteroplacental unit, and maternal release of catecholamines.[276] Higher pump flows (>2.5 $L/min/m^2$) and perfusion pressures (>70 mm Hg) are recommended to support uteroplacental blood flow.[277,278] Normothermic bypass and pulsatile flow may better preserve uteroplacental perfusion and improve fetal survival. Particularly during hypothermic bypass, acid-base disturbances can be observed. Hypocapnia should be avoided because it causes uteroplacental vasoconstriction, and hypercapnia causes acidosis and fetal acidosis with reduced cardiac function.

Neurosurgery

Neurosurgical emergencies from hemorrhage secondary to aneurysm rupture or arteriovenous malformation are not uncommon during pregnancy (see also Chapter

70). It is unclear whether pregnancy increases the risk for rupture. However, the risk for intracranial hemorrhage is increased by hypertensive diseases of pregnancy. In patients who are not pregnant, usual anesthetic treatment might include controlled hypotension, hypothermia, hyperventilation, and osmotic diuresis. These techniques need to be conducted with particular care in pregnancy. Reduction of mean arterial pressure below 70 mm Hg may significantly reduce uteroplacental perfusion, and use of fetal monitoring should be considered as a guide to fetal well-being. If hypothermia is used, the FHR will be reduced but will increase with rewarming. In fetal lambs, hypothermia to less than 18° C caused irreversible fetal acidosis and hypoxia, likely as a result of uterine vascular constriction,[279] and in case reports, fetal bradycardia with a strong maternal temperature, dependence was noted below 33° C.[280] Extreme hyperventilation also can cause uterine artery vasoconstriction and reduce uterine perfusion. Osmotic diuresis, used to reduce brain edema, may cause negative fluid shifts in the fetus. Mannitol in particular may accumulate in the fetus, leading to hyperosmolarity, reduced renal blood flow, and increased plasma sodium concentration.[281] Loop diuretics are an alternative but should be used with care and monitoring of amniotic fluid volume.

Chapter 78

Anesthesia for Fetal Surgery and Other Fetal Therapies

MARK D. ROLLINS

Key Points

- Most fetal anomalies are not appropriate for in utero treatment. A condition or situation appropriate for fetal treatment must cause ongoing irreversible harm to the fetus that would be mitigated with early treatment and occur before a gestational age at which the fetus could tolerate ex utero neonatal intervention.
- A multidisciplinary approach with thorough open communication is essential to the success of each fetal intervention.
- Maternal safety and the principle of "do no harm" should be the prime principle in determining the most appropriate therapeutic option and perioperative plan. A thorough maternal and fetal evaluation and frank discussion of risks and benefits by all team members with the mother is required to determine an appropriate care plan.
- Although open fetal surgery typically requires general anesthesia, most minimally invasive techniques can be effectively performed using local or neuraxial anesthesia.
- Randomized controlled clinical trials show improved outcomes with use of both fetoscopic laser photocoagulation of placental vessels to treat twin-to-twin transfusion syndrome and intrauterine open fetal surgery to treat myelomeningocele.
- In addition to anesthetic considerations associated with nonobstetric surgery during pregnancy, fetal surgery requires planning for fetal anesthesia and analgesia, fetal monitoring, uterine relaxation, and postoperative fetal monitoring and tocolysis.
- Membrane separation, preterm premature rupture of membranes, and preterm labor remain the most common complications and significant cause of morbidity and suboptimal outcome with fetal surgery.
- Further research into optimal anesthetic techniques for various fetal interventions is essential to improve patient outcomes and advance the field of fetal surgery.

Only recently have medical professionals focused on the human fetus as a patient, able to undergo surgery or medical intervention. This development has been primarily driven by systematic improvements in prenatal diagnosis, imaging technology, and surgical equipment. Although many fetal surgical procedures are available only at highly specialized institutions, some prenatal interventions are considered conventional therapy and have become more widespread. This chapter reviews the unique pathophysiological processes of various fetal and placental conditions amenable to intervention, current outcome data, specific procedural considerations, and perioperative anesthesia considerations.

Most fetal abnormalities are not appropriate for antenatal intervention and are more amenable to treatment after delivery. However, some anatomic malformations may result in irreversible end-organ damage and would benefit from intervention before birth. This has led to the theory that surgical or procedural correction in utero could allow normal fetal development and might mitigate much of the detrimental pathologic process observed.[1] Other defects, such as congenital airway obstruction, can be managed intrapartum by keeping the uteroplacental unit intact while the defect is repaired or airway secured, without the urgency that would be associated with attempting similar procedures immediately after birth.

Prerequisite guidelines for performing fetal surgery were initially developed more than 30 years ago at a multidisciplinary meeting with participants from 13 medical centers representing five countries.[2] Over time these guidelines have evolved and include (1) the fetal lesion is accurately diagnosed; (2) the progression and severity of the anomaly is predictable and well understood; (3) other severe associated anomalies that would contraindicate fetal intervention are excluded; (4) if left untreated before birth, the fetal abnormality would lead to fetal demise, irreversible organ damage, or severe postnatal morbidity, and, therefore, intervening before birth would benefit the neonatal outcome; and (5) the maternal risk is acceptably infrequent.[1,3]

All interventions should be preceded by a thorough multidisciplinary team deliberation of the clinical case. Discussions should focus on a comprehensive risk benefit analysis and providing the family appropriate counseling that includes options for elective termination of pregnancy or continuation of pregnancy without fetal therapy. Potential risks to the mother should be part of the informed consent, with a thorough and detailed maternal preoperative evaluation as part of the process to ensure maternal risks are minimal.[4,5]

The advancement of fetal surgery has benefited from a multidisciplinary approach and establishment of the International Fetal Medicine and Surgery Society to disseminate techniques and outcome data through an international registry. Medical centers offering fetal treatment rely on surgeons and anesthesiologists devoted to the care and counseling of these complex maternal and fetal patients, as well as the expertise of radiologists, perinatologists, geneticists, neonatologists, social workers, and numerous other support staff. A bioethics committee derived from both the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics has provided guidelines for fetal treatment centers that recommend a comprehensive informed consent and counseling process, maternal-fetal research oversight, use of a multidisciplinary approach, and participation in a collaborative data-sharing fetal therapy network.[6]

Fetal surgery is broadly categorized into three types of intervention: minimally invasive procedures, open procedures, and intrapartum procedures. A summary of conditions considered for fetal intervention with corresponding rationale and treatment is displayed in Table 78-1.

Minimally invasive fetal procedures include (1) percutaneous interventions guided by ultrasound, also known as fetal image–guided surgery for intervention or therapy (FIGS-IT), and (2) fetal endoscopic surgery using small endoscopic instruments dually guided by direct fetoscopic camera view and simultaneous real-time

TABLE 78-1 FETAL CONDITIONS CURRENTLY CONSIDERED FOR INTERVENTION

Fetal Condition	Therapy Rational	Type	Intervention
Fetal anemia or thrombocytopenia	Prevention of heart failure and fetal hydrops	FIGS-IT	Intrauterine transfusion
Aortic stenosis, intact atrial septum, or pulmonary atresia	Prevention of fetal hydrops, myocardial dysfunction, and hypoplastc left (and right) heart	FIGS-IT	Percutaneous fetal valvuloplasty or septoplasty
Lower urinary tract obstruction	Bladder decompression with reduction in renal dysfunction, pulmonary hypoplasia, oligohydramnios, and limb malformation	FIGS-IT or fetoscopy	Percutaneous vesicoamniotic shunting or fetoscopic posterior valve laser ablation
Twin reverse arterial perfusion	Prevention of high-output cardiac failure in the normal twin by stopping flow to acardiac twin	FIGS-IT or fetoscopy	Umbilical radiofrequency ablation or fetoscopic coagulation
Twin-twin transfusion syndrome	Reduction of twin-twin blood flow and prevention of cardiac failure	Fetoscopy	Fetoscopic laser photocoagulation of placental vessels
Amniotic band syndrome	Prevention of limb loss	Fetoscopy	Fetoscopic band ablation
Congenital diaphragmatic hernia	Prevention of pulmonary hypoplasia	Fetoscopy	Fetoscopic tracheal occlusion
Myelomeningocele	Reduction in hydrocephalus and hindbrain herniation with improved neurologic function	Open	Closure of fetal defect through hysterotomy
Sacrococcygeal teratoma	Prevention of high-output cardiac failure, hydrops, and polyhydramnios	FIGS-IT or open	Ablation of tumor vasculature or open fetal tumor debulking
Congenital cystic adenomatoid malformation	Reversal of pulmonary hypoplasia and cardiac failure	FIGS-IT or open	Thoracoamniotic shunting or open surgical resection
Fetal airway compression	Secured open airway and/or circulatory support to prevent respiratory compromise at birth	Open intrapartum	Ex-utero intrapartum therapy that allows stabilization while on uteroplacental circulation

Modified from Partridge EA, Flake AW: Maternal-fetal surgery for structural malformations, Best Pract Res Clin Obstet Gynaecol *26:669-682, 2012.*
FIGS-IT, Fetal image-guided surgery for intervention or therapy.

ultrasound imaging. Fetal endoscopic surgery is typically accomplished percutaneously, but sometimes requires a small maternal minilaparotomy. With these minimally invasive approaches, the risks for preterm labor and delivery are reduced compared with those in open procedures that include a hysterotomy. Unlike in open fetal procedures, the mother can safely undergo a vaginal delivery for this and future pregnancies. However, the risk for preterm premature rupture of membrane (PPROM) remains significant.

Open fetal procedures involve a maternal laparotomy, a hysterotomy, and the need for intraoperative uterine relaxation. These procedures incur significantly more risk to both the fetus and mother than minimally invasive procedures. These increased risks include PPROM, oligohydramnios, preterm labor and delivery, uterine rupture, and fetal mortality.[7,8] Additional maternal and fetal risks include not only the anesthetic risks noted for nonobstetric surgery during pregnancy (see also Chapter 77), but also pulmonary edema, hemorrhage, membrane separation, and chorioamnionitis.[4] Cesarean delivery is required after an open fetal procedure and for all future pregnancies owing to the increased risk for uterine dehiscence or rupture at the site of the hysterotomy.

For fetuses with known airway compromise or obstruction, an ex utero intrapartum therapy (EXIT) procedure[9] allows continued fetal support by the intact uteroplacental unit (placental bypass) while the fetal airway is secured or other procedures completed without the concern for postnatal respiratory compromise, hypoxia, and asphyxia. Examples of congenital lesions treated with EXIT procedures include cystic hygroma, lymphangioma, cervical teratomas, and other congenital syndromes with potential for airway compromise. Extracorporeal membrane oxygenation (ECMO) can be initiated during an EXIT procedure for a fetus with significant cardiopulmonary disease. Fetal surgical procedures in excess of 2.5 hours have been successfully performed using placental bypass with normal umbilical cord carbon dioxide and pH values at delivery.[10] The EXIT procedure has become a widely practiced fetal intervention for a growing list of indications.

Much of the success of fetal therapy in the past 3 decades can be attributed to extraordinary advances in both ultrasonography and magnetic resonance imaging (MRI), which have substantially improved the accuracy of prenatal diagnosis and expanded our understanding of the pathophysiologic factors of various untreated fetal abnormalities.

Significant advancements in ultrasonographic transducer hardware and digital signal processing have resulted in better image resolution with more accurate differentiation of abnormal fetal anatomy, wider fields of view, and improvement in the dynamic range for both near-field and far-field signal-to-noise ratio. Use of this improved ultrasonographic imaging as a real-time guide has enabled practitioners to develop and perform various diagnostic tests and fetal therapies more precisely and safely. Examples of fetal ultrasound-guided diagnostic procedures include first-trimester chorionic villus sampling, embryofetoscopy, amniocentesis, fetal blood sampling, and fetal biopsies.[11] These diagnostic advances allow more accurate prenatal consultation, the ability to intervene at an earlier gestational age, and usually enough time to change the location of antepartum care and the delivery plan if needed. Live ultrasound is typically used to guide all minimally invasive fetal procedures and is also critical to initial portions of open fetal procedures and fetal monitoring.

MRI has undergone technologic improvements that reduced image acquisition time, decreased motion artifacts, and enhanced image resolution to a point at which fetal MRI is frequently used in conjunction with ultrasound to better detect and evaluate anatomic pathologic processes.[12]

In addition to advances in imaging technology, decades of procedural innovations and research have provided the basis for the in utero fetal interventions used clinically today. Initial pioneers in the field of fetal therapy include Sir (Albert) William Liley. In the early 1960s, Liley[13] was the first to successfully treat erythroblastosis fetalis with an intraperitoneal blood transfusion that allowed the transfused red cells to be absorbed into the fetal circulation through the subdiaphragmatic lymphatics and thoracic duct.[14] Unfortunately, initial attempts to perform fetal blood transfusion through direct cannulation of the umbilical vessels were unsuccessful until 1981, when a reliable technique that employed fetoscopy was described.[15,16] With improved imaging resolution, the standard technique quickly became direct needle access of the umbilical vessels using ultrasound guidance. In the early 1970s, Liggins administered corticosteroids to the fetus via the maternal circulation to increase surfactant production in preterm fetuses at risk for respiratory distress syndrome.[15] Fetal surgery began in the early 1980s after rigorous research efforts and technical advancements in sheep[17-19] and monkey[20] models. Harrison and colleagues[21] performed the first successful human fetal surgery by creating a vesicostomy in a fetus with a congenital lower urinary tract obstruction resulting in bilateral hydronephrosis. Working with Harrison in the early 1980s, Rosen[22,23] refined fetal anesthetic techniques in monkeys[20] to improve intraoperative uterine relaxation and clinical outcome before employing them for the first human fetal surgeries and then detailing these techniques in the literature. Since the early 1980s, great advances have been made in the development of minimally invasive percutaneous surgical techniques, fetoscopy, and procedural aspects of open fetal surgery with hysterotomy. Fetal therapy also has advanced in its outcome evaluation from published case reports and series to prospective randomized controlled trials.[24]

Fetal surgery is a reasonable therapeutic intervention for certain correctable fetal anomalies with predictable, life-threatening, or serious developmental consequences. With all types of fetal intervention, meticulous planning and a multidisciplinary team approach are critical to a successful outcome. The following sections provide a review and summary of the congenital lesion, outcome data, procedural considerations, and perioperative anesthesia considerations for the various conditions currently amenable to fetal intervention.

INDICATIONS, PROCEDURES, AND OUTCOMES

ANEMIA AND INTRAUTERINE TRANSFUSION

The incidence of fetal anemia secondary to rhesus D (RhD) sensitization has decreased since the introduction of RhD immunoglobulin prophylaxis in the late 1960s, to rates of approximately 1 in 1000 pregnancies.[25] However, other red blood cell (RBC) antigens, parvovirus B19 infection, maternal-fetal hemorrhage, and homozygous thalassemia also cause fetal anemia and combine to reach a rate of approximately 6 cases in 1000 live births.[25,26] Although spectral analysis examining bilirubin levels in serial amniotic fluid samples was originally used to detect fetal anemia and determine the timing of therapy, most treatment centers currently rely on noninvasive Doppler studies of the middle cerebral artery (MCA).[26] An increased peak MCA blood flow velocity more than 1.5 multiples of the median is a threshold that has proved accurate in detecting moderate-to-severe fetal anemia requiring intervention.[27,28] The value of this peak velocity threshold may be increased with each serial transfusion treatment to decrease the false positive rate. Fetal blood sampling from the umbilical vein just before starting the intrauterine transfusion (IUT) is the gold standard for determining the degree of fetal anemia. IUT is not used before 18 to 20 weeks gestational age because reliable umbilical vein access is not possible. For cases requiring earlier intervention, intraperitoneal transfusion may initially be the intervention of choice.[29]

IUTs are typically performed using local anesthesia, with minimal maternal sedation and analgesia required. However, the anesthesiologist should be prepared for an emergent cesarean delivery at any time during the procedure if the fetus is at a viable gestational age. Using ultrasound image guidance, a 20- or 22-gauge needle is used to access the umbilical vein. The access point is typically near the placental cord insertion to provide stability (Fig. 78-1). Puncture of the umbilical artery rather than the vein is associated with prolonged bleeding and fetal bradycardia secondary to spasm.[25] Occasionally a free loop of the umbilical cord or intrahepatic portion of the umbilical vein may be used. The umbilical cord probably has no pain receptors, but needle access of the intrahepatic portion of the umbilical vein would stimulate pain receptors with passage of the needle into the fetus. Fentanyl attenuates the fetal stress response from intrahepatic fetal needle placement.[30] Yet, in one recent study, fetal stress hormone changes with IUT were unrelated to site of needle placement.[31] However, these results are difficult to interpret because hormone levels may primarily be determined by changes secondary to the underlying fetal anemia and associated hemodynamic alterations that are then changed with intravascular volume expansion. Given this uncertainty, fentanyl is administered to the fetus before use of an intrahepatic approach.

A muscle relaxant can be administered to the fetus to decrease the likelihood of fetal movement that could dislodge the needle or sheer the umbilical vein.[32] The volume of type O, rhesus (Rh)-negative, irradiated, viral

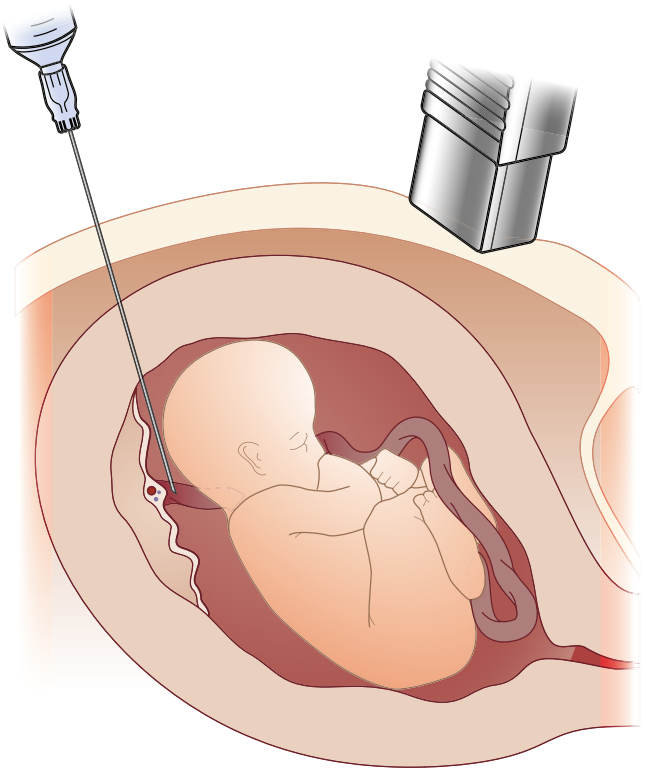

Figure 78-1. Diagram of cordocentesis procedure used in intrauterine transfusion. *(Redrawn from Ralston SJ, Craigo SD: Ultrasound-guided procedures for prenatal diagnosis and therapy,* Obstet Gynecol Clin North Am *31:101-123, 2004.)*

screened, packed RBCs transfused is estimated from the gestational age, estimated fetal weight, donor unit hemoglobin (Hb), and pretransfusion Hb.[33] The rate of transfusion is typically 5 to 10 mL/min with a target of 45% to 55% hematocrit. Steady intravascular location of the needle tip can be assessed with Doppler imaging throughout the transfusion injection. Periodic sampling is used to guide the final transfusion volume. After IUT therapy, fetal Hb levels decrease approximately 0.3 g/dL/day[34] and multiple repeat IUTs are typically required at 1- to 3-week intervals, depending on the rate of Hb decline.

Perinatal fetal loss rate is approximately 2% per IUT, and transient fetal bradycardia (8%) is a common complication.[35] In a series of 740 IUTs performed to treat 254 fetuses, the overall survival rate was 89%, with a 1.6% rate of fetal loss directly attributed to a procedural complication per IUT.[36] Rates of other complications per IUT included emergency cesarean delivery (2%), intrauterine infection (0.3%), and rupture of membranes (0.1%).[36] The survival rates are somewhat less for hydropic fetuses. In a retrospective study of 210 fetuses undergoing 593 IUTs, a 92% survival rate occurred in nonhydropic fetuses and a 78% survival rate in hydropic fetuses.[37] A few fetal treatment centers have published survival rates that exceed 95%.[38,39] A long-term outcome study of 291 children (median age of 8.2 years with a range of 2 to 17 years of age) who underwent IUT during gestation for hemolytic disease found a 4.8% rate of neurodevelopmental impairment, including cerebral palsy (2.1%), severe developmental delay (3.1%), and bilateral deafness (1.0%).[38]

Severe fetal hydrops was independently associated with neurodevelopmental impairment.

CONGENITAL HEART DEFECTS

Congenital heart anomalies occur with a frequency of 8 to 10 per 1000 live births (see also Chapter 94).[40] Of these, 3.5 to 4.0 per 1000 require intervention in infancy.[41-43] Ultrasound imaging allows diagnosis of cardiac defects as early as 12 to 14 weeks gestation.[44] The majority of fetal cardiac interventions include (1) aortic balloon valvuloplasty for treatment of critical aortic stenosis and evolving hypoplastic left heart syndrome (HLHS), (2) atrial septostomy for highly restrictive or intact atrial septum seen in HLHS, and (3) pulmonic valvuloplasty for pulmonary atresia or intact ventricular septum and hypoplastic right ventricles.[45] In utero treatment attempts to halt or reverse the morbid effects of the cardiac lesion before irreversible consequences occur. Early childhood mortality from severe cardiac defects, such as HLHS, remains in the range of 25% to 35%.[46,47] Survivors have significant associated abnormalities in neurologic development.[48,49] These fetal cardiac procedures focus on opening a stenotic valve or enlarging a restricted opening.

The most commonly performed procedure is an aortic valvuloplasty for aortic stenosis with evolving HLHS. Current selection guidelines for fetal aortic valvuloplasty focus on the presence of significant aortic stenosis, evolving HLHS, and the potential for a technically successful procedure and biventricular postnatal outcome.[46,50] Significant aortic stenosis maintains fetal circulation primarily through the low-resistance foramen ovale and diminishes left ventricular development. For this procedure,[51] the fetus is ideally positioned with the left chest anterior, and ultrasound is used to guide the percutaneous passage of an 18- or 19-gauge needle through the uterus, through the fetal chest, and into the apex of the left ventricle (Fig. 78-2, *A*). Maternal local anesthesia infiltration or neuraxial block is typically used for these procedures, and fetal resuscitation drugs must be readily available. In some cases, general anesthesia may be preferred for uterine relaxation to facilitate an external version to change fetal positioning and improve cannula trajectory. Before cannula insertion, intramuscular fentanyl and a paralytic agent are administered to the fetus with ultrasound guidance, as detailed in the discussion of fetal anesthesia and analgesia. The cannula tip is ideally positioned in the left ventricle, directly in front of the opening of the stenotic aortic valve and aligned with the left ventricular outflow tract. A balloon catheter with guidewire is passed through the cannula into the stenotic valve and positioned in the aortic annulus, where it is inflated and deflated multiple times (Fig. 78-2, *B*). Similar techniques are used for pulmonary valvuloplasty and atrial septoplasty.[52] In certain cases, a small laparotomy is used to facilitate improved cannula alignment with the cardiac lesion. Technical success for fetal aortic valvuloplasty is 70% to 75% using an angioplasty balloon over a guidewire.[50,53,54] Fetal complication rates from centers in Linz, Austria (n = 24) and Boston (n = 70) for fetal aortic valvuloplasty include, respectively, fetal bradycardia (17% and 38%), pericardial effusion (13% and 14%), ventricular thrombosis

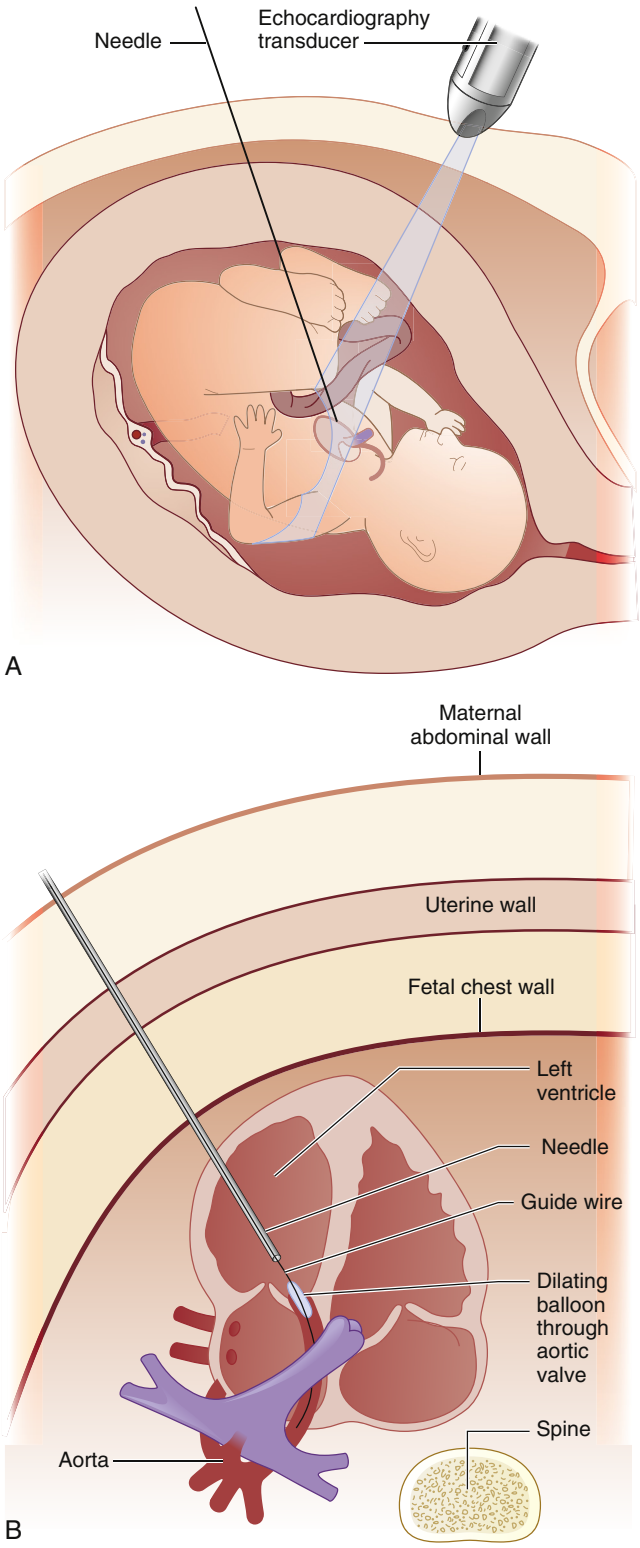

Figure 78-2. A, Depiction of ideal fetal position and insertion needle orientation. The fetal left chest is anterior, and the pathway from maternal abdomen entry point to the apex of the left ventricle is unobstructed. **B,** This linear cannula course continues from left ventrical apex to the aortic valve. *(Redrawn from Tworetzky W, Wilkins-Haug L, Jennings RW, et al: Balloon dilation of severe aortic stenosis in the fetus: potential for prevention of hypoplastic left heart syndrome—candidate selection, technique, and results of successful intervention,* Circulation *110:2125-2131, 2004; with permission from Lippincott Williams & Wilkins.)*

(21% and 15%), and fetal death (13% and 8%).[50,51,53] Approximately 40% of technically successful cases result in aortic regurgitation and minimal subsequent left ventricular growth. However, the left ventricular ejection fraction increases and aortic and mitral valvular growth improves.[45] Biventricular circulation is present at birth in approximately 30% of the successful cases.

In addition to treatment of aortic stenosis, other cardiac anomalies have been treated in utero. Outcomes from a small series of fetal atrial septostomies are promising; however, the defect created by the balloon dilation tends to close over time unless a stent is placed (which can be difficult to accurately deploy).[55,56] Pulmonary valvuloplasty for pulmonary atresia and prevention of hypoplastic right ventricle was technically successful in 7 of 11 procedures, but long-term outcome data are unavailable.[45,57] In utero placement of cardiac pacing can treat fetal cardiac arrhythmias unresponsive to conventional management with transplacentally administered antiarrhythmic drugs.[58] Unfortunately, these initial attempts have been largely unsuccessful.

OBSTRUCTIVE UROPATHY

Congenital obstructive uropathy occurs in approximately 1 in 1000 pregnancies.[59] These obstructions can be bilateral or unilateral and occur at the ureteropelvic junction, at the ureterovesical junction, or at the level of the urethra. If the obstruction is urethral or bilateral, significant developmental consequences occur (Box 78-1). Rates of perinatal mortality in these cases are as frequent as 90%, and survivors have more than 50% renal impairment.[60]

Posterior urethral valves are the most common cause of congenital bilateral hydronephrosis in male fetuses. Urethral obstruction is the most common cause in females, with other possible causes including ectopic ureter, ureterocele, megacystis megaureter, multicystic kidney, or other complex pathologic processes.[61] Ultrasound investigations of oligohydramnios resulting from the decreased fetal urine output easily detect these uropathies with high sensitivity and specificity. Fetal MRI should be considered in cases of severe oligohydramnios as an additional imaging technique to determine the presence of associated fetal anomalies.[60,62] A grading system based on ultrasound imaging of renal diameter can determine the severity of hydronephrosis.[63] The associated morbidity predicted for each type of uropathy depends on obstruction location, duration, gender, and gestational age at onset.[64] Preterm delivery allows neonatal urinary tract decompression, but morbidity from pulmonary immaturity prevents early intervention and limits the efficacy of this approach. Placement of an in utero fetal vesicoamniotic shunt for treatment of lower urinary tract obstruction (LUTO) allows decompression of the fetal bladder and urinary tract into the amniotic cavity. In animal studies, in utero intervention for LUTO improves dysplastic renal histologic conditions, increases amniotic fluid volume, and improves lung development. The translation of these results to fetal treatment of human LUTO remains controversial.[65]

An algorithm with specific criteria for karyotype, presence of additional abnormalities assessed by ultrasound, and fetal urinalysis are used to characterize the obstruction severity and improve both selection for in utero treatment and outcomes.[66] Poor prognosis is associated with earlier presentation during gestation, a more intense severity of oligohydramnios, associated structural abnormalities, and increased concentrations of fetal urine electrolytes, osmolality, protein, and β_2-microglobulin.[64,67] Each case should be thoroughly investigated to determine whether other anomalies are present and if the fetus is a suitable candidate for intervention.

Vesicoamniotic catheter shunt placement started in the 1980s. The shunt allows fetal bladder decompression in an effort to improve renal development and reduce the pulmonary hypoplasia associated with oligohydramnios. These valveless, double-coiled shunts are inserted percutaneously with ultrasonographic guidance and local anesthesia. One coil remains in the urinary bladder and the other in the amniotic cavity. Prior infusion of fluid into the amniotic cavity can aid in proper placement. Common problems associated with these catheters include difficult placement, subsequent occlusion, and position migration (malfunction occurs in up to 60% of cases).[68] Fetal complications include trauma, iatrogenic abdominal wall injury, gastroschisis, and amnioperitoneal leaking.[64] Vesicoamniotic shunting prevents the physiologic cycle of urine accumulation and emptying that is required for normal bladder development and is associated with bladder wall fibrosis in animal models.[69-71] Maternal complications include PPROM, preterm labor and delivery, and infection.[64] Neonatal survival rates after fetal vesicoamniotic shunting vary in the literature from 40% to 90%, with approximately 50% of survivors having normal renal function.[65,72-74] Currently, a multicenter, randomized controlled trial is underway (the Percutaneous Shunting in Lower Urinary Tract Obstruction [PLUTO] trial) comparing the perinatal mortality and renal function of fetuses with LUTO treated by either vesicoamniotic shunting or conservative noninterventional care with planned follow-up until 5 years of age.[75,76] Outcome data may be available in the next few years.

Fetal cystoscopy is a recent technique that allows prenatal diagnosis with visualization of the fetal urethra and prenatal treatment with ablation of the urethral obstruction. Cystoscopy facilitates diagnosis by allowing differentiation

between LUTO resulting from urethral atresia and posterior urethral valves. Two small case series show that use of fetal cystoscopy changed the diagnosis between these two pathologic processes in 25% to 36% of cases previously diagnosed by ultrasound imaging.[76-78] Fetal cystoscopy to ablate posterior urethral valves with laser fulguration may increase survival compared with expectant management, but improved perinatal survival over that with vesicoamniotic shunting has not been shown.[76]

Selective fetal intervention with shunting or cystoscopy for LUTO restores amniotic fluid volume, prevents pulmonary hypoplasia, and improves perinatal mortality. However, the effects on medium-term and long-term renal function, bladder function, and other morbidities remain unclear and additional research is needed.[79]

TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

Twin reversed arterial perfusion (TRAP) sequence is an abnormality of monozygotic twins that affects approximately 1 in 35,000 pregnancies, 1 in 100 monozygotic twin gestations, and 1 in 30 triplet gestations.[80] In this condition, one of the monozygotic twins has an absent or nonfunctioning heart and no share in the placenta. The nonviable twin is perfused with retrograde blood flow from the other twin that flows through arterioarterial anastomoses; blood returns to the normal twin by venovenous anastomoses that bypass the placenta. The inadequate perfusion of the recipient twin (primarily occurring retrograde through the umbilical artery) results in a lethal set of anomalies that include acardia and acephalus. Because the normal or "pump" twin generates blood flow for both itself and the nonviable twin, it is at risk for high-output congestive heart failure and preterm birth secondary to the increased uterine volume from polyhydramnios and increased size of the hydropic nonviable twin.[81] If untreated, TRAP sequence is associated with a 35% to 55% risk for intrauterine death of the normal pump twin, with survivors having an average gestational age of 29 weeks.[82,83] Diagnosis is confirmed with ultrasound findings of reverse flow to the nonviable twin by the umbilical artery. The goal of therapy is to interrupt the vascular communication between the two twins in an effort to prevent cardiac failure in the pump twin. Successful treatment of TRAP sequence results in cessation of flow in the recipient twin's umbilical artery and the death of this anomalous nonviable fetus.

Several approaches can accomplish these goals, including selective delivery of the nonviable fetus by hysterotomy, ligation, or transection of the cord using laser or bipolar diathermy; cord coagulation using coils or other thrombogenic material; and ablative therapy directed at the acardiac fetus near the base of the cord using laser, alcohol, or radiofrequency techniques.[84-87] In a single institution, retrospective review of 118 TRAP sequence cases treated with fetoscopic bipolar cord coagulation, the rate of miscarriage was significantly more frequent if the procedure was performed before 19 weeks gestation (45% versus 3%) and the overall survival rate was 71%.[88] Treatment with endoscopic laser photocoagulation of the vascular anastomoses or radiofrequency ablation at the base of the umbilical cord within the abdomen of the acardiac twin (Fig. 78-3) are also viable therapeutic options.[84,89] A multicenter retrospective review of 60 TRAP sequence cases treated with endoscopic laser coagulation noted survival rates near 80% and a median gestational age at delivery of 37.4 weeks.[90] Use of radiofrequency ablation in 26 TRAP sequence cases at a single center demonstrated a 92% survival rate of the viable fetus with a mean gestational age of 35.6 weeks at delivery.[89] A retrospective case series combined with a meta-analysis of six prior studies reported 88 pregnancies with TRAP sequence treated with radiofrequency ablation resulting in an 85% survival rate of the viable fetus.[86] In case-matched studies comparing radiofrequency ablation and fetoscopic bipolar cord coagulation, survival rates were similar,[91] despite a more frequent rate of PPROM with use of fetoscopic procedures in contrast to needle-based procedures.[86,92]

Minimally invasive procedures to treat TRAP are typically performed with maternal infiltration of local anesthesia at the fetoscope insertion site, although neuraxial anesthesia is also used. Ultrasound guidance and assessment is used as part of all these therapies, and procedure success is confirmed by absence of flow to the nonviable acardiac twin at the end of the procedure and again approximately 12 to 24 hours later. We still cannot determine the optimal gestational age or other criteria for intervention.

TWIN-TO-TWIN TRANSFUSION SYNDROME

Monochorionic twins share the same placenta and typically have intertwin vascular connections that create shared blood flow between the two fetuses. A significant number of these chorionic vascular anastomoses can result in unequal placental blood flow between the two monochorionic twins, creating a significant degree of intertwin discordance that can lead to twin-to-twin transfusion syndrome (TTTS). The occurrence of TTTS is approximately 1 to 3 per 10,000 births.[93,94] Monochorionic twinning occurs in approximately 20% to 25% of twin pregnancies, with TTTS complicating 10% to 15% of these monochorionic gestations.[93,95,96] TTTS usually manifests after the first trimester and is typically recognized at midgestation.[95,97]

Normally, the umbilical artery carries deoxygenated blood to the surface of the placenta, where gases and nutrients are exchanged with the maternal circulation. The returning venous blood flow is "paired" with the arterial flow, and the two components lie next to each other (Fig. 78-4). This fetal-placental vascular configuration (cotyledon) represents normal anatomy. A variety of abnormal unidirectional and imbalanced vascular connections are present in TTTS (Fig. 78-5). In TTTS, a branch of the umbilical artery descends into the placenta and cotyledon, but instead of connecting with a paired vein, it connects with a vein that brings blood to the other twin, and this results in an arteriovenous anastomosis between the two fetuses.[98] Although some intertwin arteriovenous vascular architecture is found in 90% to 95% of monochorionic twins, the shared blood flow is balanced by the presence of arterioarterial and venovenous bidirectional connections, which are found in 85% to 90% and 15% to 20% of monochorionic twin placentas, respectively.[93,99,100] The presence of arterioarterial connections is viewed as protective by allowing the overall resistances and blood flow to equalize between the twins and is associated with a significant reduction in TTTS.[96,101]

The complex pathophysiology of TTTS is dynamic and secondary to a variety of humoral, biochemical, hemodynamic, and functional changes in the two fetuses.[97,102] The increased blood flow to the recipient twin leads to polycythemia, polyuria, and polyhydramnios and can cause hypertrophic cardiomyopathy, hydrops fetalis, and fetal death. The donor twin (often described as the "stuck" or "pump" twin) is typically hypovolemic, growth-restricted, and confined against the endometrium in an oligohydramniotic sac. This twin is primarily at risk for renal failure, cardiac failure, and hydrops fetalis secondary to the high cardiac output state.

The diagnosis of TTTS requires (1) a monochorionic diamniotic pregnancy and (2) a significant discrepancy in amniotic fluid volumes with ultrasound measurements of the maximal vertical pocket (MVP) of less than 2 cm in the oligohydramniotic twin and the MVP greater than 8 cm in the polyhydramniotic twin.[93,96] Twin size discordance and the presence of intrauterine growth restriction are often present in TTTS, but are not considered necessary to confirm the diagnosis. Although a variety of staging systems exist for determining the severity of TTTS, the most commonly used is the Quintero staging

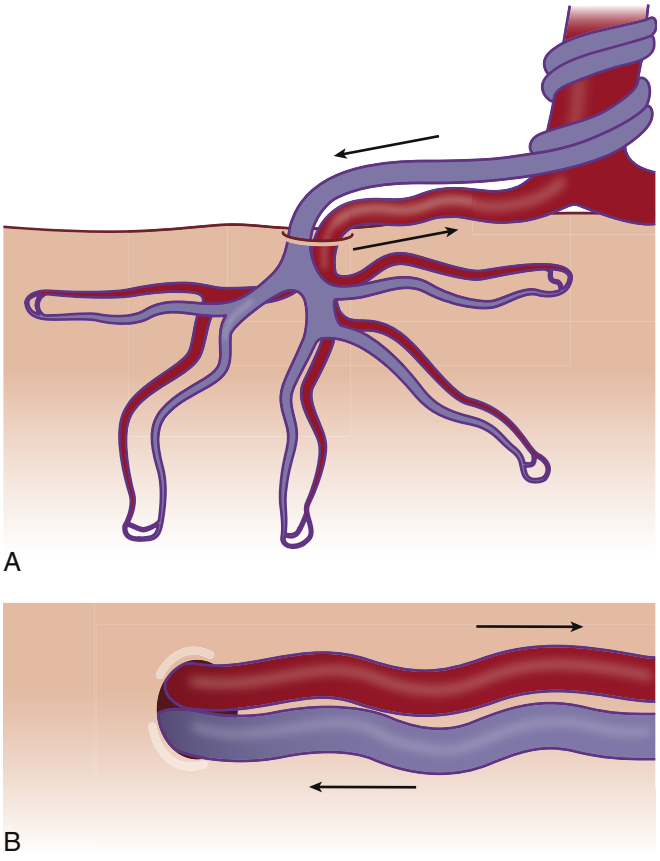

Figure 78-4. A, Normal placenta angioarchitecture (cotyledon). **B,** Superficial view of bidirectional flow into and out of a cotyledon. *(Redrawn from Rand L, Lee H: Complicated monochorionic twin pregnancies: updates in fetal diagnosis and treatment,* Clin Perinatol *36:417-430, 2009.)*

system (Table 78-2), which is based on ultrasound findings.[103,104] The progression of hypertrophic cardiomyopathy in the fetal recipient is detailed in a scoring system presented by Rychlik and colleagues[105] that provides a more detailed assessment of TTTS severity when combined with the Quintero staging system.[96]

Fetuses with TTTS are at risk for PPROM, preterm delivery, and neurologic injury with white-matter lesions and long-term disability.[106] Neurodevelopmental impairment is associated with a low gestational age at birth.[106-108] Multiple sources note TTTS results in more than 80% fetal mortality with 15% to 50% risk for significant morbidity in surviving neonates.[96,102,109] However, other sources disagree with this statistic and note an 86% overall survival rate with conservative management of stage I TTTS.[93,110] Although outcome data stratified for the advanced stages of TTTS are limited, a more frequent mortality rate is likely associated with more advanced progression of the disease.[93,110]

Several therapeutic management techniques have been developed to treat TTTS. Amnioreduction can help control polyhydramnios and thereby reduce the risk for both preterm labor and maternal respiratory distress. Also, placental blood flow may improve by decreasing amniotic hydrostatic pressure on the placental vasculature. Serial amnioreductions can improve placental perfusion and decrease the rate of preterm deliveries.[111] A retrospective review of 223 twin sets with TTTS found that use of amnioreduction resulted in an overall birth survival rate of 78%, with survival rates of 65% for recipient twins and 55% for donor twins at 1 month of age.[112] Another review of 112 TTTS cases reported a 60.9% perinatal survival rate with use of amnioreduction.[113] Use of an ultrasound-guided needle to create a surgical septostomy was hypothesized to improve TTTS outcome by equalizing the amniotic pressure between the two fetal sacs. In a prospective randomized trial comparing serial amnioreduction to septostomy, no survival difference was found between the techniques.[114] Septostomy is rarely used for TTTS treatment because it offers no outcome advantage, and the creation of a single amniotic sac can increase the risk for umbilical cord entanglement. Selective feticide with the goal of improving the chance for survival of the other twin is accomplished using techniques described in the section on twin reverse arterial perfusion. It is typically used only for the most severe cases of TTTS.

Selective fetoscopic laser photocoagulation (SFLP) of the vascular anastomoses between the two twins is the best therapeutic approach for treating TTTS (stages II to IV) between 18 and 26 weeks gestation.[93,96] By detailed fetal ultrasound examination, the location of the placenta, cord insertions, and fetal orientation and anatomy are confirmed before the start of the procedure. Either maternal neuraxial blockade or local anesthesia infiltration from maternal skin to myometrium can be used. Using ultrasound guidance, a 3-mm trocar or cannula is inserted percutaneously over a wire into the recipient twin's amniotic sac and directed perpendicular to the longitudinal axis of the donor twin.[97,109] The fetoscope is inserted into the trocar sheath and the laser fiber bundle inserted into the fetoscope guide. Vessels that cross the membrane dividing the amniotic sacs are visualized, and the abnormal connecting vessels are selectively laser coagulated, with an effort to spare the normal cotyledons.[95,98] Ideally this creates two separate placental regions with each supplying an individual fetus. Nonselective laser ablation of all crossing vessels is typically avoided because it is associated with more frequent rates of intrauterine fetal demise and is likely to unnecessarily ablate some normal placental vessels.[95,115] Ablation of all abnormal connecting vasculature is not necessary for the procedure to be successful.[116] After laser ablation, amnioreduction is also performed in an effort to decrease the risk for preterm labor.

A 2004 randomized multicenter trial compared laser therapy to amnioreduction for treatment of severe TTTS diagnosed between 15 and 26 weeks gestation.[117] Rates of at least one twin survival were more frequent in the laser treatment group at both 28 days (76% versus 56%, $P < .01$) and 6 months of life (76% versus 51%, $P < .01$). In addition, neurologic outcomes were better in the laser treatment group. A large subgroup of survivors from this trial was followed prospectively for 6 years. No additional change in either survival rate or long-term neurologic outcome was found in comparison to the original 6-month data.[118] A meta-analysis of studies published between 1997 and 2007 also determined that TTTS treated with laser ablation resulted in a higher overall fetal survival rate than that of amnioreduction.[119] This conclusion was echoed in a Cochrane review of treatment for TTTS.[120] Long-term neurologic outcome in TTTS survivors who underwent SFLP remains unclear, with rates of major neurologic abnormalities in survivors ranging from 6% to 25%.[96,107] A recent longitudinal study examining neurodevelopmental outcome at 6 years of age in 190 children who underwent SFLP for TTTS reported mild neurologic impairment in 11.6% and severe neurologic impairment in 8.9% of these children.[121]

Some practitioners advocate use of a specific sequence when coagulating the various types of abnormal anastomoses in an effort to create a net flux of blood from the recipient to the donor and thereby reduce the chance for hemodynamic compromise and hypotension during the

TABLE 78-2 STAGES OF TWIN-TWIN TRANSFUSION SYNDROME

Stage	Ultrasound Findings
I	Oligohydramnios in donor twin sac with MVP <2 cm and polyhydramnios in recipient twin sac with MVP >8 cm
II	Stage I criteria AND no visualization of donor twin bladder with over 1 hr of ultrasound observation
III	Stage II criteria AND (1) absent or reversed umbilical artery end-diastolic flow, (2) reversed ductus venosus a-wave flow, OR (3) pulsatile flow in the umbilical vein
IV	Either stage I or stage II criteria AND fetal hydrops in either twin
V	Fetal demise in either or both twins as assessed by absent fetal cardiac activity

Staging data based on criteria from Quintero RA, Morales WJ, Allen MH, et al: Staging of twin-twin transfusion syndrome, J Perinatol *19:550-555, 1999.*
MVP, Maximal vertical pocket.

procedure in the donor twin.[122] Initially, superficial arteriovenous anastomoses that contain a donor artery are ablated, then arteriovenous anastomoses with a recipient artery, then the arterioarterial anastomoses, and finally ablation is performed at the venovenous anastomoses. In a single institution review of 99 consecutive SFLP procedures for treatment of TTTS, twins treated with this sequence had better survival rates than twins whose SFLP procedure was performed without a specific sequence.[122] A prospective multicenter trial comparing use of sequential SFLP to nonsequenced SFLP found that use of sequential SFLP significantly improved the 30-day survival of both twins, as well as the donor twin survival rate.[123] However, use of this sequential technique is associated with longer operative times and increased case difficulty, particularly with a placenta located on the anterior uterine wall.

The most common complication of SFLP is PPROM with subsequent preterm labor and delivery. PPROM rates vary widely across studies, but PPROM has been reported to occur in 12% to 30% of SFLP cases for TTTS with a rate of preterm labor and delivery before 32 weeks in gestation in approximately 30% of cases.[95,96] Other possible complications include placental abruption, need for a second SFLP procedure, placement of the trocar through the placenta, hemorrhage, and possible membrane perforation resulting in limb entrapment and ischemia.[95,96]

In conclusion, treatment of TTTS with SFLP results in superior outcomes in contrast to amnioreduction. Additional research is needed to determine optimal timing, further technique refinement, and long-term neurologic outcome for the treatment of TTTS with SFLP.

AMNIOTIC BAND SYNDROME

Amniotic band syndrome (ABS) includes a wide variety of fetal anomalies associated with fibrous bands that entangle or constrict various parts of the fetus or umbilical cord in utero. The resulting malformations include limb and digit amputations, craniofacial abnormalities, visceral defects, and body wall defects. The incidence is approximately 1 in 3000 to 1 in 15,000 live births.[124,125] The primary cause and pathogenesis of ABS remains unknown, but these defects appear secondary to either a vascular insult or other cause of abnormal perfusion to the affected area.[126] Theories behind the cause of ABS include a primary defect in embryonic development, an early amniotic membrane rupture resulting in the creation of amniochorionic bands, and a vascular disruption early in pregnancy.[124,127,128] Perhaps this category of abnormalities is composed of subcategories from different causes.

Diagnosis is determined by findings on ultrasound imaging consistent with characteristic fetal anomalies of the involved anatomy. Visualization of the bands themselves is not a necessary component of the diagnosis.[129] Fetal MRI can aid in diagnosis as a complimentary technique to ultrasound, but the efficacy of its use is currently limited to case reports and a small case series.[130] In cases of limb entrapment, increasing band constriction decreases both venous and arterial flow. This decreased perfusion can eventually result in amputation distal to the constriction. In an otherwise normal fetus, use of fetoscopic-guided sectioning of the band with a laser can restore distal blood flow and may improve functional outcome in some cases.[131] Efficacy of the technique is based on review of cases in the literature, which note some favorable outcomes and a frequent rate of PPROM.[124,131] In addition to outcome studies, validation of proposed classification schemes is needed, as well as prognostic factors affecting intervention outcomes.[124]

CONGENITAL DIAPHRAGMATIC HERNIA

Approximately 1 in 2500 newborn infants has a congenital diaphragmatic hernia (CDH).[132] During early gestation, abdominal contents herniate into the thoracic cavity and compress the fetal lungs. This results in significant neonatal morbidity and mortality from pulmonary hypoplasia, respiratory insufficiency, and pulmonary hypertension. Survival rates have improved to between 60% and 92% over the past 20 years at tertiary care centers.[133-137] These highly specialized centers offer care that includes surfactant administration, specialized ventilation techniques to minimize lung trauma, surgical closure of the defect, and availability of ECMO therapy. Mortality rates vary greatly with the severity of pulmonary hypertension and respiratory dysfunction.[133] Fetal intervention for CDH aims to improve fetal lung development and prevent the morbidity of pulmonary hypoplasia.

In utero repair of diaphragmatic hernia in lamb models reversed both the parenchymal hypoplasia and pulmonary vascular changes associated with CDH.[17] Initial human in utero intervention focused on open repair of the fetal diaphragm with limited success.[138,139] However, these initial interventions advanced fetal surgery techniques and paved the way for a minimally invasive approach to CDH intervention.

Initial open intervention experience found that a fetal abdominal patch was necessary to accommodate the added abdominal viscera. The patch allowed closure without increasing intraabdominal pressure and compromise of ductus venosus blood flow. These open interventions also determined that reduction of the herniated liver compromised umbilical circulation and significantly increased fetal mortality. Performing both subcostal and thoracotomy incisions on the fetus improved surgical exposure, allowed the reduction of viscera by pushing and pulling techniques, and facilitated the reconstruction of a diaphragm with a prosthetic patch.[140] Other lessons learned include (1) the advantage of opening the uterus with a stapling device to ensure effective hemostasis; (2) improved techniques of uterine closure; and (3) use of fibrin glue to help prevent amniotic fluid leaks. However, adequate control of postoperative uterine tone remained a substantial problem. In a prospective clinical trial sponsored by the National Institutes of Health, in utero CDH treatment using an open technique for fetuses without herniation of the liver into the thorax did not improve neonatal survival compared with standard postnatal treatment.[141]

After these efforts, a minimally invasive approach was pursued, focused on tracheal occlusion. Fetal lungs secrete over 100 mL/kg/day of fluid that exits the trachea and mouth into the amniotic cavity. In fetal lamb models, tracheal occlusion restricts the normal outflow of the

Modified from Jani JC, Nicolaides KH, Gratacos E, et al: Fetal lung-to-head ratio in the prediction of survival in severe left-sided diaphragmatic hernia treated by fetal endoscopic tracheal occlusion (FETO), Am J Obstet Gynecol*;195:1646-1650, 2006.*
CDH, Congenital diaphragmatic hernia; LHR, lung area–to-head circumference ratio.
*The LHR measurements were obtained at 23 to 29 weeks gestation.

fetal lung fluid and provides an increase in pulmonary hydrostatic pressure. This increased pressure pushes the viscera out of the thorax, promotes expansion of the hypoplastic lung, and thereby improves lung growth and development.[142,143] Fetal reversible tracheal occlusion[144,145] replaced primary repair in utero for the treatment of CDH. Initially, a tracheal foam plug was inserted in the fetal airway during open surgery, but it failed to provide adequate occlusion.[146] Later, metallic hemoclips were placed around the trachea after meticulous neck dissection.[146] Unfortunately, survival with this initial open tracheal occlusion procedure was poor (15%) and lower than survival in CDH fetuses receiving postnatal standard treatment (38%).[147]

Subsequently, minimally invasive fetal endoscopic surgical techniques replaced the open technique for placement of the clips. These procedures are performed with local or neuraxial maternal anesthesia with administration of fetal anesthesia by intramuscular injection. A variety of occlusive devices, including cuffs, plugs, valves, and balloons, were attempted at various medical centers.[148] Currently, percutaneous endoscopic endotracheal intubation is used to place a small detachable occlusive balloon in the fetal trachea.[149,150] With initial procedures it was left in place until delivery (see discussion on EXIT procedures), but more recently, it is deflated and removed before term with a second fetal endoscopic surgical techniques procedure. The balloon removal may improve type II pneumocyte function, increase surfactant production, and allow a vaginal delivery when appropriate.[148] These techniques decrease morbidity from CDH, with definitive surgical repair planned postnatally.[142,151]

Use of ultrasound imaging to determine the ratio of fetal lung area to head circumference (LHR) and the presence of thoracic liver herniation ("liver up" versus "liver down") are the most reliable prognostic indicators of fetal CDH outcome.[148,152,153] Evaluation of survival in fetuses with left-sided CDH and intrathoracic liver herniation managed postnatally noted no survival with an LHR of 0.7 or less and a survival rate 72.7% or greater with an LHR 1.4 or greater (Table 78-3).[154] Unfortunately, the LHR increases exponentially with gestational age and is less useful after 28 weeks gestation.[155] The Antenatal CDH Registry Group normalized the LHR to

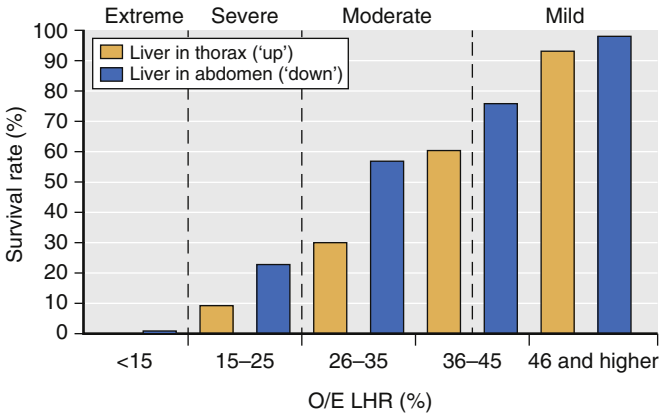

Figure 78-6. Survival rates of fetuses with isolated left-sided congenital diaphragmatic hernia (CDH), depending on measurement of the observed to expected lung area to head circumference ratio (o/e LHR) and position of the liver. *(Redrawn from Deprest JA, Nicolaides K, Gratacos E: Fetal surgery for congenital diaphragmatic hernia is back from never gone,* Fetal Diagn Ther *29:6-17, 2011.)*

gestational age by creating an observed-to-expected LHR (o/e LHR)[156] that correlates well with survival rate (Fig. 78-6).[157-159] More recently, fetal MRI measurement of lung volume (as an assessment of pulmonary hypoplasia) correlates well with neonatal survival in fetuses with isolated CDH.[134,160]

A prospective randomized trial (1999 to 2001) evaluated endoscopic fetal tracheal occlusion for prenatal treatment of CDH using both clip and balloon occlusion techniques.[161] Inclusion criteria included a 22- to 28-week gestational age, left-sided thoracic liver herniation, and a LHR of less than 1.4. The trial was closed early, and no benefit in survival or reduction in 90-day morbidity was found with prenatal treatment (n = 11) compared with control (n = 13) (survival rates of 73% versus 77%). Additionally, rates of PPROM and preterm delivery were more frequent in the fetal intervention group, with 100% of the fetoscopic intervention group having PPROM.[161] The inclusion of fetuses with an LHR of up to 1.4 may have decreased the ability to determine a significant difference, because many of these fetuses were likely to survive with standard postnatal tertiary medical care (see Table 78-3).

Three European medical centers, the Fetal Endoscopic Tracheal Occlusion (FETO) task force, began collaboration for treatment of severe cases of CDH with a high risk for mortality (LHR <1.0 and liver herniation into the hemithorax).[156,162] Because of concern for tracheal damage by very early tracheal balloon placement,[163] the tracheal balloon was placed at 26 to 28 weeks gestation and removed before birth. Data from 210 FETO task force cases through 2008 (mean gestational age of 27 weeks, LHR <1.0, and primarily left-sided CDH) were compared with historic postnatal treatment controls (1995 to 2004). Use of prenatal reversible tracheal occlusion significantly improved the survival rate (47% versus 20% in historic controls), and delivery occurred at a median gestational age of 35.3 weeks.[162] In addition, mean operating time was minimal (<10 minutes) and more than 95% of procedures were successful on the first attempt. Some of the survival benefit with in utero treatment may represent selection bias and improvement in both technique and neonatal care over time.

A more recent (2008 to 2010) randomized, controlled, single-institution trial compared cases of severe CDH (LHR <1.0 with liver herniation) randomized to either FETO (n = 21) at 26 to 30 weeks gestation or standard postnatal care (n = 20).[164] All treatment group fetuses were delivered by planned EXIT procedure at 38 weeks gestational age to allow controlled tracheal balloon removal. The overall survival rate was significantly greater in the FETO intervention group than in the postnatal management group (52.6% versus 5.3%). In 2009, a multicenter randomized Tracheal Occlusion to Accelerate Lung growth trial (TOTAL) began enrollment (http://www.totaltrial.eu).[165] It compares postnatal management to both late (30 to 32 weeks gestation) FETO intervention for moderate lung hypoplasia and earlier FETO intervention (27 to 30 weeks gestation) for severe lung hypoplasia. This trial uses o/e LHR criteria, and balloon occlusion removal is planned for 34 weeks gestation, with postnatal management standardized by a consensus protocol. Long-term outcome data on pulmonary and neurologic development are needed to better determine if and when FETO should be offered for individual cases of severe CDH.

MYELOMENINGOCELE

Spina bifida includes all defects with incomplete neural tube closure. Myelomeningocele (MMC) is the most common type of spina bifida and results in protrusion of the meninges and spinal cord through a developmental defect in the vertebrae, overlying muscles, and skin. MMC occurs during the third and fourth weeks of gestation with incomplete embryonic neural plate development. Folate supplementation in the maternal diet has decreased the rate of MMC nearly 50%, but the benefit reached a plateau without eliminating the disorder and MMC remains at a rate of approximately 1 in 3000 live births.[166,167] Improved prenatal screening with α-fetoprotein measurement and ultrasonography allows the possibility of pregnancy termination, and it is estimated that 25% to 40% of MMC pregnancies are terminated. MMC can result in lifelong morbidity and disability, including loss of motor and sensory function based on lesion level, bowel and bladder dysfunction, sexual dysfunction, hydrocephalus, Arnold-Chiari type II malformation, tethered cord, and impaired cognition.[168,169] If uncorrected in utero, surgical closure of the spinal defect must be performed within a few days after birth. Nearly 80% of children with MMC also require ventriculoperitoneal shunting for hydrocephalus.[170] Even with successful shunting, complications of central hypoventilation, vocal cord dysfunction, and swallowing difficulties can persist because of an associated Arnold-Chiari malformation.[169] The mean intelligence quotient in patients with MMC who underwent ventriculoperitoneal shunting is 80 (low normal).[171] Neonates with spina bifida have a 14% mortality rate by 5 years of age and a 35% mortality rate in those with known brainstem dysfunction and Arnold Chiari type II malformation.[166,171]

The cause of MMC remains unknown. The abnormalities and deficits of MMC are hypothesized to be the result of two separate mechanisms. The primary cause is anatomic malformation with abnormal development of the spinal cord and associated tissues. Secondary damage is likely created by exposure of these open neural elements to the amniotic fluid and direct trauma. Consequently, the ability to close the defect in utero and isolate the neural tissue from contact with the intrauterine environment has the potential to improve outcome in contrast to delaying closure until after birth.

This hypothesis has been supported by animal models that found improved neonatal neurologic function with fetal closure of the defect in utero.[172-174] Ultrasound assessment demonstrates that central and peripheral neurologic injury is progressive during gestation.[175,176] Improved motor function has been observed at 2 years of age in children with MMC who underwent cesarean delivery before labor onset compared to those delivered vaginally or by cesarean delivery after onset of labor.[166,177] Therefore, women with fetuses with MMC typically undergo cesarean delivery before onset of labor or rupture of membranes in an effort to minimize any additional injury to the open neural elements.

The rationale for fetal intervention for MMC is to improve functionality and quality of life.[178] Prenatal repair for MMC is performed with an open fetal surgical technique that requires both maternal laparotomy and hysterotomy. Considerations for anesthesiologists involved in open MMC repair include participation in comprehensive, multidisciplinary, preoperative maternal evaluation and counseling; preparation for potential intraoperative hemorrhage; planning an anesthetic that provides profound uterine relaxation; administration of analgesia and muscle relaxant directly to the fetus; intraoperative fetal assessment with preparation for potential fetal resuscitation or urgent delivery; and postoperative maternal analgesia and postoperative uterine and fetal monitoring.[179] Perioperative considerations for open fetal surgery are detailed later in the discussion of anesthetic management and considerations and management of open procedures.

MMC in utero surgery typically occurs mid–second trimester, before 26 weeks gestation. Initial human studies found that in utero repair reversed the hindbrain

*The rates of maternal and fetal and fetal and neonatal complications observed in the prenatal and postnatal repair groups in the Management of Myelomeningocele Study[182] are listed with corresponding statistical significance. Although other complication outcomes were evaluated, only those determined to be different between the two groups are included in the table. Percentage of complications within each experimental group is noted in parentheses.

herniation of the Arnold-Chiari II malformation and decreased the requirement for ventriculoperitoneal shunt placement before 1 year of age.[180] In addition, a 1999 series of 10 fetuses undergoing in utero MMC closure at 22 to 25 weeks gestation found improved lower extremity function among 6 of 9 fetuses compared with expected function based on the level of lesion, with one fetal death at 25 weeks gestation from preterm delivery and associated respiratory insufficiency.[7] A recent randomized, prospective clinical trial completed between 2003 and 2010 at three U.S. medical centers examined the risks, benefits, and outcome of open in utero repair for MMC compared with standard postnatal repair among 183 patients.[181] Open fetal repair reduced the need for ventriculoperitoneal shunting and improved lower extremity motor function at 30 months of age. However, prenatal repair significantly increased the risk for various fetal and maternal complications, including spontaneous membrane rupture, oligohydramnios, partial or complete uterine dehiscence, and preterm birth with increased risk for respiratory distress syndrome (Table 78-4). Two perinatal deaths occurred in each group. Trial participants will undergo future assessment at 6 to 9 years of age to determine potential long-term benefit from the prenatal repair.

Throughout the duration of the trial a moratorium was in effect in the United States on in utero repair for MMC outside the clinical trial. With the favorable outcomes of this trial, additional medical centers are offering in utero repair for MMC. Results of this trial should not be generalized to patients outside the inclusion criteria of the study and should be considered only at medical centers that can develop a practice with significant volume and depth of resources.[182] It was recently recommended that this procedure be offered only at medical facilities with the expertise, multidisciplinary teams, services, and facilities to provide the intensive care required for these patients, with rigorous patient selection maintained.[183]

Until further advancement occurs in the surgical technique, equipment, and information from experimentation in animal models demonstrating significant benefit of endoscopic repair, prenatal repair of MMC will require an open surgical approach. A recent European trial of minimally invasive endoscopic intrauterine MMC repair resulted in a surprisingly high rate of maternal and fetal complications.[184] In a series of 19 patients who underwent endoscopic prenatal repair for MMC, 3 fetuses died intraoperatively and another three procedures were stopped because of severe hemorrhage from the procedure. Among the patients completing the procedure, fetal intervention was associated with improved neurologic function compared with matched control neonates who underwent postnatal intervention. However, the endoscopic fetal repair resulted in significantly more complications, and the authors concluded that this technique is unsuitable for current clinical practice, pending further advances.[184]

SACROCOCCYGEAL TERATOMA

The incidence of sacrococcygeal teratoma (SCT) is approximately 1 in 27,000 to 40,000 live births.[185,186] These teratomas are typically diagnosed by ultrasound in the second trimester of pregnancy and may grow rapidly (>150 cm^3/week), with some reaching sizes of 1000 cm^3 or more.[187] The larger tumors function as a substantial arteriovenous shunt that creates a low resistance state and leads to the development of high-output cardiac failure. Perinatal mortality varies greatly in different published series, ranging from 16% to 63%.[186] Fetuses with a large SCT are associated with the development of placentomegaly, polyhydramnios, and hydrops fetalis and have a high rate of in utero mortality. In addition, fetuses with SCT are at risk for intrapartum dystocia, tumor rupture with hemorrhage, and urinary obstruction. Cesarean delivery is frequently required.

Tumor staging is based on the Altman criteria and determined by the volume of the tumor external or internal to the pelvis.[188] Stage I tumors are entirely external to the pelvis, with no presacral portion, and therefore suitable for fetal intervention. In contrast, stage IV tumors are located entirely in the pelvis and abdomen and are not considered amenable for fetal resection.[187] Fetal MRI can assist in tumor staging and determining the location of the tumor.[189] Fetuses diagnosed with SCT before 30 weeks gestation or with rapidly growing tumors have a poor prognosis, but may benefit from in utero intervention. Radiofrequency ablation, thermocoagulation, and cyst drainage have been employed to treat SCT in utero, but the benefit remains unclear.[10,185,186] SCTs have been resected in utero (Fig. 78-7) with successful outcomes, but the timing and criteria for fetal intervention remain unclear.[10,187,190] Fetal teratoma resection has a high risk for fetal hemorrhage; consequently, intraoperative placement of a venous catheter in a fetal hand, leg, or umbilical cord vein is important for the ability to transfuse compatible blood and crystalloid fluids or rapidly administer resuscitation drugs.

In certain cases, fetal SCT may lead to maternal mirror syndrome, in which maternal physiology mimics the abnormal circulatory physiology of the hydropic fetus.[191] The mother develops hypertension with increased peripheral and pulmonary edema that result from a hyperdynamic state. Maternal mirror syndrome does not resolve immediately with correction of the fetal pathophysiology, and can result in life-threatening maternal complications.[191]

CONGENITAL PULMONARY LESIONS

Congenital pulmonary airway malformations (CPAM), also known as congenital cystic adenomatoid malformations, are benign nonfunctioning pulmonary tumors composed of cystic and solid components that are usually contained within a single lung lobe.[192,193] These fetal lesions complicate approximately 1 in 25,000 pregnancies.[194] Other possible fetal lung abnormalities that require differentiation include bronchopulmonary sequestration, congenital lobar emphysema, and peripheral bronchial atresia.[195] CPAM includes five subtypes that are based on cyst size, characteristics of the epithelial lining, cyst wall thickness, and the presence of mucous cells, cartilage, and skeletal muscle.[196,197] Prenatal ultrasonography categorizes lesions as macrocystic (cysts >5 mm in diameter) or microcystic (cysts <5 mm in diameter), with microcystic lesions having a more solid or echogenic image. Prognosis depends primarily on size and growth characteristics of the CPAM rather than lesion type.[198] To normalize tumor volume to fetal size, a ratio of ultrasound measures of CPAM volume to fetal head circumference (CVR) was evaluated as a predictor of hydrops fetalis and other postnatal outcomes.[199,200] CVR is calculated from the volume of an ellipse (cubic centimeters) using the formula length × height × width × .52)/fetal head circumference (centimeters). Based on retrospective data from 71 fetuses, a CVR less than 0.56 predicts no adverse postnatal outcome (100% negative predictive value), whereas a CVR greater than 0.56 had a positive predictive value for adverse postnatal outcome of 33%.[199] In addition, a CVR greater than 1.6 is associated with greater risk for hydrops fetalis.[193,199,200] A recent retrospective analysis of a series of 24 fetuses with a CVR greater than 1.6 found that an abnormal echocardiogram with hydrops was a significant predictor of mortality and need for fetal intervention.[201]

Some lesions regress with minimal impact, whereas others grow in size. Typically, small lesions regress in the third pregnancy trimester and can be surgically resected after birth or managed conservatively without surgical intervention.[202] Large lesions can compress the great vessels, create pulmonary hypoplasia, and cause cardiac compression and mediastinal shift that often results in hydrops fetalis (secondary to heart failure). Patients with CPAM tumors associated with hydrops fetalis have a survival rate of less than 5% without intervention.[203] Large cystic lesions can be decompressed in utero by placement of shunt catheters between the cysts and the amniotic cavity (Fig. 78-8). Use of fetal analgesics and muscle relaxants delivered intramuscularly with ultrasound guidance may decrease the fetal stress response and prevent fetal movement during critical portions of the procedure. Shunt placement can prevent or reverse hydrops formation, with definitive resection deferred until after birth.[204] In a retrospective analysis of 24 nonhydropic fetuses with severe mediastinal shift, treated with thoracoamniotic shunting at 27 weeks gestation, postnatal survival was 87.5%, whereas 50 fetuses undergoing thoracentesis or thoracoamniotic shunting had a survival of only 66%.[205,206] In some CPAM

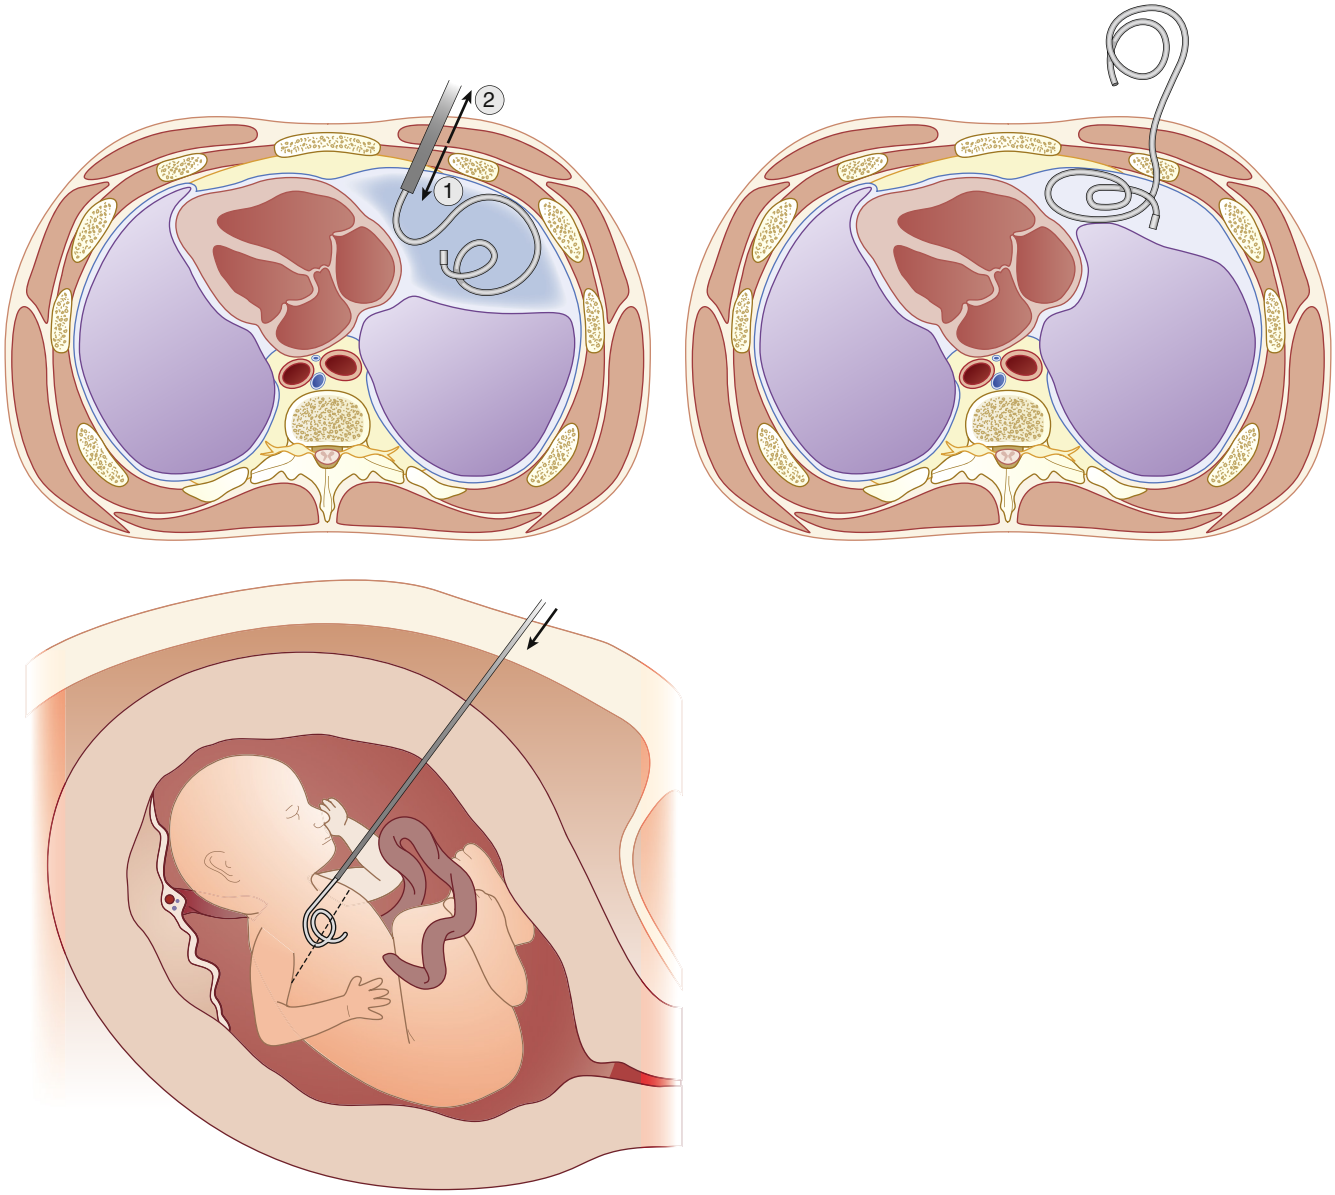

Figure 78-8. Thoracic shunt insertion (*top left* and *right*) and deployment (*bottom left*). *(Redrawn from van Mieghem T, Baud D, Devlieger R, et al: Begin equation minimally invasive fetal therapy,* Best Pract Res Clin Obstet Gynaecol *26:711-725, 2012.)*

lesions, shunts are ineffective because cysts are not in communication with each other, shunts malfunction, or they become displaced. In addition, shunt placement can cause fetal hemorrhage or chorioamnionitis.[207] Thoracoamniotic shunt placement has also successfully decompressed large congenital pleural effusions caused by fetal chylothorax that otherwise would result in hydrops fetalis, pulmonary compression, and fetal or neonatal death.[208]

Some CPAMs inappropriate for shunting can be resected with open fetal lobectomy (Fig. 78-9). Similar to open SCT resection, potential exists for significant fetal hemorrhage and need for in utero fetal resuscitation. Open resection of CPAM lesions associated with hydrops fetalis has resulted in a 30-day postnatal survival rate of 50%, with tumor resection allowing for compensatory lung growth and resolution of hydrops fetalis.[209] Maternal treatment with betamethasone also can improve hydrops fetalis and improve outcome in some fetuses with CPAM.[210] A retrospective analysis of 24 fetuses with predominantly microcystic CPAM and hydrops fetalis determined that steroid treatment improved survival in contrast to resection under open fetal surgery.[192]

In some instances, use of an EXIT procedure with fetal thoracotomy, mass resection, and a secured airway before delivery has been a successful approach for tumors with persistent mediastinal compression.[211] In a series of nine fetuses with large lung masses (CVR 1.9 to 3.6 at term) who underwent an EXIT-to-resection procedure, all procedures were successful, with no significant operative complications.[211]

PREOPERATIVE ASSESSMENT AND COUNSELING

Many considerations for perioperative management of women undergoing maternal-fetal surgery are analogous to those for nonobstetric surgery during pregnancy (see also Chapter 77). Maternal safety is the primary focus when determining a plan that will optimize fetal outcome. All members of the multidisciplinary team should be actively involved in maternal counseling, patient assessment, and perioperative planning. Optimum functioning of a fetal treatment program requires effective communication among the members of a multidisciplinary team, including surgeons, ultrasonographers, maternal fetal medicine physicians, anesthesiologists, nurses, genetic counselors, and social workers. Regularly scheduled multidisciplinary care meetings help ensure coordination of a complete and appropriate perioperative plan, ensure availability of the necessary equipment and personnel at the time of the procedure, and maximize the chance for optimal outcomes for both mother and fetus. Participation of the anesthesiologist is critical to preoperative maternal assessment to determine whether maternal risk is acceptably infrequent for potential fetal benefit. An understanding of the physiologic changes of pregnancy (for details, see Chapter 77) and their effects on anesthetic management is necessary for appropriate perioperative planning and risk assessment. In addition to details of the pregnancy

course on maternal health, information from imaging studies should also be obtained to guide surgical planning and aide in fetal drug dosing.

Maternal counseling regarding risks and benefits of the procedure should be thorough and unbiased and convey the most recent outcome and complication data about the planned intervention. For nonurgent procedures, counseling is typically a multiple-day process. The team must convey the specific condition's natural history and diagnostic limitations and whether associated anomalies are detected.[212] Discussions should focus on specific implications to the mother, the pregnancy, the fetus, postnatal care, future pregnancies, any data regarding intermediate and long-term outcomes for the proposed intervention, and all alternatives.[6] Similar discussions also should include alternative options such as nonintervention and the possibility of pregnancy termination if applicable. To provide uniform counseling, all providers should counsel the patient regarding information specific to their discipline, but be aware of the general risks and benefits of the fetal process and the proposed procedure. Distinctions should be made between interventions that are evidence based, and those that are innovative or experimental. Mothers should be informed about the planned timing and method of delivery, future reproductive implications, and—if a hysterotomy is planned—the risk for uterine rupture and need for cesarean delivery with this and all future pregnancies. Fertility does not appear to be affected by open fetal surgery, but the risk for uterine rupture or dehiscence before delivery is significant and comparable or even greater than that associated with a prior cesarean delivery performed with a classic incision.[213]

In some situations, consultation with a palliative care provider, clergy, or ethicist may be desired or required. In addition, the sequence of events should be outlined in detail, so that all questions can be answered. In most circumstances it is important that the partner or other supporting individuals be included in the counseling process, to ensure they have a better understanding of the rationale behind the treatment decisions. However, the wishes of the mother assume ultimate priority during pregnancy. Thorough counseling regarding fetuses with pediatric surgical disorders reduces parental anxiety.[11,214] Most mothers prefer specific realistic information provided in an empathetic manner, no matter how dire, and want to be allowed to hope for the best possible outcome.[215] If the fetus is of viable gestational age, additional counseling is required about the mother's wishes for possible emergent delivery and neonatal resuscitation in the event of unplanned fetal distress unresponsive to in utero treatment. Finally, the fetal intervention should not proceed until the patient has had adequate time to carefully consider all the information and offered her informed consent.

INTRAOPERATIVE MANAGEMENT AND CONSIDERATIONS

Unlike most surgical procedures performed during pregnancy in which the fetus is merely a bystander (e.g., maternal appendectomy), fetal surgery involves two surgical patients. Consequently, in addition to maternal considerations for anesthetic administration during pregnancy, it is essential to understand the impact of surgery and anesthetic administration on fetal physiology, methods for fetal analgesia and anesthesia, techniques for fetal monitoring, intraoperative anesthetic management, and postoperative care for both mother and fetus.

FETAL PHYSIOLOGY AND MONITORING

During fetal surgery, procedural and pharmacologic interventions can adversely affect fetal physiology directly or affect it indirectly by alterations in uteroplacental or fetoplacental circulation and gas exchange. Appropriate fetal monitoring facilitates early intervention. Changes in anesthetic technique, adjustment of maternal hemodynamics, and early initiation of in utero resuscitation of the fetus can decrease the risk for intraoperative fetal hypoxia, hemodynamic compromise, or demise. In addition to the physiologic effects of medications administered to the mother or fetus, a detailed knowledge of the fetal cardiovascular, neurologic, and placental physiology provides the basis for optimal fetal care. Uteroplacental and fetoplacental physiology, including uterine perfusion, placental gas exchange, and drug transfer are detailed in Chapter 77, which also discusses the effects of maternal positioning, maternal neuraxial anesthesia, and administration of general anesthesia on the uteroplacental unit.

Fetal cardiac output depends primarily on heart rate.[216] Fetal myocardium is less compliant than adult myocardium, with changes in preload having minimal effect on cardiac output.[217] Constraining forces of the fluid-filled lungs also limit ventricular filling and restrict increases in cardiac output in response to additional preload.[218] The normal fetal cardiac output (sum of right and left ventricular output) is in the range of 425 to 550 mL/min/kg throughout gestation.[216]

Fetal blood volume increases during gestation, and approximately two thirds of the fetal-placental blood volume resides within the placenta.[219] During the second trimester, fetal blood volume is estimated to be approximately 120 to 160 mL/kg of fetal body weight.[220] After midgestation, fetal blood volume can be estimated based on gestational age (GA) using the equation, estimated fetal blood volume (mL) = 11.2 × GA − 209.4.[221] In normal pregnancy, the mean fetal Hb increases linearly from 11 g/dL at 17 weeks gestation to 15 g/dL at 40 weeks gestation with a standard deviation of ±1 g/dL.[222]

Fetal lung epithelium produces more than 100 mL/kg/day of fluid that fills the lungs and facilitates appropriate pulmonary growth and development. Excess lung fluid exits the trachea and is either swallowed or flows into the amniotic fluid. Although fetal liver function is immature, coagulation factors are synthesized independent of the maternal circulation and do not cross the placenta. The serum concentrations of these factors increase with gestational age (Table 78-5),[223] but fetal clot formation in response to tissue injury is decreased in contrast to that in adults throughout gestation.

Manipulation of the fetus or umbilical cord during open fetal procedures can affect fetal cardiac output,

regional distribution of fetal circulation, or blood flow in the umbilical cord. During open procedures, the fetal circulation can be severely impaired by direct compression of the umbilical cord, inferior vena cava, or mediastinum. Fetal heart rate (FHR) monitoring during minimally invasive procedures is also important. During IUT, the transfusion needle can lacerate umbilical vessels with unanticipated fetal movement, and use of laser therapy for TTTS can disrupt surface placental vessels critical to fetal blood flow. During labor, FHR monitoring with external Doppler or a fetal scalp electrode is commonly employed to assess fetal well-being. However, during fetal procedures, echocardiography, pulse oximetry, and ultrasound imaging of umbilical artery flow are the primary methods for fetal assessment. After exposure of the fetal head during an EXIT procedure, insertion of a fetal scalp electrode has been used successfully for FHR monitoring.[224] It remains unclear whether fetal oximetry or heart rate monitoring is more sensitive to decreased umbilical-fetal blood flow. In a fetal lamb model examining the effects of umbilical cord compression, Hb desaturation was detected by fetal pulse oximetry before the onset of bradycardia.[225] However, FHR deceleration has been shown to precede fetal Hb desaturation with use of fetal pulse oximetry monitoring during labor.[226]

Intraoperative ultrasonography allows imaging of FHR, cardiac contractility, and cardiac filling, as well as Doppler assessment of umbilical cord flow. Both absent and reversed umbilical artery diastolic flow are associated with increased perinatal morbidity and mortality.[227] In many cases, ultrasonography assessment of fetal well-being can be only intermittent. This is because ultrasonography can be periodically required to guide the intervention or, during portions of the case, the probe placement can interfere with the surgical procedure.

When prolonged fetal bradycardia, Hb desaturation, or significant changes in umbilical artery flow dynamics occur during a fetal procedure, steps should be undertaken promptly to improve uterine perfusion, ensure the uteroplacental interface is intact, and relieve any compression of the umbilical cord or placenta. In some cases, ex utero fetal resuscitation may be necessary if the fetus was previously determined to be of a viable gestational age.

In utero, the fetus is unable to thermoregulate and depends on maternal body temperature. Induction of general anesthesia, surgical exposure, and hysterotomy can reduce fetal temperature dramatically. Fetal sheep studies demonstrate the fetus is unable to generate heat through thermogenesis [228] and decreases in fetal temperature can lead to tachycardia and hypertension in utero. In contrast, human reports associate hypothermia with fetal bradycardia.[229] Consequently, monitoring of temperature and maintenance of maternal euthermia with use of forced air warming likely improves fetal well-being during minimally invasive procedures. During open fetal surgery, use of warmed fluid for intrauterine irrigation and monitoring of both maternal core and amniotic fluid temperatures are also important.

FETAL ANESTHESIA AND ANALGESIA

The capability of the fetus to perceive pain remains controversial. The fetus exhibits pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli as early as 18 weeks gestation.[230,231] Although invasive fetal procedures elicit a stress response,[30,232] this response is mediated at the level of the spinal cord, brainstem, and/or basal ganglia and does not necessarily correlate with conscious perception of pain that requires the cortex.[233] Administration of opioid in preterm neonates blunts major hormonal responses to surgery (including changes in plasma adrenaline, noradrenaline, glucagon, aldosterone, corticosterone, glucose, and lactate).[234] Providing adequate anesthesia and analgesia is associated with both attenuation of the deleterious effects and improved outcomes.[232] Stress responses secondary to invasive fetal procedures are blunted with opioid administration,[30] but reduction of plasma stress hormone levels is not necessarily evidence of adequate analgesia.[233]

Pressure, temperature, and vibration sensory nerve terminals develop in human skin between 6 and 10 weeks gestation.[235] Skin nerve terminals required for peripheral sensory nociception likely develop between 10 and 17 weeks gestation. Noxious stimuli follow a reflex arc of afferent fibers that synapse on spinal cord interneurons, which then synapse with motor neurons. A fetus can reflexively withdraw from a noxious stimulus by 19 weeks gestational age, without input from the cerebral cortex.[236]

The perception of pain requires not only intact neural pathways from the periphery to the primary sensory cortex, but also higher cortical structures.[236] Using histologic studies of other thalamocortical circuits, thalamic pain fibers likely reach the somatosensory cortex at 24 to 26 weeks gestation.[236] Thalamic projections reach the visual

subplate at 20 to 22 weeks,[237] the visual cortex at 23 to 27 weeks,[238] and the auditory cortical plate at about 26 to 28 weeks to gestation.[239] However, fetuses are unlikely to experience pain before 24 weeks gestation because the cortex requires additional growth and development to establish the extensive neural network of pathways to other central nervous system (CNS) structures.

This timeline is supported by electroencephalographic (EEG) studies that demonstrate a substantial increase in cortical activity. Cortical EEG activity is present only 2% of the time in fetuses at 24 weeks gestation[240] and increases to being present 80% of the time by 34 weeks gestation, with EEG patterns becoming more distinct.[241]

Both the long-term impact of untreated fetal stress and the timing of fetal pain perception remain unknown. Given this uncertainty and the more than 30-year history of safe anesthetic administration in neonates and fetuses undergoing invasive procedures,[242-244] analgesia should be given during fetal surgery.[245] Anesthetic goals include prevention of fetal movement, inhibition of circulatory stress response, adequate pain relief, and potentially even fetal amnesia.

Opioid analgesics can be transferred to the fetus by maternal administration or direct intramuscular or intravenous umbilical cord administration using ultrasound guidance. For most invasive procedures that can cause noxious fetal stimulation, fetal intramuscular administration of fentanyl 10 to 20 μg/kg (or other opioid in equivalent dosing) is used to provide analgesia immediately before the intervention.[30,179,244] This can be achieved percutaneously using ultrasound guidance or under direct vision when a hysterotomy is performed. Some physicians administer prophylactic intramuscular atropine 20 μg/kg with opioids to minimize the risk for fetal bradycardia.[246,247] Fetal movement can be prevented by intramuscular or umbilical vessel administration of muscle relaxant using ultrasound guidance.[179,243,244,246] Drugs that have been used include pancuronium or vecuronium with doses of 0.3 mg/kg intramuscularly or 0.1 to 0.25 mg/kg intravenously. The onset of fetal paralysis varies with the specific drug and dose, but typically occurs in 2 to 5 minutes, with an approximate duration of 1 to 2 hours.[248] In many instances, opioid, anticholinergic, and muscle relaxant are combined in a single injection. Maternal administration and placental transfer of intravenous remifentanil provides adequate fetal immobility during fetoscopic interventions that involve only the umbilical cord or placenta.[244,249]

For open fetal procedures, placental transfer of maternally administered general anesthesia with volatile anesthetics provides fetal anesthesia. These anesthetics readily transfer across the placenta, with fetal concentration and the fetal-to-maternal (F/M) ratio depending on both the maternal inspired anesthetic concentration and the duration of maternal anesthetic administration. In human studies of anesthetic levels at the time of cesarean delivery (~10-minute duration of general anesthesia), isoflurane and halothane both have an F/M ratio of approximately 0.7.[250] Although placental transfer of desflurane and sevoflurane may be similar, published human F/M data are not currently available in the literature. Nitrous oxide has an F/M ratio of 0.83 after only 3 minutes of administration.[251]

High levels of volatile anesthetic can depress fetal myocardium and lead to increasing fetal acidosis.[252] In animal models, volatile anesthetic concentrations often employed for uterine relaxation (>2 minimum alveolar concentration [MAC]), demonstrate significant reductions in maternal cardiac output with associated decrease in uterine perfusion up to 30%.[253] Animal models of maternal halothane administration have shown increases in both placental and fetal vascular resistance resulting in increased fetal cardiac afterload.[254] A retrospective analysis of echocardiographic data from clinical cases of open fetal surgery and EXIT procedures reveals a moderate-to-severe left ventricular systolic fetal cardiac dysfunction with use of high concentrations of desflurane.[255] In addition, case reports have described epileptiform EEG activity and generalized tonic-clonic seizures in both adults and children exposed to high levels of sevoflurane.[256] Therefore, high concentrations of volatile anesthetic administration, useful for maternal uterine relaxation, might not be the optimal anesthetic for the fetus despite years of successful use. Remifentanil has significant placental transfer and prevents fetal movement during TTTS laser photocoagulation therapy.[249,257] Some prefer to administer maternal remifentanil and nitroglycerin as part of the anesthetic for open fetal or EXIT procedures to decrease the amount of volatile anesthetic.[246,249] Currently, no evidence indicates that any one anesthetic method provides an improved fetal or maternal outcome compared with other anesthetic methods.

Anesthetics affect neonatal brain development and create histologic changes, as well as learning and memory deficits.[258-261] Yet, specific long-term effects of anesthetics on human brain function in neonates or fetuses are currently inconclusive. In 2007, a U.S. Food and Drug Administration advisory committee concluded that based on available data, no change in clinical anesthetic practice was warranted.[260,262] It is currently unknown whether propofol has more widespread effects on neurodevelopment than do volatile anesthetics.[261] The use of a volatile anesthetic for maternal anesthesia, as the primary agent for fetal anesthesia during open fetal surgery or EXIT procedures, will likely continue in the absence of additional neurocognitive outcome data. In addition, whether in utero exposure to anesthetic drugs compared with postnatal exposure has any effect on neurocognitive outcome is not known.

MANAGEMENT OF MINIMALLY INVASIVE PROCEDURES

The same considerations that apply to nonobstetric surgery during pregnancy (see Chapter 77) should be followed for fetal procedures. For most FIGS-IT procedures (see Table 78-1), use of monitored anesthetic care with infiltration of local anesthetic into the abdominal wall provides an adequate level of maternal comfort. Administration of additional opioid, benzodiazepine, or other anesthetic can be used for maternal analgesia and anxiolysis, titrated to avoid deep sedation and the associated increased risk for pulmonary aspiration of gastric

contents or respiratory compromise during pregnancy. In addition, use of supplemental anesthetic drugs possibly decreases the likelihood of fetal movement via placental transfer.[249,263] Local anesthetic infiltration can be used for fetoscopic procedures, which typically employ endoscope trocars that are only 1 to 5 mm in diameter.[264] In certain instances, neuraxial anesthesia may be a preferable approach for fetoscopic procedures, and communication with other team members is essential to determine the best technique for the individual procedure and patient. Neuraxial techniques can be beneficial when multiple insertion sites are required, maternal immobility must be ensured, a mini-laparotomy must be performed, or concern exists about adequate patient comfort or appropriate patient cooperation during the procedure.[95,119] General anesthesia is rarely necessary for percutaneous procedures unless placental location and fetal orientation present potential technical difficulty or uterine exteriorization is needed.

Although maternal intravenous fluid administration should be guided by standard intraoperative requirements, use of significant amounts of pressurized uterine crystalloid irrigation into the amniotic cavity during fetoscopic surgery should be avoided because it has resulted in maternal pulmonary edema.[265]

In cases of IUT, cord blood sampling, or thoracic shunt placement, fetal movement may displace the needle or catheter and result in trauma, bleeding, or compromise of the umbilical circulation. In one study of fetoscopic surgery, maternal administration of a remifentanil infusion (0.1 μg/kg/min) reduced fetal movement and improved operating conditions compared with maternal administration of diazepam.[249] Although maternally administered opioids and benzodiazepines can reduce fetal motion,[117] they do not guarantee immobility for procedures directly involving the fetus. Fetal immobility can be safely achieved with direct fetal intramuscular or umbilical venous administration of muscle relaxant, as described in the previous section on fetal anesthesia and analgesia. For invasive fetal procedures that involve potentially noxious stimulation to the fetus, such as shunt catheter placement or cardiac septoplasty, an opioid should be administered either intramuscularly or intravenously.[30,243] When general anesthesia is employed, placental transfer of a volatile anesthetic provides fetal anesthesia and prevents fetal movement, but supplemental opioids can also be administered for fetal analgesia.

Weight-based unit doses of atropine 20 μg/kg and epinephrine 10 μg/kg should be immediately available in individually labeled syringes for direct administration to the fetus by the surgeon in emergent situations of fetal compromise. These medications require sterile transfer to the surgical field, meticulous labeling, and accurate dosing before commencement of the procedure. When emergently required, the surgeon can administer the indicated medication by a variety of routes, including intramuscular, intravenous, or intracardiac, depending on the procedure and urgency of the situation. If gestational development is compatible with extrauterine life, the anesthesiologist should be prepared to emergently provide general maternal anesthesia, and the obstetric team should be prepared to perform an emergency cesarean delivery if fetal bradycardia persists despite efforts to resuscitate in utero.

MANAGEMENT OF OPEN PROCEDURES

Although most women undergo cesarean delivery with neuraxial anesthesia, general anesthesia is primarily employed for fetal surgery requiring a hysterotomy. Unlike minimally invasive fetal procedures, open fetal surgery requires profound uterine relaxation, often entails additional fetal monitoring beyond intermittent ultrasonography; involves more fetal surgical stimulation, fetal hemodynamic perturbation, and risk for fetal compromise; and requires direct administration of some drugs to the fetus. The anesthesiologist and other team members should be prepared for significant maternal and fetal blood loss, and the need for maternal and fetal resuscitation, including emergent delivery. A volatile anesthetic is commonly administered to provide maternal and fetal anesthesia, as well as uterine relaxation, which may require a concentration of more than 2 MAC.[266] The perioperative considerations for open fetal surgery are detailed in Box 78-2.

Single, weight-based, unit doses of medications for fetal analgesia and muscle relaxation as previously detailed in the discussion on fetal anesthesia and analgesia should be available for administration by the surgical team. In addition, resuscitation medications (atropine 20 μg/kg, epinephrine 10 μg/kg, and crystalloid 10 mL/kg) should be prepared preoperatively for immediate availability in the emergent treatment of intraoperative fetal hemodynamic compromise. Cross-matched blood should be available for maternal transfusion. For procedures with a high risk for fetal hemorrhage, appropriate blood for fetal transfusion (i.e., O-negative, cytomegalovirus-negative, irradiated, leukocyte-depleted, maternally cross-matched) should be readily available.

Drugs and approaches should be used to minimize aspiration of gastric contents. Uterine tocolytics (i.e., indomethacin) should be given to the mother preoperatively. An epidural catheter is placed preoperatively for administration of postoperative analgesia. FHR is assessed and baseline cardiac echocardiography and ultrasound imaging of umbilical cord flow characteristics are performed before anesthetic induction and are intermittently reevaluated throughout the initial period of anesthetic administration to assess the effect on the fetus of the maternal positioning, anesthetic administration, and any maternal hemodynamic changes. The gravid uterus is displaced leftward and general anesthesia is induced with a rapid sequence technique identical to patients undergoing nonobstetric surgery during pregnancy (see also Chapter 77).

After anesthetic induction and before maternal skin incision, conventional concentrations of anesthetics are administered to the mother (~1 MAC); ventilation is controlled to maintain eucapnia (end-tidal CO_2 [$ETCO_2$] levels of 30 to 32 mm Hg); and fetal attitude, presentation, and placental location are reassessed by ultrasound. An invasive maternal intraarterial pressure catheter is placed when administration of a nitroglycerin infusion is planned for uterine tocolysis. If an intraarterial catheter is not placed, a maternal arm is positioned to remain

BOX 78-2 *Perioperative Considerations for Open Fetal Surgery**

Preoperative

- Complete maternal history and physical examination
- Complete fetal workup to exclude other anomalies
- Imaging studies to determine fetal lesion and placental location
- Maternal counseling by multidisciplinary team and presurgical team meeting
- Lumbar epidural placement with test dose before use
- Prophylactic premedications: Nonparticulate antacid (aspiration), rectal indomethacin (tocolysis)
- Blood products typed and crossmatched for potential maternal and fetal transfusion; fetal blood should be type O-negative, leukocyte depleted, irradiated, cytomegalovirus negative, and crossmatched against the mother
- Obtain estimate of fetal weight to aid in weight-based fetal dosing
- Sequential compression devices on lower extremities for thrombosis prophylaxis

Intraoperative

- Left uterine displacement and standard monitors
- Preoxygenation for 3 minutes before induction
- Rapid sequence induction and intubation
- Maintain maternal FiO_2 greater than 50% and end-tidal carbon dioxide 28 to 30 mm Hg
- Ultrasound to determine fetal and placental positioning
- Urinary catheter placed; additional large-bore intravenous access device placed, with or without arterial line
- Activation of upper, lower, or both forced air warmers to maintain maternal normothermia
- Prophylactic antibiotics administered
- Fetal resuscitation drugs and fluid transferred to scrub nurse in sterile fashion
- After skin incision, high concentrations of volatile anesthetic (2 to 3 minimum alveolar concentration) started or other technique for uterine relaxation (i.e., IV nitroglycerin)
- Blood pressure maintained with IV phenylephrine, ephedrine, and/or glycopyrrolate; typical goal is to maintain mean arterial pressure within 10% of preinduction baseline with appropriate heart rate
- Consider increasing vapor or adding IV nitroglycerin if uterine tone remains increased
- Placement of fetal monitors if needed (e.g., fetal pulse oximeter, intrauterine temperature probe)
- IM fetal administration of opioid and neuromuscular blocking agent after hysterotomy; an anticholinergic also may be given with the opioid
- Placement of fetal IV access device if significant fetal blood loss anticipated
- External irrigation of fetus with warmed saline as needed
- Crystalloid restriction to less than 2 L to reduce risk for maternal pulmonary edema; consider colloid administration
- IV loading dose of magnesium sulfate once uterine closure begins
- Discontinue volatile agents and/or nitroglycerin once magnesium sulfate load is complete
- Administer propofol, opioids, nitrous oxide as needed
- Activate epidural for postoperative analgesia
- Monitor neuromuscular blockade carefully because of magnesium sulfate
- Extubate trachea when patient is fully awake

Early Postoperative Considerations

- Continue tocolytic therapy
- Patient-controlled epidural analgesia
- Monitor uterine activity and fetal heart rate
- Ongoing fetal evaluation

*This summary may need to be modified depending on the type of open fetal surgery and patient comorbidities.

accessible in case unexpected invasive pressure monitoring is required intraoperatively (e.g., maternal hemodynamic instability). A large-bore venous catheter is placed for treatment of unexpected excessive hemorrhage. However, intravenous fluids administered to the mother are minimized (<2 L) to decrease the risk for perioperative pulmonary edema associated with the use of tocolytics, such as magnesium sulfate or administration of large doses of nitroglycerine during fetal surgery.[267] Some fetal surgery teams are more restrictive with intraoperative fluid administration (<500 mL), but no clinical trials have demonstrated benefit of severe intravenous fluid restriction in this setting.[267]

Typical maternal hemodynamic goals include maintaining systolic arterial blood pressure within 10% of baseline values and mean arterial pressure greater than 65 mm Hg. Phenylephrine administration can be used to treat maternal hypotension with minimal changes in the fetal acid-base status.[268] Bolus administration of ephedrine or glycopyrrolate can assist in maintaining maternal heart rate and cardiac output.[269] Administration of a maternal nondepolarizing muscle relaxant is usually unnecessary with administration of appropriate concentrations of volatile anesthetics, but may be used to improve operative conditions. If it is used, appropriate neuromuscular monitoring should be employed to carefully assess neuromuscular function with appropriate pharmacologic reversal of blockade before tracheal extubation, particularly with concurrent use of magnesium sulfate, which significantly potentiates neuromuscular blockade (see also Chapter 53).

Before skin incision, the inspired concentration of volatile anesthetic is increased, and before uterine incision, the volatile anesthetic end-tidal concentration is further increased (≥2 MAC) to provide profound uterine relaxation. If uterine relaxation is assessed to be inadequate by appearance of contractions or palpation, administration of additional volatile agent (up to 3 MAC) or intravenous nitroglycerin as an infusion or in small boluses (50 to 200 μg) is useful to decrease uterine tone.[270] Administration of intravenous propofol and remifentanil with desflurane at 1.5 MAC has provided adequate uterine relaxation in one retrospective study.[255] For rare patients with contraindications to either volatile anesthetics or induction of general anesthesia, a neuraxial technique in conjunction with intravenous administration of nitroglycerin in doses up to 20 μg/kg/min has been used successfully.[270] This technique may have increased risk for maternal pulmonary edema

secondary to the large doses of nitroglycerin and should be reserved for cases with a specific benefit from the technique. Although uterine relaxation is required for successful open fetal surgery, use of nitroglycerin may affect fetal vascular tone, resulting in alterations in cerebral blood flow and increased likelihood of fetal cerebral ischemia, as well as intraventricular and periventricular hemorrhage.[271] Currently, no specific anesthetic technique demonstrates significant improvement in fetal outcome.

Periodic ultrasonography is used to assess FHR and fetal cardiac function. In some open fetal procedures, pulse oximetry or additional direct fetal monitoring can be employed after the hysterotomy is performed, as discussed in the section on fetal physiology and monitoring. Rarely, when uncertainty exists regarding fetal condition, umbilical cord blood gas measurements can be obtained. As described in the prior section on fetal anesthesia and analgesia, an opioid and a muscle relaxant can be administered to the fetus intramuscularly either before uterine incision with ultrasound guidance of the injection needle or under direct vision after uterine incision. Intramuscular atropine also can be administered concurrently to reduce opioid-induced fetal bradycardia.

After uterine exposure and ultrasound placental mapping, a small hysterotomy is created away from the placenta. A stapling device with absorbable lactomer staples is used to extend the incision. The staples prevent hemorrhage from the relaxed uterus and seal the amniotic membranes to the uterine endometrium. Uterine blood loss can be rapid and difficult to estimate. Vigilant observation of the surgical field and careful maternal monitoring are essential to avoid missing occult hemorrhage. Lost amniotic fluid is replaced with warmed crystalloid to bathe the exposed fetus. Intrauterine temperature is closely monitored to prevent hypothermia and associated fetal circulatory compromise.[229]

For fetal mass resections or other open procedures with high risk for significant fetal blood loss, an intravenous catheter should be placed in a fetal limb for blood and fluid transfusions. Sterile microbore tubing can be passed over the surgical drape, primed, and connected to the catheter, allowing fetal intravenous administration by the anesthesiologist. All blood or fluids transfused to the fetus should be warmed. In urgent situations, fluids can be transfused directly into the umbilical vein through catheter access obtained in the operative field if a fetal peripheral intravenous line is not available.

In the rare event of maternal hemodynamic collapse, if maternal resuscitation has been unsuccessful in restoring adequate maternal hemodynamics after 4 minutes, the fetus should be delivered emergently to relieve aortocaval compression, improve maternal resuscitation efforts, and increase the chance for maternal survival.[272] A neonatologist and neonatal resuscitation team should be readily available in case of emergency delivery, and newborn resuscitation should proceed according to the current recommended guidelines.[273]

After completion of the fetal procedure, an initial dose of magnesium sulfate 4 to 6 g intravenously over 20 minutes is typically administered during uterine closure to reduce myometrial contractility[274] (see also Chapter 77). After the bolus, an intravenous infusion of magnesium sulfate 1 to 2 g/hr) is initiated to maintain uterine quiescence into the postoperative period. The inspired concentration of volatile anesthetic or intravenous nitroglycerin infusion is significantly decreased or discontinued after the magnesium sulfate bolus is complete. After an epidural test dose, epidural anesthesia is initiated. Maternal anesthesia is maintained with epidural anesthesia, supplemented by administration of intravenous opioid, inhaled N_2O, and/or intravenous propofol; this allows adequate time for elimination of the volatile agents during surgical closure of the abdominal incision. The mother's trachea is extubated after she awakens and after confirming adequate neuromuscular recovery and hemodynamic stability.

POSTOPERATIVE MANAGEMENT AND CONSIDERATIONS

In addition to postoperative concerns associated with a cesarean delivery (i.e., pain management, prevention of venous thromboembolism, monitoring for hemorrhage, avoiding wound infection), postoperative care of patients undergoing fetal surgery also focuses on tocolysis and fetal monitoring. For minimally invasive procedures such as cordocentesis or IUT, tocolysis is typically not required. For more invasive percutaneous procedures (e.g., shunt catheter placement, endoscopic techniques), some fetal surgery teams administer preoperative prophylactic tocolytic agents such as indomethacin, and rarely additional drugs are required in the postoperative period.

After open fetal surgery, patients frequently experience early uterine contractions and require continuous uterine monitoring for 2 or 3 days. Management of postoperative preterm labor after fetal surgery is a challenge and has led to significant fetal morbidity.[120] Magnesium sulfate infusions initiated intraoperatively are continued for approximately 24 hours or more postoperatively. Additional tocolytic agents (e.g., indomethacin, terbutaline, nifedipine) are often necessary. Administration of indomethacin requires periodic monitoring by fetal echocardiography because premature closure of the ductus arteriosus is a known complication of therapy.

The fetus is evaluated postoperatively by ultrasonography. Continuous FHR monitoring is used in the postoperative period, with a predetermined plan established for management of fetal distress. The duration of monitoring is based on gestational age, fetal condition, and plan for fetal distress. Potential fetal morbidity includes infection, fetal heart failure, fetal intracranial hemorrhage, and fetal demise. If maternal pulmonary edema is suspected, a chest radiograph should be obtained. With significant compromise, critical care admission may be required along with tracheal intubation, mechanical ventilation, hemodynamic monitoring, supplemental oxygen administration, upright positioning, and diuretic therapies.

For minimally invasive procedures, satisfactory postoperative analgesia is typically achieved by administration of oral opioid-based pain medications. For open procedures, postoperative epidural analgesia can be provided for several days using a dilute solution of local

anesthetic and opioid. Intravenous opioids administered with a patient-controlled device can be used in place of an epidural or after the epidural is discontinued. Use of opioids can decrease FHR variability [275] and create some difficulty in interpretation of the FHR tracing. Inadequate postoperative pain control can increase plasma oxytocin levels and increase the risk for preterm labor.[272]

After open fetal procedures, patients are at high risk for PPROM, preterm labor, infection, and uterine rupture. In addition to these risks, periodic assessment of fetal well-being, growth, and integrity of the pregnancy necessitate the mother remain near the fetal treatment institution for the first few weeks after the procedure. The possibility of preterm delivery may necessitate a course of steroids to improve fetal lung maturity. After open procedures, cesarean delivery is often planned for 37 weeks gestation but may be required earlier with the onset of preterm labor. The recent hysterotomy increases the chance for uterine rupture and associated need for emergent cesarean delivery.

MANAGEMENT OF EX UTERO INTRAPARTUM TREATMENT PROCEDURE

Although the initial purpose of the EXIT procedure was to provide a controlled and stable means to remove the obstructive device previously placed in the fetal airway for in utero treatment of CDH, the EXIT procedure has expanded into a technique used for a variety of other fetal disorders (Box 78-3).[246,276-280] These include conditions that compromise the fetal airway, such as large neck masses, congenital high airway obstruction, or severe micrognathia. The EXIT procedure allows the fetus to remain supported by the placental unit with adequate oxygenation and perfusion while surgical repair and resuscitation interventions are performed in a controlled manner. The procedure has been used successfully to treat fetuses requiring intrathoracic mass resection, in separation of conjoined twins, and as a bridge to extracorporeal support.

The primary goals of the EXIT procedure are to maintain a prolonged state of uterine relaxation, to delay placental separation, and to sustain placental-fetal perfusion. Similar to open fetal surgery, EXIT procedures are frequently performed under general anesthesia, employing high concentrations (≥2 MAC) of volatile anesthetic to ensure uterine relaxation. Neuraxial anesthesia in combination with remifentanil, nitroglycerin, or both also has been used successfully.[270,280,281-282] Multiple reviews of the anesthesia, surgical, and obstetric considerations for the EXIT procedure have been published.[246,276-280] The overall preoperative and intraoperative approach for anesthetic management is similar to that previously described for open fetal surgery (see Box 78-2). The primary difference occurs after delivery of the fetus, when uterine relaxation is no longer required. Thus, after delivery of the neonate, anesthetic management becomes similar to management of a cesarean delivery with general anesthesia.

A detailed multidisciplinary meeting is extremely valuable before the start of the EXIT procedure. It is essential to ensure that all required supplies for fetal monitoring; airway management; maternal, fetal, and newborn resuscitation; and postdelivery care are obtained before entering the operating room. In addition to fetal ultrasonography, a pulse oximeter and $ETCO_2$ indicator are used to monitor the fetus and assist with confirmation of a secured airway. Similar to open fetal surgery, weight-based doses of atropine, epinephrine, and calcium are prepared for possible emergency fetal resuscitation. A sterile fetal ventilation circuit with an air/O_2 source and manometer is prepared in addition to multiple sizes of endotracheal tubes, laryngoscopes, and neonatal-sized laryngoscope blades for fetal tracheal intubation. Sterile tourniquets, intravenous catheters, crystalloid and blood (i.e., O-negative, CMV-negative, leukocyte depleted, maternally cross-matched) should be available for fetal venous access and volume replacement if needed.

Anesthetic considerations for the mother are similar to those for open fetal surgery (see Box 78-2). They include possible placement of an epidural catheter for postoperative analgesia, large-bore intravenous access, invasive monitoring readily available or placement of an intraarterial catheter, possible need for uterotonic drugs after delivery of the placenta, and cross-matched maternal blood in the operating room. Maternal anesthetic induction and tracheal intubation are similar to general anesthetic

BOX 78-3 ***Fetal Indications for the Ex Utero Intrapartum Therapy Procedure***

- Cervical mass
  - Cystic hygroma
  - Goiter
  - Hemangioma
  - Lymphangioma
  - Neuroblastoma
  - Teratoma
- Craniofacial anomaly
  - Severe micrognathia
  - Severe retrognathia
- Lung mass
  - Bronchopulmonary sequestration
  - Congenital cystic adenomatoid malformation
- Mediastinal mass
  - Lymphangioma
  - Teratoma
- Congenital high airway obstruction syndrome
  - Laryngeal atresia/stenosis
  - Tracheal atresia/stenosis
- Ex utero intrapartum therapy to extracorporeal membrane oxygenation
- Aortic stenosis with intact/restrictive atrial septum
  - CDH with severe pulmonary compromise
  - Hypoplastic left heart syndrome with intact/restrictive atrial septum
- Reversal of tracheal occlusive device placed during fetal surgery to treat CDH
- Conjoined twins

Data from Garcia PJ, Olutoye OO, Ivey RT, et al: Case scenario: anesthesia for maternal-fetal surgery: the Ex Utero Intrapartum Therapy (EXIT) procedure, Anesthesiology *114:1446-1452, 2011; and Ngamprasertwong P, Vinks AA, Boat A: Update in fetal anesthesia for the ex utero intrapartum treatment (EXIT) procedure.* Int Anesthesiol Clin *50:26-40, 2012.*

CDH, Congenital diaphragmatic hernia.

techniques employed for cesarean delivery, and maintenance of appropriate maternal hemodynamics is critical to ensuring adequate fetal perfusion (see also Chapter 77). Similar to techniques used for open fetal surgery, high concentrations of a volatile anesthetic (≥2 MAC) with or without intravenous administration of nitroglycerin (bolus doses of 50 to 200 μg or as an infusion) may be required for adequate prolonged uterine relaxation. Fetal anesthesia from transplacental transfer of maternal volatile anesthetic can be supplemented by fetal intramuscular administration of an opioid (e.g., fentanyl 5 to 15 μg/kg or morphine 0.1 mg/kg, depending on the indication) and a paralytic agent (rocuronium 1 to 3 mg/kg or pancuronium 0.1 to 0.3 mg/kg). Sometimes intramuscular atropine 20 μg/kg) is given to prevent fetal bradycardia.[246,276] The intramuscular fetal anesthetic drugs can be administered either before uterine incision using ultrasound guidance of the injection needle or under direct vision after performing the hysterotomy. There is significant variation in fetal serum fentanyl concentrations based on umbilical cord blood sampling during EXIT procedures.[283] Although possible causes for this observed variability are multiple, it is likely that significant variability also may exist with fetal serum concentrations of muscle relaxants and other agents administered to the fetus, making their pharmacologic actions less predictable.

Intravenous remifentanil administered to the mother rapidly crosses the placenta; some practitioners provide maternal anesthesia for EXIT procedures with neuraxial block supplemented with remifentanil infusions (0.1 to 0.2 μg/kg/min) and report adequate fetal immobilization without use of the intramuscular fetal anesthetic drugs previously described.[257,280,281] An alternative anesthetic approach uses maternal neuraxial anesthesia combined with intravenous administration of nitroglycerin in an effort to avoid many of the risks associated with administration of general anesthesia as previously described.[270,280-282,284] Significant doses of intravenous nitroglycerin 1 to 10 μg/kg/min are often required to achieve adequate prolonged uterine relaxation. Although nitroglycerin crosses the placenta, a significant amount is metabolized at the placental interface, and there are minimal fetal effects.[270,282] Invasive monitoring with a maternal intraarterial catheter is recommended when prolonged use of nitroglycerin is planned, and the patient should be monitored for onset of pulmonary edema. No prospective clinical trials have been conducted to determine the best anesthetic technique for the EXIT procedure.

After assessment of appropriate uterine relaxation, the placental border is determined by ultrasonography. A small initial hysterotomy is extended outside the placental border with a stapling device to prevent excessive blood loss. If the EXIT procedure is performed to facilitate fetal intubation or neck mass resection, only the fetal head and shoulders are initially delivered (Fig. 78-10). For more extensive procedures requiring access to the thorax or other anatomic locations, the entire body may be delivered.

Before hysterotomy, the fetus is monitored with echocardiography and ultrasonographic evaluation of umbilical cord flow. After hysterotomy, a pulse oximeter probe is placed on the fetal hand and shielded from ambient light. Warmed crystalloid fluids are irrigated continuously in the uterine cavity to maintain fetal temperature and prevent placental separation or spasm of umbilical vessels. Care should also be taken to avoid inadvertent compression or unnecessary manipulation of the umbilical cord, which could lead to vascular reactivity and decreased flow.

Figure 78-10. During an ex utero intrapartum therapy procedure, the head and upper torso of a fetus with a neck mass are delivered and the airway secured using direct laryngoscopy. *(Courtesy Dr. Anita Moon-Grady, University of California, San Francisco Fetal Treatment Center, San Francisco, Calif.)*

Depending on the indication, the duration of an EXIT procedure ranges from a few minutes (e.g., intubation) to several hours (intrathoracic mass resection, neck mass resection with tracheostomy, or ECMO cannulation). Anesthetic techniques have successfully provided safe maternal and fetal anesthesia with uterine relaxation and uteroplacental stability over several hours.[285] Before ventilation of the fetal lungs, fetal oxyhemoglobin saturation is typically 40% to 70%.[286] After initiating ventilation of the fetal lungs, oxyhemoglobin saturation should increase significantly to above 90%. When fetal lung ventilation fails to result in an appropriate increase in oxyhemoglobin saturation, this represents an indication for ECMO initiation before clamping the umbilical cord and fetal delivery.[287] An $ETCO_2$ indicator is also beneficial in confirming correct placement of the endotracheal tube. If needed, pulmonary surfactant may be administered once the endotracheal tube is placed. Transporting the neonate to the intensive care area for further care requires significant vigilance to ensure the critical, tentative airway remains secured.

Once the fetus is delivered, the inspired concentration of the volatile agent is significantly decreased, the nitroglycerin infusion stopped, or both to allow the uterus to contract and diminish the risk for maternal hemorrhage.[276,288] N_2O, propofol, and/or an opioid can be administered to maintain adequate anesthesia. Oxytocin is routinely administered and additional uterotonic drugs are given when necessary, as detailed in Chapter 77. Once the patient is hemodynamically stable with appropriate uterine tone, epidural analgesia may be initiated.

CONCLUSIONS AND FUTURE CONSIDERATIONS

Establishment of organized, multidisciplinary, and comprehensive fetal intervention programs at a variety of academic centers is critical to improving patient outcomes with innovative surgical techniques, improved diagnostic and treatment strategies, and clinical trials powered to address long-term neonatal outcome, as well as associated maternal and neonatal morbidity. Advancement of surgical technology and prenatal diagnostic and management strategies is likely to decrease both maternal and fetal risk and allow safe intervention for additional congenital anomalies and treatment of less severe abnormalities. Examples of future improvements might include dynamic tracheal occlusive devices to treat CDH, in utero placement of fetal pacemakers, and endoscopic repair of MMC. In addition, stem cell and gene therapy research may lead to novel fetal treatment that allows normal development despite presence of a congenital anomaly.[289] Improvements in managing preterm labor and delivery would greatly improve outcome in fetal therapy. Preterm birth is associated with morbidities such as respiratory distress syndrome, necrotizing enterocolitis, and intraventricular hemorrhage that all have long-term impact on the child and carry substantial cost.[290]

Fetal surgery is a relatively new and rapidly evolving area of clinical medicine. In utero treatment raises complex and difficult ethical, social, and legal issues that go far beyond that of most adult or pediatric surgical interventions and include questions regarding maternal rights, access to care, and the option for pregnancy termination.[291]

Evaluation of each new therapy or change in treatment strategy should be conducted in multicenter clinical trials only after appropriate translational research and animal studies are completed and demonstrate a potential benefit. This transition from innovative breakthrough, to randomized clinical trial, to standard care must be managed in a responsible and ethical framework. In addition, in utero treatment outcomes from new institutions with minimal experience and intervention for patients outside the strict inclusion criteria of clinical trials are likely to result in less favorable results with increased morbidity compared with the outcomes demonstrated at more established fetal treatment centers participating in the clinical trials.[292] To address these concerns, a bioethics committee from the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics provided recommendations for centers offering fetal therapy.[6] A summary of these recommendations includes a thorough informed consent process, appropriate institutional research safeguards, involvement of a multidisciplinary team, and the need for open collaborative research networks. Although this approach has high financial costs, thorough basic science, and translational and clinical research in fetal therapy is essential to appropriately manage the unique risks and benefits of future innovations. Appropriate patient selection (both maternal and fetal) and timing of the intervention also need to be better established.

The principal of *primum non nocere* argues that until a therapy is appropriately tested in animal models, it is unethical to pursue in human trials.[293,294] Advances in fetal surgery not only require determination of fetal benefit but also must be powered to appropriately evaluate additional fetal and maternal morbidity. A recent study comparing intrauterine endoscopic MMC repair to matched controls found frequent complication rates to mothers and fetuses and a frequent rate of fetal mortality.[184] Although the endoscopic repair demonstrated a benefit of segmental spine neuroprotection, it was concluded by the authors that, "before considering clinical implementation of fetal endoscopic MMC closure as standard care, the frequency of complications should be appropriately reduced and results assessed in larger groups over a longer period of time."[184]

Only the results of animal research and descriptive summaries of clinical series currently guide clinical anesthetic care for fetal surgery. Further rigorous research is needed to determine optimal anesthetic techniques to ensure maternal and fetal cardiovascular stability, to evaluate the best gestational age of anesthetic exposure, to assess the impact of anesthetic management strategies on myometrial tone and uteroplacental perfusion, and to improve our ability to determine the adequacy of fetal anesthesia to cause immobility and blockade of the fetal stress response.[295,296]

Areas of clinical growth of the field include the potential need for anesthesia and other subspecialty training programs in fetal treatment and the development of standard guidelines for fetal anesthesia and perioperative care of these unique procedures. Fetal treatment is a relatively new, rapidly evolving field of clinical medicine that holds great promise for treating morbid conditions and improving quality of life over the entire lifetime of the patient. Equally significant are the research efforts, technologic advancements, and ethical standards that must be supported to achieve these goals.

Acknowledgments

The author gratefully acknowledges the contribution and editing of Dr. Mark Rosen to the development of this chapter. The chapter author has recently coauthored two other textbook chapters of similar scope with Dr. Rosen,[297,298] and although this work represents a new unique effort, there may be some similarity in the general layout of ideas, concepts, and presentation of current data surrounding fetal therapy.

Chapter 79

Anesthesia for Orthopedic Surgery

MICHAEL K. URBAN

Key Points

- Older age is a significant risk factor for poor outcome after orthopedic surgery. Older patients presenting for orthopedic surgery often have multiple comorbid conditions that must be considered in the perioperative anesthetic plan.
- Patients with arthritis (osteoarthritis, rheumatoid arthritis, ankylosing spondylitis) have special problems that must be addressed in an anesthetic plan.
- For many orthopedic procedures, regional anesthesia may reduce perioperative complications compared with general anesthesia and provide superior postoperative analgesia.
- Fat embolism syndrome is a well-recognized complication of orthopedic trauma and major joint replacement. Early intervention and stabilization of these patients may avoid significant morbidity.
- Corrective surgery for spinal deformities (scoliosis, kyphosis, kyphoscoliosis) presents a significant challenge to the anesthesiologist. These patients are at risk for large blood loss, pulmonary complications, neurologic deficits, and postoperative loss of vision. Changes in anesthetic management may reduce the incidence of some of these complications.

Patients undergoing orthopedic procedures can be particularly challenging for anesthesiologists. These patients represent a broad scope of problems, ranging from an elderly patient with multiple comorbid conditions to a young, deceptively healthy trauma patient who may have associated injuries that can have a significant impact on the type of anesthetic administered. It is imperative that the anesthesiologist examine the entire patient and not just focus on the area of surgery. In this regard, a complete medical history is important because it may reveal chronic connective tissue diseases that may alter the anesthetic plan.

The field of orthopedics also is changing in many ways that affect the anesthesia care of these patients. Demand for joint replacements in the active aging population is increasing, with the expectation of regional anesthesia, a postoperative pain management plan, and early hospital discharge. More orthopedic procedures are now performed as ambulatory surgery, and the anesthesiologist becomes responsible for which patients can be discharged and how their pain is to be managed. Adult spinal surgery also is dramatically increasing. These procedures can be the most challenging to the anesthesiologist because of difficult airways, hours patients spend in the prone position, large blood loss, and significant postoperative pain.

This chapter discusses the perioperative factors that potentially alter outcome after orthopedic surgery. Complications associated with specific procedures are emphasized with regard to recognition of such complications, avoidance when possible, and management. Choice of the best anesthetic based on current evidence for a given orthopedic procedure also is discussed. In many cases, the pros and cons of regional versus general anesthesia are presented, but this chapter does not concentrate on the technical aspects of regional anesthesia. This chapter provides guidance for anesthesia for patients undergoing common orthopedic procedures.

PREOPERATIVE EVALUATION

All patients presenting for orthopedic surgery warrant a thorough preoperative medical evaluation (also see Chapter 38). Any orthopedic patient could represent an anesthetic challenge. Specific types of patients, however, are more likely to have orthopedic surgery and are more likely to have perioperative complications.

GERIATRIC ORTHOPEDIC PATIENTS

In 2011, 13% of the U.S. population (41 million) was older than 65 years of age and at least 20 million of these individuals had "advanced" osteoarthritis (see also Chapter 80). In the same year over 600,000 knee replacements were performed. By 2030, the number of U.S. citizens older than 65 years of age is expected to almost double to 72 million.[1] This means that older patients with multiple comorbid conditions will be having increasingly more orthopedic procedures, including total joint replacements.

Postmenopausal and age-associated osteoporosis affects older individuals, increasing their risk for fractures. Age-associated osteoporosis may be the result of increased circulating parathyroid hormone and decreased vitamin D, growth hormone, and insulin-like growth factors.[2] With osteoporosis, a disproportionate loss of trabecular (structural) bone occurs, placing the patient at risk for stress fractures. Although all bones are theoretically at risk, the thoracic and lumbar spine, proximal femur, proximal humerus, and wrist are at the highest risk.[3] Compression fractures of the thoracic and lumbar spine also are common and may require surgical intervention. Osteoporosis compromises the incidence and quality of postoperative fusions. The National Osteoporosis Foundation recommends measuring bone mineral density at the hip or spine in patients at risk and postmenopausal women. Osteoporosis can be partially treated with increased dietary calcium intake and vitamin D and doing weight-bearing and muscle-strengthening exercises,[4] but this population is at risk for fractures with minimal-impact trauma and the pain-relieving joint replacements.

The mortality after hip and knee arthroplasty surgery ranges from 0.4% to 4.6%, depending on primary versus revision replacement surgery.[5-9] Recent studies suggest that the in-hospital mortality and morbidity after total joint arthroplasty may be decreasing (0.13% to 0.18%), although increased major complications may occur.[9,10] The in-hospital mortality after repair of hip fractures is 4.8%, and mortality increases to 30% after the first year after hospitalization. The major risk factor for perioperative mortality in all of these studies was advanced age, and the most frequent perioperative complications were cardiopulmonary issues.[11,12] In their review of 1636 consecutive hip and knee replacements, Parviz and colleagues[7] reported a 6.4% incidence of serious postoperative complications, with the most frequent complication associated with cardiac comorbidities. The reported incidence of a perioperative myocardial infarction at an orthopedic hospital was 0.6% of all nonambulatory procedures (~8000), and 6.5% of those patients were at risk for myocardial ischemia.[13] A nationwide cohort study from the Netherlands reported a significant increase in perioperative myocardial ischemia in the first 2 weeks after total hip replacement (25-fold) and after total knee replacement (31-fold) surgical procedures compared with matched control nonsurgical patients.[14]

Postoperative Complications

Cardiac Complications. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend preoperative cardiac testing in patients at increased cardiac risk on the basis of clinical risk profile, functional capacity, and type of surgery.[15] The ACC/AHA classify orthopedic surgery as intermediate-risk surgery, which in most cases involves intermediate-risk patients. Older patients have an increased risk for perioperative myocardial morbidity and mortality after orthopedic surgery (see also Chapter 80). The possible reasons for this increased risk are as follows: (1) Many elderly patients have multiple medical comorbid conditions,[16,17] (2) elderly patients have limited functional capacity, (3) some orthopedic procedures initiate a systemic inflammatory response syndrome, (4) some orthopedic procedures are associated with significant blood loss and fluid shifts, and (5) postoperative pain is a major management problem after orthopedic surgery[18] (see also Chapters 61 and 98). All these factors can trigger a stress response leading to tachycardia, hypertension, increased oxygen demand, and myocardial ischemia.

Because a significant incidence of postoperative cardiac complications occurs after orthopedic surgery, and it is difficult to assess the functional status of these patients owing to the limitations imposed by their orthopedic disease, many of these patients are subjected to preoperative cardiac testing. Data for orthopedic surgery showing that preoperative risk stratification or coronary revascularization, or both, has an effect on outcome are limited, however (see also Chapters 37 and 38). A report by Salerno and associates[9] suggested that preoperative abnormal noninvasive cardiac testing rarely changed medical management before orthopedic surgery. The Decrease-II study questioned the value of preoperative cardiac testing in patients of intermediate risk before noncardiac surgery.[19] In the Coronary Artery Surgery Study (CASS) Registry, Eagle and colleagues[20] reported that coronary artery bypass graft surgery offered no advantage before orthopedic surgery in reducing cardiac mortality. Similar results have been obtained using percutaneous coronary intervention. Postoperative myocardial infarction and death have not been reduced for noncardiac surgery in patients at cardiac risk when preceded by percutaneous coronary intervention.[21,22] In patients in whom percutaneous coronary intervention involved the placement of stents, restenosis and thrombosis are added risks if antiplatelet therapy has to be discontinued before surgery and increased perioperative bleeding if these medications are not discontinued.[23]

If preoperative cardiac testing and revascularization does not decrease postoperative cardiac morbidity, hemodynamic stress reduction might be the answer. Numerous studies have indicated that the use of perioperative adrenergic β-blockers can reduce myocardial ischemia and postoperative myocardial infarctions.[19,24,25] Several more recent reports have questioned the efficacy of β-blockers in preventing postoperative cardiac complications, particularly in patients at intermediate risk.[26,27] In older patients undergoing orthopedic procedures, β-blockers should be continued perioperatively in patients taking long-term β-blockers and initiated in patients at the highest risk, with a target heart rate less than 80 beats/minute.[24,28]

Patients undergoing orthopedic procedures who are at risk for perioperative cardiac complications should be assessed postoperatively for myocardial ischemia. The diagnosis of a postoperative myocardial infarction is important because these events can be associated with significant cardiac morbidity and mortality if not treated appropriately. In addition, the decision to initiate postoperative physical therapy and rehabilitation, activities that are imperative for optimal mobility in orthopedic patients, depends on whether there has been a diagnosis of a postoperative myocardial infarction. The introduction of plasma cardiac troponin I analysis has markedly increased the ability to detect myocardial damage.

Increases in the plasma concentrations of cardiac troponin I are highly specific for cardiac injury and are a more specific marker for a myocardial infarction after orthopedic surgery than the creatine kinase MB isoenzyme.[29,30]

Respiratory Complications. The changes in the respiratory system secondary to age may predispose older patients to increased postoperative pulmonary complications. These changes include a progressive decrease in arterial O_2 tension, an increase in closing volumes, and a decrease of approximately 10% in the forced expiratory volume in 1 second (FEV_1) with each decade of life. Many of these changes are the result of alterations in chest wall mechanics, which are exacerbated in older patients with arthritis. Older patients who have sustained hip fracture have significantly lower PaO_2 values than other surgical patients of comparable ages.[31] The hypoxia in these patients may reflect the previously noted respiratory changes caused by age, as well as the embolization of bone marrow debris to the lungs after arthroplasty surgery. In addition, with high rates of obesity and obstructive sleep apnea (OSA) prevalent among patients undergoing arthroplasty and spine surgery, respiratory concerns and complications should remain in the forefront of our attention. Patients with OSA are at increased risk for perioperative complications. In a retrospective analysis of patients undergoing hip and knee arthroplasty, OSA was associated with an increased incidence of postoperative transfer to an intensive care unit (ICU).[32] Insufficient evidence exists to propose the best perioperative management of patients with OSA; however, preoperative screening using tools such as the STOP-Bang questionnaire and prudent postoperative management would appear to be the best approach.[33]

Neurologic Complications. After cardiac and pulmonary complications, confusion or delirium is the third most common complication seen in older patients after orthopedic surgery. In 2004, $69 billion from Medicare was spent on the treatment of hospital-acquired delirium. Delirium is associated with an increased length of hospital stay, poor functional recovery, progression to dementia, and increased mortality.[34,35] Postoperative delirium manifests as attention and awareness deficits, including acute confusion, reduced ability to focus, change in cognition, irritability, anxiety, paranoia, and hallucinations. Delirium develops acutely, but generally has a fluctuating course over several days (see also Chapter 80).[36] Some patients manifest a hypoactive form of delirium, confused but quiet and nondisruptive, which can be difficult to diagnose. The major risk factors for postoperative delirium are advanced age, alcohol use, preoperative dementia or cognitive impairment, psychotropic medications, and multiple medical comorbid conditions. Perioperative events that may trigger delirium include hypoxemia, hypotension, hypervolemia, abnormal electrolytes, infection, sleep deprivation, pain, and administration of benzodiazepines and anticholinergic medications.

Aging alters the pharmacokinetics and pharmacodynamics of most medications, including anesthetics and analgesics. The "usual" adult doses of these medications may have longer and more profound central nervous system (CNS) effects on older patients. Strategies used to reduce the incidence of postoperative delirium include identifying risk factors and vulnerable and affected patients early, preserving orientation, early mobilization, adequate pain control, maintenance of normal sleep cycles, and avoidance of psychotropic medications. Because in most cases patients present with a change in mental status, delirium represents a diagnosis of exclusion. The diagnosis is obtained by conducting a neurologic examination to rule out focal deficits; blood laboratory analysis to eliminate electrolyte abnormalities, hypercarbia, and hypoxemia; a review of all medications to eliminate unnecessary central-acting medications; and adequate pain management. The treatment options range from simple observation with the assignment of a caregiver to pharmacologic management to provide sedation and anxiolytics to prevent the combative patient from harming self or others. Atypical antipsychotics, which are devoid of extrapyramidal side effects, are effective for the acute treatment of delirium.

BOX 79-1 ***Gurd's Diagnosis of Fat Embolism Syndrome***

Major Features (At Least One)

Respiratory insufficiency
Cerebral involvement
Petechial rash

Minor Features (At Least Four)

Pyrexia
Tachycardia
Retinal changes
Jaundice
Renal changes

Laboratory Features

Fat microglobulinemia (required)
Anemia
Thrombocytopenia
High erythrocyte sedimentation rate

From Gurd AR, Wilson RI: The fat embolism syndrome, J Bone Joint Surg Br *56:408-416, 1974.*

FAT EMBOLISM SYNDROME

Fat embolization is a well-known complication of skeletal trauma and surgery involving instrumentation of the femoral medullary canal.[37] Fat embolism syndrome (FES) is a physiologic response to fat within the systemic circulation. Fat embolization and FES are not synonymous. The embolization of fat can be detected in almost all patients who sustain a pelvic or femoral fracture, but the incidence of FES is less than 1%.

The clinical manifestations of FES include respiratory, neurologic, hematologic, and cutaneous signs and symptoms. The manifestation of FES can be gradual, developing over 12 to 72 hours, or fulminant, leading to acute respiratory distress and cardiac arrest. Gurd and Wilson[38] in 1974 suggested major and minor criteria to be used for the diagnosis of FES (Box 79-1). The presence of any one major finding plus four minor criteria and evidence of fat microglobulinemia was required for the diagnosis of FES. The requirement for fat droplets in the circulation has been

BOX 79-2 ***Schonfeld Fat Embolism Syndrome Index****

Sign	Score
Petechial rash	5
Diffuse alveolar infiltrates	4
Hypoxemia: PaO_2 less than 70 mm Hg, FiO_2 100%	3
Confusion	1
Fever greater than 38° C (>100.4° F)	1
Heart rate greater than 120 beats/minute	1
Respiratory rate greater than 30 breaths/minute	1

* Score greater than 5 required for diagnosis of fat embolism syndrome.

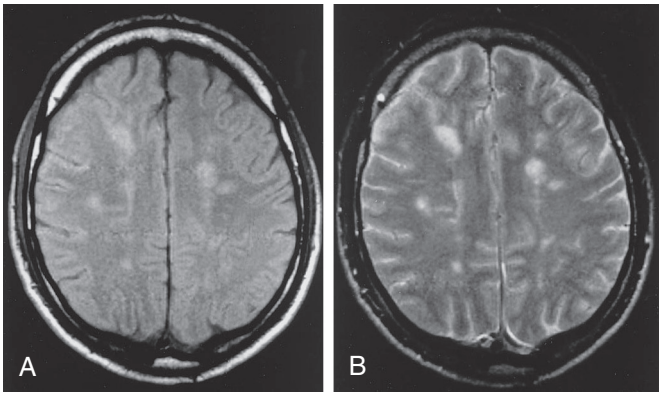

Figure 79-1. Cerebral fat embolism. Multiple hyperintense lesions on proton density–weighted (**A**) and T2-weighted (**B**) magnetic resonance images in the centrum semiovale. *(From Stoeger A, Daniaux M, Felber S, et al: MRI findings in cerebral fat embolism,* Eur Radiol *8:1590-1593, 1998. © Springer-Verlag.)*

criticized, however, because fat droplets can be detected in the blood of healthy volunteers, and their presence in trauma patients is not always associated with FES.

In addition, Gurd and Wilson[38] recommended the daily assessment of fat droplets in blood, hypothesizing that a change in the quantity of fat would correlate with symptoms. More recent investigations have indicated that the quantity of fat in the circulation does *not* correlate with the severity of FES symptoms or the development of acute respiratory distress syndrome (ARDS).[39]

A petechial rash is pathognomonic of FES, with the rash usually present on the conjunctiva, oral mucosa, and skin folds of the neck and axillae. This is reflected in the Schonfeld FES index, which ranks signs and symptoms of FES in relation to their incidence of presentation (Box 79-2).[40] Respiratory signs also are common in FES; approximately 75% of patients present with mild hypoxemia and radiologic evidence of bilateral alveolar infiltrates, but less than 10% progress to ARDS. Neurologic manifestations of FES range from drowsiness and confusion to obtundation and coma. CNS symptoms have developed in the absence of significant pulmonary complications and may represent the passage of fat droplets across an atrial septal defect or other atrioventricular shunt.[41] Magnetic resonance imaging of the brain of these patients has revealed lesions characteristic of fat embolization (Fig. 79-1).

The pathophysiology of FES is unclear, but it probably involves two processes: the embolization of fat and bone marrow debris, which can mechanically obstruct the capillaries of end organs and the triggering of a systemic inflammatory response.[37] Using transesophageal echocardiography (TEE) during total hip arthroplasty (THA), embolization of bone marrow debris has been detected in the right heart at the time of insertion of the cemented femoral prosthesis (Fig. 79-2).[42,43] In some patients, this embolization resulted in segmental wall motion abnormalities, elevated pulmonary arterial pressures, decreased right ventricular function, and, in one case, cardiac arrest and death.[43,44]

In most cases, the embolic events during THA are clinically benign, but some patients still progress to FES. The fat emboli lodged in the microvasculature of the lung and other end organs are metabolized to free fatty acids, which trigger a systemic inflammatory response. This inflammatory response involves the invasion of inflammatory cells, the release of cytokines, and, in the lung, pulmonary endothelial damage and ARDS.[45]

The treatment of FES is supportive with early resuscitation and stabilization to minimize the stress response to hypoxemia, hypotension, and diminished end-organ perfusion. Patients at risk for developing FES should be monitored with pulse oximetry, and tracheal intubation and mechanical ventilation should be instituted before respiratory failure. Although 10% of patients with FES may require mechanical ventilation, in most of these patients the symptoms resolve within 3 to 7 days. Corticosteroids have been studied extensively in the management of FES, with many investigators reporting beneficial effects, but other reports contradict these results.[46,47] Well-controlled studies with defined outcomes are required before corticosteroids can be recommended in the treatment of FES.

SPECIAL CONSIDERATIONS IN CONDITIONS LEADING TO ORTHOPEDIC SURGERY

Osteoarthritis

Approximately 22% of the U.S. population (46 million) has been diagnosed as having arthritis, and 8% (17 million) have limitations in physical activity because of arthritis.[48] Osteoarthritis is the most common type of arthritis and involves the loss of articular cartilage and associated inflammation. In most cases, osteoarthritis is a disease of aging, with 90% of women and 85% of men demonstrating the radiologic loss of articular cartilage after age 65 years.[49] Clinical manifestations include pain, crepitance, reduced mobility, and deformity of involved joints. Physical examination of the hands may reveal spurring and swelling of the distal interphalangeal joints (Heberden nodes) and proximal interphalangeal joints (Bouchard nodes).

Although osteoarthritis has no systemic manifestations, the anesthesiologist should be cognizant of previous orthopedic surgeries (including joint replacements) and which joints are painful and have limited mobility.

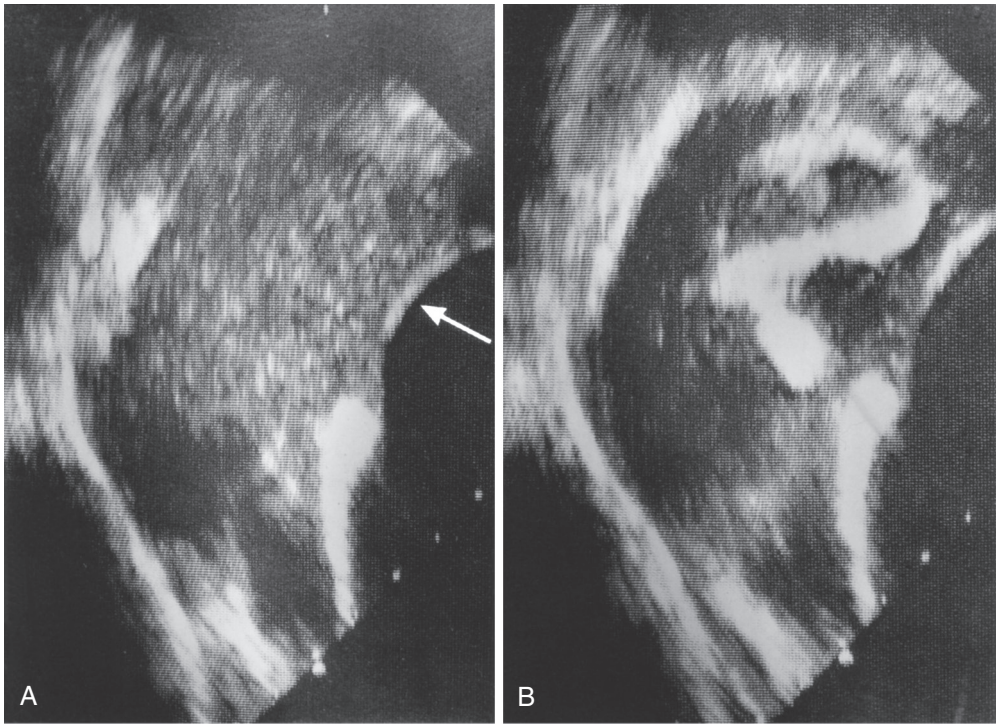

Figure 79-2. Right atrium during echocardiography. **A,** Multiple, small emboli (*arrow*) in the right atrium. **B,** Large embolus (7 cm long), which is probably a cast of the femoral vein. *(Modified from Christie J, Burnett R, Potts HR, et al: Echocardiography of transatrial embolism during cemented and uncemented hemiarthroplasty of the hip,* J Bone Joint Surg Br *76:409-412, 1994.)*

This information is important for surgical positioning and the choice of an appropriate anesthetic. An axillary block of the brachial plexus for forearm surgery is inappropriate in a patient with significant ipsilateral shoulder arthritis. Although the operative site would be completely anesthetized, the patient may complain of painful shoulder movement during the procedure. The appropriate regional anesthetic would include the arthritic shoulder; an appropriate anesthetic might be an interscalene block.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory form of arthritis that affects approximately 1% of adults, with a prevalence two to three times higher in women than in men. RA is characterized by persistent joint synovial tissue inflammation leading to bone erosion, destruction of cartilage, and loss of joint integrity. RA is also a systemic disease, affecting multiple organ systems.[50] It often progresses through multiple exacerbations and remissions, but 20% to 30% of affected individuals become permanently disabled within 3 years of diagnosis.

The diagnosis of RA is primarily clinical. Patients commonly present with pain and stiffness in multiple joints. RA is characterized by morning stiffness often lasting more than 1 hour after initiating activity. Usually the wrists and metacarpophalangeal joints are involved; this distinguishes RA from osteoarthritis, which often affects distal interphalangeal joints. The symptoms may emerge over weeks and months, progressing from one joint to multiple joints, and may be accompanied by symptoms of anorexia, fatigue, and weakness. The rheumatoid joints are usually boggy, tender to the touch, and warm. Patients may have prominent epitrochlear, axillary, and cervical lymph node enlargement. Subcutaneous nodules (rheumatoid nodules) may surround joints, extensor surfaces, and bony prominences.

No single diagnostic laboratory test confirms the diagnosis of RA, but rheumatoid factor, an antiimmunoglobulin antibody, is elevated in 90% of patients with RA. In addition, C-reactive protein and erythrocyte sedimentation rate are elevated in patients with RA and are often used to monitor the course of the disease. RA also must be differentiated from other diseases that manifest as polyarthropathies, including seronegative spondyloarthropathies, connective tissue diseases (scleroderma, lupus), fibromyalgia, hemochromatosis, polyarticular gout, polymyalgia rheumatica, and sarcoidosis.

Because joint destruction begins early with RA, disease-modifying antirheumatic drugs should be initiated immediately with the therapeutic goal of preservation of function and quality of life. The most commonly used disease-modifying antirheumatic drugs include methotrexate, hydroxychloroquine, sulfasalazine, leflunomide, infliximab (Remicade), and etanercept (Enbrel). These medications are associated with an increased risk for infection, which is a significant concern in patients with joint replacements. Pharmacotherapy also usually involves a nonsteroidal antiinflammatory drug (NSAID) and oral or intraarticular glucocorticoids. Patients with RA who are taking NSAIDs should be assessed for gastrointestinal side effects and renal complications. Glucocorticoids, although highly effective at relieving symptoms, should be used at low doses and sparingly because of their side effects, which include osteoporosis, cataracts, cushingoid symptoms, and hyperglycemia. Patients taking significant quantities of glucocorticoids need stress-dose steroids for their operations.

Because of the myriad systemic problems associated with RA and the side effects of the medications administered

TABLE 79-1 ANESTHETIC CONSIDERATIONS FOR PATIENTS WITH RHEUMATOID ARTHRITIS

Airway	Limited TMJ movement
	Narrow glottic opening
Cervical spine	Atlantoaxial instability
Cardiac	Pericarditis
	Cardiac tamponade
Eyes	Sjögren's syndrome
Gastrointestinal	Gastric ulcers secondary to ASA, steroids
Pulmonary	Diffuse interstitial fibrosis
Renal	Renal insufficiency secondary to NSAIDs

ASA, Acetylsalicylic acid; *NSAIDs,* nonsteroidal antiinflammatory drugs; *TMJ,* temporomandibular joint.

to manage RA, the anesthetic considerations can be complex (Table 79-1). The skin is often susceptible to tearing from adhesive tape and bruising from automated blood pressure devices and pressure from positioning. Airway management can be particularly challenging in patients with RA and requires preplanning even in patients receiving regional anesthesia because of the complexity of their airways (see later discussion). Synovitis of the temporomandibular joint may significantly limit mandibular motion and mouth opening in these patients. Arthritic damage to the cricoarytenoid joints may result in diminished movement of the vocal cords, resulting in a narrowed glottic opening; this is manifested preoperatively as hoarseness and stridor. During laryngoscopy, the vocal cords may appear erythematous and edematous, and the reduced glottic opening may interfere with passage of the endotracheal tube.[51] Risk also increases for cricoarytenoid dislocation with traumatic endotracheal intubations.

Arthritis of the cervical spine is common in patients with RA. Anterior subluxation of C1 on C2 (atlantoaxial subluxation) may occur in 40% of patients with RA, with symptoms of progressive neck pain, headaches, and myelopathy (Fig. 79-3). Posterior and vertical migration of the odontoid process is less common. Flexion of the head in the presence of atlantoaxial instability could result in the displacement of the odontoid process into the cervical spine and medulla and compression of the vertebral arteries (Fig. 79-4). This may precipitate quadriparesis, spinal shock, and death. Preoperative cervical flexion-extension radiographs should be evaluated in patients with RA who have limited neck movement and neurologic symptoms. If the distance from the anterior arch of the atlas to the odontoid process exceeds 3 mm, the patient should undergo an awake fiberoptic tracheal intubation and the cervical spine should be protected with a cervical collar during the procedure. These patients require postoperative monitoring with pulse oximetry and judicious administration of opioid analgesics because emergent airway management, including tracheotomy, is extremely difficult.

The anesthesiologist also should be aware of several extraarticular manifestations of RA, which could potentially result in significant perioperative morbidity. Patients with RA frequently are affected with acute pericarditis. Restrictive pericarditis is characterized by

Figure 79-3. Magnetic resonance image of a patient with advanced rheumatoid arthritis shows invagination of the odontoid process of C2 (*arrow*) through the foramen magnum, compressing the brainstem. Notice the degeneration of C4 and C5, a common problem in rheumatoid arthritis.

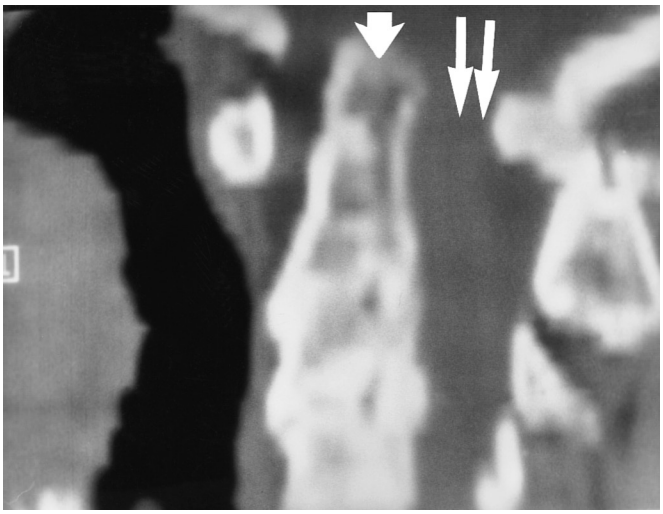

Figure 79-4. Computed tomography scan of the neck shows moderate subluxation of C1 and C2. The odontoid *(single arrow)* tends to compress the spinal cord (*double arrow*) against the posterior arch of C1, especially during neck flexion.

dyspnea, right heart failure, fever, chest pain, pericardial friction rub, and pulsus paradoxus. Patients with RA who have these symptoms should be evaluated by echocardiography. Pleural disease and intrapulmonary nodules can occur in RA, but are usually asymptomatic. Some patients with RA also may have diffuse interstitial fibrosis

with pneumonitis, producing symptoms of progressive dyspnea and a chronic cough. Pulmonary function tests show a restrictive ventilatory pattern. This pattern can progress to respiratory insufficiency, pulmonary hypertension, and right heart failure. These patients would be at higher risk with any orthopedic procedure.

Overlapping connective tissue syndromes also occur. Patients with RA can develop Sjögren's syndrome, which is associated with drying of the eyes and corneal and conjunctival lesions. It is usually treated with artificial tears and ophthalmic ointments, which should be continued perioperatively. Patients with RA and chronic constitutional systems may develop Felty syndrome, which includes splenomegaly, lymphadenopathy, anemia, thrombocytopenia, and leukopenia involving the neutrophils.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic inflammatory arthritic disease that results in fusion of the axial skeleton. Ankylosing spondylitis involves ossification of the axial ligaments progressing from the sacral lumbar region cranially, resulting in a significant loss of spinal mobility (Fig. 79-5). These patients are a significant challenge to the anesthesiologist with regard to airway management because of the reduced movement of their cervical spines and their temporomandibular joints. In most cases, awake fiberoptic endotracheal intubation is required for general anesthesia. The increased rigidity of the thoracic spine in most cases also necessitates intraoperative controlled mechanical ventilation. Although sometimes neuraxial anesthesia can be an attractive alternative to general anesthesia, in these patients the ossification of the spinal ligaments closes the intervertebral spaces, which may block access to the epidural space and prevent successful spinal anesthesia. In some cases, caudal epidural anesthesia may be a feasible alternative approach.

Extraskeletal manifestations of ankylosing spondylitis include aortic insufficiency, cardiac conduction abnormalities, iritis, upper lobe fibrobullous disease, and pleural effusions. Strict attention to intraoperative positioning is needed to avoid fracture of the fused spine with concomitant spinal cord trauma.

Achondroplasia

Achondroplasia is the most common cause of dwarfism, with short stature, short trunk, and disproportionate development. The estimated incidence is 1 in 26,000. Achondroplasia is transmitted by an autosomal dominant gene. Affected individuals are of normal intelligence and can lead a full and productive life. Their associated medical problems often require orthopedic surgical intervention, however, with the risk for perioperative complications.[52-54] The most serious complication of achondroplasia is premature fusion of the base of the skull resulting in a narrowed cervical canal, foramen magnum stenosis, or both. Kyphoscoliosis with potential neurologic symptoms is another common complication associated with this genetic condition. These affected individuals undergo numerous orthopedic (spinal) procedures, including suboccipital craniotomy for foramen magnum stenosis, correction or stabilization of kyphoscoliosis, and laminectomies for spinal nerve root compressions.

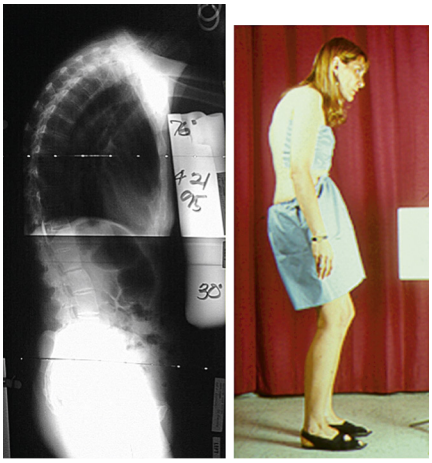

Figure 79-5. Patient with ankylosing spondylitis, exhibiting significant kyphosis of the spine. Note significant kyphosis in the lateral radiograph.

Conventional laryngoscopy and tracheal intubation can be difficult and dangerous in achondroplastic dwarfs. Laryngeal exposure via direct visualization may be difficult in dwarfs with cervical kyphosis, and neck flexion should be avoided in dwarfs with atlantoaxial instability or foramen magnum stenosis. Awake fiberoptic tracheal intubation is the safest approach to securing the airway in these patients. Intravenous sedation should be administered judiciously during the preparation of the airway because many of these patients experience central sleep apnea owing to brainstem compression. Severe episodes of sleep apnea also can occur in these patients without any other clinical evidence of cord compression.

When the airway is secured, dwarfs can still represent an anesthetic challenge because of restrictive lung disease and pulmonary hypertension. Pulmonary hypertension develops from chronic hypoxemia and hypercarbia secondary to airway obstruction, sleep apnea, and thoracic kyphoscoliosis. Preoperative spirometry can be difficult to interpret in a dwarf, with successive changes in measurements more useful than absolute values.[55] An echocardiogram should be obtained before major surgery to assess the degree of pulmonary hypertension and intracardiac shunts. Pulmonary hypertension leading to cor pulmonale is the most common and devastating cardiovascular complication that develops in dwarfs. In these patients, the anesthetic must avoid aggravating pulmonary hypertension (hypoxemia and acidosis) and ensure adequate cardiac output and end-organ perfusion. In many cases, it is safer to allow the patient to remain intubated and monitored in the ICU until fully awake and spontaneously ventilating.

ORTHOPEDIC PROCEDURES IN CHILDREN WITH SPECIAL CONDITIONS

The anesthetic management of pediatric patients undergoing orthopedic surgery is beyond the scope of this chapter (see also Chapters 92 and 93). In most cases, care of pediatric patients would be similar to that for other surgical procedures, except that in many cases regional

TABLE 79-2 **ANESTHETIC CONSIDERATIONS FOR PATIENTS WITH OSTEOGENESIS IMPERFECTA**

Airway	Risk for fractures of the mandible, maxillary surface, and cervical spine
Bleeding	Platelet abnormalities
Cardiac	Congenital and valvular heart disease, cystic degeneration of proximal aorta
Eyes	Exophthalmos—prone positioning
Hyperthermia	Malignant hyperthermia, hydration, possible cooling
Positioning	Risk for repeated fractures
Pulmonary	Kyphoscoliosis—restrictive lung disease
Regional anesthesia	Fractures, intraosseous injections

anesthesia might be a preferred alternative to general anesthesia. However, a few pediatric diseases predispose children to multiple orthopedic procedures.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is inflammation of the synovium of the joints that occurs before 16 years of age. JIA is classified into five types, as follows:

1. Oligoarthritis accounts for 50% of JIA and involves fewer than five joints; often these patients also have uveitis.
2. Polyarthritis involves arthritis in five or more joints.
3. Systemic arthritis accounts for 10% to 20% of JIA and is characterized by associated high fevers, rash, and nonarticular organ involvement.
4. Enthesitis-related arthritis affects the spine, hips, and attachment points of tendons to bones.
5. Psoriatic arthritis includes psoriasis and arthritis.

As in adult RA, the disease is chronic with quiescent periods interspersed with acute exacerbations. Also as in adult RA, airway issues can make tracheal intubation difficult and potentially dangerous. In most cases, fiberoptic intubation should be performed, and this can be done after the child has been anesthetized and is breathing spontaneously. Muscle relaxants should be reserved until the airway is secured. In contrast to adult RA, pulmonary disease is uncommon, but patients with JIA can have associated pleuritis, pleural effusions, and pneumonitis. Pericarditis is common in patients with JIA, and it responds to steroid therapy. Some patients with JIA also have myocarditis and conducting system abnormalities. In addition, vascular access in patients with JIA can be extremely difficult because of fragile veins and a tendency to bruise and bleed easily. As with adult RA, patients with JIA are managed with similar groups of medications with similar potential complications.

Osteogenesis Imperfecta

Osteogenesis imperfecta is a rare autosomal dominant inherited disease that results in extremely brittle bones because of a defect or deficiency in type I collagen production.[56,57] Repeated and multiple bone fractures are the most significant clinical manifestation of this disease (Table 79-2). In the most extreme form, multiple fractures occur during delivery and are often fatal. In the milder variations, the individual is affected by multiple fractures produced with seemingly inconsequential force or trauma. Fractures are more common in the lower extremity, with the femur being the most commonly broken bone. Fracture deformities of the pelvis can lead to acetabular protrusions into the abdomen. Kyphoscoliosis is common secondary to decreased ligamentous stability. Affected children usually have a blue sclera because of defective collagen production. Impaired platelet function with increased perioperative bleeding also occurs.

Although osteogenesis imperfecta has been associated with malignant hyperthermia, this has not been verified by muscle biopsy (see also Chapter 43).[58] Hyperthermia and metabolic acidosis can, however, be common intraoperative clinical manifestations of osteogenesis imperfecta. Associated cardiac abnormalities include patent ductus arteriosus, septal defects, and acquired aortic regurgitation and cystic degeneration of the proximal aorta (see also Chapters 93 and 94).

The fragility of connective tissue and bones in osteogenesis imperfecta demands extreme care in positioning and padding during anesthesia. The area under the blood pressure cuff must be padded, and for longer procedures insertion of an arterial catheter avoids the repeated inflation of the cuff and the risk for a humeral fracture. Because patients with osteogenesis imperfecta often have reduced mobility of the cervical spine, tracheal intubation must be achieved with minimal neck manipulation. Fiberoptic intubation techniques in many cases would be the prudent approach. The administration of succinylcholine should be avoided for the induction of anesthesia not only because of the theoretic risk for hyperkalemia and hyperthermia but also because muscle fasciculations may produce bony fractures. Patients with osteogenesis imperfecta should have a preoperative echocardiogram, and any abnormal findings should be managed accordingly.

The bleeding status of patients with osteogenesis imperfecta should be evaluated preoperatively to prepare for the perioperative transfusion of platelets. In some cases, desmopressin (DDAVP) may reverse the platelet abnormality. Because of the risk for intraoperative hyperthermia and metabolic acidosis, patients with osteogenesis imperfecta should be aggressively hydrated, and, if necessary, active cooling should be instituted. Regional anesthesia is an attractive alternative to general anesthesia, but must be approached with caution to avoid bone punctures and intraosseous injections (see also Chapters 57 and 58).

Cerebral Palsy

Cerebral palsy is a nonprogressive motor impairment arising from lesions in the brain that occurred during the early stages of development—in utero (75%), at birth (10%), and soon after birth (15%) (see also Chapter 93). The cause of cerebral palsy remains unclear; however, intrapartum asphyxia, which was originally thought to be the major cause of the disease, may be responsible for only 10% of the cases. Perioperative infections and low birth weight may play a much more important role. Cerebral palsy is divided into four major classifications to describe the different movement impairments: spastic, athetoid/dyskinetic, ataxic, and mixed. Spastic cerebral palsy, which is the most common type, results from

damage to the corticospinal tract, motor cortex, or pyramidal tract. Many of these affected children also have epilepsy and cognitive disorders.[59]

Although the neurologic deficit in cerebral palsy is nonprogressive, the secondary orthopedic consequences of the disease lead these patients to multiple surgical procedures. Normal skeletal development requires stress from the musculature to attain proper shape and size. Without these stresses or with abnormal stresses, as in cerebral palsy, various angular joint deformities and gracile (thin) shafts and abnormal articular joints develop. Orthopedic surgeries often involve loosening of tight muscles (hip adductor and iliopsoas release), releasing fixed joints, straightening abnormal twists (derotational osteotomy of the femur), rhizotomies to reduce spasm, and spinal surgery to correct kyphoscoliosis.

Patients with cerebral palsy have significant gastroesophageal reflux and poor laryngeal reflexes, placing them at risk for pulmonary aspiration. In most cases, surgical procedures in patients with cerebral palsy require general anesthesia with tracheal intubation, even if also accompanied by regional anesthesia to reduce the need for systemic anesthetics and to provide postoperative analgesia. Postoperative epidural analgesia with local anesthetic alone eliminates the potential complications of opioids and permits continued dosing with diazepam to relieve spasms. Regional anesthesia also may shorten emergence from general anesthesia, which can be prolonged because of inherent cerebral damage and the effects of antiseizure medications. Postoperative pulmonary complications are common owing to multiple causes, including aspiration, poor respiratory effort, and reduced thoracic compliance. After major surgical procedures, cerebral palsy patients should be observed in a monitored setting for several hours.

REGIONAL VERSUS GENERAL ANESTHESIA

Many orthopedic procedures are well suited for regional anesthetic techniques (see also Chapters 57 and 92). The controversy as to whether regional anesthesia has an advantage over general anesthesia has been debated for decades without clear evidence documenting the superiority of one method. Regional anesthesia may reduce the incidence of major perioperative complications with certain surgical procedures, however, including deep vein thrombosis (DVT), pulmonary embolism (PE), blood loss, respiratory complications, and death.[60-62] In addition, regional anesthetic techniques provide superior pain relief after orthopedic surgery.[63] Peripheral nerve blocks employing long-acting anesthetics or catheters provide both excellent intraoperative anesthesia and superior postoperative analgesia.[64,65] Regional anesthesia may provide preemptive analgesia, and some evidence exists that regional analgesia may block the progression of severe acute postoperative pain into a chronic pain syndrome.[66] In addition to improved pain control, functional outcome in the form of physical therapy milestones may benefit from both regional anesthesia and analgesia.[67]

As stated earlier, orthopedic patients often pose difficult airway management problems. Regional anesthesia avoids manipulation of the airway, and conscious patients can aid in the safest and most comfortable positioning for surgery. It is prudent, however, to recognize the warnings of Benumof[68]: "Use of regional anesthesia in the patient with a recognized difficult airway does not solve the problem of the difficult airway; it is still there." A well-defined plan for the management of the airway must be devised for these patients in the event of a regional anesthetic failure or the need to secure the airway during an emergency.

A further advantage to the use of regional anesthetic techniques for orthopedic surgery has been the suggestion of decreased intraoperative blood loss. Since 1966, 17 randomized trials of patients undergoing THA have shown diminished blood loss with regional anesthesia compared with the same procedure performed under general anesthesia.[69] Modig[70] compared blood loss in patients undergoing THA randomly assigned to epidural anesthesia, general anesthesia with spontaneous ventilation, and general anesthesia with positive-pressure ventilation. The epidural group showed the smallest blood loss, but no significant relationship between arterial blood pressure and blood loss was identified. The authors suggested that epidural anesthesia reduces venous blood pressure (measured in the operative wound), which is the significant factor in determining surgical bleeding.

PERIOPERATIVE MANAGEMENT OF ORTHOPEDIC PATIENTS

THROMBOPROPHYLAXIS IN ORTHOPEDIC SURGERY

Thromboembolic complications remain one of the leading causes of morbidity and mortality after orthopedic surgery.[71,72] THA, total knee arthroplasty (TKA), and hip and pelvic fracture surgery have the highest incidence of venous thromboembolism, including DVT and PE. Patients with DVT and PE are at risk for short-term and long-term morbidity and mortality. Patients with a symptomatic PE have an 18-fold higher risk for death than patients with a DVT alone. The short-term complications of survivors of acute DVT and PE include prolonged hospitalization, bleeding complications related to DVT and PE treatments, local extension of the DVT, and further embolization. Long-term complications include postthrombotic syndrome (hypoxemia and pulmonary hypertension) and recurrent DVTs.

Because venous thrombi consist of fibrin polymers, anticoagulants should be administered for the prevention and treatment of DVT. Thrombolytics should be administered only in the event of a severe, possibly fatal PE. Perioperative treatment should follow the guidelines of the Ninth American College of Chest Physicians Conference on postoperative DVT and PE.[73-74] Low-molecular-weight heparin (LMWH) is recommended over unfractionated heparin (intravenous or subcutaneous) for initial therapy of DVT and PE. LMWHs do not require monitoring for the degree of anticoagulation. Although DVT prophylaxis may be more efficient when started preoperatively, the risk for surgical bleeding also increases. LMWH for thromboprophylaxis should be started either 12 hours or more preoperatively, or 12 hours or more postoperatively,

rather than within 4 hours or less preoperatively or 4 hours or less postoperatively (grade 1B).[74,75] Extended prophylaxis to 35 days after surgery in the outpatient period would be supported in most patients undergoing major orthopedic surgery (grade 2B).[74] Risk factors for the development of PE after surgery are advanced age, obesity, previous PE and DVT, cancer, prolonged bed rest, and thrombophilia. Thombophilia is a prothrombotic condition that increases the risk for perioperative DVT. Many are hereditary conditions that increase the activity of coagulation factors. Factor V Leiden is the most common hereditary thrombophilia associated with DVT. Warfarin (Coumadin) is often employed in the long-term treatment of DVT, with a target international normalized ratio (INR) of 2.5 maintained for the duration of therapy. Warfarin exerts its anticoagulant effect by blocking vitamin K–dependent coagulation factors (predominantly factor VII); thus a lag occurs in biologic effectiveness while endogenous factor activity decays and new inactive factors are synthesized. Therefore, because the anticoagulation effects of warfarin may take days and its biologic activity can be unpredictable, many have advocated the use of LMWH. In the United States, LMWH (enoxaparin) is administered at 30 mg every 12 hours, and considerably higher doses of LMWH are administered for DVT treatment. In all cases, spinal hematoma is a risk after neuraxial anesthesia.

Recently alternatives to warfarin and LMWH have been developed. Fondaparinux, a synthetic pentasaccharide, is a selective inhibitor of factor Xa and has a plasma half-life of approximately 18 hours. When administered once daily, fondaparinux produces a predictable anticoagulant response.[76] Dabigatran is a thrombin inhibitor with a plasma half-life of approximately 8 hours, which is prolonged in individuals with renal insufficiency. Dabigatran will prolong the activated partial thromboplastin time, but this effect is not linear and should not be used as an indication of the degree of anticoagulation. At present, the only reversal agent available for dabigatran is recombinant factor VIIa.

The American College of Chest Physicians guidelines do not recommend the sole use of aspirin for DVT prophylaxis after THA, TKA, and hip fracture surgery. Some recent reports, however, have supported the use of aspirin, pneumatic compression, and early mobilization as the sole effective prophylaxis for DVT after THA and TKA.[77]

The use of perioperative anticoagulants has a significant impact on the use of regional anesthesia, in particular neuraxial anesthesia, with the potential risk for an epidural hematoma. The American Society of Regional Anesthesia (ASRA) published and updated consensus conference recommendations with regard to the use of anticoagulants and regional anesthesia.[78] Full anticoagulation is a contraindication to regional techniques. The risk for an epidural hematoma is significantly increased with the use of LMWH, so the ASRA issued the recommendations listed in Box 79-3.

Aspirin and NSAIDs do not appear to increase the risk for an epidural hematoma after neuraxial anesthesia.[79] The latest ASRA recommendations for patients receiving warfarin and other anticoagulants are listed in Box 79-4.

BOX 79-3 ***Anesthetic Management of the Patient Receiving Low-Molecular-Weight Heparin***

1. The anti-Xa level is not predictive of the risk for bleeding. We recommend against the routine use of monitoring of the anti-Xa level (grade 1A).
2. Antiplatelet or oral anticoagulant medications administered in combination with LMWH increase the risk for spinal hematoma. Education of the entire patient care team is necessary to avoid potentiation of the anticoagulant effects. We recommend against concomitant administration of medications affecting hemostasis, such as antiplatelet drugs, standard heparin, or dextran, regardless of LMWH dosing regimen (grade 1A).
3. The presence of blood during needle and catheter placement does not necessitate postponement of surgery. We suggest that initiation of LMWH therapy in this setting should be delayed for 24 hours postoperatively and that this consideration be discussed with the surgeon (grade 2C).
4. Preoperative LMWH.
   - Patients on preoperative LMWH thromboprophylaxis can be assumed to have altered coagulation. In these patients, we recommend that needle placement should occur at least 10 to 12 hours after the LMWH dose (grade 1C).
   - In patients receiving higher (treatment) doses of LMWH, such as enoxaparin 1 mg/kg every 12 hours, enoxaparin 1.5 mg/kg daily, dalteparin 120 units/kg every 12 hours, dalteparin 200 units/kg daily, or tinzaparin 175 units/kg daily, we recommend delay of at least 24 hours to ensure normal hemostasis at the time of needle insertion (grade 1C).
   - In patients administered a dose of LMWH 2 hours preoperatively (general surgery patients), we recommend against neuraxial techniques because needle placement would occur during peak anticoagulant activity (grade 1A).
5. Postoperative LMWH. Patients with postoperative LMWH thromboprophylaxis may safely undergo single-injection and continuous catheter techniques. Management is based on total daily dose, timing of the first postoperative dose and dosing schedule (grade 1C).
   - *Twice-daily dosing.* This dosage regimen is associated with an increased risk for spinal hematoma. The first dose of LMWH should be administered no earlier than 24 hours postoperatively, regardless of anesthetic technique, and only in the presence of adequate (surgical) hemostasis. Indwelling catheters should be removed before initiation of LMWH thromboprophylaxis. If a continuous technique is selected, the epidural catheter may be left indwelling overnight, but must be removed before the first dose of LMWH. Administration of LMWH should be delayed for 2 hours after catheter removal.
   - *Single-daily dosing.* The first postoperative LMWH dose should be administered 6 to 8 hours postoperatively. The second postoperative dose should occur no sooner than 24 hours after the first dose. Indwelling neuraxial catheters may be safely maintained. However, the catheter should be removed a minimum of 10 to 12 hours after the last dose of LMWH. Subsequent LMWH dosing should occur a minimum of 2 hours after catheter removal. No additional hemostasis-altering medications should be administered because of the additive effects.

From Horlocker TT, Wedel DJ, Rowlingson JC, et al: Regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy: American Society of Regional Anesthesia and Pain Medicine evidence-based guidelines (third edition), Reg Anesth Pain Med *35:64-101, 2010.*

LMWH, Low-molecular-weight heparin.

BOX 79-4 *Regional Anesthetic Management of the Patient on Oral Anticoagulants*

1. Caution should be used when performing neuraxial techniques in patients recently discontinued from long-term warfarin therapy. In the first 1 to 3 days after discontinuation of warfarin therapy, the coagulation status (reflected primarily by factor II and X levels) may not be adequate for hemostasis despite a decrease in the INR (indicating a return of factor VII activity). Adequate levels of II, VII, IX, and X may not be present until the INR is within reference limits. We recommend that the anticoagulant therapy must be stopped (ideally 4 to 5 days before the planned procedure) and the INR must be normalized before initiation of neuraxial block (grade 1B).
2. We recommend against the concurrent use of medications that affect other components of the clotting mechanisms and may increase the risk for bleeding complications for patients receiving oral anticoagulants and do so without influencing the INR. These medications include aspirin and other NSAIDs, ticlopidine and clopidogrel, UFH, and LMWH (grade 1A).
3. In patients who are likely to have an enhanced response to the drug, we recommend that a reduced dose be administered. Algorithms have been developed to guide physicians in the appropriate dosing of warfarin based on desired indication, patient factors, and surgical factors. These algorithms may be extremely useful in patients at risk for an enhanced response to warfarin (grade 1B).
4. In patients receiving an initial dose of warfarin before surgery, we suggest that the INR should be checked before neuraxial block if the first dose was given more than 24 hours earlier or if a second dose of oral anticoagulant has been administered (grade 2C).
5. In patients receiving low-dose warfarin therapy during epidural analgesia, we suggest that their INR be monitored on a daily basis (grade 2C).
6. Neurologic testing of sensory and motor function should be performed routinely during epidural analgesia for patients on warfarin therapy. To facilitate neurologic evaluation, we recommend that the type of analgesic solution be tailored to minimize the degree of sensory and motor blockade (grade 1C).
7. As thromboprophylaxis with warfarin is initiated, we suggest that neuraxial catheters should be removed when the INR is less than 1.5. This value was derived from studies correlating hemostasis with clotting factor activity levels greater than 40%. We suggest that neurologic assessment be continued for at least 24 hours after catheter removal for these patients (grade 2C).
8. In patients with INR greater than 1.5 but less than 3, we recommend that removal of indwelling catheters should be done with caution and the medication record reviewed for other medications that may influence hemostasis that may not affect the INR (e.g., NSAIDs, ASA, clopidogrel, ticlopidine, UFH, LMWH) (grade 2C). We also recommend that neurologic status be assessed before catheter removal and continued until the INR has stabilized at the desired prophylaxis level (grade 1C).
9. In patients with an INR greater than 3, we recommend that the warfarin dose be held or reduced in patients with indwelling neuraxial catheters (grade 1A). We can make no definitive recommendation regarding the management to facilitate removal of neuraxial catheters in patients with therapeutic levels of anticoagulation during neuraxial catheter infusion (grade 2C).

LOWER EXTREMITY SURGERY

Arthroscopy

Arthroscopic procedures for the knee, hip, and ankle are increasingly performed as ambulatory procedures (see also Chapter 89). These cases can be particularly challenging for the anesthesiologist who must decide on the appropriateness of the patient and procedure for outpatient surgery and an anesthetic that is adequate for the procedure, but also provides the patient's expectation of an uncomplicated postoperative recovery with minimal pain.

Limited data are available to determine which patients are inappropriate adult ambulatory patients. In most centers, morbidly obese patients and patients with sleep apnea require monitored observation overnight after procedures in which systemic anesthetics and analgesics have been administered.[33] The presence of stable preexisting disease does not increase the incidence of postoperative complications in ambulatory patients, but the American Society of Anesthesiologists (ASA) grade 3 and 4 patients should have a medical clearance that documents the stability of their medical conditions. It follows then that medically unstable patients are not outpatient surgical candidates.

In a prospective study of 1088 patients for ambulatory surgery, Pavlin and co-workers[80] reported that the most important factors in determining discharge time were pain, nausea and vomiting, unresolved neuraxial blocks, and urinary retention. This study emphasizes the role of anesthesia in prolonging ambulatory surgical stay. General anesthesia is a safe and effective anesthetic for arthroscopic surgery, but it has been associated with increased postoperative nausea and vomiting and pain. A properly designed regional anesthetic may reduce the importance of some of these factors.

Arthroscopic knee surgery can be performed with a combination of extraarticular and intraarticular injections of local anesthetics. Short-duration local anesthetics are often combined with longer acting local anesthetics (bupivacaine) and morphine to provide postoperative analgesia. Intraarticular morphine does not provide significant additional analgesia after arthroscopic knee surgery. For more involved arthroscopic procedures, such as an anterior cruciate ligament repair, surgical relaxation is also required. Spinal anesthesia with pencil-point atraumatic needles to prevent postdural puncture headaches provides excellent operating conditions for these procedures.

Problems related to neuraxial anesthesia for ambulatory surgery include unpredictable onset and regression of the spinal blockade, urinary retention, and transient neurologic symptoms (TNS). A dose of 45 mg of isobaric spinal mepivacaine results in a mean motor block of 142 ± 37 minutes. Using 30 to 40 mg of spinal chloroprocaine, Yoos and Kopacz[81] reported 155 ± 34 minutes to ambulation in outpatient surgical patients. TNS are

symptoms of pain in the gluteal region that can radiate down both legs and appear within a few hours to 24 hours after an uneventful spinal anesthetic.[82,83] The incidence of TNS is more frequent after outpatient surgery performed in the lithotomy position and in patients undergoing knee arthroscopy. The pain can vary from mild to severe, last 2 to 5 days, and is best treated with NSAIDs. TNS is more common after a spinal anesthetic with lidocaine (~14%) than with mepivacaine (6.5%) and bupivacaine (<1%). For ambulatory patients, the benefit of short-acting spinal anesthetic must be weighed against the risk for developing TNS. For postoperative analgesia after anterior cruciate ligament repairs, a femoral nerve block with a long-acting local anesthetic is superior to intraarticular injections. Because the quadriceps muscle is blocked, it is important for the patient to be fitted with a knee brace before ambulation. Blocking the saphenous nerve in the adductor canal may provide postoperative analgesia without also interfering with early ambulation.[84]

Hip arthroscopy has become a common outpatient procedure for the diagnosis and treatment of pathologic processes in the hip. The patient can be placed in either the supine or the lateral position (operative side up) with 50 to 75 lb of traction applied to the operative limb to gain access to the joint with the arthroscope. In positioning the patient, the anesthesiologist must ensure that the perineal post is padded and not compressing the pudendal nerve and that excessive traction for prolonged periods is not applied (see also Chapter 41). Because complete muscle relaxation is required for the procedure, the patient must have either a general anesthetic or a neuraxial block. A lumbar plexus block can be performed for postoperative analgesia.

Hip Fractures

Hip fractures in older individuals are common (1 in 50 individuals older than 60 years of age), and as previously stated are associated with significant morbidity and mortality (1-year mortality of 30%).[5] The high perioperative complication rate is related to many factors, including cardiac conditions, pulmonary conditions, DVT, and delirium. Postoperative confusion and delirium are common, reported in 50% of older patients after the repair of hip fractures and associated with increased mortality.[34-36] In many cases, dehydration and electrolyte abnormalities contributed to this delirium. In one study, the incidence of hyponatremia was 4% and was associated with a sevenfold increase in hospital mortality.[85]

These patients often arrive in the hospital in pain and under considerable stress, which may elicit signs and symptoms of myocardial ischemia. Although preoperative preparation is essential, delaying surgery may exacerbate these problems and increase the incidence of complications. Early surgery (<12 hours) has resulted in lower pain scores, decreased length of hospital stay, and reduced perioperative complications.[86] However, early surgery has not been associated with increased overall survival in contrast to delaying surgery. Using geriatric services has been shown to improve outcomes, especially better lower limb function.[87]

Patients with hip fracture are often dehydrated and anemic because the fracture site can accommodate considerable extravasated blood. Blood hematocrit values are often normal because of the contracted blood volume in a dehydrated patient. A normal intravascular blood volume should be restored before anesthesia and surgery; this is best achieved with central venous catheter monitoring. Central venous catheter monitoring also may prevent overhydration, which can precipitate congestive heart failure. Placement of an arterial catheter permits accurate blood pressure monitoring during surgery and the ability to follow serial arterial blood gases. Hypoxemia, possibly owing to fat embolization, has been a major determinant of mortality in these patients.

Several studies have reported improved outcome with regional anesthesia compared with general anesthesia in these patients.[61] Patients undergoing hip fracture surgery have the greatest risk for death from a PE.[71] In a meta-analysis of patients undergoing the repair of femoral neck fractures, the incidence of DVT was almost four times greater in the patients who received general versus regional anesthesia.[88] A spinal anesthetic with isobaric 0.5% bupivacaine provides a stable regional anesthetic of sufficient duration to complete the surgical repair. Epidural anesthesia with postoperative analgesia is usually not indicated, because in most cases aggressive postoperative anticoagulation is instituted.[73] Intravenous sedation during the procedure must be coupled with the ability of the patient to remain adequately oxygenated. Long-acting benzodiazepines should be avoided because of their association with postoperative confusion. In many cases, these patients require postoperative monitoring in an ICU-like setting.

PELVIC FRACTURES

Pelvic fractures are often the result of significant trauma to the lower trunk and hence are accompanied by additional injuries, including chest (21%), head (16%), and liver and spleen (8%).[89] The 3-month mortality for pelvic fractures approaches 14%. Acute mortality directly related to the pelvic fracture may result from retroperitoneal bleeding. An indication for emergency exploratory surgery after a pelvic fracture would include persistent hypotension and increasing abdominal girth. Injuries to the bladder and urethra are also often associated with pelvic fractures; thus urology clearance is usually indicated before inserting a Foley catheter. Because there is a significant risk of DVT and PE, many of these patients require a temporary inferior vena cava filter before surgery.

Recent reports suggest that the optimal time for stabilization of a pelvic fracture is within the first week of trauma; however, associated injuries often delay the operation. An optimal anesthetic may be the combination of a general anesthetic with the placement of an epidural catheter for postoperative analgesia. Because iatrogenic sciatic nerve injury is the most frequent surgical complication (~18%), the use of intraoperative neuromuscular monitoring precludes dosing of the epidural catheter during the procedure and dictates waiting to dose the catheter until after the preservation of lower extremity movement and sensation has been confirmed. In most cases, these patients require monitoring with arterial and central venous catheters, as well as the placement of large-gauge venous catheters in the event of sudden surgical hemorrhage.

HIP AND KNEE ARTHROPLASTIES

As the population ages and remains physically active through their sixth decade, major orthopedic joint replacement procedures are increasingly more common. Between 1991 and 2010, the number of annual TKA procedures in Medicare patients increased 162% from 93,230 to 243,802.[90] The rate of major adverse events after hip and knee arthroplasties is 6.4%, and as stated earlier the most important risk factor is advanced age (see also Chapter 80).[4-10] The most common complications after THA and TKA are cardiac events, PE, pneumonia and respiratory failure, and infection.[5,10,91,92] Older patients with major comorbidities, including cardiac disease, pulmonary disease, and diabetes, should have a complete preoperative medical evaluation. In addition, obesity, particularly in a patient who has undergone TKA, can be a problem anesthetically, as well as postoperatively, with regard to OSA and infections.[33,92] Many of these patients require prolonged postoperative monitoring in the postanesthesia care unit or ICU (see also Chapter 96).

THA may be performed via an anterior or lateral approach. The anterior approach offers the advantage of exposure without violation of the muscles, but restricts full access to the femur, with the risk for lateral femoral cutaneous nerve injury. The lateral posterior approach provides excellent exposure to the femur and the acetabulum with minimal muscle damage, but increases the risk for posterior dislocation. Most surgeons prefer the lateral posterior approach, which places the patient in the lateral decubitus position, surgical side up, for the operation. The anesthesiologist must be aware that this position may compromise oxygenation, particularly in obese and severely arthritic patients, as a result of ventilation-perfusion mismatch. In addition, to prevent excessive pressure on the axillary artery and brachial plexus by the dependent shoulder, an anterior roll or pad must be placed beneath the upper thorax.

The nerve supply to the hip joint includes the obturator, inferior gluteal, and superior gluteal nerves. Regional anesthesia for THA is best achieved with a spinal or epidural anesthetic. Although most studies suggest decreased postoperative respiratory complications, including a reduction in the incidence of DVT and PE with regional anesthesia compared with rates in general anesthesia, some controversy still remains.[61] A lumbar paravertebral block may be used for postoperative analgesia when postoperative anticoagulation requires removal of the epidural catheter.[93]

Blood loss during THA can be significant, and with revision procedures the patient can lose 1 to 2 L of blood. Several studies have shown that controlled hypotensive epidural anesthesia with mean arterial blood pressures of 50 to 60 mm Hg can reduce intraoperative blood loss to as low as 200 mL for primary THAs.[94] Older patients (mean age 72 years) were able to tolerate this degree of blood pressure reduction without cognitive, cardiac, or renal complications.[95] In addition to reduced overall blood loss during THA, hypotensive anesthesia may improve the prosthesis-to-bone fixation by limiting bleeding in the femoral canal.[96] An intravenous bolus injection of tranexamic acid or intraoperative fibrin spray also have been shown to reduce blood loss after joint arthroplasty.[97]

The femoral prosthesis can be fixed to the femoral canal through methyl methacrylate cement or bony ingrowth. Cemented fixation of the femoral prosthesis has been complicated by the bone-cement implantation syndrome, which may result in intraoperative hypotension, hypoxia, and cardiac arrest and FES postoperatively (Fig. 79-6; see Fig. 79-2).[42-44] Several mechanisms have been suggested for these events, including embolization to the circulation of bone marrow debris during pressurization of the femoral canal, toxic effects of circulating methyl methacrylate monomer, and release of cytokines during reaming of the femoral canal that promote the formation of microthrombi with subsequent pulmonary vasoconstriction. The intravenous

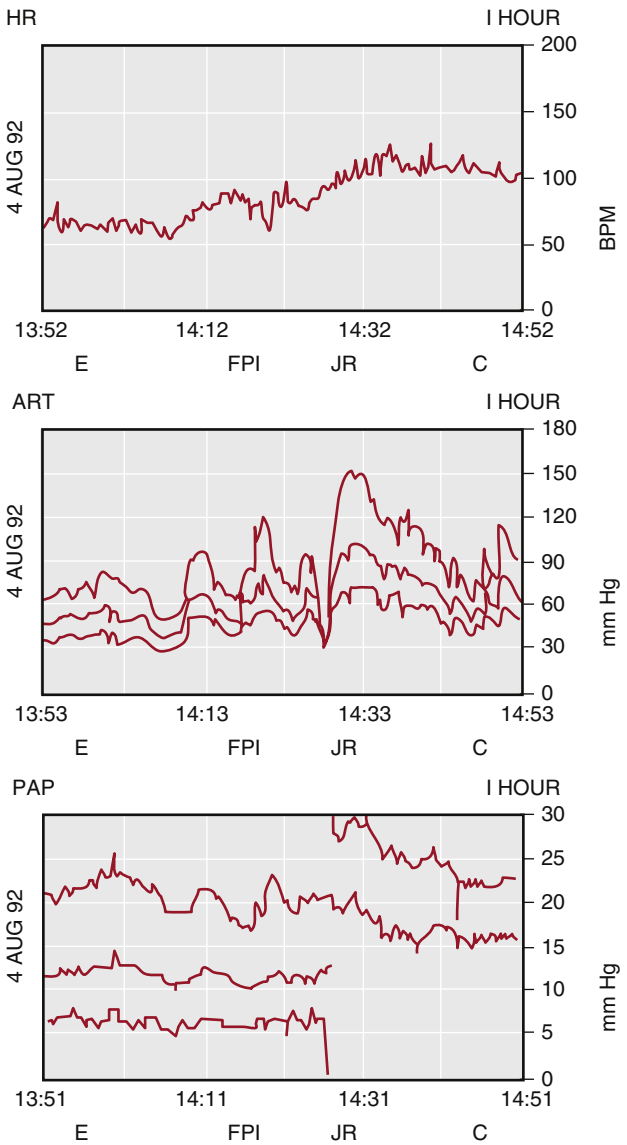

Figure 79-6. Intraoperative heart rate (*HR*), systemic arterial blood pressure (*ART*), and pulmonary arterial pressure (*PAP*) tracings of a patient undergoing revision total hip arthroplasty. *E,* Induction of epidural anesthesia; *FPI,* insertion of a cemented femoral prosthesis; *JR,* reduction of prosthetic hip joint, producing hypotension with rebound from epinephrine injection; *C,* wound closure. *(From Urban MK, Sheppard R, Gordon MA, et al: Right ventricular function during revision total hip arthroplasty,* Anesth Analg *82:1225-1229, 1996.)*

injection of the cement monomer in dogs induces systemic hypotension, but not most of the other systemic events, including myocardial depression, which are manifested during the FES.[98] The embolization of intramedullary debris is the most likely explanation for the FES, because this debris can be visualized in the right heart using TEE (see Fig. 79-2).

The hypotensive events that follow bone marrow embolization should be treated with epinephrine. In addition, the hemodynamic consequences of bone marrow embolization can be ameliorated through high-pressure pulsatile lavage of the femoral canal and drilling a vent hole in the femur before prosthesis insertion. Risk factors for this complication include revision surgery, a long-stem femoral prosthesis, THA for a pathologic fracture, preexisting pulmonary hypertension, and the quantity of cement used. These patients should be monitored with arterial and central venous catheters.

During THA, embolization of a blood thrombus is possible. The hip is dislocated and the femoral vein is probably obstructed during reaming and insertion of the femoral prosthesis, resulting in blood stasis and blood clot formation. With relocation of the hip and unkinking of the femoral vein, the embolic material generated is released into the circulation. At some institutions an intravenous bolus of heparin is administered before dislocation of the hip. TKA also is becoming a major orthopedic procedure in the aging population, and these patients require the same preoperative medical evaluation as outlined for patients undergoing THA. The innervation of the knee includes the tibial nerve, the common peroneal nerve, the posterior branch of the obturator nerve, and the femoral nerve. Although general anesthesia can be safely provided for TKA, a prospective case-controlled study found general anesthesia with endotracheal intubation to be a major risk for nonsurgical complications after TKA.[60] Regional anesthesia in the form of a neuraxial block (spinal or epidural) or a combination of a femoral and sciatic block can be provided for the surgery. However, in TKAs for valgus deformities, sciatic nerve blocks may prevent the early detection of sciatic and peroneal nerve palsies.

Patients who have undergone TKA have severe postoperative pain, and several studies have reported a reduction in postoperative complications and improved outcomes when this pain is managed with regional anesthesia.[99-101] Single-injection femoral nerve blocks in combination with intravenous and epidural patient-controlled analgesia have been employed to manage postoperative pain and improve functional recovery. When LMWH is used for DVT prophylaxis, the infusion of local anesthetics through continuous femoral nerve catheters may be used in place of patient-controlled epidural anesthesia.

A pneumatic tourniquet is routinely inflated over the thigh during TKA to reduce intraoperative blood loss and provide a bloodless field for cement fixation of the femoral and tibial components. When the tourniquet is deflated, however, blood loss begins and usually continues for the next 24 hours. Tourniquets are usually inflated to a pressure 100 mm Hg above the patient's systolic blood pressure for 1 to 3 hours. Nerve injury after extended tourniquet inflation (>120 minutes) has been attributed to the combined effects of ischemia and mechanical trauma. A peroneal nerve palsy, which is a recognized complication of TKA (incidence of 0.3% to 10%), may be caused by the combination of tourniquet ischemia and surgical traction.[102] Horlocker and colleagues[102] reported an incidence of combined tibial and peroneal nerve dysfunction in 7% of patients who had undergone TKA that was associated with younger age, the presence of preoperative flexion deformities, and longer total tourniquet times. When prolonged tourniquet inflations are required, deflating the tourniquet for 30 minutes of reperfusion may reduce neural ischemia.

Pain related only to tourniquet inflation also may occur after 60 minutes, despite the presence of a regional anesthetic that is adequate for the surgery. It has been postulated that tourniquet pain is caused by the unblocking of unmyelinated C fibers during recession of a neuraxial block. The addition of opioids to spinal or epidural anesthesia may ameliorate tourniquet pain. After tourniquet release, mean arterial blood pressure decreases significantly, partly owing to the release of metabolites from the ischemic limb into the circulation and the decrease in peripheral vascular resistance. In patients with known preexisting sciatic neurapraxias, neuropathic pain, and vascular disease in the operative leg, the operation can be performed without a tourniquet.

Many patients have symptomatic arthritis of both knees and require bilateral TKA to achieve functional improvement in pain and lifestyle. However, controversy still exists as to whether both knees should be replaced sequentially in a single operation (simultaneous bilateral total knee arthroplasty [SBTKA]) or as a two-staged procedure, usually separated by several months. The advantages of SBTKA include exposure to the risks of one anesthetic, one postoperative course of pain, reduced rehabilitation and hospitalization, and an earlier return to baseline function. However, SBTKA has been associated with a higher incidence of serious perioperative complications, including myocardial infarction, fat embolization, and thromboembolic events. Serious postoperative complications are more prevalent in older patients with cardiovascular disease.[102-106] Patients undergoing SBTKA also require increased numbers of blood transfusions, are more likely to be transferred to a rehabilitation center, and have a higher incidence of postoperative ICU admissions.

Two more recent reports suggest that SBTKA can be performed without major complications.[107,108] Urban and associates[107] reported that with regional anesthesia and aggressive clinical management, which included 24-hour postoperative monitoring in an ICU, patients undergoing SBTKA had a major complication rate similar to that in matched control patients undergoing unilateral TKA, with a significantly higher incidence of FES and cardiac arrhythmias than patients undergoing unilateral TKA, possibly because of an enhanced inflammatory response.[109] Using published reports of patients who underwent SBTKA and who were at risk for postoperative complications, Urban and associates[107] published guidelines for the exclusion of patients from SBTKA (Box 79-5).

BOX 79-5 ***Patients Excluded for Single Operation for Bilateral Total Knee Arthroplasty***

Age ≥75 years
ASA class III
Active ischemic heart disease (positive stress test)
Poor ventricular function (LVEF <40%)
Oxygen-dependent pulmonary disease
Patients considered at increased risk for morbidity and mortality
- IDDM
- Renal insufficiency
- Pulmonary hypertension
- Steroid-dependent asthma
- Morbid obesity (BMI >40)
- Chronic liver disease
- Cerebrovascular disease

FOOT AND ANKLE SURGERY

Regional anesthesia that combines sciatic and femoral nerve blocks is sufficient for all surgical procedures below the knee that do not require a thigh tourniquet. The femoral nerve innervates the medial leg to the medial malleolus, and the remainder of the leg below the knee, including the foot, is innervated by the common peroneal nerve and tibial nerve, both branches of the sciatic nerve. The sciatic nerve is usually blocked high in the popliteal fossa to ensure anesthesia to the tibial and peroneal nerves. The nerves are identified through the use of a nerve-stimulating needle with foot inversion as the motor response or with ultrasound guidance. For procedures that also involve the medial aspect of the leg, the femoral nerve (saphenous nerve) can be blocked on the medial aspect of the leg, just below the knee. The popliteal sciatic nerve block has been shown to reduce postoperative pain and opioid requirements after foot and ankle surgery, when performed as a single preoperative injection or as a continuous catheter infusion.[109-112]

Acute compartment syndrome exists when edema and blood accumulate within a confined osseofascial space, compromising the circulation and tissues within that space.[113,114] If not treated promptly, the pressure in the compartment leads to muscle and nerve ischemia and necrosis, with potential loss of limb. Compartment syndrome can occur after fractures of the tibia, followed less commonly by fractures of the femur and ankle. Delay in diagnosis and treatment (surgical decompression) is the most common cause of serious complications. Pain out of proportion to the clinical situation is the usual early symptom. Thus, after the surgical repair of tibial and ankle fractures, a discussion with the surgeon with regard to the risk for compartment syndrome should occur before administering long-acting sciatic nerve blocks.

The ankle block is used for surgical procedures on the foot that do not require the use of a thigh tourniquet, although an ankle-level Esmarch tourniquet may be used. Because the block is primarily an infiltrative block, it usually is not performed by eliciting a paresthesia.

Five terminal nerves are usually blocked to provide complete anesthesia to the foot: (1) posterior tibial nerve, which provides sensation to the plantar surface; (2) saphenous nerve, which innervates the medial malleolus; (3) deep peroneal nerve, which supplies the interspace between the great and second toes; (4) superficial saphenous nerve, which supplies the dorsum of the foot and the second through the fifth toes; and (5) sural nerve, which supplies the lateral foot and lateral fifth toe (Fig. 79-7). Mineo and Sharrock[115] reported that the ankle block performed at the midtarsal level with 30 mL of 0.75% bupivacaine provided a mean duration of 17 hours of analgesia with safe blood levels of local anesthetic.

UPPER EXTREMITY SURGERIES

Surgery for the upper extremity, from the shoulder to the hand, can be performed successfully by blocking the brachial plexus at several points until it branches into peripheral nerves (Table 79-3). Several methods are used to document the optimal location for neural blockade of the brachial plexus, including eliciting a paresthesia, motor nerve stimulation, ultrasound guidance, and perivascular infiltration. Regional anesthesia for the upper extremity also can provide postoperative analgesia using long-acting local anesthetics or continuous catheter techniques.

Regional anesthesia for shoulder surgery (see also Chapters 57 and 58) has not gained wide acceptance because of the thought by anesthesiologists and surgeons that it is often inadequate for surgical anesthesia and the concern for postoperative neurologic symptoms (PONS). Several studies have reported 97% or greater successful surgical anesthesia using the interscalene block (ISB) approach to the brachial plexus with documentation of a paresthesia or the use of a nerve stimulator or ultrasound guidance to locate the optimal site of injection.[116-119]

TABLE 79-3 BRACHIAL PLEXUS ANESTHESIA

Site of Block	Stimulated Brachial Plexus	Response
Interscalene	Roots, trunks	Shoulder to hand
Supraclavicular	Trunks (middle, inferior)	Upper arm to hand
Infraclavicular	Lateral cord	Forearm flexion
		Hand pronation
	Posterior cord	Wrist extension
	Medial cord	Fingers and thumb
Axillary	Median nerve	Forearm pronation
		Wrist flexion
	Ulnar nerve	Finger flexion
		Thumb opposition
	Radial nerve	Wrist extension

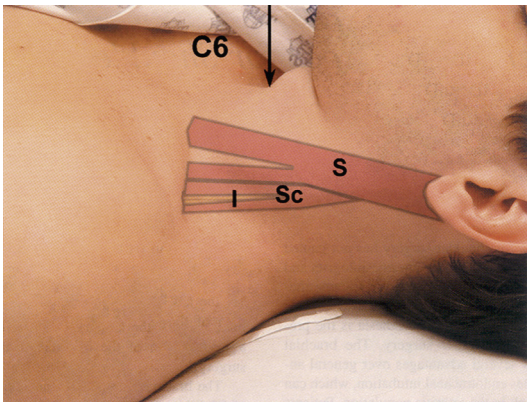

Figure 79-8. Interscalene approach to brachial plexus. At the level of the cricoid cartilage (*C6*), the anesthesiologist's finger is rolled laterally from the posterior border of the sternocleidomastoid muscle (*S*) into the interscalene groove (*I*) between the anterior and middle scalene muscles (*Sc*). The needle is inserted at point *I* and directed 45 degrees caudad and perpendicular to all planes. *(From Urban MK: The interscalene block for shoulder surgery,* Tech Shoulder Elbow Surg *5:61-65, 2004.)*

The brachial plexus is formed from the ventral rami of C5-T1 nerve roots. After these roots pass between the anterior and middle scalene muscles, they fuse into three trunks (superior C5-6, middle C7, inferior C8-T1). During performance of the ISB, local anesthetic is injected between the scalene muscles at the level of the cricothyroid notch (C6) (Fig. 79-8).

The major acute complications and side effects associated with ISB are respiratory depression, intravascular injection with seizures and cardiac arrest, pneumothorax, epidural and spinal anesthesia, Horner syndrome, hoarseness, and dysphagia. The ipsilateral phrenic nerve is blocked in all patients undergoing ISB, resulting in hemidiaphragmatic paresis.[120] Because hemidiaphragmatic paresis may result in a 25% reduction in pulmonary function, patients with severe respiratory disease may not tolerate an ISB without the addition of mechanical ventilation. An ISB would be contraindicated in patients after pneumonectomy on the contralateral side and for bilateral operative procedures. The supraclavicular approach to the brachial plexus with ultrasound guidance may provide effective shoulder anesthesia without complete ipsilateral paresis of the phrenic nerve.[121]

TABLE 79-4 INTERSCALENE BLOCK COMPLICATIONS: POSTOPERATIVE NEUROLOGIC SYMPTOMS

Reference	Acute Symptoms (%)	Chronic Symptoms (%)
Conn et al[122]	—	2
Urban and Urquhart[116]	9	0.4
Borgeat et al[123]	14	0.2
Faryniarz et al[118]	1.4	0
Liguori et al[117]	10	0

Because of the proximity to major vascular structures (vertebral artery, carotid artery, jugular vein), CNS toxicity is usually cited as a major risk of ISB. The reported incidence of CNS effects has been very low, however. Conn and associates[122] reported that ISB resulted in 3 of 100 patients experiencing CNS symptoms and only one seizure. Urban and Urquhart[116] reported that 2 of 266 patients had CNS symptoms and none had seizures.

PONS related directly to brachial plexus anesthesia is often cited as the reason to avoid regional anesthesia for shoulder and hand surgery. The few large studies that have attempted to ascertain the extent of nerve injury associated with ISB have concluded that although some patients may have neurologic issues after surgery, many of the problems cannot be attributed to the anesthetic and most of them resolve (Table 79-4). In the retrospective study by Conn and associates,[122] 2 of 100 patients had PONS that persisted for 7 months and 18 months, respectively. In the prospective analysis of 266 patients by Urban and Urquhart,[116] 9% reported paresthesias on the day after surgery, two thirds of which resolved after 2 weeks and one that persisted beyond 6 weeks. Liguori and colleagues[117] reported the incidence of PONS after ISB performed with either the documentation of a paresthesia (10 of 108) or the use of a nerve stimulator (11 of 109), with a median duration of 2 months and resolution of all cases of PONS within 1 year.

Arthroscopic shoulder surgery is often performed in the sitting (beach chair) position. Hypotensive and bradycardic events, some progressing to asystolic arrest, have been associated with shoulder surgery in the sitting position under regional anesthesia.[124] There is some evidence that these events are the result of a cardiac inhibitory reflex, the Bezold-Jarisch reflex, which occurs in response to diminished ventricular volume (venous pooling in the sitting position) and a hypercontractile ventricle. Prophylactic administration of β-blockers, anxiolytics, and intravenous fluids reduces the incidence of these events.[125]

For surgery from the elbow to the hand, the brachial plexus can be blocked via either the infraclavicular block approach or the axillary approach. Blockade of the nerves to the arm at the axilla can be achieved by a transarterial technique or the stimulation of a single nerve or multiple nerves. Advocates of the multiple paresthesia technique cite the report by Thompson and Rorie,[126] which states that within the axillary sheath the nerves are separated by discrete septa. Using a transarterial approach, Urban and Urquhart[116] reported a success rate of 93%. Advocates of the paresthesia or nerve stimulator technique for

the axillary block argue that the transarterial approach may produce a hematoma with the potential for ischemic damage to the brachial plexus. When the transarterial axillary block was used in 242 patients for forearm and hand surgery, 23% of the patients complained of tenderness and bruising at the axilla, and 19% had acute PONS.[116]

The infraclavicular block to the brachial plexus may be the best approach for elbow surgery, and it may result in less patient discomfort and PONS when used for forearm and hand surgery compared with the axillary approach, although objective evidence is still lacking.[127,128] Using the nerve stimulator technique, two large series of infraclavicular blocks reported 90% to 94% success with only posterior cord stimulation, whereas other reports still recommend a double stimulation technique. Performing the infraclavicular block with ultrasound guidance may avoid the need for multiple needle passes and the complications of vascular puncture and pneumothorax.[129]

Forearm and hand surgery also can be performed under intravenous regional anesthesia. Intravenous regional anesthesia is a simple technique that involves exsanguinating the arm by wrapping it with a tight band, inflating an upper arm tourniquet to approximately 250 mm Hg, and injecting in a hand vein approximately 50 mL of a short-acting local anesthetic (0.5% lidocaine). A second tourniquet, proximal to the first, is often inflated 15 minutes later with subsequent deflation of the first, to minimize tourniquet pain. This technique is limited to short surgical procedures (~1 hour). Complications occur when the tourniquet fails during initial anesthetic injection or the tourniquet is deflated early (<30 minutes), risking systemic local anesthetic toxicity.

SPINAL SURGERY

In the United States with an active, aging population, 4.6 million individuals will require spinal surgery at some time during their life. Spinal surgery includes a wide variety of procedures ranging from a microdiskectomy for a herniated disk to complex reconstructive surgery for spinal deformities. These procedures can be simple or involve fusions at multiple levels, anterior or posterior approaches, and considerable blood loss. A few procedures, such as a diskectomy, can be performed under regional anesthesia.[130]

Most spinal surgeries require general anesthesia. In this patient population with preexisting arthritic conditions, tracheal intubation often poses a challenge (Box 79-6). Awake, sedated fiberoptic intubation of many of these patients is the safest approach to general anesthesia. This is the standard of care in a patient with cervical spinal instability who requires posterior stabilization. These patients should be intubated first with a flexible fiberoptic bronchoscope, then positioned prone for surgery sedated but awake (if possible) and assessed for movements of upper and lower extremities before the induction of general anesthesia. Some patients with reduced but stable cervical mobility, may be intubated using glide scope technology after the induction of general anesthesia.

The careful positioning of patients for spinal surgery is an important shared responsibility of the anesthesiologist and surgeon (see also Chapter 41). As stated previously, patients at risk for spinal cord compression should be positioned under light sedation, then observed for upper and lower extremity movement before inducing general anesthesia. Because some posterior cervical spine decompressions are done in the sitting position, preparations must be made for the possibility of a venous air embolism. Complex spinal deformity procedures often require anterior and posterior approaches to the spine. For a low lumbosacral anterior approach, the patient is supine with the legs spread wide. Pelvic retraction during this procedure may compromise blood flow to the legs, and a pulse oximeter placed on a toe may be used as a monitor for compromised lower extremity blood flow. Patients undergoing anterior thoracolumbar procedures are usually positioned in the lateral decubitus position, in which attention must be focused on the dependent arm and leg and the position of the neck. Table 79-5 outlines possible complications from prone positioning for these spinal procedures.

Postoperative airway management in patients after single-stage multilevel anterior, posterior, or both cervical spinal decompressions and fusions should be a major concern of the anesthesiologist. Postoperative complications include dysphagia (12%), dysphonia (4%), and

BOX 79-6 ***Predictors of a Difficult Endotracheal Intubation***

Facial dissymmetry (trauma)
Tracheal deviation
Cervical fractures
Small mouth opening (interincisor gap)
Inability to visualize the faucial pillars and uvula (Mallampati)
Limited neck range of motion
Prominent incisors
Distance between thyroid cartilage and mandible less than 6 cm
Narrow maxillary arch

TABLE 79-5 COMPLICATIONS OF THE PRONE POSITION*

Airway	ETT kinking, dislodgment Upper airway edema
Neck	Hyperextension or hyperflexion Cervical rotation—compromised blood flow to brain
Eyes	Orbital pressure—central retinal artery occlusion, supraorbital nerve Corneal abrasion
Abdomen	Pressure transmitted to epidural veins, increased bleeding
Upper extremity	Brachial plexus stretch—arms out Ulnar nerve compression—arms at the side
Lower extremity	Flexion of hips—occlusion of femoral vein, DVT, kinking of vascular grafts Pressure lateral to fibula—peroneal nerve palsy Pressure on iliac crest—lateral femoral cutaneous nerve

*See Chapter 41.
DVT, Deep vein thrombosis; *ETT,* endotracheal tube.

airway compromise (up to 14%).[131] Tissue trauma from the procedure often causes airway edema, which can progress to complete airway obstruction. Reported risk factors for postoperative respiratory complications are length of surgery, volume of infused crystalloid, obesity, revision surgery, four or more levels fused, and fusion of C2. A protocol for the management of these patients should be established such that patients at risk for postoperative airway complications are monitored with emergency airway equipment and specialists available and/or the patients kept intubated overnight and extubated when upper airway edema has subsided.

Posterior lumbar fusions for degenerative disk disease are often accompanied by anterior fusions to stabilize the surgical area and increase the success of the fusions. The anterior open procedures have recently been replaced in many cases by minimally invasive techniques, including transperitoneal anterior lumbar interbody fusion and extreme lateral interbody fusion.[131] To reduce the risk for nerve root injury during disk excision, intraoperative electromyographic monitoring is used, which precludes the use of neuromuscular blocking drugs. Large-bore venous access out of proportion to the usual blood loss should be secured in these patients, because the techniques are performed in close proximity to major vascular structures that are at risk for iatrogenic injury.

Complex corrective surgery of the spine includes patients with scoliosis, kyphosis, kyphoscoliosis, and revision surgery on patients with previous thoracolumbar fusions. Kyphosis is an exaggerated anterior flexion of the spine, as seen in ankylosing spondylitis. Scoliosis is defined as a lateral rotation of the spine greater than 10 degrees accompanied by vertebral rotation. Scoliosis is classified as idiopathic, congenital, or neuromuscular. Congenital scoliosis is the result of early embryonic errors in vertebral column formation, and half of the cases are associated with other organ system anomalies. Adolescent idiopathic scoliosis is common, present in 2% to 4% of children 10 to 16 years of age. Only 10% of these adolescents have curves that require some type of medical intervention. Surgical intervention occurs when the curve magnitude estimated by the Cobb method is more than 40 degrees (Fig. 79-9) and the likelihood of curve progression is strong. Most idiopathic scoliosis curves are right-sided; a left thoracic curve is more likely to be associated with other thoracic anomalies.

Thoracic scoliosis results in a narrowed chest cavity producing a decrease in chest wall compliance and restrictive lung disease. Cobb angles of greater than 65 degrees usually cause significant decreases in lung volumes. Although exercise tolerance is an important determinant of the effects of the severity of the curve on respiratory function, formal pulmonary function studies should be obtained before surgery. This information guides decisions regarding the extent of surgery permitted at one time and the requirement for postoperative ventilatory support. A vital capacity of less than 40% of the normal range is predictive of the requirement for postoperative ventilation. The major abnormality in arterial blood gases is hypoxemia, secondary to ventilation-perfusion inequalities caused by alveolar hypoventilation.

Figure 79-9. Radiograph of a patient with scoliosis. The Cobb angle is an angle formed by a line drawn perpendicular to the top of the superior vertebra of the scoliotic curve and a similar perpendicular line drawn along the bottom of the inferior vertebra. The Cobb angle in this patient is 62 degrees. *(From Reamy BV, Slakey JB: Adolescent idiopathic scoliosis: review and current concepts,* Am Fam Med *64:1-10, 2001.)*

Chronic hypoxemia produces elevated pulmonary vascular resistance, which ultimately leads to cor pulmonale. An echocardiogram should be assessed for pulmonary hypertension and right ventricular hypertrophy. In patients with pulmonary hypertension, the electrocardiogram may reveal evidence of right ventricular hypertrophy and right atrial enlargement.

Surgical spinal corrections involving high anterior thoracic levels or video-assisted thoracoscopic surgery require the isolation of one lung. One-lung ventilation traditionally has been achieved with a double-lumen endotracheal tube. In single-staged anterior then posterior spinal fusions and for postoperative ventilation, the double-lumen endotracheal tube must be replaced with a single-lumen endotracheal tube. A single-lumen endotracheal tube with an enclosed bronchial blocker also can provide one-lung ventilation, but has the advantage of being left in place as a single-lumen endotracheal tube with the blocker deflated at the end of the anterior procedure.[132] In patients with restrictive lung disease, adequate oxygenation may be difficult during one-lung ventilation and may require continuous positive airway pressure to the nonventilated lung and positive end-expiratory pressure to the ventilated lung.

Surgery for the correction of spinal deformities is usually associated with large blood losses. Multiple factors have been suggested to influence the magnitude of this blood loss, including surgical technique, operative time, number of vertebral levels fused, anesthetics, mean arterial blood pressure, platelet abnormalities, dilutional coagulopathy, and primary fibrinolysis.[133] Several techniques have been employed to reduce this blood loss and limit the need for homologous blood transfusions, including proper positioning of the patient to reduce intraabdominal pressure, surgical hemostasis, deliberate

controlled hypotensive anesthesia, reinfusion of salvaged blood, intraoperative normovolemic hemodilution, use of pharmacologic agents that promote clot formation, and preoperative donation of autologous blood.

Controlled hypotensive anesthesia has been used commonly in limiting blood loss during idiopathic scoliosis corrections in adolescents, but must be used with caution in older patients.[134] In a young healthy patient, a mean arterial pressure of 50 to 60 mm Hg is well tolerated, but higher pressures may be required in adult patients with cardiovascular disease. In addition, perfusion of the spinal cord during deformity-correcting surgery may be exquisitely sensitive to low perfusion pressures. The adequacy of end-organ perfusion can be estimated with invasive monitoring, a urine output of 0.5 to 1 mL/kg/hr, and periodic blood gas analysis looking for evidence of metabolic acidosis.[135] In addition, central venous oxygen saturation with an arterial blood gas provides an indication of end-organ oxygen supply and demand. Although an increase in heart rate during hypotensive anesthesia may indicate anemia, hypovolemia or "light" anesthesia, the use of a β-blocker to reduce the risk for myocardial ischemia and ameliorate renin release with concomitant pressure rebound when the surgery has ended eliminates this physiologic marker. Synthetic lysine analogues, such as aminocaproic acid and aprotinin, a polypeptide with serine protease inhibitor activity, also have been used to limit blood loss during these procedures by reducing fibrinolysis, but there may be concern because of more recent findings in postoperative cardiac cases.[136]

A postoperative neurologic deficit is one of the most feared complications of complex spinal reconstructive surgery. In a large survey of 97,586 spinal surgeries, neurologic deficits occurred in 0.55% of the cases.[137] To reduce this complication, Vauzelle and colleagues[138] introduced the concept of waking the patient up during surgery to determine the functional integrity of the spinal cord. This test is limited to gross motor movements of the lower extremities and can be influenced by anesthetics and the cognitive integrity of the patient. In addition, complications related to the test include inadvertent extubation of the patient during movement in the prone position, air embolism during a deep inspiration, and dislodgment of the instrumentation during violent movements.

Multimodal intraoperative monitoring has become the standard of care for complex reconstructive spinal surgery.[139] This monitoring includes somatosensory evoked potential (SSEP), motor evoked potential (MEP), and electromyogram (EMG) monitoring. EMGs are used to monitor nerve root injury during pedicle screw placement and nerve decompressions (see also Chapter 49). The posterior (sensory) portion of the spinal cord is evaluated using SSEP monitoring. MEPs assess the integrity of the anterior (motor) spinal cord. Potential adverse effects of MEP monitoring include cognitive deficits, seizures, bite injuries, intraoperative awareness, scalp burns, and cardiac arrhythmias. It is advisable to employ a soft bite block during MEP monitoring to prevent tongue biting and dental damage. MEP monitoring should be avoided in patients with active seizures, vascular clips in the brain, and cochlear implants. In SSEPs, an impulse is sent from a peripheral nerve and measured centrally. In MEPs, an impulse is triggered in the brain and monitored as movement of a specific muscle group. SSEPs and MEPs are evaluated with regard to amplitude—strength—of the signal and latency—time it takes the signal to travel through the spinal cord—compared with the patient's nonsurgical control values.

Numerous physiologic factors attenuate SSEP and MEP monitoring, including hypotension, hypothermia, hypocarbia, hypoxemia, anemia, and anesthetics. The potent inhaled agents reduce the amplitude of the signal and increase latency in a dose-dependent manner. If a volatile anesthetic is used for the anesthesia, the concentration should be kept at approximately half minimum alveolar concentration and not varied throughout the procedure. Nitrous oxide produces a decrease in the amplitude of the signal and may have to be eliminated during MEP monitoring. Total intravenous anesthesia has been used successfully for MEP and SSEP monitoring.

MEPs are the least affected by opioids, midazolam, and ketamine, but are depressed by propofol. The depressant effect of propofol is diminished, however, with ketamine, such that the best total intravenous anesthetic may be an infusion of an opioid, ketamine (at low doses), and propofol.[140,141] Muscle relaxants cannot be administered during MEP monitoring.

Postoperative visual loss (POVL) is another devastating complication of spinal surgery (see also Chapter 100). POVL is rare after spinal surgery (≤0.1%) and may be caused by ischemic optic neuropathy (ION), retinal artery or vein occlusion, and cortical brain ischemia. In an attempt to delineate the cause of POVL, the ASA Committee on Professional Liability established a POVL registry to collect detailed information on these cases.[142] Most patients with central retinal artery occlusion had evidence of unilateral ocular trauma, suggesting a role for improper head positioning. ION was the most common cause of POVL after spinal surgery. ION can be divided into anterior ION and posterior ION depending on the visual field cut and whether edema to the optic disk is present early (anterior ION) or later (posterior ION). Both types are the result of reduced blood flow or oxygen delivery from end-arteriole branches of the ophthalmic artery.

The ASA registry of 93 POVL cases after spinal surgery reported that most patients were relatively healthy and that blood loss greater than 1000 mL and duration in the prone position for longer than 6 hours were present in 96% of the cases. ION occurs in the absence of direct pressure on the eye. In a multicenter case-control study that compared the 80 adult patients with ION in the ASA registry to 315 adult patients who had undergone central spinal fusion without ION, the risk factors for ION identified were obesity, Wilson frame use, length of surgery, blood loss, and decreased colloid use with fluid replacement.[143] Because ION occurred in the absence of vascular injury to other critical organs and in cases in which neither hypotension nor anemia was reported, optic nerve blood supply may be uniquely vulnerable to hemodynamic perturbations in the prone position.

Patients experience considerable pain after multilevel spinal fusions with instrumentation (see also Chapter 98). Most of these patients are initially treated with intravenous opioids, but because of the multiple side effects of

these drugs, a multimodality approach with other agents has been recommended. For lumbar fusions, an epidural catheter placed at a level above the incision can be used for patient-controlled epidural anesthesia infusions of local anesthetics and opioids. For procedures involving more extensive spinal levels, intrathecal morphine administered during surgery has been shown to provide reliable postoperative pain control.[144] NSAIDs may have a negative influence on the success of spinal fusions, however. For opioid-tolerant patients, subanesthetic doses (0.2 mg bolus, then 2 mcg/kg/hr) of ketamine reduced postoperative pain after posterior spine fusions.[145]

Chapter 80

Geriatric Anesthesia

FREDERICK SIEBER • RONALD PAULDINE

Key Points

- An important principle of aging is a progressive loss of functional reserve in all organ systems, with considerable variation from person to person.
- Older patients are more sensitive to anesthetic drugs. Less medication is usually required to achieve a desired clinical effect, and drug effects are often prolonged. Hemodynamic responses to intravenous anesthetics may be exaggerated because of interactions with the aging heart and vasculature.
- The incidence of postoperative delirium is substantially more frequent in patients with preoperative dementia.
- The ability to predict patients at high risk for postoperative delirium has enabled proactive interventions to prevent or attenuate the severity or duration of postoperative delirium. The cornerstone of management of delirium is the recognition and treatment of any predisposing or precipitating factors for delirium.
- Postoperative cognitive dysfunction (POCD) in older patients occurs in the first days to weeks after surgery. POCD is well documented, and early POCD is reversible.
- Perioperative management of depression is a lower priority than management of the patient's more acute medical illnesses.
- Although advance directives can be helpful in perioperative decision making, accurate documentation of advance care planning is often lacking for many older patients.
- In older patients perioperative complications lead to poor outcome. The most important risk factors for perioperative complications in older patients are age, the patient's physiologic status and coexisting disease (American Society of Anesthesiologists class), whether the surgery is elective or urgent, and the type of procedure.
- The success of surgical intervention in geriatric patients depends partly on whether patients can return to their previous level of activity and independence.
- Recognizing acute illness and exacerbation of chronic disease in older adults can be challenging. Not infrequently, acute illness may have an atypical presentation.

Defining and implementing optimal perioperative care for older adults is of increasing importance to all stakeholders in health care, including consumers, insurers, and government agencies. Health care reform legislation has focused an increasing emphasis on cost containment, value, and rigorous assessment of meaningful outcomes for older patients. The demographic considerations are sobering. The U.S. Census 2010 data revealed the number of persons older than 65 years of age in the United States had increased to 40.4 million, with 21.7 million 65 to 74 years old, and 13.1 million 75 to 84 years of age, with 5.5 million over the age of 85 years. The average life expectancy was 78.2 years. It is estimated that by 2030, 20% of U.S. citizens will be older than 65 years. By 2034, baby boomers in the United States will all be over 70 years of age. By 2050 those over 85 years of age will represent 14% of the population over 65 years.[1] Worldwide, nearly 2 billion people will be over 60 years of age.[2]

Older individuals frequently access health care. In 2003, older patients represented roughly 12% of the U.S. population, accounted for one third of all hospitalizations and 43.6% of inpatient hospital charges.[3] Patients 65 years of age and older have surgery at a rate 2 to 3 times that of younger patients and tend to have longer hospital stays.[4]

CORE CONCEPTS IN THE ANESTHETIC MANAGEMENT OF THE OLDER PATIENT

Two important principles must be kept in mind when discussing the physiology of aging. First, aging is associated with a progressive loss of functional reserve in all organ systems. Second, the extent and onset of these changes vary from person to person. In most older patients, physiologic compensation for age-related changes is adequate and underlying limitation in physiologic reserve may become evident only during times of physiologic stress, including exercise, illness, and surgery. Anticipating the interaction of underlying disease, limited end-organ reserve, and the stress of the perioperative period should aid the perioperative physician in providing the best care possible.

MECHANISMS OF AGING

Aging is a universal and progressive physiologic process characterized by declining end-organ reserve, decreased functional capacity, increasing imbalance of homeostatic mechanisms, and an increasing incidence of pathologic processes.[5] Aging is now viewed as an extremely complex multifactorial process with interaction of various pathways to differing degrees and effect.[6] Theories of aging may be grouped into broad categories including evolutionary and physiologic mechanisms. These may also be defined according to the "programmed" or biologic clock theory, in which genetic mechanisms program declining function, and "error" theories, in which environmental damage to processes lead to impaired function and progressive decline. These processes of aging overlap and may be further defined by the organizational level of an organism in which a given process occurs. Changes at one level influence processes at another level. Molecular effects will influence cellular function, which in turn causes alterations in major organ systems and may ultimately exert evolutionary pressure by influencing survival and reproduction. Theories of aging have been reviewed.[5,7] These are summarized in Table 80-1.

CENTRAL NERVOUS SYSTEM

With aging, several important processes occur that are of interest to the anesthesiologist.[8] These changes may be further modified by other underlying pathologic or age-related processes.[9] Memory decline occurs in more than 40% of persons over 60 years of age but is not a universal finding.[10] Importantly, age-related memory decline can dramatically affect performance of the activities of daily living (ADL).

Structurally, a decrease occurs in the volume of both gray matter and white matter in the central nervous system (CNS).[11] Regions of the brain are affected in a selective and differential manner. The decrease in gray matter volume is likely secondary to neuronal shrinkage as opposed to neuronal loss. A small overall loss occurs of neurons from the neocortex.[8] This decrease in neuron number is not as massive as older studies had indicated. Some neocortical areas do not lose any neurons with aging. There may be 15% loss, however, of white matter with aging.[8] These structural changes result in gyral atrophy and increased ventricular size. Shrinkage in the subcortical white matter and hippocampus may be accelerated by hypertension and vascular disease.

Whether the aging process alters the number of synapses present in the cortex is controversial. Data from nonhuman primates suggest significant regional reductions with aging in the neurotransmitters dopamine, acetylcholine, norepinephrine, and serotonin.[12] Levels of glutamate, the primary neurotransmitter in the cortex,

TABLE 80-1 **CLASSIFICATION AND BRIEF DESCRIPTION OF THEORIES OF AGING**

Biologic Level and Theory	Description
Evolutionary	
Mutation accumulation	Mutations that affect health at older ages are not selected against
Disposable soma	Somatic cells are maintained only to ensure continued reproductive success; after reproduction, soma becomes disposable
Antagonistic pleiotropy	Genes beneficial at younger age become deleterious at older age
Molecular	
Gene regulation	Aging is caused by changes in the expression of genes regulating both development and aging
Codon restriction	Fidelity and accuracy of mRNA is impaired as a result of inability to decode codons in mRNA
Error catastrophe	Decline in fidelity of gene expression with aging results in increased fraction of abnormal proteins
Somatic mutation	Molecular damage accumulates primarily to DNA and genetic material
Dysdifferentiation	Gradual accumulation of random molecular damage impairs regulation of gene expression
Cellular	
Senescence-telomere theory	Phenotypes of aging are caused by an increase in frequency of senescent cells as a result of telomere loss or cell stress
Free radical	Damage caused by free radical production from oxidative metabolism
Wear-and-tear	Accumulation of normal injury
Apoptosis	Programmed cell death
System	
Neuroendocrine	Alterations in neuroendocrine control of homeostasis leads to physiologic change
Immunologic	Decline in immune function leads to altered incidence of infection and autoimmunity
Rate-of-living	Assumes a fixed amount of metabolic potential for every living organism (live fast, die young)

Modified from Weinert BT, Timiras PS: Invited review: theories of aging. J Appl Physiol *95:1707, 2003. With permission.*

are not affected. Coupling of cerebral electrical activity, cerebral metabolic rate, and cerebral blood flow remains intact in older individuals.

Although biochemical and anatomic changes have been described in the aging brain, the exact mechanisms causing changes in functional reserve are unclear. Decreases in brain reserve manifest by decreases in functional ADL, increased sensitivity to anesthetic medications, increased risk for perioperative delirium, and increased risk for postoperative cognitive dysfunction (POCD).

Neuraxial changes include a reduction of the area of the epidural space, increased permeability of the dura, and decreased volume of cerebrospinal fluid. The diameter and number of myelinated fibers in the dorsal and ventral nerve roots are decreased in older individuals. In peripheral nerves, inter–Schwann cell distance is decreased, as is conduction velocity. These changes tend to make older individuals more sensitive to neuraxial and peripheral nerve blocks.[13]

CARDIOVASCULAR CHANGES

Primary changes in the vasculature, or arterial aging, cause important secondary changes in the heart and other end organs including the brain and kidney. The process of vascular aging is accelerated by the presence of primary cardiovascular disease, including hypertension and atherosclerosis, as well as other risk factors such as diabetes, tobacco abuse, and obesity. Primary changes in cardiac function also occur with advancing age. Morphologic changes include decreased myocyte number, thickening of the left ventricular wall, and decreases in both conduction fiber density and the number of sinus node cells.[14] Functionally, these changes translate to decreased contractility, increased myocardial stiffness and ventricular filling pressures, and decreased β-adrenergic sensitivity.[14] Breakdown of elastin in the proximal thoracic aorta and proximal branches of the great vessels leads to progressive central aortic dilatation, increased thickness of the arterial wall, and increased vascular stiffness with advancing age.[15] Alterations in nitric oxide–induced vasodilatation also contribute.[16] Functionally, these changes are readily observed in terms of an elevated mean arterial pressure and increased pulse pressure.[17,18]

Increased vascular stiffness leads to important secondary responses in the heart. Functionally, the vascular system acts as both a cushion and a conduit to ensure the mechanically efficient and smooth delivery of blood to the periphery. In youth, the cardiac pump and the blood vessels are optimally coupled to maximize efficiency.[19] With increased resistance in the blood vessels, the velocity of conduction of pulse waves down the vascular tree increases. Increased pulse wave velocity results in earlier reflection of pulse waves from the periphery. In younger humans, wave reflection occurs later as a result of slower propagation such that reflected waves reach the heart after aortic valve closure. This timing preserves pressure in the compliant central aorta, promoting coronary blood flow during diastole. In the setting of increased pulse wave velocity with wave reflection occurring earlier, reflected pulse waves reach the heart during the latter phases of ejection, resulting in an increased cardiac load.[18] Alterations in left ventricular afterload lead to left ventricular wall thickening, hypertrophy, and impaired diastolic filling.[20] Decreased ventricular compliance and increased afterload combine to cause compensatory prolongation of myocardial contraction. This occurs at the expense of decreased early diastolic filling time. Under these conditions the contribution of atrial contraction to late ventricular filling becomes more important and explains why cardiac rhythm other than sinus is often poorly tolerated in older adults and why older patients are often preload sensitive.

Peripheral blood pressure measurements probably do not accurately represent central aortic pressures. In youth, pulse pressure amplification occurs as pulse waves travel down the vascular tree. This is observed as an increase in systolic pressure of 10 to 15 mm Hg between the central aorta and the periphery, with a slight decrease in diastolic and mean pressures. With aging, this is lost, which results in an augmentation of central aortic pressure (Fig. 80-1). Several methods have been described to estimate changes in aortic stiffness. These include noninvasive technologies to measure aortic pulse pressure, pulse wave velocity, and aortic augmentation index.[21] Increased vascular stiffness as assessed by these methods is associated with adverse cardiovascular events.[22,23] Differential responses to drugs with regard to central aortic pressure and peripheral arterial pressure may have important implications for treatment of cardiovascular disease.[21]

Changes in the autonomic system with aging include a decrease in response to β-receptor stimulation and an increase in sympathetic nervous system activity.[24] Decreased β-receptor responsiveness is secondary to both decreased receptor affinity and alterations in signal transduction.[25] Decreased β-receptor responsiveness assumes functional importance when increased flow demands are placed on the heart. Normally β-receptor–mediated mechanisms act to increase heart rate, venous return, and systolic arterial pressure while preserving preload reserve. In contrast, the attenuated β-receptor response in older individuals during exercise and stress is associated with decreased maximal heart rate and decreased peak ejection fraction. This causes the increased peripheral flow demand to be met primarily by preload reserve, making the heart more susceptible to cardiac failure.[14] Sympathetic nervous system activity increases with aging. Although changes in β-receptor responsiveness are well defined, it is controversial whether the aging process alters the α-receptor response. Increased resting sympathetic nervous system activity may contribute to increases in systemic vascular resistance and mechanical stiffening of the peripheral vasculature.[14] This explains in part the exquisite sensitivity of many older patients to interventions that decrease sympathetic tone. Clinically, these autonomic changes lead to a greater likelihood of adverse intraoperative hemodynamic events and decreased ability to meet the metabolic demands of surgery.

Although the age-related changes in cardiovascular physiology are generally well tolerated, several pathophysiologic states deserve mention. Impairment of diastolic relaxation leads to diastolic dysfunction in the aging heart. In its severest form, diastolic dysfunction may manifest as diastolic heart failure, now referred to

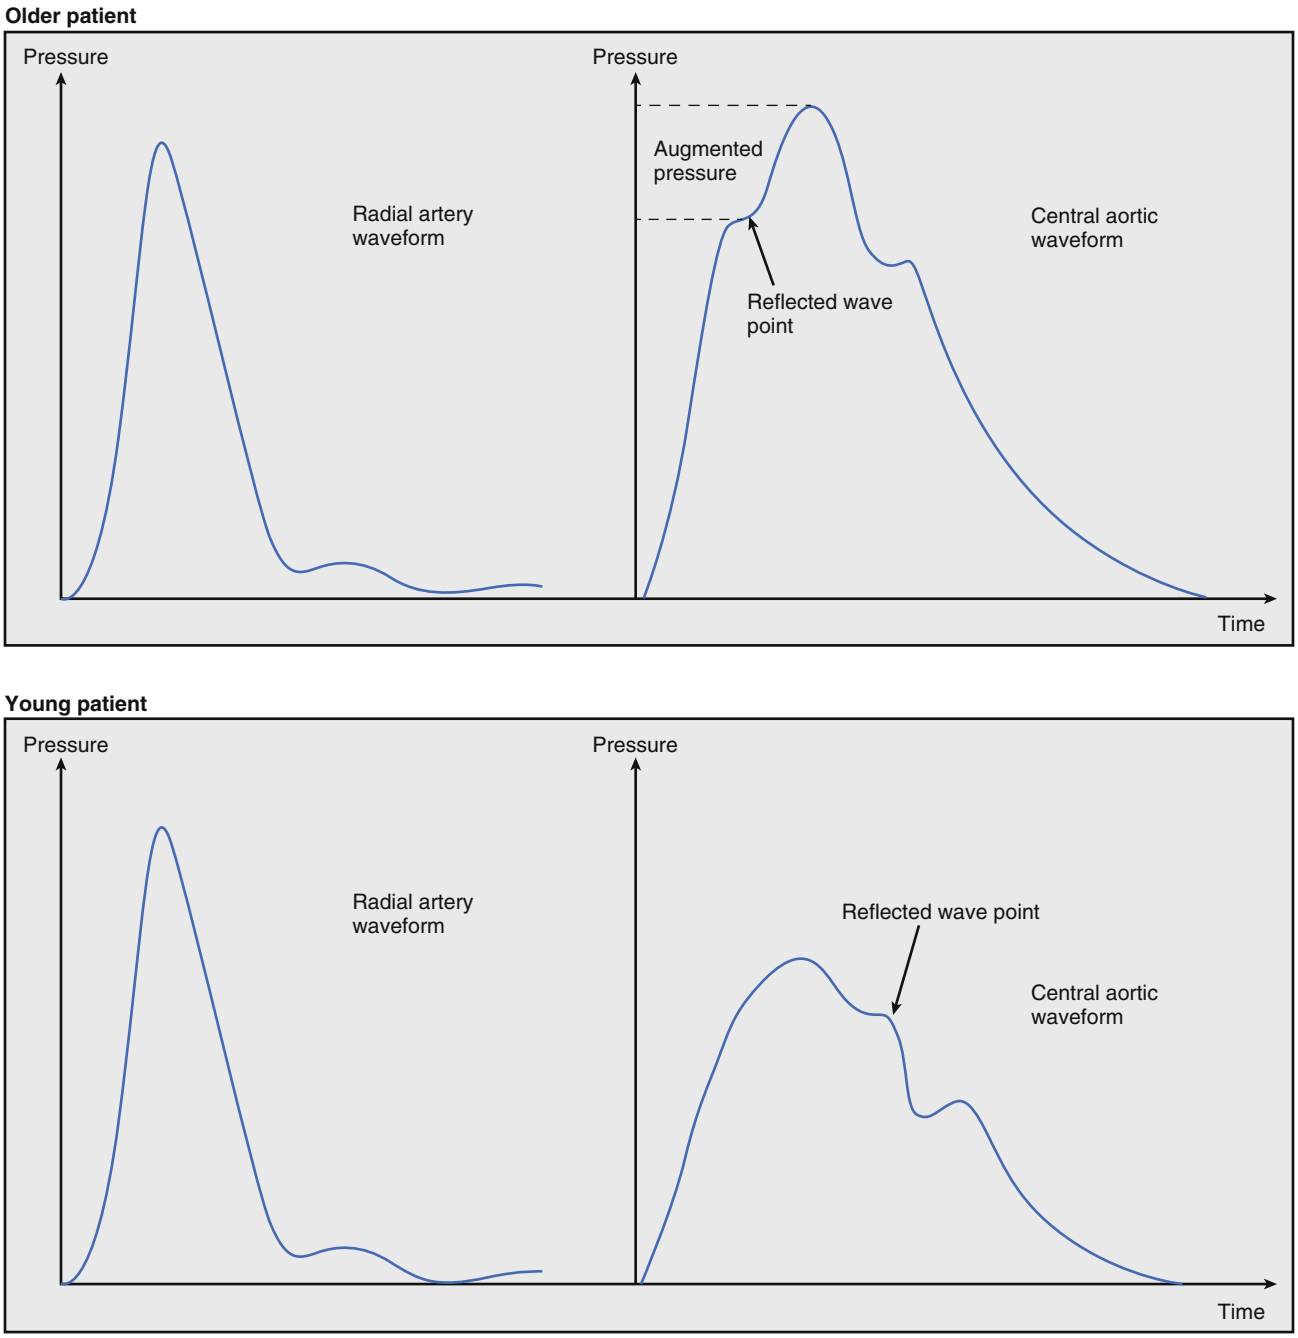

Figure 80-1. Illustration of the influence of increased vascular stiffness on peripheral (radial) and central (aortic) derived pressures. Note the similarity of peripheral radial pressures in individuals with normal (*lower left panel*) and increased (*upper left panel*) vascular stiffness. In young individuals with normal vascular stiffness, central aortic pressures are lower than radial pressures (*lower panels*). In contrast, in older individuals with increased vascular stiffness, central aortic pressures are increased and can approach or equal peripheral pressures as a result of wave reflection and central wave augmentation during systole (*top panels*). *(Redrawn from Barodka VM, Joshi BL, Berkowitz DE, et al: Implications of vascular aging [Review article],* Anesth Analg *112:1048-1060, 2011. With permission)*

as heart failure with preserved ejection fraction (HFpEF). Predisposing disease states for HFpEF include hypertension with left ventricular hypertrophy, ischemic heart disease, hypertrophic cardiomyopathies, and valvular heart disease. HFpEF is twice as prevalent in females.[26] Population-based studies suggest that diastolic dysfunction is common and associated with an increase in all-cause mortality.[27] Furthermore, in patients with clinically evident heart failure, ejection fraction is preserved in over half, with 40% manifesting overt HFpEF. Mortality in the cohort with preserved ejection fraction is similar to that in patients with reduced ejection fraction (HFrEF).[28] The pathophysiologic process includes decreased left ventricular compliance during diastole, resulting in greatly increased left ventricular diastolic pressure with retrograde conduction to the pulmonary circulation, which causes pulmonary venous congestion and pulmonary edema. HFpEF is often related to systemic blood pressure

and does not necessarily imply volume overload. Diagnosis can be difficult because the clinical picture appears identical to that of left ventricular systolic failure. Making the correct diagnosis is important because interventions commonly employed in systolic failure—such as diuretics and inotropes—may exacerbate diastolic dysfunction.[29] Echocardiography is the diagnostic modality of choice. Classically, echocardiography will demonstrate preserved or hyperdynamic left ventricular systolic function and characteristic changes of flow velocity at the mitral valve. Left ventricular systolic dysfunction and diastolic dysfunction often coexist. Pulmonary arterial pressures increase in aging, and HFpEF may be a contributing factor.[30]

Aortic valve sclerosis and mitral annular calcification are common echocardiographic findings in older adults. These represent non–flow-limiting calcifications around the aortic and mitral valves, respectively. Aortic valve sclerosis is common in older individuals and is associated with an increase in the risk for adverse cardiovascular and coronary events.[31]

RESPIRATORY CHANGES

Alterations in control of respiration, lung structure, mechanics, and pulmonary blood flow place older adults at increased risk for perioperative pulmonary complications. Ventilatory responses to hypoxia, hypercapnia, and mechanical stress are impaired secondary to reduced CNS activity.[32] In addition, the respiratory depressant effects of benzodiazepines, opioids, and volatile anesthetics are exaggerated.[32,33] These changes compromise the usual protective responses against hypoxemia after anesthesia and surgery in older patients.

Structural changes in the lung with aging include the loss of elastic recoil after reorganization of collagen and elastin in lung parenchyma. This combined with altered surfactant production leads to an increase in lung compliance. Increased compliance leads to limited maximal expiratory flow and a decreased ventilatory response to exercise.[34] Loss of elastic elements within the lung is associated with enlargement of the respiratory bronchioles and alveolar ducts and a tendency for early collapse of the small airways on exhalation, leading to an increased risk for air trapping and hyperinflation. Progressive loss of alveolar surface area occurs secondary to increases in size of the interalveolar pores of Kohn. The functional results of these pulmonary changes are increased anatomic dead space, decreased diffusing capacity, and increased closing capacity, all leading to impaired gas exchange.

Changes in chest wall compliance result in greater elastic load during inspiration, with an increased work of breathing. Loss of height and calcification of the vertebral column and rib cage leads to a typical barrel chest appearance with diaphragmatic flattening. The flattened diaphragm is mechanically less efficient, and function is further impaired by a significant loss of muscle mass associated with aging.

Although alterations in lung volumes occur with aging, total lung capacity is relatively unchanged. Residual volume increases by 5% to 10% per decade. Therefore, vital capacity decreases. Closing capacity—the volume at which small dependent airways start to close—increases with age. Although functional residual capacity is unchanged or slightly increased, closing capacity is unaffected by body position. Change in the relationship between functional residual capacity and closing capacity causes an increased ventilation-perfusion mismatch and represents the most important mechanism for the increase in the alveolar-arterial gradient for oxygen observed in aging.[35]

TABLE 80-2 NORMAL VALUES FOR ARTERIAL PARTIAL PRESSURE OF OXYGEN

Age (yr)	Mean and Range (mm Hg)
20-29	94 (84-104)
30-39	91 (81-101)
40-49	88 (78-98)
50-59	84 (74-94)
60-69	81 (71-91)

From Nunn J: Nunn's applied respiratory physiology, *ed 4, Oxford, Butterworth-Heinemann, 1995, p 269.*

In younger individuals, closing capacity is less than functional residual capacity. At 44 years of age, closing capacity equals functional residual capacity in the supine position, and at 66 years of age, in the upright position.[35] When closing capacity encroaches on tidal breathing, ventilation-perfusion mismatch occurs. When functional residual capacity is below closing capacity, shunt will increase and arterial oxygenation will fall. This effect is observed in the decreased resting arterial oxygen (O_2) tension with aging and impairs the effectiveness of breathing O_2 before induction of general anesthesia (Table 80-2). Another effect of increasing closing capacity in concert with depletion of muscle mass is a progressive decrease in forced expiratory volume in 1 second (FEV_1) by 6% to 8% per decade. Increases in pulmonary vascular resistance and pulmonary artery pressure occur with age and may be secondary to decreases in the cross-sectional area of the pulmonary capillary bed.[36] Hypoxic pulmonary vasoconstriction is blunted in older adults and may cause difficulty with one-lung ventilation.

Older patients may have an increased sensitivity for bronchoconstriction and a diminished response to treatment with inhaled β-agonists.[37] Alterations in immune responses in older adults may lead to an increased susceptibility to environmental exposure and lung injury.[38]

RENAL AND VOLUME REGULATION

Structural and functional changes occur in the kidney as part of normal aging. Nephrosclerosis is observed with increasing age but may not correlate with decreases in glomerular filtration rate (GFR).[39] Renal blood flow decreases approximately 10% per decade after 40 years of age, with a decline in GFR of 8 mL/min/1.73 m^2 from a baseline of 140 mL/min/1.73 m^2.[40]

With normal aging, serum creatinine remains relatively unchanged in the face of a progressive decrease in creatinine clearance. This occurs because muscle mass also decreases with aging. Therefore, serum creatinine is a poor predictor of renal function in older individuals.[40,41]

This concept is important in proper dosage adjustment for medications excreted by the kidneys.

Functional changes in the kidneys with aging include alterations in response to abnormal electrolyte concentrations and the ability to concentrate and dilute urine.[42] Renal capacity to conserve sodium is decreased. Overall, the older patient has a tendency to lose sodium in the setting of inadequate salt intake. This paired with a decreased thirst response may place the older patient at risk for dehydration and sodium depletion. The older patient also has a diminished ability to respond properly to an increased salt load, as evidenced by increased sodium retention and expansion of the extracellular volume during the perioperative period. This change assumes importance under conditions of limited fluid intake.

HEPATIC CHANGES

Liver volume decreases approximately 20% to 40% with aging. Hepatic blood flow decreases approximately 10% per decade.[43] A variable decrease occurs in the liver's intrinsic capacity to metabolize drugs. Effects on phase I reactions predominate. Decreases in hepatic blood flow may decrease maintenance dose requirements in drugs that are rapidly metabolized. The pharmacokinetics of drugs that are slowly metabolized are more affected by innate liver capacity than blood flow.[44]

COGNITIVE ISSUES IN OLDER ADULTS

DEMENTIA

Dementia is common in the geriatric population. In the population 65 years of age and older, 5% to 8% of people experience dementia. For those 75 years of age and older, 18% to 20% suffer dementia. For individuals over 85 years of age, more than one third may have dementia.[45] Dementia has many causes, with Alzheimer disease accounting for the majority of cases. The main perioperative management issues concerning the demented patient include detection, informed consent, possible anesthetic interactions causing delayed emergence, postoperative delirium, pain management, and increased mortality.

Many instruments of varying length are available to test for cognitive impairment.[46] However, accurate diagnosis of dementia is not always easy. For dementia screening, the AD8, an 8-item questionnaire that distinguishes between people who have dementia and people who do not, is a quick and reliable instrument.[47] For preoperative evaluation of baseline cognitive status, rather than detection of dementia, the Short Blessed Test allows for quick screening.[48] In addition, insight may be gained by speaking with the patient's family concerning baseline function and ADL. Some of the instruments for testing cognition may be used to help guide the physician in determining the patient's capacity to consent.[49]

The patient with dementia may display one of a number of psychiatric symptoms, including agitation, depression, and sleep disturbances.[50] Many of the drugs used to manage dementia and its symptoms interact with general anesthetics,[51] causing delayed emergence. It is unclear whether use of the bispectral index (BIS) monitor (see also Chapter 50) or other processed electroencephalography methods for guidance of drug administration is helpful because dementia does alter baseline BIS values.[52] When determining an anesthetic plan, no anesthetic technique or drug has been shown to be superior in older patients. However, patient cooperation may be an issue with regional anesthesia (see also Chapters 56 and 57).

Dementia is critical in risk stratification for postoperative delirium. The incidence of postoperative delirium is substantially more frequent in individuals with preoperative dementia than in those without.[53]

Pain management in the patient with dementia is challenging for several reasons (see also Chapter 98). Pain assessment can be difficult.[54] Despite use of the best available pain assessment instruments, decreased pain scores and opioid administration occur postoperatively in patients with dementia.[55] Pain management can be more nursing intensive because patient-controlled analgesia often is not an option in these patients. Furthermore, the clinician must maintain a delicate balance between opioid CNS effects and the role of poorly treated pain in precipitating delirium.[56,57]

Dementia has many associated comorbidities, including vascular disease, diabetes, alcoholism, and neurodegenerative disease (e.g., Parkinson, Huntington). Dementia is associated with a 2.18 (1.10 to 4.32) relative risk for developing a patient-related adverse event during an unplanned acute hospital admission.[53,58] Long-term postoperative mortality is related to the presence of dementia,[59] with the severity of cognitive impairment being associated with higher mortality.[60]

Whether general anesthesia accelerates the progression of senile dementia is controversial.[61,62] Certainly, much evidence exists both in vitro and in animal models suggesting that inhaled anesthetics enhance amyloid β oligomerization,[63] increase plaque density in transgenic mice (human *APP* gene),[64] induce caspase-3 activation (one of the final steps of apoptosis), and increase amyloid β protein (Aβ) levels in cell culture.[65] However, in humans, recent retrospective data suggest that long-term cognitive decline is neither independently attributable to surgery (and anesthesia) or illness, nor have surgery (and anesthesia) or illness been associated with accelerated progression of dementia.[66,67] Unfortunately, no prospective human data convincingly answer this question. Thus, the relationship between anesthetic exposure and accelerated progression of dementia remains unclear; "Available human studies on anesthesia and Alzheimer disease are inconclusive because they are under-powered or confounded by coincident illness, independent risk factors for dementia and, of course, surgery."[68]

DELIRIUM

The overall prevalence of delirium in older patients after surgery has been estimated to be 10%.[69] The incidence of postoperative delirium in older patients varies widely depending on the type of surgery, underlying comorbidities, and intensive care unit (ICU) stay. For

instance, cardiac surgery and hip fracture repair may have an increased incidence over that of other procedures.[69] Delirium occurs in 60% to 80% of patients in the ICU.[70]

Postoperative delirium has profound financial implications. Delirium is associated with prolonged hospital stay, increased incidence of nursing home placement, and an increased incidence of postoperative complications.[71] Overall 2 to 3 million older patients per year sustain delirium during their hospital stay, involving more than 17.5 million inpatient days.[70] The total direct 1-year health costs attributable to delirium range from $143 billion to $152 billion nationally.[72] Adding to these costs, the occurrence of postoperative delirium is associated with an accelerated trajectory of cognitive decline in patients with underlying dementia.[73]

Delirium and POCD are not the same. Postoperative delirium is an acute confusional state with alterations in attention and consciousness. On the other hand, POCD is a decline in a variety of neuropsychological domains (e.g., memory, executive function, speed of processing). Delirium is a syndrome characterized by acute onset of variable and fluctuating changes in level of consciousness accompanied by a range of other mental symptoms. By convention, the presence or absence of delirium is based on application of diagnostic criteria articulated in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV): "The essential feature of a delirium is a disturbance in consciousness that is accompanied by a change in cognition that cannot be better accounted for by a preexisting or evolving dementia"[74] (Box 80-1). Postoperative delirium may have several presentations with the hyperactive ("wild man"), hypoactive ("out of it"), and mixed (hypoactive alternating with hyperactive) presentations accounting for 1%, 68%, and 31% of cases, respectively.[75]

Several instruments are available to diagnose delirium. The Confusion Assessment Method (CAM)[76] is the most widely used instrument in North America. The CAM is a bedside rating scale developed to assist clinicians not trained in psychiatry in the rapid and accurate diagnosis of delirium in clinical settings. The CAM is designed to be administered by any clinician, including physicians or nurses, and may be administered by trained lay interviewers. Geriatricians, nurses, and trained lay interviewers perform as well as psychiatrists in rating the CAM.[77] The sensitivity of the CAM against the gold standard of psychiatric diagnosis is 94% to 100%, with specificity 90% to 95%.[76] The CAM-ICU has been adapted for measuring delirium in ventilated patients in the ICU.[78]

Many possible pathophysiologic mechanisms can account for delirium. Delirium may be associated with inflammatory mediators or alterations in one of several neurotransmitter systems.[79] Although we do not yet fully understand the basic mechanisms of delirium, in the geriatrics paradigm, delirium epitomizes an atypical presentation of disease[80] in which acute illness is manifested in the most vulnerable organ system, or "the weakest link"—in this case, the brain. This theory holds that the normal aging process can be characterized as homeostenosis, the progressive constriction of each organ system's ability to respond to stress.[81] In addition, the aging brain is more likely to be affected by diseases and drugs that cloud the sensorium. The sum of these effects leads some older adults to be teetering on the brink of neurodysfunction. Add any stressor, and these individuals develop acute worsening of their mental status. Based on the concept that "lack of brain reserve" predisposes older patients to delirium when exposed to stress, investigators have examined which preexisting vulnerability factors predispose older patients to delirium.

In medical patients, Inouye and Charpentier[82] developed a risk model for delirium that showed that the greater the number of preexisting vulnerability factors, the less acute are the stressors required to invoke delirium. The important preexisting vulnerability factors defined in the medical model of delirium are advanced age, visual impairment (visual acuity <20/70), severe illness (apache score >16), cognitive impairment (Mini–Mental State Examination score <24), and dehydration (blood urea nitrogen-to-creatinine [BUN/Cr] ratio ≤18). Kalisvaart and associates[83] attempted to validate the medical risk factor model of delirium in older patients who have had hip surgery. Their study showed the usefulness of the medical risk factor model in predicting postoperative delirium in surgery patients and supports the concept that when more preexisting vulnerability factors are present, a more frequent risk is seen for postoperative delirium.

The ability to predict patients at high risk for postoperative delirium has enabled the clinician to enact proactive interventions to prevent or attenuate the severity or duration of postoperative delirium. Thus, a cornerstone of management of delirium is the recognition and treatment of any predisposing or precipitating factors for delirium (Box 80-2). Interventions consisting of standardized protocols for the management of known risk factors for delirium (e.g., cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration) result in significant reductions in the number and duration of episodes of delirium in hospitalized older patients.[84] Another simple, nonpharmacologic intervention helpful in delirium prevention is early proactive geriatric consultation in the medical

BOX 80-1 ***Diagnostic and Statistical Manual of Mental Disorders IV Diagnostic Criteria for 293.0 Delirium***

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention
B. A change in cognition (e.g., memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia
C. The disturbance develops over a short time (usually hours to days) and tends to fluctuate during the course of the day
D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiologic consequences of a general medical condition

BOX 80-2 ***Predisposing and Precipitating Factors for Postoperative Delirium***

Demographic characteristics: Age older than 65 years, male
Cognitive impairment or depression
Functional impairment
Sensory impairment, especially visual and hearing
Decreased oral intake
Drugs: Polypharmacy, alcoholism, psychoactive, sedatives, opioids, anticholinergic
Comorbidity: Severe illness and neurologic disease
Some types of surgery: High-risk surgery (American Heart Association guidelines) and orthopedic surgery
Intensive care unit admission
Pain
Sleep deprivation
Immobility or poor physical condition

Modified from Inouye SK: Delirium in older persons. N Engl J Med *354:1157-1165, 2006.*

management of patients.[85] More recent studies have examined prophylactic administration of antipsychotics in high-risk patients. Both haloperidol and the atypical antipsychotics may have some efficacy when used in this capacity.[86,87] Anesthetic-specific interventions include correction of metabolic and electrolyte disorders and perioperative continuation of pharmacologic therapy for neuropsychiatric disorders. Other interventions may be aimed at decreasing exposure to any known pharmacologic drugs triggering delirium (e.g., opioids, benzodiazepines, dihydropyridines, antihistamines).[88] Type of anesthesia (regional versus general) and intraoperative hemodynamic complications have not been associated with delirium.[89,90] However, the incidence of postoperative delirium may be decreased by using lighter levels of sedation during regional anesthetic techniques.[91]

An increased incidence of delirium occurs with larger intraoperative blood loss, more postoperative blood transfusions, and postoperative hematocrit less than 30%.[89] However, recent randomized controlled trials have found no impact of blood transfusion strategy on severity or incidence of delirium.[92]

Systematic reviews of postoperative pain management with opioids demonstrate that meperidine is the only opioid consistently associated with delirium.[93] No difference in cognitive outcome is seen when comparing fentanyl, morphine, and hydromorphone. In addition, no difference in cognitive outcome is noted when comparing epidural and intravenous opioid administration.[93] Two important pain management techniques associated with decreased incidence of postoperative delirium include the use of peripheral nerve blockade[94] and the use of multimodal pain therapy featuring gabapentin.[95] One might also consider opioid rotation, a well-described approach to decreasing opioid-induced delirium in the management of cancer pain.[96] (See also Chapters 98 and 99.)

Should delirium occur despite preventive measures, it is important to first provide supportive care and focus on prevention of complications. Next, the clinician should diligently search for and treat any underlying precipitating medical causes. If pharmacologic intervention is needed, algorithms for pharmacologic treatment of delirium have been outlined in several more recent reviews.[97] Typical and atypical antipsychotics are similar in efficacy for the treatment of delirium, with the atypical agents having fewer extrapyramidal side effects.[98]

POSTOPERATIVE COGNITIVE DYSFUNCTION

Short-term changes in cognitive test performance during the first days to weeks after surgery are well documented and typically involve multiple cognitive domains, such as attention, memory, and psychomotor speed (see also Chapter 99). POCD is important because it affects quality of life and has significant social and financial implications.[99]

Unfortunately, POCD is not a formally recognized condition with DSM criteria. Rather, the criteria for POCD are based on changes between preoperative and postoperative scores on a set of neuropsychological tests that evaluate a broad range of cognitive domains.[100] The time point at which POCD is said to exist has not been clearly defined. In addition, patient subjective complaints of POCD have not always been borne out by objective testing. The most important risk factor for POCD is increasing age.[101] In comparing all age groups, POCD is clearly more frequent in older individuals.[102]

Initial uncontrolled observational studies in patients undergoing coronary artery bypass graft (CABG) procedures reported a 36% incidence of cognitive decline at 6 weeks and a 42% incidence of cognitive decline at 5 years postoperatively (see also Chapter 67).[103,104]

However, later investigations addressing the issue of neurocognition and CABG procedures, including comparison with nonsurgical control groups, concluded that long-term POCD may result from factors other than anesthesia and surgery. First, patients with underlying coronary artery disease, regardless of whether they undergo surgery, have lower baseline cognitive test scores than controls without coronary artery disease.[105] Second, long-term cognitive outcome of on-pump and off-pump CABG is similar.[106] Third, long-term neurocognitive performance in CABG and nonsurgical controls with comparable coronary artery disease is similar.[107] These data suggest that the cause of long-term cognitive changes after anesthesia and surgery may be related to underlying cerebrovascular disease risk factors. However, in contrast to the studies mentioned previously, other investigators report that cardiovascular risk factors are not predictive of POCD.[108] The reported incidence of cognitive dysfunction after major noncardiac surgery in patients older than 65 years of age is 26% at 1 week and 10% at 3 months.[100]

Postoperative cognitive decline after major noncardiac surgery is reversible in most cases, but may persist in approximately 1% of patients.[109] Chronic POCD is important to identify because of its association with more frequent 1-year mortality.[102] The identified risk factors for long-term POCD after noncardiac surgery include age (odds ratio [OR] 2.58 [1.42 to 4.70]), infectious complication in the first 3 months postoperatively (OR 2.61 [1.02 to 6.68]), and POCD at 1 week postoperatively (OR 2.84 [1.34 to 5.96]).[109]

POCD has been attributed to multiple causes. The most likely causative elements include medications, surgery, or issues with the patient. Whether anesthesia contributes to long-term POCD is controversial and an area of intense clinical and laboratory investigation.[110] Studies comparing coronary angiography (sedation) versus total hip replacement versus CABG report similar incidence of POCD at 3 months in all three groups, suggesting that POCD may be independent of both surgery and anesthesia.[108] The cause of long-term POCD may be more related to underlying patient comorbidities than other factors. Minimal cognitive impairment could be a risk factor for postoperative cognitive deficits.[111] Similarly, in orthopedic surgery, dementia is a risk factor for POCD.[112] Future studies examining underlying minimal cognitive impairment may help better define patients at risk for long-term POCD.

In conclusion, current evidence suggesting POCD occurs in the first days to weeks after surgery is well documented, especially in older patients. For the most part, this early POCD is reversible. However, in a small percentage of patients, POCD may persist. Unfortunately, no well-defined anesthesia best practice to prevent POCD has been determined. The regional versus general anesthesia approach shows no difference in POCD incidence, and no anesthetic drug is associated with less POCD. At present no specific treatment for POCD is available.

DEPRESSION

Depression is estimated to occur in 8% to 16% of the community-dwelling population over the age of 65 years.[113] Preoperative depression is an independent predictor of postoperative delirium.[114] Depression predicts greater risk for major adverse cardiac events.[115] After CABG, preoperative and persistent postoperative depression carry an increased risk for death over that of patients without depression.[116]

Antidepressants should be continued during the perioperative period because their cessation may increase symptoms of depression and confusion.[117] Perioperative management of depression is a lower priority than management of the patient's more acute medical illnesses. However, preoperative assessment of mood and cognition is important for baseline data to provide the practitioner with a yardstick to measure against when evaluating postoperative delirium, dementia, or depression.

CONSENT, SURROGATE DECISION MAKERS, AND ADVANCE DIRECTIVES

Issues of consent and end-of-life decisions for older adults are complex and familiar to the practicing anesthesiologist. The most important principle in health care decision making for older patients is autonomy.[118] However, autonomy implies mental competence. The legal standards for competence include the abilities to communicate a choice, understand relevant information, appreciate the current situation and its consequences, and manipulate information rationally.[119] Cognitive and sensory difficulties frequently jeopardize informed consent in frail older patients. Dementia, depression, hearing difficulties, and stroke all may interfere with the ability to make independent decisions. If one's ability to make decisions becomes severely impaired, a surrogate must give consent. However, caution must be exercised in this situation. A low rate of agreement has been demonstrated when comparing the health care decisions made by surrogates and the desires of the older patients involved.[120]

Advance directives, when available, can be extremely helpful, but even with them, difficult problems remain. Accurate documentation of advance care planning is often lacking.[121] Patients presenting to the operating room with "do not resuscitate" orders are an increasingly common problem reviewed recently.[122] The presence of "do not resuscitate" status does not appear to influence short-term surgical outcome.[123,124]

RISK ASSESSMENT AND PREOPERATIVE EVALUATION

THE ROLE OF COMPLICATIONS

Increased life expectancy, safer anesthesia, and less invasive surgical techniques have made it possible for a greater number of geriatric patients to be considered for surgical intervention (see also Chapter 38). Although it is possible to safely manage older surgical patients during the perioperative period, surgical mortality and morbidity are increased in this patient population.[125] Many factors contribute to surgical morbidity and mortality,[126] but in older patients, perioperative complications are directly related to poor outcome.[127] Major perioperative complications increase with age[128] and are associated with more frequent mortality.[129] The most important risk factors for perioperative complications in older adults are age, physiologic status, and coexisting disease (American Society of Anesthesiologists [ASA] class), whether the surgery is elective or urgent, and the type of procedure.

How does aging alter surgical risk? The association between age and surgical risk is related to the aging process and its ongoing decrease in functional organ reserve and associated increased incidence of chronic systemic disease processes. It is difficult to disentangle the effects of aging alone from those caused by concurrent disease. Acute and chronic pathologic insults occur in the setting of a decreased physiologic reserve that can have profound effects on the usual compensatory mechanisms. These factors become especially confusing in considering perioperative risk in older patients. Extremes of age do incur additional risk. For instance, when compared with younger patients, patients 90 years of age or older are more likely to die during hospitalization after hip fracture repair.[130] However, chronologic age is a less important risk factor for complications than the sum of underlying comorbidities.[131] Thus, age alone should not necessarily be a deterrent from surgery.

Emergency surgery is an independent predictor of adverse postoperative outcomes in older surgical patients undergoing noncardiac surgery.[131,132] Poorer preoperative physiology and preparation has a large influence on these results. Emergent care presents special problems,

such as atypical presentations, alterations in the pulmonary and circulatory system, and fluid and electrolyte balance changes secondary to modifications in metabolic needs and body composition with aging that complicate resuscitation.

Surgical mortality in older patients varies widely according to procedure.[133] The fact that risk varies widely depending on the type of surgery is well recognized. The current guidelines for cardiovascular evaluation of patients undergoing noncardiac surgery provide a useful means of categorizing procedures into those of low, intermediate, and high risk.[134]

PREOPERATIVE EVALUATION

Age and Age-Related Disease

Several principles should be kept in mind when performing preoperative evaluation of the geriatric patient (see also Chapter 38). First, a high index of suspicion is necessary for disease processes commonly associated with aging. Common diseases of older adults may have a major impact on anesthetic management and require special care and diagnosis. Second, of the many types of postoperative complications that may occur in older individuals, neurologic, pulmonary, and cardiac morbidities are the most common,[135] and the anesthesiologist should pay attention to these specific organ systems (anesthetic physiology of cardiovascular disease, neurologic, and pulmonary disorders is discussed in Parts VI and V of this edition). Third, the degree of functional reserve of specific, pertinent organ systems—as well as the patient as a whole—should be assessed before surgery. Laboratory and diagnostic studies, history, physical examination, and determination of functional capacity should attempt to evaluate the patient's physiologic reserve. This will help better predict how the patient will manage the stress of surgery and anesthesia.

Functional Status and Assessment of Functional Reserve

The greatest concern of older patients and the most important outcome in determining the success of surgical intervention in geriatric patients is whether patients can return to their previous level of activity and independence. Evidence suggests that the current level of function is helpful in predicting long-term outcomes in medical patients.[136] A variety of instruments are available to evaluate functional activity[137] and health-related quality of life.[138] Commonly used screening tools for determining patient independence and functional level for the preoperative assessment are the ADL and instrumental activities of daily living (IADL) checklists. ADL represents activities involved in physical day-to-day self-care, and the IADL represents more complex tasks. These instruments are useful for indicating specifically how a person is performing at the present time. When they are used longitudinally over time, they serve as documentation of a person's functional improvement or deterioration. IADL and ADL assessments are important for their predictive ability. For instance, any ADL impairment is associated with a relative risk of 1.9 (1.2 to 2.9, 95% confidence interval [CI]) for 90-day mortality in medical patients. Any IADL impairment is associated with a relative risk of 2.4 (1.4 to 4.2, 95% CI) for 90-day mortality in medical patients.[136] Furthermore, any impairment of one to two ADL is associated with a 1.47 (1.08 to 2.01, 95% CI) hazard ratio of recovering independent function from a disability.[139]

Frailty

Frailty refers to a multisystem loss of physiologic reserve that makes a person more vulnerable to disability during and after stress. It is a clinical syndrome characterized by weight loss, fatigue, and weakness. Chronic inflammation and endocrine dysregulation appear to be key drivers in the underlying pathophysiology of this process.[140-143] The components of the frailty syndrome include mobility, muscle weakness, poor exercise tolerance, unstable balance, and factors related to body composition such as weight loss, malnutrition, and muscle wasting[143,144] (Box 80-3). The incidence of frailty in the community-dwelling population older than 65 years of age is approximately 6.9%.[145]

Frailty is a prognostic factor for poor outcomes.[145,146] When followed over a period of 3 years, frailty is predictive of disability, hospitalization, and death. Studies in various

BOX 80-3 *Criteria Used to Define Frailty**

Weight Loss Criterion

The patient is asked the question, "In the last year, have you lost more than 10 lb unintentionally (i.e., not as a result of dieting or exercise)?"

Patients answering "Yes" are categorized as frail by the weight loss criterion.

Exhaustion Criterion

The patient is read the following two statements: (1) I felt that everything I did was an effort; (2) I could not get going. The question is asked, "How often in the last week did you feel this way?" The patient's response is rated as follows: 0 = rarely or none of the time (<1 day); 1 = some or little of the time (1 to 2 days); 2 = a moderate amount of the time (3 to 4 days); or 3 = most of the time.

Patients answering "2" or "3" are categorized as frail by the exhaustion criterion.

Physical Activity Criterion

The patient is asked about weekly physical activity.

Patients with low physical activity are categorized as frail by the physical activity criterion.

Walk Time Criterion

The patient is asked to walk a short distance and timed.

Patients who are slow walkers are categorized as frail by the walk time criterion.

Grip Strength Criterion

The patient's grip strength is measured.

Patients with decreased grip strength are categorized as frail by the grip strength criterion.

Modified from Fried LP, Tangen CM, Walston J, et al: Frailty in older adults: evidence for a phenotype. J Gerontol A Biol Sci Med Sci *56:M146-M156, 2001.*

*Frailty is defined as a clinical syndrome in which three or more of the frailty criteria are met.

surgical populations have identified frailty as an independent risk factor for major morbidity, mortality, protracted length of stay, and institutional discharge.[147-151]

SPECIAL PERIOPERATIVE CONSIDERATIONS FOR THE OLDER PATIENT

ATYPICAL PRESENTATION OF DISEASE

Recognizing acute illness and exacerbation of chronic disease in older adults can be challenging. Not infrequently, acute illness may have an atypical presentation.[152] For instance, the appearance of pneumonia in the older patient may be heralded by such uncharacteristic features as confusion, lethargy, and general deterioration of condition.[153,154] Significant differences may be seen in the presentation of disease in patients who have dementia and those who do not. The nonspecific presentation of disease in older people is primarily linked to the presence of dementia rather than a characteristic feature of the aging process.[155]

POLYPHARMACY

Polypharmacy occurs in 61% of acutely hospitalized older patients.[156] The number of medications used is directly proportional to the likelihood of having an adverse drug reaction. The anesthesia provider must be familiar not only with potential interactions between the medications a particular patient is taking but also clearly must understand the interaction with medications introduced in the perioperative period.

MALNUTRITION, IMMOBILITY, AND DEHYDRATION

In the community-dwelling aged population, malnutrition has been reported to occur in 16.9% of females and 11.4% of males.[84] Among the acutely hospitalized older patients, the prevalence of malnutrition is 52%.[156] Surgical patients who are malnourished have increased morbidity, mortality,[157] and length of stay.[158] No uniformly accepted definition of malnutrition in older adults has been determined.[159] The diagnosis of malnutrition should be made on the basis of both preoperative history and physical and laboratory tests.

Bed rest induces loss of skeletal muscle, which may influence functional capacity.[160] Bed rest also leads to ventricular atrophy, hypovolemia, and orthostatic intolerance.[161] In 2008, dehydration accounted for greater than 99,000 Medicare admissions.[162] Dehydration is often associated with hypernatremia and accompanied by infection.

TRAUMA

The leading cause of traumatic injury and death in the population over 65 years of age is unintentional falls (see also Chapter 81).[163] Substance abuse, particularly alcohol, is often an underappreciated factor in these events.[164,165] Alcohol disorders may be present in 5% to 14% of older patients in the emergency department.[166]

Falls are a common problem both in and out of the hospital. As with any traumatic injury, prevention is the primary goal. Simple interventions, including identifying patients at risk, physical therapy, modification of the environment, and avoiding medications associated with orthostatic hypotension, may mitigate risk.[167] Age is associated with increased mortality with many types of traumatic injuries. This may result from a variety of factors, including decreased reserve, comorbidity, and multiple medications, particularly anticoagulants. For instance, mortality and functional outcome after head injury is considerably worse in older patients with preinjury anticoagulation or antiplatelet therapy.[168,169]

The American College of Surgeons has recognized that older patients should have a lower threshold for transport to a trauma center.[170] However, evidence exists that older patients are often undertriaged. This may occur as a result of inaccuracy of standard criteria in this population or to an age bias in referral patterns.

CHRONIC PAIN

Chronic pain occurs in 25% to 50% of community-dwelling older persons (see also Chapter 64).[171] Surveys of nursing home residents show arthritis is the most prevalent indication for analgesics (41.7% of residents), followed by bone fracture (12.4%) and other musculoskeletal conditions (9.7%). More residents (76.8%) have chronic pain than acute pain (19.9%), and 3.0% have both chronic and acute pain.[172]

Chronic pain is frequently undetected, and the current use of pain medication should be reviewed.[173] The consequences of persistent pain in older patients are numerous and include depression, sleep disturbance, and impaired ambulation.[171]

ANESTHETIC MANAGEMENT

CLINICAL PHARMACOLOGY

Factors that affect the pharmacologic responses of older patients are well described and include changes in plasma protein binding, body content, drug metabolism, and pharmacodynamics.

The main plasma binding protein for acidic drugs is albumin and for basic drugs is α_1-acid glycoprotein. The circulating level of albumin decreases with age, whereas α_1-acid glycoprotein levels increase. The effect of alterations in plasma binding protein on drug effect depends on which protein the drug is bound to and the resulting change in fraction of unbound drug. The relationship is complex, and, in general, changes in plasma binding protein levels are not a predominant factor in determining how pharmacokinetics are modified with aging.

Changes in body composition with aging reflect a decrease in lean body mass, an increase in body fat, and a decrease in total body water. We might infer that a decrease in total body water could lead to a smaller central compartment and increased serum concentrations after

bolus administration of hydrophilic drugs. The increase in body fat might result in a greater volume of distribution, with the potential to prolong the clinical effect of lipophilic medications.[174,175]

As discussed previously, alterations in both hepatic and renal clearance occur with aging. Depending on the degradation pathway, decreases in liver and kidney reserve can affect a drug's pharmacokinetic profile.

The clinical response to anesthetic medications in older adults may be the result of alterations in sensitivity of the target organs (pharmacodynamics). A given anesthetic's physical properties and alterations in receptor numbers or sensitivity will determine the relative influence of pharmacodynamic alterations on anesthetic effect in older patients. Generally, older individuals are more sensitive to anesthetic drugs. Less medication is usually required to achieve a desired clinical effect, and drug effect is often prolonged. Undesired hemodynamic perturbations also tend to occur more frequently and in greater magnitude. Hemodynamic responses to intravenous anesthetics may be exaggerated as a result of interactions with the aging heart and vasculature. Expected compensatory or reflex responses are often blunted or absent because of physiologic changes associated with normal aging and age-related disease. Regardless of the cause of altered pharmacologic effect, the aged patient usually requires a downward adjustment in medication dose.

CLINICAL PHARMACOLOGY OF SPECIFIC AGENTS

Table 80-3 summarizes the clinical pharmacology of anesthetic drugs in older patients.

TABLE 80-3 CLINICAL PHARMACOLOGY OF ANESTHETIC AGENTS IN OLDER PATIENTS

Drug	Brain Sensitivity	Pharmacokinetics	Dose
Inhaled agents	↑	—	↓
Thiopental	—	↓Initial distribution volume	↓
Etomidate	—	↓ Initial distribution volume ↓ Clearance	↓
Propofol	↑	↓ Clearance	↓
Midazolam	↑	↓ Clearance	↓

Inhaled Anesthetics

The minimum alveolar concentration (MAC) decreases approximately 6% per decade for most inhalation anesthetics. A similar pattern is observed for MAC-awake.[176] The mechanism of action of inhalation anesthetics is related to altered activity of neuronal ion channels associated with nicotinic, acetylcholine, γ-aminobutyric acid ($GABA_A$), and glutamate receptors. Perhaps with aging, alterations in ion channels, synaptic activity, or receptor sensitivity may occur to account for these changes in pharmacodynamics.

Intravenous Anesthetics and Benzodiazepines

Although thiopental is not often used in modern anesthesia, certain pharmacologic principles are important (see also Chapter 30). No change in brain sensitivity to thiopental occurs with age,[177] yet the dose of thiopental required to achieve anesthesia decreases with age. The age-related decrease in thiopental dose is related to an age-related decrease in the initial distribution volume of the drug. The decrease in initial distribution volume results in higher serum drug levels after a given dose of thiopental in older patients.[177] Likewise, in the case of etomidate, age-dependent changes in pharmacokinetics (decreased clearance and initial volume of distribution) rather than altered brain responsiveness account for the decrease in etomidate dose requirement in the older patient.[178] The brain becomes more sensitive to the effects of propofol with age.[179] In addition, clearance of propofol is reduced. These additive effects are associated with a 30% to 50% increased sensitivity to propofol in older adults.[174]

The dose requirement of midazolam to produce sedation during upper gastrointestinal tract endoscopy is decreased approximately 75% in older patients.[180] These changes are related to both increased brain sensitivity and decreased drug clearance.[181]

Opiates

Age is an important predictor of postoperative morphine requirements, with older patients needing less drug for pain relief (see also Chapter 31).[182] Morphine and its metabolite morphine-6-glucuronide have analgesic properties. Morphine clearance is decreased in older adults.[183]

Morphine-6-glucuronide depends on renal excretion.[184] Patients with renal insufficiency may have impaired elimination of morphine glucuronides, and this may account for some of the enhanced analgesia from a given dose of morphine in the older patient.[185]

Shafer[174] provided a comprehensive review of the pharmacology of sufentanil, alfentanil, and fentanyl in older patients. Sufentanil, alfentanil, and fentanyl are approximately twice as potent in older patients. These findings are primarily related to an increase in brain sensitivity to opioids with age, rather than alterations in pharmacokinetics.

Aging is associated with changes in both the pharmacokinetics and pharmacodynamics of remifentanil. An increase in brain sensitivity to remifentanil occurs with age. Remifentanil is approximately twice as potent in

the older adults, and half the bolus dose is required.[186] The volume of the central compartment, V1, and clearance decrease with age, and approximately one-third the infusion rate is required in the older adult.[186]

Neuromuscular Blocking Drugs

Generally, age does not significantly affect the pharmacodynamics of muscle relaxants (see also Chapter 34). Duration of action may be prolonged, however, if the drug depends on liver or renal metabolism. One would expect that pancuronium clearance would decrease in older patients because of its dependence on renal excretion. Yet, changes in pancuronium clearance with aging are controversial.[187,188] Atracurium depends to a small extent on hepatic metabolism and excretion, and elimination half-life is prolonged in older individuals. Clearance is unchanged with age, suggesting that alternative pathways of elimination (ester hydrolysis and Hofmann elimination) assume importance in older patients.[189] Cisatracurium undergoes Hofmann degradation and is unaffected by age. Plasma clearance of vecuronium is slower in older patients.[188] The age-related prolonged duration of action of vecuronium may reflect decreases in renal or hepatic reserve.[190] Rocuronium is associated with a prolonged duration in older patients, and recovery after administration of sugammadex may be delayed.[191,192]

Neuraxial Anesthesia and Peripheral Nerve Blocks

Age has no effect on duration of motor blockade with bupivacaine spinal anesthesia (see also Chapter 56).[193] The time of onset is decreased, however, and spread is more extensive with hyperbaric bupivacaine solution.[193,194] Effects of age on duration of epidural anesthesia have not been determined with 0.5% bupivacaine.[195] When using 0.75% ropivacaine for peripheral nerve block, age is a major factor in determining duration of motor and sensory blockade.[196]

ANESTHETIC TECHNIQUE

Advantages of Specific Drugs in Older Adults

Perioperative care should be tailored to comorbid disease and requirements of the surgical procedure. Several comments concerning pharmacologic and physiologic management are in order, however. A role may exist for shorter acting anesthetics in caring for older patients. A more predictable method of opioid titration may be to use a shorter acting opioid, such as remifentanil. By adjusting the bolus and infusion doses, the variability in remifentanil pharmacokinetics is considerably less than for other intravenous opioids.[197] Similarly, shorter acting muscle relaxants probably should be used. An increased incidence of residual neuromuscular block and pulmonary complications occur in patients receiving pancuronium in contrast to atracurium or vecuronium[198] (see also Chapters 34 and 35). When comparing inhaled anesthetics, there does not appear to be a significant difference in recovery profile of cognitive function. Desflurane is associated with the most rapid emergence.[199,200]

Generally, it is unclear what constitutes the optimal physiologic management to produce the best surgical outcomes. Yet, hemodynamic responses to anesthesia and surgery may be associated with adverse outcome. These findings are in opposition to earlier work suggesting hypotension can be well tolerated in older patients.[90] A recent study reports a strong association between 30-day mortality and hypotension in the presence of low BIS and low minimum alveolar gas concentrations during noncardiac surgery.[201] An association between severity and duration of intraoperative hypotension and 1-year mortality in older patients also has been reported.[202] It is unclear if these studies are identifying a susceptible population with decreased end-organ reserve based on sensitivity to anesthetics or suggesting a potential therapeutic target for intraoperative management. However, earlier studies have demonstrated that older patients can safely receive controlled hypotensive anesthesia (mean arterial blood pressure range of 45 to 55 mm Hg) during orthopedic procedures without increased risk.[90] Further controversy surrounds the question of whether better outcomes are obtained with goal-directed therapy when hemodynamic monitoring is used to optimize hemodynamics and fluid administration. No benefit is thought to exist for therapy directed by pulmonary artery catheter over standard care in older, high-risk surgical patients requiring intensive care.[203]

Regional Versus General Anesthesia

The difference in outcome between regional and general anesthesia in older patients is not clear.[204] Many types of surgery, including major vascular and orthopedic procedures, have been studied.[205,206] Furthermore, the incidence of POCD is similar with regional versus general anesthesia.[207] Yet, other specific effects of regional anesthesia may provide some benefit. First, regional anesthesia affects the coagulation system by preventing postoperative inhibition of fibrinolysis.[208] Deep vein thrombosis or pulmonary embolism may occur in 2.5% of patients after certain high-risk procedures.[209] Regional anesthesia may decrease the incidence of deep vein thrombosis after total hip arthroplasty.[210] These findings are controversial, however, because similar results have not been reported with total knee arthroplasty.[211] In lower extremity revascularization, regional anesthesia is associated with a decreased incidence of postoperative graft thrombosis in contrast to that with general anesthesia.[212] Second, the hemodynamic effects of regional anesthesia may be associated with decreased blood loss in pelvic and lower extremity surgery.[213,214] Third, regional anesthesia does not necessitate instrumentation of the airway and may allow patients to maintain their own airway and level of pulmonary function. Older patients are likely more susceptible to hypoxemic episodes in the recovery room. Patients who undergo regional anesthesia may have a lower risk for hypoxemia.[215] However, it is unclear whether fewer pulmonary complications occur with regional versus general anesthesia. Finally, well-conducted regional anesthesia has opiate-sparing effects that may benefit older patients after total joint arthroplasty.[216]

POSTOPERATIVE CONSIDERATIONS

Postanesthesia Care Unit

No guidelines for postanesthesia care unit (PACU) management relate specifically to older patients because many issues of anesthetic recovery are shared by all age groups (see also Chapter 96). Postoperative management of pulmonary problems is of particular importance because the most important patient-related factors for postoperative pulmonary complications are age and ASA status.[217] In the PACU, older patients have a greater reported incidence of postoperative desaturation.[218] In addition, the aged may be at higher risk for aspiration secondary to the progressive decrease in laryngopharyngeal sensory discrimination and associated dysfunctional swallowing.[219] Urinary retention is more common in older adults[220]; nausea and vomiting are not.[221]

Treatment of Acute Postoperative Pain

Experimental and clinical studies provide support for the notion of an age-related decrease in pain perception.[222,223] However, whether the observed changes are caused by the aging process or reflect other age-associated effects such as an increased presence of comorbid disease is not known.[224] A greater problem occurs in cognitively impaired patients. Alzheimer disease is associated with a decrease in reported pain.[225] In contrast to older persons without dementia, patients with Alzheimer disease appear to perceive pain less intensely and with a corresponding decrement in its affective component.[226]

Although the sensory-discriminative component of pain is maintained in patients with Alzheimer disease, pain tolerance increases with the severity of dementia.[227] The basic principles of evaluation of pain in older patients are similar to those in other age groups. In addition, aging alters functional organ reserve and pharmacokinetics. Thus, the combination of pain assessment and drug dose adjustment provides challenges in the management of postoperative pain in older patients. Many of the principles of postoperative pain management in older patients are discussed in Chapters 64 and 98. Several general principles should be kept in mind when managing frail, older patients. For one, multiple modalities of analgesia should be considered, such as intravenous patient-controlled analgesia and regional nerve blocks, which will enhance analgesia and reduce opioid toxicity. This principle is especially important in frail elders, who often tolerate systemic opioids poorly. Second, the use of site-specific analgesia is a helpful adjunct. Certain operative sites, such as the upper extremity, are especially amenable to local nerve blocks. Third, whenever possible, nonsteroidal antiinflammatory drug preparations should be used to spare opioids, enhance analgesia, and decrease inflammatory mediators. Unless the patient has a contraindication or strong concern exists about hemostasis or peptic ulceration, nonsteroidal antiinflammatory drugs should generally be administered.[228] Opioid-based postoperative pain management may be used in older patients. However, it is imperative to keep in mind the alterations in dose requirements that occur with age.

Iatrogenic Complications

Numerous hazards of hospitalization exist for the older surgical patient. Iatrogenic complications are common and of increased severity in older adults.[229]

Those of importance to the anesthesiologist include adverse drug events, dehydration, delirium, and functional decline. Adverse drug events have a reported prevalence of 14.6% in hospitalized patients 70 years of age and older and are associated with both the number of new inpatient medications and admission cognitive status. Patients experiencing an adverse drug event often incur a longer length of stay and functional decline.[230-232]

OUTCOMES

The goal of a surgical intervention should be to preserve or improve activity and independence while avoiding disability.[233] Although many procedures can be performed with relatively low mortality rates, functional recovery may be challenging and require significant time for many high-risk older patients.[129] After major abdominal surgery, functional recovery may take up to 6 months or longer for patients older than 60 years.[234] Many patients undergoing vascular surgery experience a decline in capacity for independent function.[235] Postoperative complications are common in hospitalized older patients, with the incidence ranging from 20% to 50% and associated with both short-term and long-term mortality.[236]

For older patients requiring admission to an ICU, survival to discharge is most closely related to severity of illness at the time of admission, and age and prehospital functional status correlate most closely with long-term survival.[237] Recovery is often a long process, with many elders requiring assistance with IADL up to 1-year after discharge.[238]

Chapter 81

Anesthesia for Trauma

MAUREEN MCCUNN • THOMAS E. GRISSOM • RICHARD P. DUTTON

Key Points

- Successful perioperative anesthesia care for patients who have undergone acute trauma depends on an understanding of trauma system design and surgical priorities.
- Successful emergency airway management is based on having a clear plan, such as the American Society of Anesthesiologists algorithm for difficult airways adapted for trauma. In general, rapid-sequence induction of anesthesia and in-line cervical stabilization, followed by direct laryngoscopy or video laryngoscopy, is the safest and most effective approach. The use of cricoid pressure is controversial and is no longer a class I recommendation.
- Recognition of hemorrhagic shock is at the center of advanced trauma life support. Hemorrhagic shock indicates the need for rapid operative treatment, with the possibility of a damage control approach. Although establishing an adequate airway remains the initial priority, obvious hemorrhage should be concurrently addressed through immediate application of tourniquets or direct pressure.
- Resuscitation during acute hemorrhagic shock has undergone a significant change in emphasis. Current recommendations are to maintain deliberate hypotension during active bleeding by limitation of crystalloid infusion. Recognizing the impact of early coagulopathy in trauma, a "hemostatic" resuscitation should be employed, with an emphasis on maintenance of blood composition by early transfusion of red blood cells, plasma, and platelets and viscoelastic monitoring (see also Chapter 61) when available.
- Management of patients with severe traumatic brain injury (see also Chapter 70) requires monitoring and maintenance of cerebral perfusion and oxygenation for successful operative and intensive care management.
- Trauma anesthesiology includes a substantial component of critical care practice (see also Chapter 101). Use of intraoperative advanced ventilator strategies, including permissive hypercapnia and facilitated spontaneous ventilation (bilevel or airway pressure release ventilation), may improve outcomes.
- Prehospital, interhospital, and intrahospital transport of critically injured patients is the province of the trauma anesthesiology team and requires planning and attention to detail.

Unintentional injury is the leading cause of death between the ages of 1 and 45 years in the United States and the fifth leading cause of death overall.[1] Because it affects primarily the young, trauma is *the* leading cause of years of life lost before the age of 75 years. The World Health Organization (WHO) estimates that injury is the leading cause of death worldwide for both men and women from the age of 15 to 44 years; and by 2020, injuries will be the third leading cause of death and disability in all age groups.[2] Unlike in developed nations, where road traffic deaths are predicted to decrease by 2020, annual road traffic mortality is expected to increase by 80% in low- and middle-income countries.[3]

Globally, approximately 16,000 people die of injuries every day and approximately 5.8 million people every year, which corresponds to an annual mortality rate of 97.9 per 100,000 population. Mortality from injury underrepresents the true burden of disease inasmuch as hundreds of people require hospital treatment for every death. According to the 2002 *World Report on Violence and Health,* injury accounts for 12.2% of the total burden of disease.[4] In contrast to other disease and health conditions, morbidity and disability as a result of injury account for a disproportionate number of deaths in children and young adults. This leads to a major burden on health sector and social welfare services, and the

economic consequences include both the cost of care and a substantial amount of lost productivity.

Globally, more than nine people die every minute from injuries or violence. The three leading causes of injury and violence-related deaths are road traffic incidents, suicides, and homicides.[5] Many patients in the world have little or no access to trauma care. In the United States, research shows that receiving care at a Level I trauma center can decrease the risk for death among seriously injured patients by 25%.[6] The Centers for Disease Control and Prevention (CDC) National Center for Injury Prevention and Control and the WHO Violence and Injury Prevention program have several global projects under way that are aimed at building trauma-response capacity to decrease this burden of injury.

Management of trauma patients presents unique challenges to the health care system because they require resource-intensive care, they have multiple injuries to multiple body systems, and their acute injuries overlie and interact with a variety of chronic medical conditions. Anesthesia providers in practice at designated trauma centers are involved in the care of trauma patients, beginning with airway and resuscitation management in the emergency department (ED) and proceeding through the operating room (OR) to the intensive care unit (ICU). Trauma patients represent a significant proportion of all OR cases managed during night and weekend shifts. Critical care and pain management specialists often see trauma patients as a significant fraction of their practice, depending on the overall purpose of their respective medical centers. Yet even practitioners at outpatient surgery centers encounter trauma patients in need of reconstructive, orthopedic, or plastic surgery.

At the same time, very few anesthesiologists in the United States consider trauma their primary specialty. This is distinct from European practice, in which an anesthesiologist also works in the prehospital environment, as an ED director, or as leader of a hospital's trauma team. The U.S. model, in which many anesthesiologists treat trauma patients but few do so exclusively, has led to a relative dearth of research, publication, and education in this field, except for publications resulting from trauma in a military situation (i.e., wars), which is discussed later in this chapter. This situation is unfortunate because nonmilitary domestic trauma is a rapidly evolving field of study that presents unique challenges to the clinician and one in which improvements in care can have a dramatic impact on society as a whole.

Anesthesia for trauma patients is different from routine OR practice. Most urgent cases occur during off-hours, when the most experienced OR and anesthesia personnel may not be available. In small hospitals and military and humanitarian practice, austere conditions may influence the resources available. Patient information may be limited, and allergies, genetic abnormalities, and previous surgeries may create sudden crises. Hopefully, with the increasing dependence of medicine on information technology (computers), such patient information will become more readily available. Patients are frequently intoxicated, with full stomachs and the potential for cervical spine instability. Simple operations may become complicated, and specialty surgical and anesthesia equipment may be required on short notice. Patients often have multiple injuries requiring complex positioning, multiple procedures, and the need to consider priorities in management. Occult injuries, such as tension pneumothorax, can be manifested at unexpected times. Fortunately, there does not appear to be a higher risk for medical liability associated with the provision of anesthesia for trauma versus nontrauma surgical anesthesia cases.[7] Successful perioperative care of these patients requires a good understanding of the basics, supplemented by preparation, flexibility, and the ability to react quickly to changing circumstances.

As with other endemic diseases, successful treatment of trauma extends well beyond the boundaries of an individual hospital. Community-based prevention has included efforts to incorporate airbags in motor vehicles, mandate helmet use on motorcycles, encourage citizens to wear seat belts, punish intoxicated drivers, and promote responsible handgun ownership.[8] These measures have had an impact on the demographics of injury in much the same fashion that smoking cessation, dietary modification, and routine mammography have affected the incidence of heart disease and cancer. When prevention fails, outcomes after injury are heavily influenced by the community's commitment to an organized system of trauma care.[9]

A systems approach to the delivery of trauma care improves outcome. Trauma care systems represent a continuum of integrated care that is a coordinated effort between out-of-hospital and hospital providers with close cooperation of medical specialists in each phase of care. In 1998, the first Academic Symposium to Evaluate Evidence Regarding the Efficacy of Trauma Systems (the Skamania Conference) systematically reviewed the published literature in an effort to quantify the understanding of trauma system effectiveness at that time and to chart a course to outline future research endeavors.[10,11] The Skamania Symposium concluded that treatment at a trauma center versus a nontrauma center is associated with fewer inappropriate deaths and less disability. This conclusion was substantiated in 2006 by a *New England Journal of Medicine* study showing that mortality is reduced when care is provided at a trauma center versus a nontrauma center.[12] Studies in the United States have shown that a reduction in unnecessary deaths from more than 30% to less than 5% occurred in trauma centers compared with general hospitals and that a regionalized system with triage criteria and dedicated trauma centers also reduces the potentially preventable mortality rate to as infrequent as 1% to 3%. However, based on a U.S. study evaluating rates of mortality after implementation of a statewide trauma system program, a mean of *9 years* elapsed after passage of enabling legislation before a significant benefit in survival was achieved.[13]

The degree to which the trauma system is organized and regulated varies widely from state to state across the United States. States such as Maryland, Pennsylvania, Connecticut, and Illinois have established protocols for the care of trauma patients that begin at the moment of first contact with the emergency medical system. In other states the system may be more fragmentary, and care may vary widely across jurisdictions. Mature trauma systems

include protocols for patient triage and transport, standards for hospitals providing trauma care, and data collection systems that facilitate benchmarking. Although some states have written their own standards for certifying trauma hospitals, the most influential national document is *Resources for Optimal Care of the Injured Patient,* published by the American College of Surgeons Committee on Trauma in 2006.[14] This reference offers standards for accreditation of trauma hospitals based on the availability of key resources, the volume of trauma patients treated, and the institutional commitment to prevention and education. The presence of an experienced anesthesiologist and the immediate availability of an open OR are both core resource standards for accreditation of a level 1 trauma center. Patient outcomes are improved when a hospital pursues and attains designation as a trauma center.[15,16]

The numerous innovations in trauma care that have occurred in just the past decade dictate the need for ongoing education, including targeted hemostatic resuscitations; "damage control" surgical techniques; diagnostic modalities such as high-speed computed tomography (CT), angiography, and focused abdominal ultrasound; and perfusion-focused strategies for managing traumatic brain injury (TBI). The coming decades will see new pharmacologic therapies for shock and reperfusion, new strategies for achieving hemostasis, and better patient monitoring. Improving patient outcomes requires a commitment to continuing education on the part of the anesthesiologists and every member of the trauma team.

This chapter provides an overview of important areas of trauma care for the anesthesiologist. We begin with a description of the initial approach to an injured patient, followed by discussions of emergency airway management, resuscitation, and care of patients with central nervous system (CNS) injuries. We briefly cover the needs of orthopedic and reconstructive surgery patients and then conclude with a discussion of postoperative and critical care issues for the trauma anesthesiologist.

PRIORITIZING TRAUMA CARE

The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons is the most widely recognized training program for trauma physicians of all disciplines.[17] Although not comprehensive in subspecialty areas, the ATLS curriculum nonetheless provides a framework and a common language for the care of injured patients. ATLS is based on a primary survey that includes simultaneous efforts to identify and treat life-threatening and limb-threatening injuries, beginning with the most immediate. This focus on urgent problems first is captured by the "golden hour" catchphrase and is the most important lesson of ATLS. Put simply, better outcomes are achieved with faster diagnosis and treatment. Resolution of urgent needs is followed by a meticulous secondary survey and further diagnostic studies designed to reduce the incidence of missed injuries. Knowing the basics of ATLS is essential for *any* physician who interacts with trauma patients. Figure 81-1 is a simplified representation of the ATLS protocol.

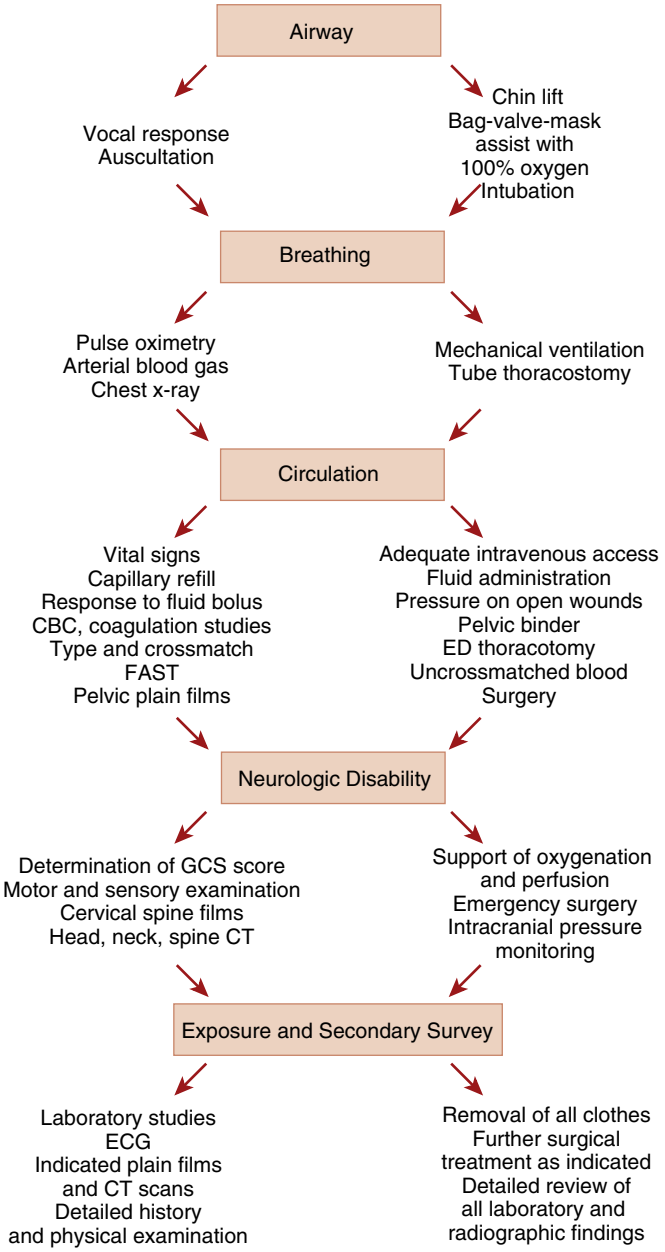

Figure 81-1. Simplified assessment and management of the trauma patient. *CBC,* Complete blood count; *CT,* computed tomography; *ECG,* electrocardiogram; *ED,* emergency department; *FAST,* focused assessment by sonography for trauma; *GCS,* Glasgow Coma Scale. *(Modified from the Advanced Trauma Life Support curriculum of the American College of Surgeons.)*

ATLS emphasizes the ABCDE mnemonic—airway, breathing, circulation, disability, and exposure (see also Chapter 108). Verification of a patent airway and acceptable respiratory mechanics is of primary importance because hypoxia is the most immediate threat to life. Inability to oxygenate the patient will lead to permanent brain injury and death within 5 to 10 minutes. Trauma patients are at risk for airway obstruction and inadequate respiration for the reasons listed in Box 81-1. Endotracheal intubation, whether performed in the prehospital environment or in the ED, must be confirmed immediately by capnometry. Esophageal intubation or endotracheal tube dislodgement

BOX 81-1 *Causes of Obstructed Airway or Inadequate Ventilation in a Trauma Patient*

Airway Obstruction

Direct injury to the face, mandible, or neck
Hemorrhage in the nasopharynx, sinuses, mouth, or upper airway
Diminished consciousness secondary to traumatic brain injury, intoxication, or analgesic medications
Aspiration of gastric contents, blood, or a foreign body (i.e., dentures, broken teeth, soft tissue)
Misapplication of oral airway or endotracheal tube (esophageal intubation)

Inadequate Ventilation

Diminished respiratory drive secondary to traumatic brain or high cervical spine injury, shock, intoxication, hypothermia, or oversedation
Direct injury to the trachea or bronchi
Pneumothorax or hemothorax
Chest wall injury
Aspiration
Pulmonary contusion
Cervical spine injury
Bronchospasm secondary to smoke or toxic gas inhalation

are common and devastating if not promptly corrected. When cardiac arrest exists, end-tidal carbon dioxide values may be very low; direct laryngoscopy should be performed if there is any question about the location of the endotracheal tube (see also Chapter 55).

If establishment of a secure airway and adequate ventilation requires a surgical procedure such as a tracheostomy, tube thoracostomy, or open thoracotomy, this procedure must precede all others. Indeed, these procedures are commonly performed in the ED, often before the arrival of an anesthesiologist. Subsequent surgery to convert a cricothyroidotomy to a tracheostomy or close an emergency thoracotomy may then follow in the OR.

Hemorrhage is the next most pressing concern inasmuch as ongoing blood loss is inevitably fatal. The symptoms of shock are presented in Box 81-2. Shock is presumed to result from hemorrhage until proved otherwise. Assessment of the circulation consists of an early phase, during active hemorrhage, and a late phase, which begins when hemostasis is achieved and continues until normal physiology is restored. In the early phase, diagnostic efforts focus on the five sites of bleeding detailed in Table 81-1, the only areas in which exsanguinating hemorrhage can occur. Immediate actions to control hemorrhage can include application of pelvic binders for bleeding associated with pelvic fractures or tourniquet application for extremity injuries. Any surgical procedure to diagnose or control active hemorrhage should be immediately transported to the OR. This includes exploration of the neck or pericardium to rule out hemorrhage in sensitive compartments. In the OR, the trauma surgeon focuses on anatomic control of hemorrhage, whereas the anesthesiologist is responsible for restoring the patient's physiology. Goals for early and late resuscitation are discussed in more detail later.

After management of the circulation is assessment of the patient's neurologic status by calculation of the Glasgow Coma Scale (GCS) score (Box 81-3)[18]; examination of the pupils for size, reactivity, and symmetry; and determination of sensation and motor function in each of the extremities. Significant abnormalities on the neurologic examination are an indication for immediate cranial CT. Most trauma patients with a diminished GCS score will have nonoperative

conditions, but for the few who require operative evacuation of an epidural or subdural hematoma, timeliness of treatment has a strong influence on outcome. Patients with unstable spinal canal injuries and incomplete neurologic deficits will also benefit from early surgical stabilization.

The final step in the primary survey is complete exposure of the patient and a head-to-toe search for visible injuries or deformities, including deformities of bones or joints, soft tissue bruising, and any breaks in the skin. The anesthesiologist can assist in this procedure by support of the head and neck, maintenance of the airway, and care in manipulating the spine.

After the primary survey a more deliberate secondary examination should be undertaken that includes a thorough history and physical examination, diagnostic studies, and subspecialty consultation. Any remaining injuries are diagnosed at this time and treatment plans established. Indications for urgent or emergency surgery also may arise during the secondary survey. The presence of a limb-threatening injury as a result of vascular compromise, compartment syndrome, or a severely comminuted fracture is one such indication. Although the awakening, breathing, coordination, delirium monitoring and management, and early mobility (ABCDE) issues must be addressed first, a pulseless extremity, compartment syndrome, near-amputation, or massively fractured extremity must go to the OR as soon as the patient is otherwise stable.

Another category of urgency arises in patients with a time-dependent potential for systemic infection. Because sepsis is a leading cause of complications and death in trauma patients, open injuries should be thoroughly debrided—and closed if appropriate—at the earliest opportunity (see also Chapters 101 and 102). Other urgent indications for surgery include perforation of the bowel, open fracture, and extensive soft tissue wounds. The frequency of infectious complications of open fractures increases in a linear fashion with time from the moment of injury until operative debridement[19] although a recent meta-analysis has challenged the traditional 6-hour rule for initial debridement.[20] Nonetheless, the need for early surgery must be balanced against the need for diagnostic studies, adequate preoperative resuscitation, and the priority of other cases.

Figure 81-2, an algorithm for prioritizing surgical management in trauma patients, is presented with the understanding that individual situations will vary according to available resources and patient response to therapy. A trauma patient often will arrive at the OR with the need for more than one surgical procedure by more than one surgical service. A trauma patient may have injuries requiring emergency surgery coexisting with injuries that can be repaired at any time. The anesthesiologist plays an important role in determining which procedures to perform, in which order, and which procedures should be postponed until the patient is more stable.

ANESTHESIA IN WAR AND AUSTERE CONDITIONS

"While it is evident that the general principles of anesthesia are not affected by the circumstances of war, it is equally evident that it is our duty to assiduously seek those means in anesthesia which are especially suited to the exigencies of battle."[21]

Although written in 1942, these words are still true today, and many of the principles developed from earlier

wars still apply on the modern battlefield or in a large-scale disaster (see also Chapter 83). Recent conflicts and events have allowed anesthesiologists, nurse anesthetists, and other providers to help improve management of traumatically injured patients in the areas of anesthesia, resuscitation, and damage control surgery. Management of battlefield casualties typically follows the same flow as outlined earlier, but with special consideration in the areas of prehospital interventions, resuscitation, technologic and logistic support, patient movement, mass casualty management, and surgical interventions.[22] Pain management considerations also may be affected by the nature of the injuries and transport considerations.[23]

Modern advancements in battle armor, prehospital interventions, provision of forward surgical support, and resuscitative strategies have had an impact on survival from combat injuries. During the most recent conflicts in Iraq and Afghanistan, the killed-in-action rate decreased to 13.9% from 20.2% in Vietnam and World War II.[24] This is mirrored by a similar reduction in the case fatality rate. Paradoxically, the ability to get many of the severely wounded patients to a hospital (e.g., rapidly by helicopter) has led to an increase in the "died-of-wounds" rate. Most likely this rate would be even higher if not for improvements in surgical management such as damage control techniques, improved ICU care, earlier recognition of abdominal compartment syndrome, liberal use of fresh whole blood (see also Chapter 61), and institution of a theater-wide trauma system approach.

One of the major advances in battlefield medical support has been the rapid movement of patients out of the theater of operations to more comprehensive medical facilities. Even in the late l960s, wounded soldiers were evacuated out of Vietnam within 3 days of injury. In the most recent conflict, the time from injury in the Middle East until return to the United States is frequently less than 81 hours for even the most seriously injured patients.[25] This may include initial in-theater damage control surgery followed by one or two aeromedical evacuation missions lasting up to 12 hours with a critical care air transport team (CCATT). In preparation for such rapid movement, the anesthesiologist must ensure that perioperative interventions such as airway management, pain control, and adequacy of resuscitation are addressed before transfer. In addition, anesthesiologists are frequently assigned to a CCATT as the physician team member based on their overall skill set and ability to provide support en route to critically ill or injured patients. Beyond the support provided during wartime, the CCATT also has proved useful for the movement of critical patients during large-scale disasters such as occurred after Hurricane Katrina in 2005.[26]

Mass casualty situations are not uncommon in wartime conditions, although the role of the anesthesiologist will vary depending on the number of patients and requirements for urgent surgical interventions. Given the limited number of anesthesia providers in most combat-related scenarios, often they are not involved in the triage process. If available, however, anesthesia support can enhance emergency airway management, establishment of venous access, and supervision of resuscitative efforts. Only 10% to 20% of arriving casualties require immediate lifesaving interventions, although a much larger percentage will ultimately require surgical procedures.[27] A well-developed trauma system is persistently evolving, and management of mass casualty scenarios will become routine.[28]

Overall, anesthetic management of battlefield casualties is similar to that for patients in a civilian trauma setting; however, many factors must be considered in the perioperative plan for a combat casualty.[29] Environmental considerations such as extremes of temperature, availability of water, contamination with sand, lack of consistent electricity, and other aspects may have to be taken into consideration. Logistic support chains may be long and unable to provide sufficient supplies in the early phases of a conflict. Deployable equipment, such as drawover vaporizer systems or portable ventilators, may be different from those used during

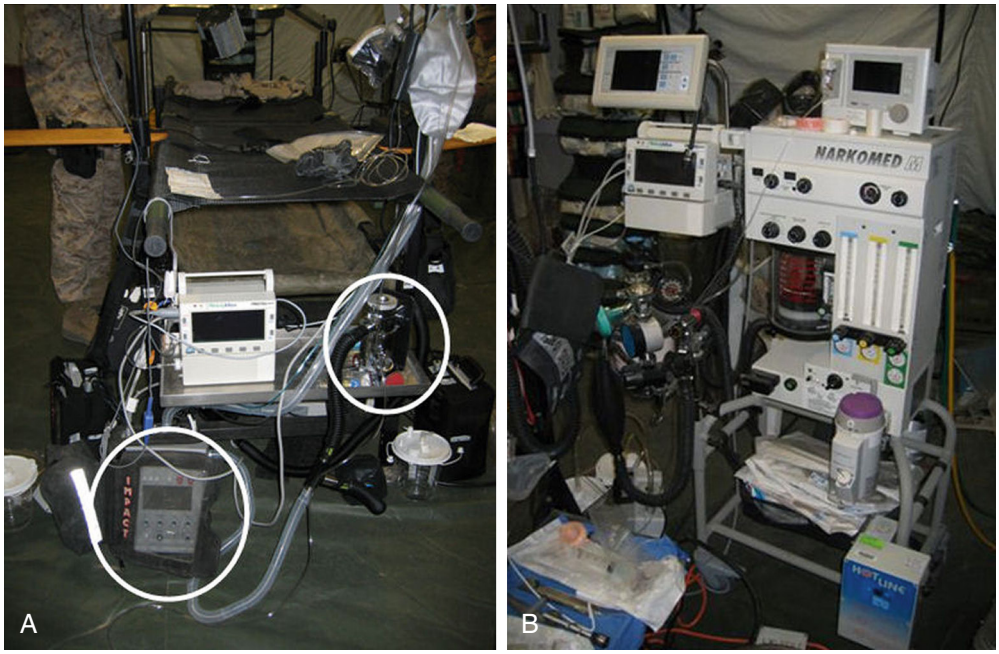

Figure 81-3. Deployable military anesthesia equipment. **A,** Drawover vaporizer and portable ventilator *(circled)* in field hospital. **B,** Portable anesthesia machine. *(Used with permission from CPT Bruce Baker, MD, USN.)*

peacetime, so predeployment training is vital (Fig. 81-3).[30] In addition, techniques such as total intravenous (IV) anesthesia and regional anesthesia or analgesia will frequently be used and thus require familiarity with their management and associated equipment (see also Chapter 57).[29]

Optimal care of wartime casualties or victims of large disasters requires not only familiarity with a broad range of anesthetic principles and techniques but also the ability to be flexible in the face of a rapidly changing environment. With special training in airway management, provision of anesthesia and sedation, resuscitation, and pain management, anesthesiologists may find themselves involved in triage, emergency management, and perioperative and critical care.

EMERGENCY AIRWAY MANAGEMENT

The American Society of Anesthesiologists (ASA) algorithm for management of difficult airways modified for trauma (see also Fig. 55-2) is a useful starting point for the trauma anesthesiologist, whether in the ED or the OR (see also Chapter 55).[31,32] The concept of the algorithm is an important one. The anesthesiologist should have a plan for the initial approach to the airway and for coping with any difficulties that might develop. Figure 81-4 is a typical algorithm for emergency intubation of an unstable trauma patient. Note that it differs from the ASA algorithm in that reawakening the patient is seldom an option because the need for emergency airway control will presumably remain. Once the decision to obtain a definitive airway is made, efforts will continue until a cuffed tube is in position in the trachea, whether by conventional intubation or via a surgical approach. Failure to commit to a surgical airway soon enough results in bad outcomes more commonly than do complications of a procedure that might have been unnecessary.

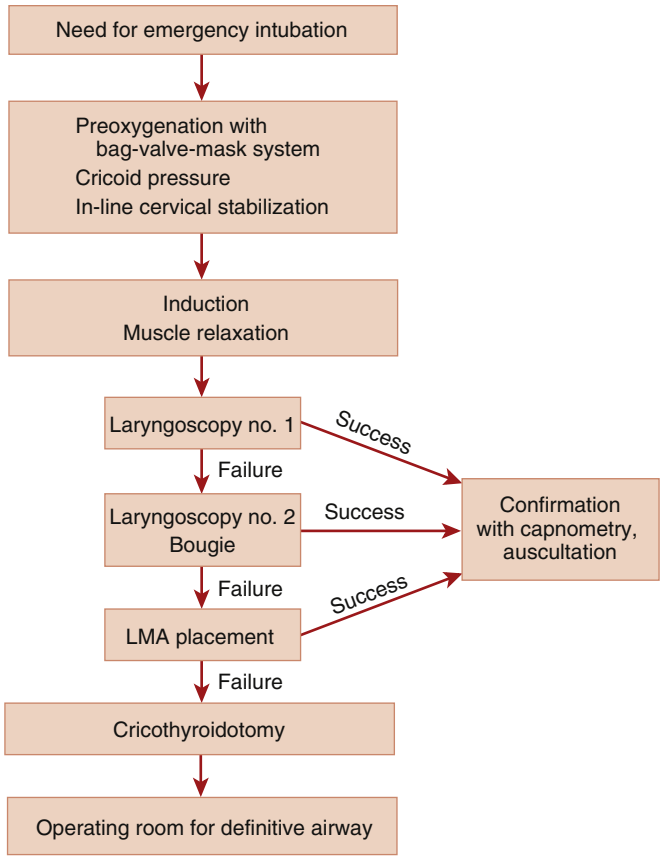

Figure 81-4. Emergency airway management algorithm used at the R. Adams Cowley Shock Trauma Center, presented as an example. Individual practitioners and trauma hospitals should determine their own algorithm, based on available skills and resources. *LMA,* Laryngeal mask airway.

INDICATIONS

The goal of emergency airway management is to ensure adequate oxygenation and ventilation while protecting the patient from the risks for aspiration. Endotracheal intubation is commonly required and is specifically indicated in the following conditions:

- Cardiac or respiratory arrest
- Respiratory insufficiency (see Box 81-1)
- Airway protection
- Need for deep sedation or analgesia, up to and including general anesthesia
- Transient hyperventilation of patients with space-occupying intracranial lesions and evidence of increased intracranial pressure (ICP)
- Delivery of a 100% fraction of inspired oxygen (FiO_2) to patients with carbon monoxide poisoning
- Facilitation of the diagnostic workup in uncooperative or intoxicated patients

APPROACH TO ENDOTRACHEAL INTUBATION

In general, monitoring standards for airway management should be the same in the ED and OR, including an electrocardiogram (ECG), blood pressure, oximetry, and capnometry. Appropriate equipment, including an O_2 source, bag-valve-mask ventilating system, mechanical ventilator, suction, and a selection of laryngoscope blades, endotracheal tubes, and devices for managing difficult tracheal intubations, should be available in any location where emergency intubation is likely, including the ED.

Endotracheal intubation is best accomplished in almost all cases with a modified rapid-sequence approach by an experienced clinician. Although concern may exist that the use of neuromuscular blocking drugs and potent anesthetics outside the OR will be associated with a more frequent complication rate, in fact the opposite is more likely correct. Anesthesia and neuromuscular blockade allow the best tracheal intubating conditions on the first approach to the airway, which is advantageous in an uncooperative, hypoxic, or aspirating patient. Attempts to secure the airway in an awake or lightly sedated patient increase the risk for airway trauma, pain, aspiration, hypertension, laryngospasm, and combative behavior. Experienced providers, supported by appropriate monitoring and equipment, have achieved results of medication-assisted intubation outside the OR that are equivalent to those for emergency tracheal intubation within the OR (Table 81-2).[33-35]

PROPHYLAXIS AGAINST PULMONARY ASPIRATION OF GASTRIC CONTENTS

A trauma patient should always be treated as having a full stomach and at risk for aspiration of gastric contents during induction of anesthesia (see also Chapter 55). Reasons include ingestion of food or liquids before the injury, swallowed blood from oral or nasal injuries, delayed gastric emptying associated with the stress of trauma, and administration of liquid contrast medium for abdominal CT scanning. As with obstetric anesthesia (see also Chapter 77), nonparticulate antacids should be given to a trauma patient before induction of anesthesia if time and patient cooperation exist.

Cricoid pressure—the Sellick maneuver—has been recommended to be applied continuously during emergency airway management from the time the patient loses protective airway reflexes until endotracheal tube placement and cuff inflation are confirmed. The Sellick maneuver consists of elevating the patient's chin (without displacing the cervical spine) and then pushing the cricoid cartilage posteriorly to close the esophagus. However, cricoid pressure may worsen the laryngoscopic grade of view in up to 30% of patients[36] without providing effective prevention of aspiration of gastric contents.[37] In a recent prehospital study evaluating the impact of cricoid pressure on subsequent intubation success, discontinuing cricoid pressure usually facilitated intubation of the trachea without worsening the grade of laryngoscopic view.[38] Thus, cricoid pressure should be released in the trauma patient if a difficult intubation can be facilitated. The lack of evidence supporting the use of cricoid pressure and its potential to make intubation more difficult led the American Heart Association to recommend discontinuation of its use during cardiac arrest situations.[39] Additionally, the Eastern Association for the Surgery of Trauma Practice Management Guidelines for emergency tracheal intubation have removed it as a class 1 recommendation.[40]

In the traditionally defined rapid-sequence induction of anesthesia, any attempt at ventilation between administration of medication and intubation is avoided, presumably because positive-pressure ventilation may force gas into the patient's stomach, leading to regurgitation and aspiration. Sellick's original paper described ventilation during cricoid pressure in patients with full stomachs with the belief that cricoid pressure during mask ventilation would prevent gastric inflation.[41] Although this may be true, cricoid pressure reduces tidal volumes, increases peak inspiratory pressure, or prevents ventilation.[37] On the other hand, the increase in O_2 consumption in trauma patients necessitates preoxygenation whenever possible. If preoxygenation is not possible as a result of facial trauma, decreased respiratory effort, or agitation, *rapid desaturation is a possibility. Positive-pressure ventilation during all phases of induction provides the largest possible O_2 reserve during emergency airway management and will help mitigate hypoxia if intubation proves difficult. In this situation, large tidal volumes and high peak inspiratory pressures should be avoided. Application of cricoid pressure during attempts at positive-pressure ventilation should be considered to reduce gastric inflation, but it may prevent effective ventilation in some patients necessitating discontinuation.

PROTECTION OF THE CERVICAL SPINE

Standard practice dictates that all victims of blunt trauma be assumed to have an unstable cervical spine until this condition is ruled out. The airway management of these patients receives much attention from anesthesiologists because direct laryngoscopy causes cervical motion, with the potential to exacerbate spinal cord injury (SCI). Stabilization of the cervical spine will generally occur in the prehospital environment, with the patient already having a rigid cervical collar in place. This collar may be kept in place for several days before the complete gamut of tests to rule out cervical spine instability have been completed (see later discussion). The presence of an "uncleared" cervical spine mandates the use of in-line manual stabilization (not traction) throughout any attempt at intubation.[17] This approach allows removal of the front of the cervical collar to facilitate wider mouth opening and jaw displacement; however, this may slightly lengthen the time to intubation and worsen laryngeal visualization during laryngoscopy.[42] In-line stabilization has been tested through considerable clinical experience and is the standard of care in the ATLS curriculum. Emergency awake fiberoptic intubation, though requiring less manipulation of the neck, is generally very difficult because of airway secretions and hemorrhage, rapid desaturation, and lack of patient cooperation and is best reserved for cooperative patients with known cervical instability under controlled conditions. Indirect video laryngoscopy with systems such as the Bullard laryngoscope[43] or GlideScope[44,45] offer the potential to enjoy the best of both worlds: an anesthetized patient and decreased cervical motion.[46,47] In comparative studies of direct laryngoscopy, video laryngoscopy, fiberoptic intubation, blind nasal intubation, or cricothyrotomy—in patients with known cervical cord or spine injuries, or both—there is no difference in neurologic deterioration with technique used, and no clear evidence that direct laryngoscopy worsens outcome.[48]

PERSONNEL

Emergency endotracheal intubation requires more assistance than an intubation performed under controlled conditions (see also Chapter 7). Three providers are required to ventilate the patient and manage the airway,

Figure 81-5. Emergency intubation of a trauma patient, immobilized on a long spine board. The front of the cervical collar is removed once in-line manual stabilization of the spine is established, allowing for cricoid pressure and greater excursion of the mandible. *(Reprinted with permission from Dutton RP: Spinal cord injury,* Int Anesthesiol Clin *40:111, 2002.)*

administer medications, and provide in-line cervical stabilization; a fourth provider may be needed to provide cricoid pressure if deemed appropriate. Figure 81-5 is an illustration of this approach. Additional assistance may be required to restrain a patient who is combative as a result of intoxication or TBI.

The immediate presence of a surgeon or other physician who can expeditiously perform a cricothyroidotomy is desirable. Even if a surgical airway is not required, additional experienced hands may prove useful during difficult intubations. The surgeon may also wish to inspect the upper airway during laryngoscopy if trauma to the face or neck has occurred. Urgent tube thoracostomy may prove necessary in some trauma patients to treat the tension pneumothorax that develops with the onset of positive-pressure ventilation.

ANESTHETICS AND INDUCTION OF ANESTHESIA

Any IV anesthetic administered to a trauma patient in hemorrhagic shock may cause profound hypotension and even cardiac arrest as a result of inhibition of circulating catecholamines. Although propofol is the mainstay of IV induction in the OR, its use in trauma patients is especially problematic because of its vasodilatory and negative inotropic effects. Moreover, the effects of hemorrhagic shock on the brain potentiate anesthetics, with propofol doses as small as one tenth of normal producing deep anesthesia in animals in shock.[49] Etomidate is a frequently espoused alternative because of its cardiovascular stability in contrast to other IV hypnotic drugs in the trauma population,[50-52] although its inhibition of catecholamine release may still produce hypotension.

Ketamine continues to be popular for induction of anesthesia in trauma patients because it is a CNS stimulant.[53] However, it is also a direct myocardial depressant.[54,55] In normal patients the effect of catecholamine release masks cardiac depression and results in hypertension and tachycardia. In hemodynamically stressed patients the cardiac depression may be unmasked and lead to cardiovascular collapse.[56]

Hypotension will develop in patients with hypovolemia with the administration of any anesthetic because of interruption of compensatory sympathetic outflow and the sudden change to positive-pressure ventilation. Previously healthy young patients can lose up to 40% of their blood volume before hypotension occurs, thereby leading to potentially catastrophic circulatory collapse with induction of anesthesia, regardless of the anesthetic chosen. The dose of anesthetic must be decreased in the presence of hemorrhage, including no anesthetic at all in patients with life-threatening hypovolemia. Rapid-sequence induction of anesthesia and endotracheal intubation may proceed with muscle relaxants alone, although onset time may be prolonged in a patient with circulatory impairment. Subsequent patient recall of intubation and emergency procedures is highly variable and affected by the presence of coexisting TBI, intoxication, and the depth of hemorrhagic shock (see also Chapters 13 and 14). Decreased cerebral perfusion inhibits memory formation but cannot be reliably associated with any particular blood pressure or chemical marker. Administration of 0.2 mg of scopolamine (a tertiary ammonium vagolytic) may inhibit memory formation in the absence of anesthetic drugs in this situation, but it may interfere with subsequent neurologic examination because of its long half-life. Small doses of midazolam will reduce the incidence of patient awareness but also can contribute to hypotension. Although recall of ED and OR events is not unusual in this circumstance, anesthesia provider liability appears to be limited; an analysis of intraoperative awareness lawsuits in the ASA Closed Claims Database revealed no claims related to surgery in trauma patients.[57]

NEUROMUSCULAR BLOCKING DRUGS

Succinylcholine remains the neuromuscular blocker with fastest onset—less than 1 minute—and shortest duration of action—5 to 10 minutes (see also Chapters 34 and 35). These properties make it popular for rapid-sequence induction of anesthesia. Although the use of succinylcholine may allow return of spontaneous respiration before the development of significant hypoxia in the "cannot intubate, cannot ventilate" situation, this is unlikely to be of benefit in an emergency intubation in a trauma patient. The anesthesiologist should not rely on return of spontaneous breathing in time to salvage a difficult airway management problem but should instead proceed with efforts to obtain a definitive airway, including cricothyroidotomy if other possibilities have been exhausted.

Administration of succinylcholine is associated with several adverse consequences. Increases in serum potassium of 0.5 to 1.0 mEq/L are expected, but in certain patients K^+ may increase by more than 5 mEq/L.[58] A hyperkalemic response is typically seen in burn victims and those with muscle pathology secondary to direct trauma, denervation (as with SCI), or immobilization. Hyperkalemia is not seen in the first 24 hours after these injuries, and succinylcholine may be used safely for acute

airway management. Patients at risk are those with underlying pathologic processes before their traumatic event or those undergoing subsequent surgery in the weeks to months after injury.

Succinylcholine causes an increase in intraocular pressure and should be used cautiously in patients with ocular trauma.[59] Succinylcholine may also increase intracranial pressure (ICP),[60] so its use in patients with brain trauma is controversial. In both these cases, however, hypoxia and hypercapnia may be as damaging as the transient increase in pressure caused by the drug. If the use of succinylcholine will lead to faster intubation, its benefits may outweigh its risks. The provider must weigh the use of succinylcholine in each individual situation based on the acuity of CNS injury, the anticipated speed with which intubation can be accomplished, and the likelihood that hypoxia will develop.

Alternatives to succinylcholine include rocuronium 0.9 to 1.2 mg/kg and vecuronium 0.1 to 0.2 mg/kg. Rocuronium is preferred because it has a more rapid onset of action than that of vecuronium. Also, large doses of rocuronium can be immediately reversed with a relatively new antagonist, sugammadex. Basically, the combination of rocuronium and sugammadex provides all the advantages of succinylcholine, but none of the complications. Because these drugs have no significant cardiovascular toxicity, large doses can be administered to achieve rapid (1- to 2-minute) paralysis.

Specific situations will always exist in which maintaining spontaneous ventilation during intubation is the preferred manner in which to proceed. If patients are able to maintain their airway temporarily but have clear indications for an artificial airway (e.g., penetrating trauma to the trachea), slow induction with ketamine or inhaled sevoflurane through cricoid pressure will enable placement of an endotracheal tube without compromising patient safety.

ADJUNCTS TO ENDOTRACHEAL INTUBATION

Equipment to facilitate difficult intubation should be readily available wherever emergency airway management is performed (see also Chapter 55). The particular equipment available depends on the preferences of the anesthesiologist; the usefulness of most special equipment depends more on previous experience than on any intrinsic properties of the device. Certain items deserve mention, however, because they are frequently cited as aids to management of a difficult airway.

The gum elastic bougie, or intubating stylet, is an inexpensive and easily mastered adjunct for management of a difficult airway. The stylet is placed through the vocal cords via direct laryngoscopy, and the endotracheal tube is then advanced over the stylet into the trachea. Placement of the bougie is easier than direct placement of an endotracheal tube because of both its smaller diameter and the ability of an experienced operator to feel it enter the trachea even when the glottic opening cannot be visualized. The bougie is passed under the epiglottis and gently advanced; if resistance is met, the bougie is withdrawn, rotated slightly, and advanced again. In this fashion the anesthesiologist can blindly palpate the larynx until the bougie advances into the trachea. The bougie also can be used with indirect video laryngoscopy systems such as the GlideScope (Verathon, Bothell, Wash) and is especially useful in the ED when the sniffing position cannot be used because of uncertainty about the cervical spine. The GlideScope may provide improved visualization (based on the Cormack score) and facilitate safe intubation in patients wearing a cervical collar.[61]

The laryngeal mask airway (LMA) (LMA North America, San Diego, Calif) is recommended in the ASA algorithm for management of a patient with a difficult airway. The LMA can be used as a guide for intubation when an unsuspected difficult intubation is encountered in a trauma patient; an endotracheal tube may be placed blindly through the lumen of the LMA and into the trachea, or a fiberoptic bronchoscope may be used to guide the tube through the LMA. The LMA is an appropriate rescue device for a difficult airway situation in trauma, provided no major anatomic injury or hemorrhage is present in the mouth and larynx. In our practice the LMA has most commonly been used as a bridge to emergency tracheostomy because it allows more controlled conditions than a cricothyroidotomy.

ORAL VERSUS NASOTRACHEAL INTUBATION

The most recent ATLS guidelines suggest that practitioners providing emergency airway management should proceed with the method of intubation with which they are most proficient.[17] In general, oral intubation is preferable to nasal intubation in the emergency setting because of the risk for injury to the brain from nasal instrumentation in the presence of a basilar skull or cribriform plate fracture. Furthermore, nasal intubation poses a risk for sinusitis in a patient who will be mechanically ventilated for longer than 24 hours, and use of a smaller diameter tube will also increase the difficulty of subsequent airway suctioning and fiberoptic bronchoscopy. If nasal intubation is most likely to be successful in a given situation, however, this is the route that should be used. Change to an oral tube with a larger internal diameter can occur once the patient's condition has stabilized.

FACIAL AND PHARYNGEAL TRAUMA

Trauma to the face and upper airway poses particular difficulties for the anesthesiologist. Serious skeletal derangements may be masked by apparently minor soft tissue damage. Failure to identify an injury to the face or neck can lead to acute airway obstruction secondary to swelling and hematoma. Laryngeal edema is also a risk in patients who have suffered chemical or thermal injury to the pharyngeal mucosa. Intraoral hemorrhage, pharyngeal erythema, and change in voice are all indications for early intubation.

In general, both maxillary and mandibular fractures will make ventilation by mask more difficult, whereas mandibular fractures will make endotracheal intubation easier. Palpation of the facial bones before manipulation of the airway will alert the anesthetist to these possibilities. Patients with injuries to the jaw and zygomatic arch often have trismus. Although the trismus will resolve with the administration of neuromuscular blocking agents,

preinduction assessment of airway anatomy may be difficult. Bilateral mandibular fractures and pharyngeal hemorrhage may lead to upper airway obstruction, particularly in a supine patient, although intubation may be easier because of loss of skeletal resistance to direct laryngoscopy. A patient arriving at the ED in the sitting or prone position because of airway compromise is best left in that position until the moment of anesthetic induction and intubation.

RESUSCITATION FROM HEMORRHAGIC SHOCK

Resuscitation refers to restoration of normal physiology after injury. Resuscitation from hemorrhagic shock refers specifically to restoration of normal circulating blood volume, normal vascular tone, and normal tissue perfusion. Resuscitation begins immediately after injury, via the patient's own compensatory mechanisms, and continues through the prehospital, ED, OR, and ICU phases of care.

PATHOPHYSIOLOGY OF HEMORRHAGIC SHOCK

During massive hemorrhage an imbalance occurs between systemic O_2 delivery and O_2 consumption. Blood loss leads to hemodynamic instability, coagulopathy, decreased O_2 delivery, decreased tissue perfusion, and cellular hypoxia. The initial response to hemorrhage takes place on the macrocirculatory level and is mediated by the neuroendocrine system. Decreased arterial blood pressure leads to vasoconstriction and release of catecholamines to preserve blood flow to the heart, kidney, and brain, whereas other regional beds are constricted. Pain, hemorrhage, and cortical perception of traumatic injuries lead to the release of hormones and other inflammatory mediators, including renin, angiotensin, vasopressin, antidiuretic hormone, growth hormone, glucagon, cortisol, epinephrine, and norepinephrine.[62] This response sets the stage for the microcirculatory response that follows.

Individual ischemic cells respond to hemorrhage by taking up interstitial fluid, thus further depleting intravascular fluid.[63] Cellular edema may choke off adjacent capillaries and result in the no-reflow phenomenon, which prevents reversal of ischemia even in the presence of adequate macroperfusion.[64] Ischemic cells produce lactate and free radicals, which accumulate in the circulation if perfusion is diminished. These compounds cause direct damage to the cell and form the bulk of the toxic load that washes back to the central circulation when flow is reestablished. Ischemic cells also produce and release inflammatory factors—prostacyclin, thromboxane, prostaglandins, leukotrienes, endothelin, complement, interleukins, tumor necrosis factor, and others.[65] Figure 81-6 shows the inflammatory response to shock, with an emphasis on immune system amplification. This inflammatory response, once begun, becomes a disease process independent of its origin. Such alterations lay the foundations for subsequent

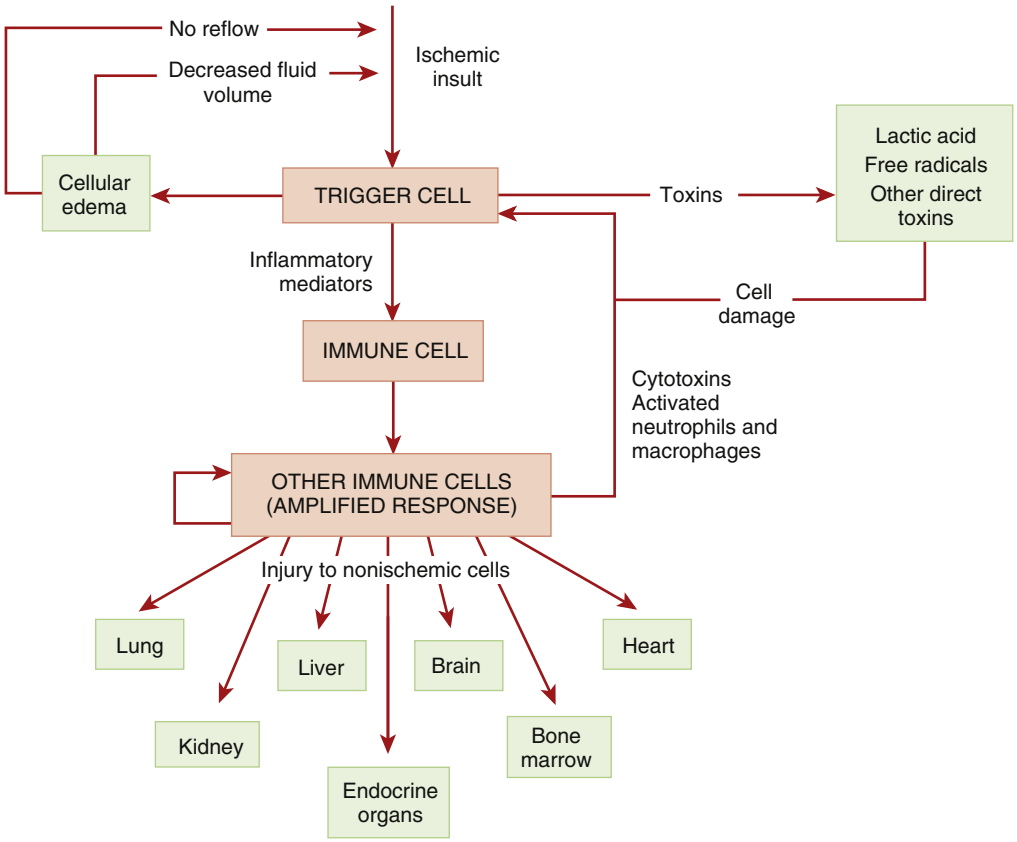

Figure 81-6. The "shock cascade." Ischemia of any given region of the body will trigger an inflammatory response that will impact nonischemic organs even after adequate systemic perfusion has been restored. *(Reprinted with permission from Dutton RP: Shock and trauma anesthesia. In Grande CM, Smith CE, editors:* Anesthesiology clinics of North America: trauma. *Philadelphia, 1999, WB Saunders, pp 83-95.)*

development of multiple organ failure, a systemic inflammatory process that leads to dysfunction of different vital organs and accounts for high mortality rates.[66]

Specific organ systems respond to traumatic shock in specific ways. The CNS is the prime trigger of the neuroendocrine response to shock, which maintains perfusion to the heart, kidney, and brain at the expense of other tissues.[67] Regional glucose uptake in the brain changes during shock.[68] Reflexes and cortical electrical activity are both depressed during hypotension; these changes are reversible with mild hypoperfusion but become permanent with prolonged ischemia. Failure to recover preinjury neurologic function is a marker for a poor prognosis, even when normal vital signs are restored.[69]

The kidney and adrenal glands are prime responders to the neuroendocrine changes associated with shock and produce renin, angiotensin, aldosterone, cortisol, erythropoietin, and catecholamines.[70] The kidney maintains glomerular filtration in the face of hypotension by selective vasoconstriction and concentration of blood flow in the medulla and deep cortical area. Prolonged hypotension leads to decreased cellular energy and an inability to concentrate urine (renal cell hibernation), followed by patchy cell death, tubular epithelial necrosis, and renal failure.[71]

The heart is preserved from ischemia during shock because of maintenance of or even an increase in nutrient blood flow, and cardiac function is well preserved until the late stages. Lactate, free radicals, and other humoral factors released by ischemic cells all act as negative inotropes and, in a bleeding patient, may produce cardiac dysfunction as the terminal event in the shock spiral.[72] A patient with cardiac disease or direct cardiac trauma is at great risk for decompensation because a fixed stroke volume inhibits the body's ability to increase blood flow in response to hypovolemia and anemia. Tachycardia is the patient's only option, with potentially disastrous consequences on the O_2 supply-demand balance in the heart. Therefore, shock in older patients may be rapidly progressive and not respond predictably to fluid administration.[73]

The lung is the filter for the inflammatory by-products of the ischemic body. Immune complex and cellular factors accumulate in pulmonary capillaries and lead to neutrophil and platelet aggregation, increased capillary permeability, destruction of lung architecture, and acute respiratory distress syndrome (ARDS)[74,75] (see also Chapter 101). The lung is the sentinel organ for the development of multiple organ system failure (MOSF) in a patient with traumatic shock.[76,77] Pure hemorrhage, in the absence of hypoperfusion, does not produce pulmonary dysfunction.[78] Traumatic shock is obviously more than just a hemodynamic disorder.

The gut is one of the earliest organs affected by hypoperfusion and may be the prime trigger of MOSF. Intense vasoconstriction occurs early and frequently leads to a no-reflow phenomenon, even when the macrocirculation is restored.[79] Intestinal cell death causes a breakdown in the barrier function of the gut that results in increased translocation of bacteria to the liver and lung, thereby potentiating ARDS.[80]

The liver has a complex microcirculation and may experience reperfusion injury during recovery from shock.[81] Hepatic cells are also metabolically active and contribute to the ischemic inflammatory response and to irregularities in blood glucose.[82] Failure of synthetic function of the liver after shock is almost always lethal.

Skeletal muscle is not metabolically active during shock and tolerates ischemia better than do the other organs. The large mass of skeletal muscle, though, makes it important in the generation of lactic acid and free radicals from ischemic cells. Sustained ischemia of muscle cells leads to an increase in intracellular sodium and free water, with an aggravated depletion of fluid in the vascular and interstitial compartments.[83]

ACUTE TRAUMATIC COAGULOPATHY

During resuscitation from hemorrhagic shock, attention must also be directed to avoidance or correction of coagulopathy (see also Chapter 61). In patients with identical injury severity scores (ISS), the presence of coagulopathy is associated with at least a twofold to fourfold increase in mortality[84,85]; thus, current resuscitation strategies focus on coagulopathy and shock during the initial and subsequent resuscitation. The presence of trauma-induced coagulopathy (TIC)—defined as a "multifactorial, global failure of the coagulation system to sustain adequate hemostasis after major trauma"—has an endogenous component linked to hypoperfusion and tissue injury referred to as acute traumatic coagulopathy (ATC).[86] A proposed mechanism for the development of ATC is endothelial activation of protein C secondary to the traumatic inflammatory response described earlier.[87] Activated protein C (APC) is generated by thrombomodulin-thrombin complex production as a result of tissue hypoperfusion. APC inactivates factors Va and VIIIa, and in combination with the reduction in thrombin availability for fibrin formation, supports the development of ATC.[88] Additionally, degradation of the endothelial glycocalyx as a result of hypoperfusion may play a supporting role in ATC.[89]

By clinical definition, ATC starts by the early presence of reduced clot strength as demonstrated by viscoelastic monitoring and changes in laboratory-based coagulation testing associated with an increase in mortality and likelihood of receiving a massive transfusion.[90] Davenport and colleagues[90] proposed a clot amplitude threshold of less than 35 mm at 5 minutes using ROTEM (Tem Innovations, Munich, Germany) analysis, which predicted the subsequent need for a massive transfusion with a detection rate of 77% and false-positive rate of 13% (see also Chapter 61). Similar results have been obtained using RapidTEG (Haemonetics, Niles, Ill) viscoelastic testing.[91] Laboratory-based coagulation testing is of limited utility in early detection of ATC because of time considerations. However, Frith and associates[92] found patients with a prothrombin ratio of greater than 1.2 on admission to have larger transfusion requirements and increased mortality.[92] Regardless of the means used to detect coagulopathy in the severely traumatized patient undergoing resuscitation for hemorrhagic shock, the resuscitation itself should include consideration for early treatment of ATC.

In addition to the described cascade, hyperfibrinolysis occurs in some of the more severely injured patients and contributes to ATC.[93,94] The mechanism behind this early fibrinolysis is not clearly understood but may be related

to hypoperfusion-induced APC formation resulting in the consumption of plasminogen activator inhibitor. The latter normally serves to down-regulate tissue plasminogen activator (tPA), which promotes fibrin clot degradation. The reported incidence of hyperfibrinolysis varies significantly based on the methods and cutoffs used to diagnose fibrinolysis, but its presence is clearly associated with the increased mortality and transfusion requirements seen with ATC.

INITIAL RESUSCITATION

Fluid administration is the cornerstone of resuscitation (see also Chapters 59 and 108). Intravascular volume is lost to hemorrhage, uptake by ischemic cells, and extravasation into the interstitial space. Administration of IV fluids will predictably increase cardiac output and arterial blood pressure in a hypovolemic trauma patient. The ATLS curriculum advocates rapid infusion of up to 2 L of warmed isotonic crystalloid solution in any hypotensive patient, with the goal of restoring normal arterial blood pressure.[17]

Conversely, fluid administration during active hemorrhage may be counterproductive. Dilution of red cell mass reduces O_2 delivery and contributes to hypothermia and coagulopathy. Increased arterial blood pressure leads to increased bleeding as a result of disruption of clots and reversal of compensatory vasoconstriction.[95] The result of aggressive fluid administration is often a transient increase in arterial blood pressure, followed by increased bleeding, another episode of hypotension, and the need for more volume administration. This vicious circle has been recognized since the First World War and remains a complication of resuscitation therapy today. The ATLS manual characterizes such patients as "transient responders" with active, ongoing hemorrhage.[17] Resuscitation of these patients should be considered in the following two phases:

- Early: While active bleeding is still ongoing
- Late: Once all hemorrhage has been controlled

Managing late resuscitation is driven by end-point targets and consists of giving enough fluid to maximize O_2 delivery. Early resuscitation is much more complex because the risks associated with aggressive intravascular volume replacement (Box 81-4), including the potential for exacerbating hemorrhage and thus prolonging the crisis, must be weighed against the risk for hypoperfusion and ischemia.

Deliberate hypotensive management is an accepted standard of anesthetic care for elective surgical procedures such as total joint replacement, spinal fusion, radical neck dissection, reconstructive facial surgery, and major pelvic or abdominal procedures.[96] Application of this technique to the initial management of hemorrhage is controversial and has been the focus of numerous laboratory and clinical research efforts. In 1965, Shaftan and colleagues[97] published the results of a study of coagulation in dogs that demonstrated that the formation of a soft extraluminal clot limits bleeding after arterial trauma. This study compared the quantity of blood lost from a standardized arterial injury under a variety of conditions. The least blood loss occurred in hypotensive animals (whether hypotensive from hemorrhage or from administration of a vasodilator), followed by the control group and then vasoconstricted animals. The largest amount of blood was lost in animals that underwent vigorous reinfusion during the period of hemorrhage.

BOX 81-4 ***Risks of Aggressive Volume Replacement during Early Resuscitation****

Increased blood pressure
Decreased blood viscosity
Decreased hematocrit
Decreased clotting factor concentration
Greater transfusion requirement
Disruption of electrolyte balance
Direct immune suppression
Premature reperfusion
Increased risk for hypothermia

*Most complications of volume resuscitation arise from increased hemorrhage volume or excessive hemodilution.

Laboratory data have shown the benefits of limiting intravascular fluid volumes and blood pressure in actively hemorrhaging animals.[98-101] In the most sophisticated models, direct assessment of cardiac output and regional perfusion showed no difference between moderate-volume or large-volume resuscitation in terms of cardiac output, arterial blood pressure, or regional perfusion of the heart, kidneys, and intestines. Moderate resuscitation to a lower than normal blood pressure improved perfusion of the liver.[102] Burris and co-workers[103] studied both conventional resuscitation fluids and various combinations of hypertonic saline and dextran and found that rebleeding was correlated with higher mean arterial pressure (MAP) and that survival was best in groups resuscitated to lower than normal MAP. The optimum target blood pressure for resuscitation varied with the composition of the fluid used.[103] A 1994 consensus panel on resuscitation from hemorrhagic shock noted that mammalian species are capable of sustaining MAP as low as 40 mm Hg for periods as long as 2 hours without deleterious effects. The panel concluded that spontaneous hemostasis and long-term survival were maximized by reduced administration of resuscitation fluids during the period of active bleeding in an attempt to keep perfusion only just above the threshold for ischemia.[104]

The literature contains two prospective studies of deliberate hypotensive resuscitation in trauma patients and preliminary data from a third study. The first was that of Bickell and colleagues[105] and Martin and associates[106] in 1994. The investigators randomized victims of penetrating torso trauma to one of two treatment groups: standard of care (up to 2 L of crystalloid infused in the prehospital setting) or delayed resuscitation (no fluid until the patient reached the OR). This well-managed 37-month study eventually included 598 patients. Average times of transport and care were 30 minutes from injury to the ED and then 50 minutes before reaching the OR; the fluid-restricted group received an average of about 800 mL of fluid during this time. The immediate-resuscitation group received an average of 2500 mL of crystalloid and 130 mL of blood over this same period. Although substantially different during the period of study, blood pressure on arrival at the OR was similar in both groups, which the authors took as evidence that the unresuscitated group had achieved spontaneous hemostasis. Survival to hospital discharge in the delayed-resuscitation group was significantly

TABLE 81-3 RESULTS OF A RANDOMIZED TRIAL OF DELIBERATE HYPOTENSIVE RESUSCITATION*

	Conventional	Hypotensive	Total
Patients enrolled	55	55	110

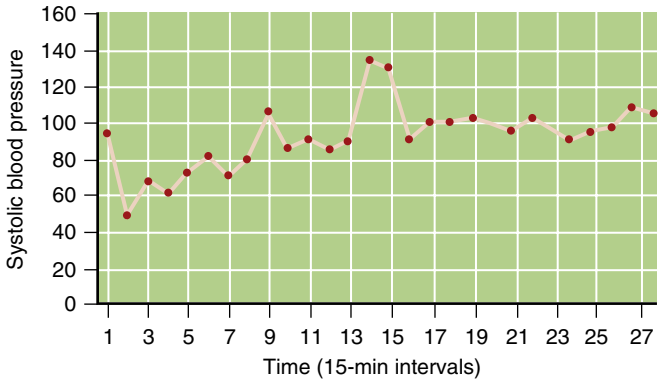

Figure 81-7. Typical systolic blood pressure measurements of a patient undergoing damage control surgery for a grade V liver injury during deliberate hypotensive management. Oscillations of blood pressure are common during early resuscitation as a result of ongoing hemorrhage and bolus fluid administration. Once hemorrhage is controlled, blood pressure will stabilize.

improved over the immediate-resuscitation group (70% versus 62% [$P < .04$]). No data were presented on the conduct of anesthesia after arrival at the OR but before control of hemorrhage or on the incidence of rebleeding after volume loading and induction of anesthesia in patients who had achieved hemostasis preoperatively.

A retrospective review of trauma admissions to the Los Angeles Medical Center published in 1996 supported these findings. Patients brought to the hospital by private conveyance fared substantially better than those delivered by paramedics, even with high levels of injury severity.[107] Further corroboration was provided by retrospective examination of outcomes in a population of hemorrhaging trauma patients who received fluids via a commercial rapid infusion system (RIS, Haemonetics, Niles, Ill) during initial resuscitation.[108] The survival rate of this group was compared with that predicted by the institution's trauma registry. Patients who received fluid by the rapid infusion system, when compared with case-matched controls, had a survival rate of only 56.8% versus 71.2% for patients of similar age with similar injuries ($P < .001$).

This retrospective review was followed in 2002 by the second prospective trial of delayed resuscitation in trauma patients.[109] Patients with systolic blood pressure lower than 90 mm Hg and clinical evidence of blood loss were randomized to fluid resuscitation titrated to a systolic blood pressure of 100 mm Hg (normal group) or 70 mm Hg (study group) until the end of surgical interventions to control hemorrhage. The results of this study are summarized in Table 81-3. As in the Bickell study, hypotension allowed spontaneous resolution of hemorrhage and autoresuscitation; blood pressure would increase without exogenous fluid administration once hemostasis was achieved. The typical patient began with a low initial pressure, followed by recovery to the vicinity of the target, overshoots and undershoots as bleeding and fluid administration continued, and an eventual rise above the target when the hemorrhage resolved, even in the absence of further fluid administration (Fig. 81-7). The 93% overall survival rate in this study was more frequent than predicted from historical data and substantially more frequent than seen in Bickell's group. This reflects the exclusion of patients who died in the prehospital phase or arrived at the trauma resuscitation unit in a moribund condition. It may also reflect improvements in overall care, an observation effect (i.e., patients in both groups received better care than did patients not in the study), or a bias in subject recruitment. Over the first 24 hours, lactate and base deficit cleared to normal in both groups and required similar amounts of fluid and blood products, thus suggesting that both groups were reaching an equivalent resuscitation end point. The authors concluded that administration of fluids to an actively hemorrhaging patient should be titrated to specific physiologic end points, with the anesthesiologist navigating a course between the Scylla of increased hemorrhage and the Charybdis of hypoperfusion.

In the most recent study, Morrison and colleagues compared a hypotensive resuscitative strategy targeting a MAP of 50 mm Hg to one targeting a MAP of 65 mm Hg with conventional resuscitation for patients requiring emergent surgery. In a preliminary report, they found that patients in the hypotensive resuscitation group had a lower, early postoperative mortality, a reduced incidence of coagulopathy, and lower mortality related to coagulopathy. Taken in combination, the current consensus at major trauma centers is to allow for hypotensive resuscitation. While the optimal arterial blood pressure remains controversial, a reasonable approach is to target a systolic pressure of less than 100 mm Hg with MAP between 50 to 60 mm Hg.[110]

Finally, the effect of anesthetic drugs on the body's response to hemorrhage is an important difference between deliberate hypotension occurring in the elective operative setting and hemorrhagic shock occurring in the ED. Trauma patients who are hypertensive receive a minimum of anesthetics, even for induction of anesthesia, because of the obvious effect of these drugs on arterial blood pressure. A hypotensive trauma patient is thus in a state of profound vasoconstriction, as opposed to a patient undergoing elective intraoperative hypotension who is vasodilated by general anesthesia before any blood loss. Table 81-4 summarizes the physiologic contrasts between these two states. It should be noted that blood loss without shock does not produce systemic complications such as ARDS in experimental models.[78] Based on this physiology, the recommended goals for early resuscitation are expressed in Box 81-5, and an algorithm for management is presented in Figure 81-8. The emphasis in

TABLE 81-4 DIFFERENCES IN PRESENTATION BETWEEN SURGICAL PATIENTS UNDERGOING ELECTIVE DELIBERATE HYPOTENSION AND EMERGENCY TRAUMA CASES*

Aspect	Elective	Trauma
Intravascular volume	Euvolemic	Hypovolemic
Temperature	Normal	Likely hypothermic
Capillary beds	Dilated	Constricted
Level of general anesthesia	Deep	Usually light
Preexisting mental status	Normal	May be impaired
Coexisting injuries	None	May be significant
Comorbid conditions	Known and managed	Unknown

*Each of these factors produces a real or perceived contraindication to the use of deliberate hypotensive technique in the trauma patient.

BOX 81-5 *Goals for Early Resuscitation**

Maintain systolic blood pressure of 80 to 100 mm Hg
Maintain hematocrit of 25% to 30%
Maintain prothrombin time and partial thromboplastin time in normal ranges
Maintain platelet count at greater than 50,000 per high-power field
Maintain normal serum ionized calcium
Maintain core temperature higher than 35° C
Maintain function of pulse oximeter
Prevent increase in serum lactate
Prevent acidosis from worsening
Achieve adequate anesthesia and analgesia

*Fluid administration to limit hypoperfusion is balanced against an undesirable increase in blood pressure and thus bleeding.

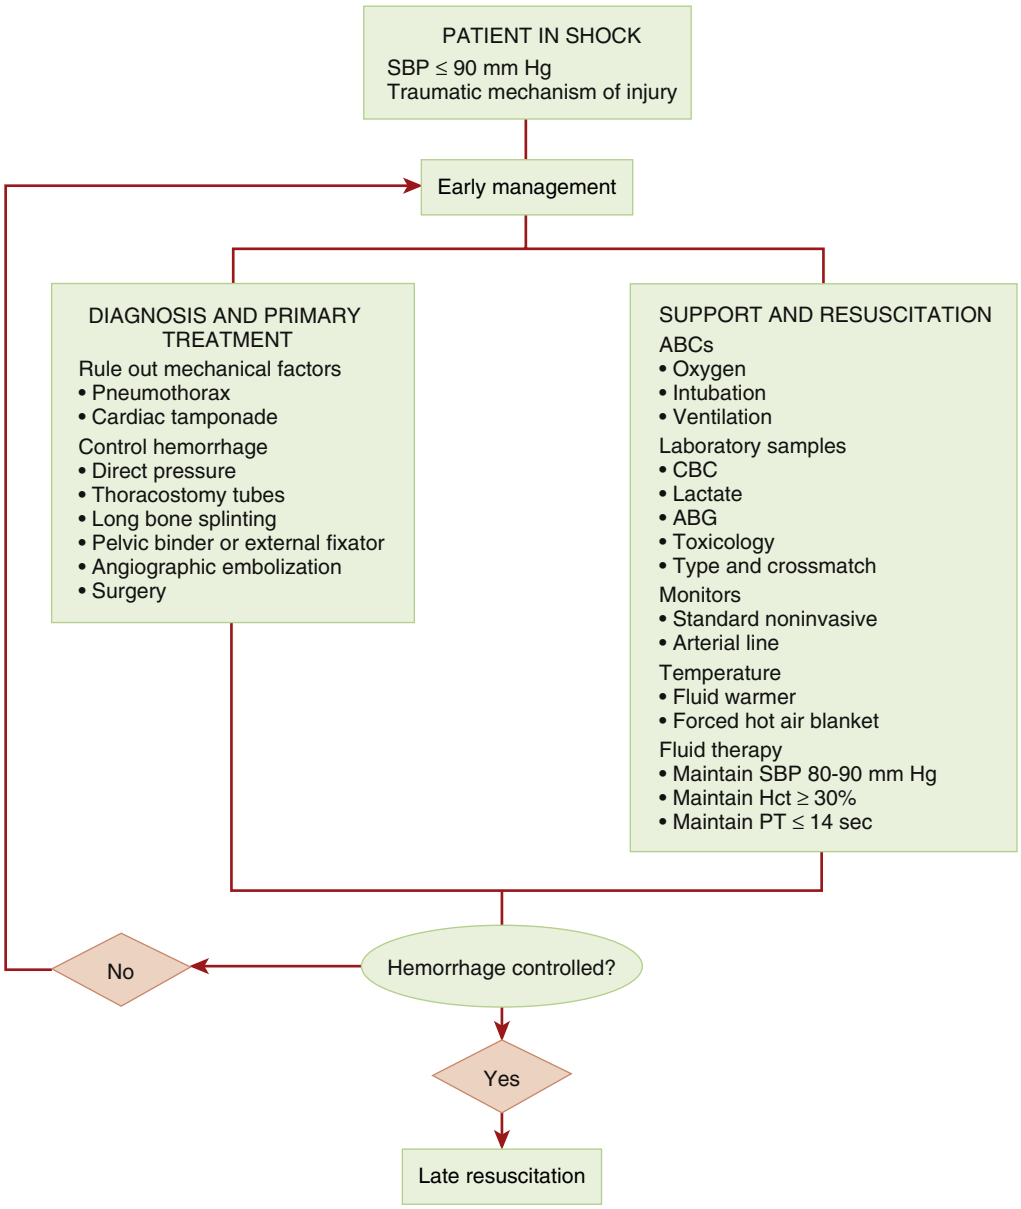

Figure 81-8. Algorithm for management of early hemorrhagic shock. *ABCs,* Airway, breathing, circulation; *ABG,* arterial blood gas; *CBC,* complete blood count; *Hct,* hematocrit; *PT,* prothrombin time; *SBP,* systolic blood pressure.

this situation must be on rapid diagnosis and control of ongoing hemorrhage; vascular volume should be restored and anesthesia provided together by shifting the patient from a vasoconstricted to a vasodilated state while facilitating hemostasis by maintenance of a decreased arterial blood pressure.

HEMOSTATIC RESUSCITATION

As discussed earlier, management of the early coagulopathy associated with trauma must be incorporated into the overall resuscitation strategy—often referred to as a hemostatic resuscitation. Little utility is found in targeting end points of resuscitation in the face of ongoing hemorrhage. Life-threatening coagulopathy is one of the most serious complications of patients in profound shock from massive hemorrhage and is generally predictable at an early stage.[111]

The majority of trauma patients initially present with normal or prothrombotic coagulation profiles. As discussed earlier, the most seriously injured are likely to present with evidence of hypocoagulability, accelerated fibrinolysis, or both, with evidence of ATC.[112,113] The patient's coagulation status must be assessed to initiate appropriate therapy as part of the early resuscitation. Standard laboratory tests such as prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), fibrinogen level, and platelet count are still the most common coagulation assays in clinical use, despite considerable evidence that they provide an extremely incomplete picture of in vivo hemostasis,[114,115] that they are poor predictors of clinical bleeding,[116] and that they do not provide an adequate basis for rational targeted hemostatic resuscitation.[117] Although significantly increased admission PT and PTT levels are predictive of increased mortality from injury,[85] they do not provide a realistic target for resuscitation. In addition, the delay between admission and obtaining the values may be significant when earlier treatment would be beneficial. Moderately increased values may have little clinical significance, and correction to "normal" values may require large amounts of resuscitation fluids, especially fresh frozen plasma (FFP). In the absence of active clinical bleeding, attempts to normalize laboratory values have the potential to introduce transfusion-related and intravascular volume–related complications

These deficiencies underscore the need for reliable point-of-care hemostatic monitoring with clinical relevance in situations of generalized coagulopathy resulting from massive hemorrhage. Increasing evidence indicates that viscoelastic monitoring technologies such as thromboelastography and ROTEM are superior for detecting clinically relevant hemostatic abnormalities in trauma and surgical patients with massive bleeding and diffuse coagulopathy[118,119] (see also Chapter 61). Schöchl and colleagues[120] published a detailed review on the use of viscoelastic monitoring on targeted resuscitations. Both viscoelastic and standard coagulation tests are generally performed after warming specimens to 37° C and do not reflect the potentially considerable effects of hypothermia on in vivo hemostasis.[121]

Because of evidence that severely injured trauma patients are likely to develop an early and aggressive endogenous coagulopathy separate from later loss and dilution of clotting factors compounded from hypothermia and acidosis,[85,88,122] the practice of hemostatic resuscitation has become commonplace in the most severely injured patients with shock and ongoing hemorrhage. This entails the early and aggressive use of hemostatic products combined with red blood cells (RBCs) as the primary resuscitation fluids to avoid rapid deterioration into the "bloody vicious cycle" and the classic lethal triad of hypothermia, acidosis, and coagulopathy.[123] Two very distinct paradigms of hemostatic resuscitation have emerged: (1) the damage control resuscitation model, which uses preemptive administration of empiric ratios of blood and hemostatic products to approximate whole blood, often according to an established institutional massive transfusion protocol[124-127] (Fig. 81-9); and (2) goal-directed hemostatic resuscitation approaches (also often protocol based), which generally use point-of-care viscoelastic monitoring combined with the prompt administration of hemostatic concentrates[114,115,120,128] (see also Chapter 61).

The application of damage control resuscitation relies on hypotensive resuscitation and limited crystalloid usage, as discussed previously in conjunction with the administration of empiric ratios of blood and hemostatic products. In a retrospective review of combat casualties, Borgman and colleagues[129] found a mortality rate of 65% in patients receiving less than 1 unit plasma for every 4 units RBCs, but only 20% in those with a ratio of 1:2 or above. Evidence exists of a survivor bias because patients bleeding more rapidly were likely to die after receiving RBCs but before plasma could reach the bedside. Although the issue of a survivor bias does exist, this approach has been substantiated in published reviews.[129,130] Currently a ratio of 1:1:1 is most commonly adopted, although some experts believe that the amount of FFP can be reduced in most cases.

In addition to the hypocoagulability associated with ATC, fibrinolysis is especially deleterious in severely injured trauma patients and carries an associated mortality well upward of 50%.[112,131] Many patients with primary fibrinolysis from severe hemorrhagic shock may never survive to reach the ICU. The recently concluded Clinical Randomisation of an Antifibrolytic in Significant Haemorrhage 2 (CRASH-2) trial is the only class I evidence showing a 30-day survival benefit for a resuscitative therapy including tranexamic acid (TXA).[132] Subgroup analysis showed that the benefit was greatest when therapy was instituted within 1 hour of admission. A subsequent analysis, however, showed that mortality actually increased when therapy was instituted after 3 hours, suggesting that the risks of therapy outweighed the benefits in patients who survived beyond that timeframe.[133] Many resuscitative protocols for massive hemorrhage now include the early administration of TXA based on this and subsequent studies.[134]

Other potential drugs that may play a role in hemostatic resuscitation include recombinant activated human coagulation factor VII (rFVIIa), prothrombin complex concentrates (PCC), and fibrinogen concentrates. rFVIIa

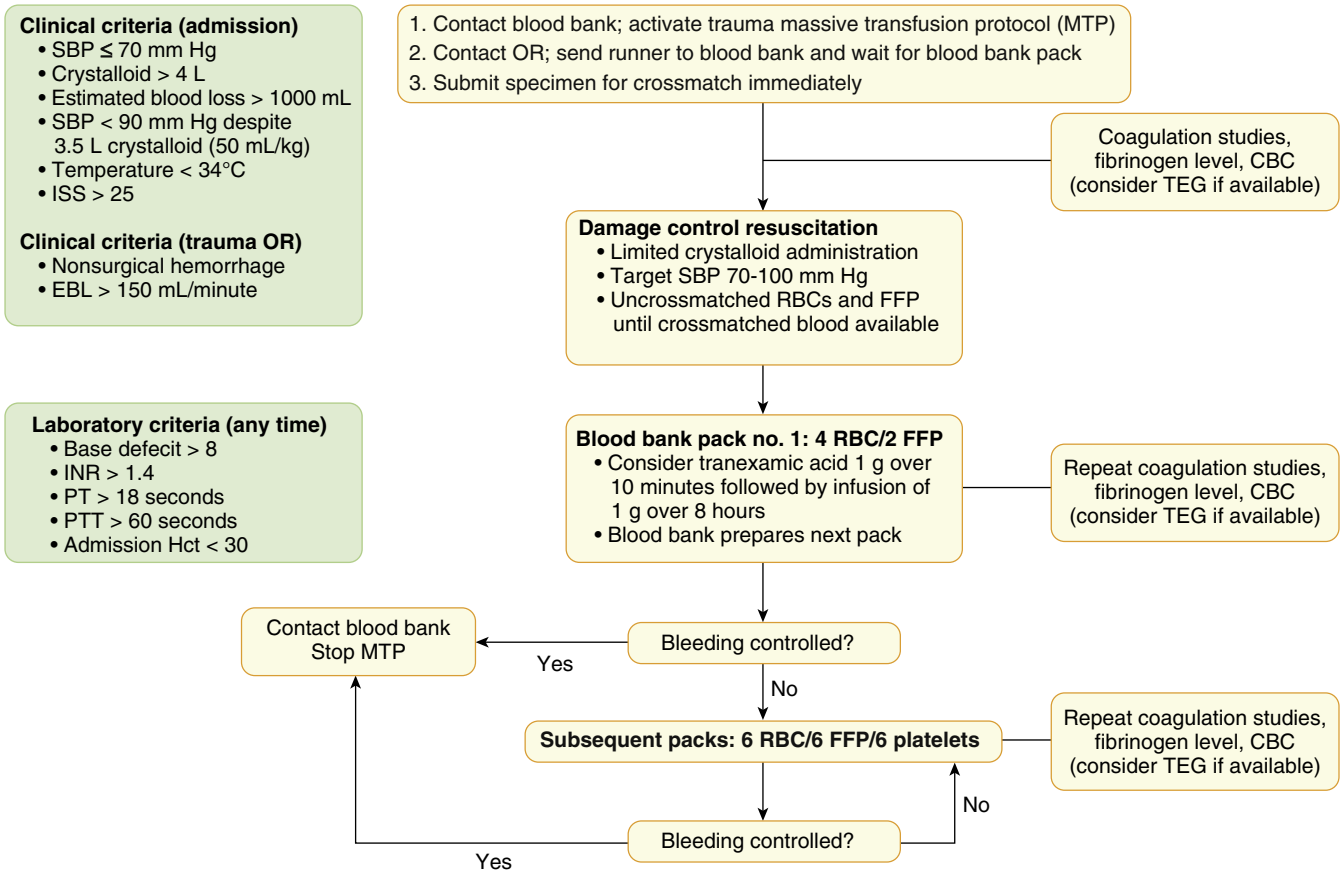

Figure 81-9. Example of a massive transfusion protocol using specified ratios of blood products. *CBC,* Complete blood count; *EBL,* estimated blood loss; *FFP,* fresh frozen plasma; *INR,* international normalized ratio; *ISS,* injury severity score; *OR,* operating room; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *RBC,* red blood cell; *SBP,* systolic blood pressure; *TEG,* thromboelastogram.

is licensed for the treatment of patients with hemophilia with active or anticipated hemorrhage and known antibodies to factor VIII (see also Chapters 59 and 61). The observation of rapid hemostasis in this population led to the anecdotal use of rFVIIa in other congenital and acquired coagulopathies, including the dilutional coagulopathy of traumatic hemorrhage. Factor VIIa in pharmacologic doses works by triggering a burst of thrombin on the surface of platelets activated by exposed tissue factor, which produces rapid clot formation. Because tissue factor is required, coagulation is limited to the site of vascular injury, and inappropriate clotting of uninjured organs or vessels, though an acknowledged risk, occurs at only low frequency.[135] Prospective trials of rFVIIa have demonstrated decreased blood loss in patients undergoing elective open prostate surgery[136] and rapid reversal of coagulopathy in patients taking warfarin.[137] Retrospective reports have suggested a role for rFVIIa in the management of acute traumatic hemorrhage,[138] gastrointestinal hemorrhage secondary to cirrhosis,[139] hemorrhage after cardiovascular surgery[140] and liver transplantation,[141] and intracranial hemorrhage in both neonates[142] and older patients.[143] One small placebo-controlled trial of rFVIIa in hemorrhaging trauma patients has demonstrated decreased blood loss, decreased transfusion requirements, and improved outcome,[144] although a large, randomized trial failed to show a mortality benefit.[145]

Experience with PCCs in clinical practice is limited. PCC has been used for many years for the treatment of congenital coagulation disorders and is recommended for reversing oral anticoagulation. PCCs contain coagulation factors II, VII, IX, and X. Differences exist among products in the concentrations of these factors and other constituents, including heparin, protein C, and protein S, so results obtained with one product may not be obtained with a different formulation. Fibrinogen concentrates also may have a role in a hemostatic resuscitation for the patient with a coagulopathy with low levels of fibrinogen.[146]

VULNERABLE PATIENT POPULATIONS

Clinical trials of deliberate hypotensive resuscitation have avoided the application of this technique to populations perceived to be at greater risk for ischemic complications,[105,109] including patients with known ischemic coronary disease, older patients, and those with injuries to the brain or spinal cord (see also Chapters 39, 70, and 80). The prohibition against hypotension in patients with TBI is especially well established because of the observed disparity in outcome between TBI patients who experience hypotension and those who do not.[147,148] Older trauma patients suffer worse outcomes from similar injuries than younger patients, presumably because of their reduced

physiologic reserve.[149] Clinical care of these patients is focused on avoidance of ischemic stress and rapid correction of hypovolemia. It may well develop, however, that deliberate hypotensive management to enable rapid control of hemorrhage is equally beneficial in vulnerable populations. No clinical trials to date have been conducted on this subject, but a laboratory study did find a benefit of deliberate hypotension in animals with both TBI and hemorrhagic shock.[150] Absent convincing evidence in humans, deliberate hypotension in older patients or patients with brain injury should generally be avoided.

RESUSCITATION FLUIDS

Isotonic crystalloids (normal saline, lactated Ringer solution, Plasma-Lyte A) are the initial resuscitative fluids administered to any trauma patient (see also Chapter 59). They have the advantage of being inexpensive, readily available, nonallergenic, noninfectious, and efficacious in restoring total body fluid. They are easy to store and administer, they mix well with infused medications, and they can be rapidly warmed to body temperature. Disadvantages of crystalloids include their lack of O_2-carrying capacity, their lack of coagulation capability, and their limited intravascular half-life. More recent laboratory data have implicated specific crystalloid solutions as immunosuppressants and triggers of cellular apoptosis.[151] Unlike necrosis, apoptosis is highly regulated and involves gene modulation and complex pathways of signal transduction. It seems clear that apoptosis is an important element of reperfusion injury. In a rat model of controlled hemorrhage, animals receiving lactated Ringer solution showed an immediate increase in apoptosis in the liver and small intestine after resuscitation.[152] Neither whole blood nor hypertonic saline increased the amount of apoptosis.

Hypertonic saline solutions, with or without the addition of polymerized dextran (HS or HSD), have been extensively studied in resuscitation from hemorrhagic shock.[153] In theory, HS will draw fluid into the vascular space from the interstitium and thereby reverse some of the nonhemorrhagic fluid loss caused by shock and ischemia. A given amount of HS will thus have an enhanced ability to restore intravascular volume in contrast to an equivalent volume of an isotonic solution. This has made HS a popular choice for fluid resuscitation under austere conditions. HSD is licensed for prehospital use in some European countries and is used for resuscitation by units of the U.S. military. Multiple studies of otherwise lethal hemorrhage in animals have demonstrated improved survival after resuscitation with HSD versus either normal saline solution or the components of HSD alone. Studies of the efficacy of HSD in trauma patients have been inconclusive[154]; the most obvious benefit occurred in a subset of polytraumatized patients with both hemorrhage and TBI, in whom improved neurologic status was demonstrated in those who received HSD as a resuscitation fluid. Indeed, HS is commonly used as an osmotic agent in the management of TBI with increased ICP.[155]

Colloids, including starch solutions and albumin, have been advocated for rapid plasma intravascular volume expansion (see also Chapter 61). Like crystalloids, colloids are readily available, easily stored and administered, and relatively inexpensive. As with hypertonic solutions, colloids will increase intravascular volume by drawing free water back into the vascular space. When IV access is limited, colloid resuscitation will restore intravascular volume more rapidly than crystalloid infusion will and at a lower volume of administered fluid. Colloids do not transport O_2 or facilitate clotting; their dilutional effect will be similar to that of crystalloids. Systematic reviews continue to show no benefit of colloids over crystalloids in the setting of trauma resuscitation,[156] although this topic continues to generate significant controversy and would benefit from several well-conducted, randomized trials.[157] Recent concerns, however, have been expressed about specific colloids such as 6% hetastarch and an adverse effect on renal function (see also Chapter 61).[158]
