Although these criteria published in 2007[27] are commonly used in many sleep centers for clinical and research purposes all over the world, questions about whether the new criteria should be used in children[45] and the scoring of some respiratory events are still unanswered.

PHYSIOLOGY

EVOLUTION

In a rhythmic world, organisms must adapt to alternating changes in the environment, such as daily and seasonal rhythms in light intensity, ambient temperature, and humidity. It is unknown why we sleep; however, one can imagine that evolutionary pressure would favor systems that are optimized for nature's rhythms.[46-48]

Species-dependent temporal behavior can be adapted depending on the environmental conditions: behaviorally, anatomically, and physiologically. Circadian rhythms affect almost every aspect of the body, including activity and rest patterns, cognitive function (e.g., learning and memory), physiology (e.g., heart rate, metabolism, and hormone secretion), and gene expression; 15% of the genes in the human body show daily rhythms.

CIRCADIAN RHYTHMS

Virtually all species show circadian rhythms that regulate periodic changes in behavioral and physiologic parameters within a period of approximately 24 hours.[49] These rhythms can be characterized as a synchronization of activity to the external light-dark cycle in the majority of living creatures. Bacteria, plants, animals, and humans exhibit such a behavior that helps them stay in tune with the environmental light-dark cycles.[50] Clock genes generate endogenous clock pulses in most (if not all) cells of the body, synchronized by regulatory pathways across the body to a superior rhythm generator (a so-called master clock). Desynchronization of these rhythms seems to be involved in the pathogenesis of metabolic, psychiatric, and other disorders.[50] The superior rhythm generator in humans is located in the suprachiasmatic nucleus that receives external inputs about light and darkness from the retinal cells and synchronizes inputs of melatonin levels. While this master clock synchronizes the behavioral and biological rhythms of the human body to the changing demands of the environment during the solar day, sleep itself entrains circadian rhythms,[50-52] and the temporal organization of circadian rhythms and nocturnal sleep must be preserved to accomplish a restful and refreshing experience that fulfills the sleep needs produced by the second major regulatory factor, sleep homeostasis. During waking, "sleep pressure" continuously increases, leading to a consecutive decrease in the threshold preventing a transition from wakefulness to sleep.[53] Increasing homeostatic sleep pressure can be partly offset by a sufficient circadian wakening stimulus during the circadian wake phase, but

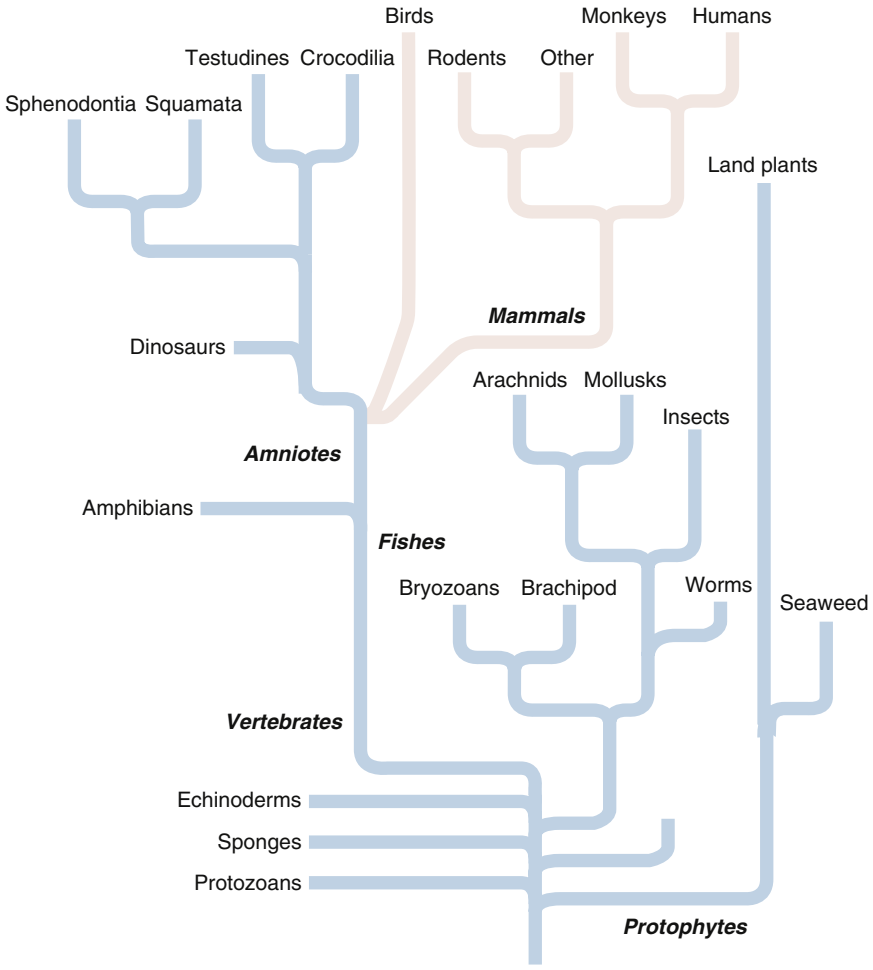

Figure 14-3. Evolutionary tree. Circadian rhythms are common among all living beings. However, only mammals and birds *(red)* have integrated sleep with different stages. Fish, reptiles, insects, and plants *(blue)* manifest circadian rhythms as periods of activity and rest.

the circadian wake stimulus disappears in the presence of an overwhelming sleep pressure.[54,55] In this situation, sleep sufficient in quantity and quality is needed to reestablish proper functioning.

Although circadian and homeostatic regulation of sleep can be observed in almost all living organisms,[56] differentiation of sleep into NREM and REM sleep ("integrated sleep") probably has developed during the last 300 to 350 million years because it appears only in birds and the majority of terrestrial mammals (Figure 14-3).[57,58]

Sleep Stages and Sleep Cycles

Sleep architecture, which is a structured temporal order of different sleep stages, are important determinants of sleep quality. If tired individuals rest in their individual sleeping postures, the increasing level of drowsiness is paralleled by continuous EEG slowing from EEG activity seen during attention and cortical activation (16 to 30 Hz, "beta activity") to slower frequencies, predominantly between (7.5 and 11 Hz, "alpha activity," typically observed in subjects at reduced attention and closed eyes). During this state of vigilance the individuals do not sleep, and a full level of cognitive function can be established easily even without a strong sensory stimulus. The transition from the alpha state to sleep is paralleled by a decrease in alpha and beta activity and an increase of EEG activity in the theta band (4.5 to 7.5 Hz; Figure 14-4).

This transition from alpha to theta activity is widely accepted as the electroencephalographic correlate of sleep onset.[59] At this transition from wakefulness to NREM sleep stage 1, heart rate and heat production decrease resulting in a slight decrease in body temperature. Furthermore, respiration is regular and deep. As sleep deepens, EEG activity shows low amplitudes and theta activity with intermittent sleep spindles and K-complexes. The latter can represent an activation of brainstem and subcortical brain areas during sleep,[60,61] potentially representing selective processing of unexpected sensory inputs (e.g., sounds) that require complete arousal and restoration of consciousness to address a potential threat.[62] In accordance with that hypothesis, in comatose patients with brain injury, the presence of K-complexes in response to an acoustic stimulus during coma seems to be a marker of a better outcome compared to comatose patients with no evoked K-complexes.[63]

With increasing depth of sleep, during NREM sleep, electrical activity of the cortex measured by EEG is dominated by slower frequencies and high amplitudes (stage 3 and 4 R&K[26] and NREM sleep 3 AASM[40]), also referred to as *slow-wave sleep*.

REM sleep, or paradoxic sleep, is associated with an alteration of homeostatic regulation, increased heart rate variability, irregular respiration, and impaired body temperature control. Brain metabolism increases while

Figure 14-4. Electroencephalogram recording during sleep onset *(arrow)*. The *two top rows* show bipolar electroencephalogram (EEG) signals from left (C3-A1) and right (C2-A1) frontal leads. Rows 3 to 5 show the relative amount (EEG power) of beta, alpha, and theta activity calculated using fast fourier transformation.

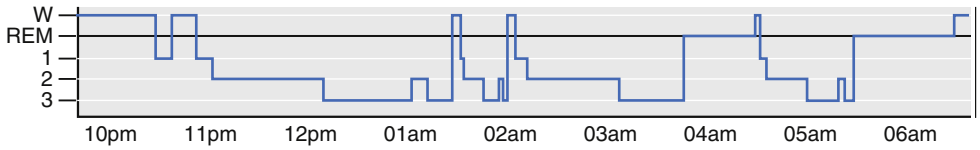

Figure 14-5. Hypnogram of a night of physiologic sleep. During one night (time on *x* axis) of sleep, humans transition repetitively from one sleep stage to another with short episodes of occasional wakefulness (indicated on *y* axis). *REM,* Rapid eye movement sleep; *W,* awake; *1,* non-REM sleep stage 1; *2,* non-REM sleep stage 2; 3, non-REM sleep stage 3 (slow wave seep).

EEG recordings show similarities to wakefulness with low voltage and mixed-frequency power spectra. There are also prominent theta waves generated by the hippocampus. These waves are not apparent in the scalp EEG recording from humans, but in rodents, in which the hippocampus is larger and closer to the brain surface, the EEG is dominated by theta during REM. This sleep state is associated with a decreased tone in skeletal muscles (except for extraocular muscles that control eye movement). Dreaming is a typical experience during REM sleep,[77] but can happen also during NREM sleep.[65] During physiologic sleep, an individual typically switches back and forth across sleep stages, interrupted by occasional arousals from sleep (Figure 14-5).

NEUROANATOMY OF SLEEP

Sleep Promoting and Arousal Pathways

Several neuronal pathways have evolved to maintain cortical activation and behavioral arousal during normal waking, and others have evolved to promote and maintain sleep (Figure 14-6). It is the balance between these two systems that determines whether one is awake or asleep.

Ascending Arousal System. The ascending arousal system (AAS) is the main wakefulness-mediating network in the brain. Main pathways within the network receive cholinergic, monoaminergic, dopaminergic, and glutamatergic inputs. Cholinergic inputs originate from pedunculopontine and laterodorsal tegmental nuclei, and they mainly innervate the lateral hypothalamus, prefrontal cortex, basal forebrain, and thalamic relay nuclei (i.e., medial and lateral geniculate nuclei; mediodorsal nucleus; pulvinar; anterior, ventral and lateral thalamic cell groups).[66,67] Glutamatergic neurons that provide inputs to the AAS are mainly located within a small area just ventral of the locus coeruleus (LC), the precoeruleus area (PC), as well as in the parabrachial nuclei that mainly project to the basal forebrain and the lateral hypothalamus.[68-73] Monoaminergic inputs mainly come from noradrenergic neurons within the locus coeruleus, histaminergic neurons of the tuberomammillary nuclei (TMN), serotoninergic neurons of the median and dorsal raphe nuclei,[74-76] as well as dopaminergic neurons adjacent to dorsal raphe nuclei.[76,77] Beside

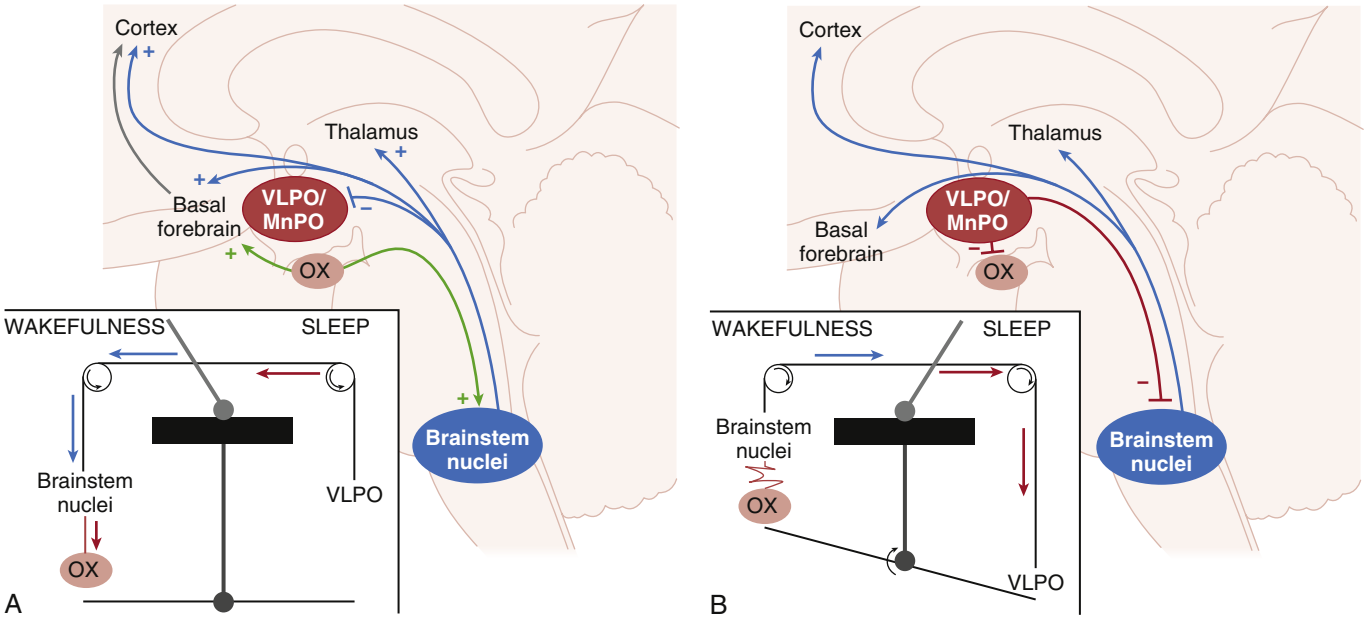

Figure 14-6. Flip-Flop switch ensuring rapid transitions between wakefulness and sleep. During wakefulness *(top)*, brainstem nuclei of the ascending arousal system (AAS) directly and indirectly provide excitatory input to the thalamus, basal forebrain (BF), and the cerebral cortex, while they inhibit the ventrolateral (VLPO) and median (MnPO) preoptic nuclei (switch flips to wakefulness). The excitatory, wake-promoting stimulus is enforced by additional excitatory input of orexinergic neurons (OX) to the BF and the AAS. During sleep *(bottom)*, neurons of VPLO and MnPO inhibit the brainstem and orexinergic neurons of the AAS (switch flops to sleep) *(Modified from Saper CB et al: Hypothalamic regulation of sleep and circadian rhythms,* Nature *437:1257–1263, 2005; and Saper CB et al: Sleep state switching,* Neuron *68:1023–1042, 2010.)*

projections to the basal forebrain, multiple inputs are sent to the thalamus, mainly the inter-laminar and reticular nuclei, as well as the amygdala and cerebral cortex. Furthermore, noradrenergic neurons of the LC project mainly to the posterior part of the lateral hypothalamus. In return, the latter area of the lateral hypothalamus projects to the LC and to the TMN.

Some neurons of the posterior hypothalamus produce orexin A and B (also known as hypocretin 1 and 2). These neurons project to the basal forebrain and the amygdala and cerebral cortex and other important arousal areas, and they are essential for stabilizing the waking state.[78] Orexin deficiency causes narcolepsy (severe daytime sleepiness) with cataplexy (abrupt loss of muscle tone),[79] a disorder showing some characteristics of REM sleep (i.e., REM sleep atonia during wakefulness [discussed later]).

NREM Sleep-Promoting Pathways. About 100 years ago during the epidemic of encephalitis lethargica, it was observed that lesions in the preoptic region around the rostral end of the third ventricle were associated with profound insomnia,[80] which was confirmed in neuroanatomic experiments (lesion studies) in rats and cats.[81,82] Recent data show that neurons in the preoptic area are active during sleep.[83-87] Two key nuclei within this area are the ventrolateral preoptic nucleus (VLPO) as well as the median preoptic nucleus. VLPO neurons fire at a higher frequency during sleep compared with wakefulness.[85,88] Anatomically, the VLPO consists of a dense core of sleep-active, galanin-positive neurons innervating the TMN (which is part of the AAS) while being surrounded dorsally and medially by a more diffuse population of sleep-active, galanin-positive neurons that project to the dorsal raphe and LC.[89,90] Physiologically, the VLPO neurons constitute a sleep-promoting pathway that inhibits many components of the arousal system during sleep. Likewise, parts of the arousal system such as the laterodorsal tegmental nucleus and the pedunculopontine tegmental nucleus, as well as the locus coeruleus, the parabrachial nucleus, the dorsal raphe nucleus, the precoeruleus area, the ventral periaqueductal gray, and the TMN are capable of inhibiting the VLPO. The mutually inhibitory relationship of the arousal and sleep-promoting pathways produces the conditions for a flip-flop switch, which can generate rapid and complete transitions between waking and sleeping states[91,92] (see Figure 14-3). It also makes simultaneous activation of arousal and sleep circuits highly improbable.

Because animal experiments showed that even large lesions of the VLPO substantially reduce but do not completely erase sleep, other brain areas beside this nucleus are likely involved in promoting sleep.[93] Several basal forebrain areas,[84,87,94] as well as some γ-aminobutyric acid (GABA)-ergic interneurons across the cerebral cortex[95] have been implicated to function as sleep-active neurons. Nevertheless, the role of these brain regions in the promotion or regulation of sleep remains unclear.

REM Sleep-Promoting Pathways and NREM-REM Transition. During normal sleep that presents at onset as a sharp alpha-theta EEG activity transition, a similar sharp transition from NREM to REM sleep can be observed. Two groups of mutually inhibitory neurons located in the pons are involved in mediating the switch between NREM and REM sleep.[71] The first group consists of REM active inhibitory neurons of the sublaterodorsal nucleus and the precoeruleus region.[73,92,96] These neurons inhibit and are

inhibited by a second group of neurons that are located in ventrolateral periaqueductal gray and adjacent lateral pontine tegmentum. This mutually inhibitory relationship produces a REM-NREM flip-flop switch, promoting rapid and complete transitions between sleep states.[92]

Within the sublaterodorsal nucleus and PC, glutamatergic neurons are mixed within the population of REM-on GABAergic neurons. The glutamatergic sublaterodorsal nucleus neurons project to the spinal cord and are important for REM sleep atonia; the glutamatergic PC neurons activate forebrain pathways driving EEG desynchronization and hippocampal theta rhythms—that is, the characteristic EEG signs of REM-sleep.[97]

BIOLOGIC EFFECTS OF SLEEP AND SLEEP DEPRIVATION

Sleep conserves energy and suppresses energy-consuming behaviors, similar to the effect of hibernation.[57,98] Recent findings indicate that sleep can protect against aging-related neurodegeneration by decreasing effects of oxidative stress. More specifically, sleep deprivation increases oxidative stress in the hippocampus and subcortical brain regions and impairs the generation of new neurons in the dentate gyrus of the hippocampus.[99] Together, these data suggest that NREM sleep has a general role in allowing or facilitating neurogenesis, preventing neurodegeneration, and neuronal energy consumption.[57]

In addition, compelling evidence links sleep to the metabolic, endocrine, immune, and inflammatory systems.[100-104] For example, sleep deprivation during influenza vaccination delays the increase of antibody titers.[105] Furthermore, even short sleep deprivation in otherwise healthy young subjects has been shown to be associated with impaired glucose tolerance, glucose effectiveness, and early insulin response, to levels usually seen in patients in the early course of diabetes mellitus, as well as changes in the activity of the hypothalamo-pituitary-adrenal axis with altered plasma levels of cortisol and thyrotropin.[106] These findings have been hypothesized to affect the outcome of critically ill patients[107] (see also Sleep in the Intensive Care Unit).

SLEEP AND BREATHING

RESPIRATORY REGULATION DURING SLEEP

Sleep puts breathing at risk. The upper airway dilator muscle activity is decreased during sleep compared with wakefulness, particularly at sleep onset and during REM sleep. Furthermore, the ventilatory response to hypoxia can be impaired, such that critical hypoxia levels can occur during sleep that can be offset only by arousal from sleep.

The major determinant of minute ventilation during wakefulness and sleep is the arterial partial pressure of carbon dioxide ($PaCO_2$). In contrast to wakefulness where $PaCO_2$ is maintained close to 40 mm Hg, the chemosensitivity to CO_2 decreases during sleep, as does the chemosensitivity for oxygen. This leads to $PaCO_2$ values of 45 mm Hg commonly occurring during stable sleep, while ventilatory demand is decreased and the arousal threshold varies with sleep stages.

Accordingly, the changes in respiratory muscle activity, ventilatory demand, and arousal threshold observed from wakefulness to sleep and across sleep stages challenge ventilatory control and can lead to instability in breathing. A structured approach to evaluating breathing instabilities is the loop gain. This engineering term is used to describe the stability of a feedback-controlled system (in this case, the chemical feedback loop controlling an individual's ventilation). In the setting of ventilatory control, loop gain reflects the propensity of an individual to develop periodic (unstable) breathing. Patients with a high loop gain caused by a more sensitive respiratory controller (i.e., high controller gain), more effective CO_2 excretion (i.e., high plant gain), or an increased delay because of slowed CO_2 distribution from peripheral tissues to the central chemoreceptors based on, for example, reduced blood circulation (i.e., mixing gain), may be more vulnerable to disturbances of the feedback system, such as slight hypoventilation that occurs as a consequence of decreased upper airway dilator muscle activity during the transition from wakefulness to sleep (Figure 14-7).

If airway obstruction causes arousal, there will be an abrupt decrease in the CO_2 set-point. Excessive hyperventilation as a consequence of high loop gain will lead to relative hypocapnia as the system overcompensates. It is believed that this lower CO_2 level will suppress upper airway dilator muscle activity and make the individual more susceptible to subsequent airway occlusion when he or she returns to sleep. Thus, high loop gain may contribute to severity of obstructive sleep apnea. Moreover, subjects with a high loop gain have been shown to be more likely to develop breathing instabilities such as Cheyne-Stokes respiration (CSR; see *Central Sleep Apnea*).

SLEEP-DISORDERED BREATHING

Sleep-associated respiratory signs and symptoms of dysfunction are referred to as *sleep-disordered breathing* (SDB) and are defined by the occurrence of respiratory events, which are cessations in breathing rhythm (apneas) or momentary or sustained reduction in the breathing amplitude (hypopnea) during the sleeping state, leading to arterial hypoxemia.[108] They are usually caused either by increases in upper-airway resistance because of a reduction in the airway intraluminal diameter (the obstructive event), marked reduction or cessation of brain stem respiratory motor output (the central event), or both. A specification of SDB into predominantly obstructive or central sleep apneas is being developed based on the type of respiratory events.

Obstructive Sleep Apnea

Definition. The most common type of SDB is OSA, usually quantified by the number of respiratory events per hour of sleep. A quantification of nocturnal respiratory events is necessary because a low number of short apneas and hypopneas can occur up to about five times

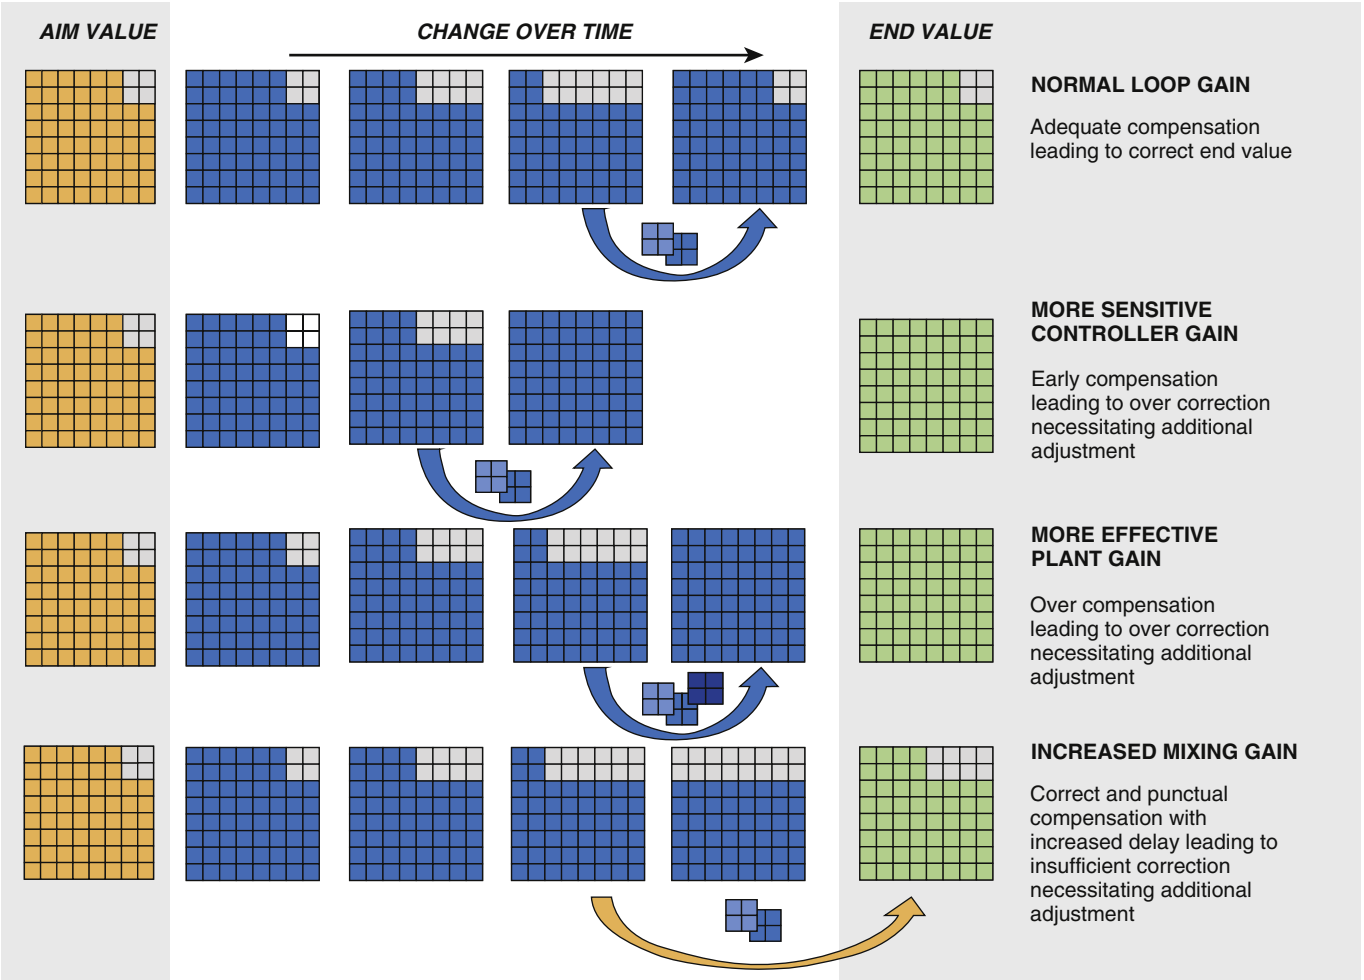

Figure 14-7. Model of changes in loop gain and its effect on the stability of a feedback controlled system. Low or normal loop gain provides adequate compensation of external disturbing stimulus *(top),* while increased controller gain *(second from top),* increased plant gain *(third from top),* or mixed gain *(bottom)* result in an inadequate duration of compensatory mechanisms *(red arrow),* thus leading to an instability in the feedback controlled system.

$$\text{AHI} = \frac{\text{Apneas (10 sec without flow)} + \text{Hypopneas (reduced flow with desaturation)}}{\text{Total sleep time (h)}}$$

$$\text{RDI} = \frac{\text{Apneas} + \text{Hypopneas} + \text{Arousals (in EEG) associated respiratory event}}{\text{Total sleep time (h)}}$$

Figure 14-8. Definition of apnea hypopnea index (AHI) and respiratory disturbance index (RDI).

per hour in healthy subjects. Two measures can be used for this purpose: the apnea hypopnea index (AHI) and the respiratory disturbance index (RDI). Typically, the AHI (number of hypopneas and apneas per hour of sleep; Figure 14-8, *top*) and RDI (number of hypopneas, apneas, and arousals related to respiratory events per hour of sleep; see Figure 14-8) are used to quantify the severity of SDB.

RDI values of five or more predominantly obstructive events per hour of sleep are commonly referred to as OSA; this cut-off value has been used as an indication for treatment by clinicians based on the current clinical guidelines of the AASM,[27,28] in which the severity of sleep apnea is further characterized as mild with 5 to 15 or less events per hour of sleep, as moderate with 15 to 30 or less events per hour of sleep, and as severe sleep apnea with 30 or more events per hour of sleep (Table 14-4).[27,31,109]

Epidemiology. OSA with daytime symptoms affects 0.3% to 5% of the general population.[110-112] As obesity is one of the major risk factors for OSA, the prevalence might continue to increase with higher rates of obesity in the general population.[113-115] The prevalence of SDB without daytime symptoms is even higher, with rates of up to 9% in women and 24% in men between the ages of 30 and 60 years and is often unrecognized.[116,117]

TABLE 14-4 SEVERITY OF SLEEP APNEA BASED ON RDI OR AHI

	RDI (per hour)	AHI (per hour)
No sleep apnea	<5	<5
Mild sleep apnea	≥5 to <15	≥5 to <15
Moderate sleep apnea	≥15 to <30	≥15 to <30
Severe sleep apnea	≥30	≥30

A respiratory disturbance index (RDI) less than 5 per hour is physiologic and found in healthy humans. Sleep apnea is mild with RDI between 5 and 15 per hour, moderate with RDI between 15 and 30 events per hour, and considered severe with an RDI of 30 and greater per hour of sleep. Equal cutoff values are similar for severity based on the apnea hypopnea index (AHI).

BOX 14-1 ***Symptoms of Obstructive Sleep Apnea***

Nighttime Symptoms

- Frequent awakening during the night (e.g., pseudo nocturia)
- Awaking from own snoring with choking sensation
- Tachycardia
- Sleep that is not restorative

Daytime Symptoms

- Awaking with dry mouth
- Dull headache in the morning
- Daytime sleepiness
- Falling asleep during monotonic situations (e.g., watching television)
- Subjective impairment of cognitive function

Symptoms Reported by Bed Partner

- Snoring, especially when loud and arrhythmic
- Observed pauses in breathing during sleep

Furthermore, the prevalence of OSA varies widely between different populations. Individuals with a high susceptibility to OSA include the obese (see Chapter 71), the elderly (see Chapter 80), and those with specific comorbidities (e.g., stroke, myocardial infarction), as well as surgical patients. Depending on methodology, the rates of OSA in surgical patients is between 45%[118] and 75%.[119] A recent study in patients undergoing bariatric surgery revealed an incidence of OSA of as high as 77.5% (618 of 797 patients) in this population.[120]

Clinical Symptoms. Approximately one third of patients with OSA complain of typical signs and symptoms occurring during wakefulness. Awaking with dry mouth, headache in the morning, daytime sleepiness, falling asleep during monotonous situations (e.g., watching television), as well as subjective impairment of cognitive function are frequently reported. This combination of OSA with daytime symptoms is usually referred to as OSA syndrome (OSAS).[121,122]

Sleep-associated signs and symptoms of OSAS include witnessed pauses in breathing or snoring, and a high number of nocturnal awakenings, mostly reported as pseudonocturia with patients occasionally complaining of tachycardia or respiratory distress upon awakening (choking sensation) and other symptoms (Box 14-1).

During clinical examination, craniofacial abnormalities affecting the airway, or other facial anatomic structures limiting the upper airway diameter might, indicate a patient at risk for OSA. A neck circumference of 43.2 cm (17 inches) in men or 40.6 cm (16 inches) in women has been shown to be associated with an increased risk for OSA. Although OSA is more frequent in obese patients, it might also occur in patients with normal or even low body mass indices. Given the variety of pathophysiologic mechanisms of OSA, it is not a surprise that even slim patients have OSA or OSAS.

Consequences and Comorbidities. Obstructive sleep apnea is associated with meaningful medical consequences, such as hypertension, myocardial infarction, stroke,[121,123-129] impaired glucose tolerance, diabetic neuropathy, as well as cognitive dysfunction resulting in occupational difficulties and motor vehicle crashes.[130-134] The development of cognitive impairment in patients with OSA[135] is paralleled by an atrophy of brain structures relevant for cognition and memory (hippocampal areas)[136] that can at least be partially reversed by adequate treatment.[137] Whether the negative effects of OSA are due to impaired sleep architecture or effects of intermittent hypoxia remain unclear,[138] because data investigating the effect of intermittent hypoxia without other symptoms in OSA patients are limited. Nevertheless, recent findings suggest that even asymptomatic OSA might be associated with cardiovascular effects, such as altered daytime autonomic regulation (i.e., heart rate variability).[139]

Given the frequent rate of complications associated with OSA, it is not a surprise that OSA leads to increased socioeconomic costs because of significantly more frequent rates of health-related contacts and medication use, and even higher rates of unemployment.[140]

Risk Factors. Predisposing factors for obstructive sleep apnea are obesity,[141] age,[141,142] male sex,[141] factors leading to swelling of the superficial tissue of the upper airway (smoking),[143] allergic rhinitis,[144] and decreased muscle tone of upper airway dilator muscles (e.g., central nervous system) caused by depressants.[145-147]

Pathophysiology. Respiratory events during OSA are characterized by decreased respiratory flow with persisting respiratory effort due to reduced intraluminal diameter of the upper airway up to complete pharyngeal airway collapse (see Figure 14-2). The muscles involved in respiration are morphologically and functionally skeletal muscles and can be classified by their anatomic function into two groups: upper airway dilator muscles and respiratory pump muscles.

Upper airway dilator muscles counterbalance the negative inspiratory pressure generated by the pump muscle to permit airflow during inspiration. Respiratory pump muscles are the collection of muscles responsible for generating inspiratory and expiratory forces in the thorax across the breathing cycle (Figure 14-9). The patency of the upper airway is maintained by balancing dilating forces (generated by the upper airway dilator muscles) and collapsing forces (i.e., negative intraluminal pressure generated by the respiratory pump during inspiration and compressive extraluminal forces from the surrounding tissues).[148]

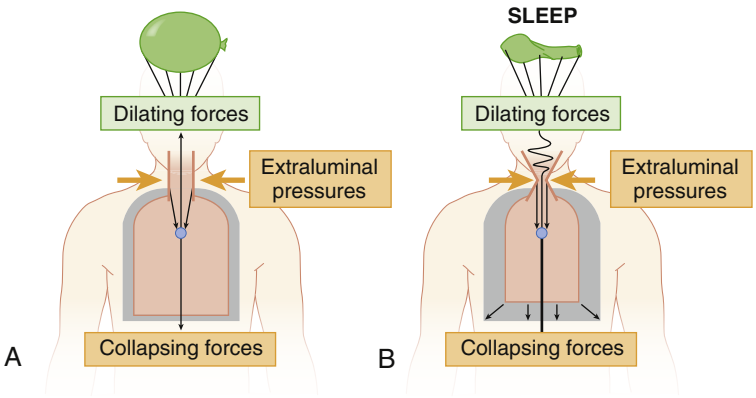

Figure 14-9. Relationship of upper airway patency and respiratory pump activation. During wakefulness, the force of the upper airway dilator muscles (*green balloon,* dilating forces) counterbalance the collapsing forces imposed on the upper airway by extraluminal pressures and negative inspiratory pressure generated by the respiratory pump muscles (represented by the *orange counterweight* [collapsing forces]). In obstructive sleep apnea, sleep onset *(blue needle)* leads to decreased upper airway patency by reducing the dilating forces. *(Modified from Sasaki N et al: Postoperative respiratory muscle dysfunction: pathophysiology and preventive strategies,* Anesthiology *118:961-978, 2013.)*

TABLE 14-5 SOME MUSCLES OF THE UPPER AIRWAY RELEVANT FOR UPPER AIRWAY STABILITY

	Activity (Tonic* and Phasic†)		
Muscle		**Insp.**	**Exp.**

Thyrohyoid	X	X	X

+, present; –, absent; *X,* insufficient data.
Major muscles of the upper airway and their activity during breathing. Tonic activity, as well as inspiratory [Insp.] and expiratory [Exp.] muscle activity.
*Tonic activity is noted in columns 2 through 4.
†Phasic activity is noted in columns 3 and 4.

Upper Airway Dilator Muscles. The most extensively studied of the upper airway dilating muscles are the genioglossus and the tensor palatini (Table 14-5). The genioglossus receives a variety of inputs, including phasic (inspiratory) and tonic (noninspiratory) drive, which are distributed differentially across the hypoglossal motoneuron pool.[149] In response to negative pharyngeal pressure created by the respiratory pump during inspiration, the genioglossus reflexively stabilizes the upper airway in animals and humans.[150,151] This reflex is likely a product of signaling from inspiratory modulated motor units. Whereas the genioglossus responds to phasic input on top of its tonic (nonrespiratory) activation, the tensor palatini is considered a tonic muscle with consistent tone throughout the respiratory cycle.[152]

Anatomic Vulnerability to Collapsing Forces. The soft tissues of the pharynx are enclosed and stabilized by bony structures, such as the mandible and the spine, and complete collapse of the pharyngeal airway ordinarily requires extraluminal forces, such as hematoma, edema, or peripharyngeal masses. Pharyngeal manifestation of obesity compresses the airway.[153] Craniofacial abnormalities can further increase the collapsing effects of excessive pharyngeal extraluminal soft tissue in obese patients and lead to pharyngeal collapse and OSA.[154] The extraluminal soft tissue, as well as size and shape of the bony enclosure, are determinants of the extraluminal pressure that need to be antagonized by the upper airway dilator muscle contraction during inspiration, to avoid an upper airway obstruction related apnea.[154] In addition, the upper airway is more vulnerable to collapse in the supine position than in the lateral or sitting positions.[155-157] These improvements in airway patency caused by the lateral and sitting positions as compared with the supine position are due to gravitational effects.

Excessive intravenous fluid administration can affect upper airway patency. In awake, healthy volunteers, the inflation of antishock trousers displaced so much fluid from the lower extremities that neck circumference increased, the pharynx narrowed,[158] and the upper airway had a lower threshold for collapse.[159] This concept is reinforced in studies of subjects with lower extremity venous insufficiency[160] and congestive heart failure.[161] These studies have shown nocturnal redistribution of fluid from the lower extremities into the neck increases upper airway collapsibility[160] and the severity of central apnea and OSA.[161]

Another important component of airway patency is the interplay between lung volume and upper airway collapsibility. Higher end-expiratory lung volumes are associated with a decrease in upper airway resistance to airflow in awake healthy humans,[162] and an increase in upper airway lumen dimensions in subjects with and without OSA.[163] The mechanism for the interaction between upper airway patency and lung volume is thought to lie in the generation of longitudinal traction forces in the trachea.[164,165] Upon inspiration, the lung inflates and effectively forces the carina into a more caudal position, creating stretching forces on the fixed trachea.[164] These forces are transferred to the upper airway walls through assorted soft tissue connections, resulting in improved upper airway dilatation.[165] Effectively, tracheal traction allows the respiratory pump muscles to contribute to upper airway patency.

Collapsing Intraluminal Pressure. The respiratory pump is the motorized action driving inspiration and expiration. It is the force that broadens the thoracic cavity and creates negative intrathoracic pressure to draw a breath in, and, when needed, positive intrathoracic pressure to exhale rapidly. Inspiratory pump muscles are an anatomically diverse group with the most studied being the muscles of the thoracic wall and the diaphragm, which accounts for 60% to 70% of lung volume change

during simple respiration.[166] During inspiration, the volume of the thoracic cavity increases as a result of contraction of the diaphragm and the external intercostal muscles. The lungs expand secondarily to the increased negative intrathoracic pressure generated by these phasic actions of the inspiratory pump muscles. The negative intrathoracic pressure translates into a negative intraluminal pressure in the upper airway, forcing the airway to collapse as soon as this pressure drops below a critical value.[167,168]

Although this critical airway pressure is typically negative (approximately –5 cm H_2O) in paralyzed healthy controls, the upper airway in patients with OSA has been shown to collapse when paralyzed, and positive intraluminal pressure is required for reopening the airway in patients with OSA.[169] Thus, the two compressing factors, negative intraluminal pressure and positive extraluminal pressure, need to be actively compensated by muscular activity of the upper airway dilator muscles to maintain airway patency.[108]

Wakefulness Stimulus and Sleep. Excitatory inputs to the upper airway motoneurons (e.g., hypoglossal motoneurons) include those from serotoninergic and noradrenergic neurons that fire predominantly during wakefulness,[170-173] resulting in a "wakefulness stimulus" that increases the activity of upper airway dilator muscles during this arousal state. On sleep onset, this arousal-dependent neuronal input (active awake, less active, or inactive asleep) disappears, leading to a decrease in upper airway muscle activity and causing increased upper airway resistance in healthy controls and airway collapse in patients with OSA.[174-177]

Respiratory Arousal. Respiratory arousal is arousal from sleep owing to cumulative and progressive increases in stimuli related to breathing (hypoxia, hypercapnia, and respiratory effort).[178]

Three primary inputs contribute to arousal-related restoration of breathing following an apnea (Figure 14-10):

1. Peripheral and central chemoreceptors sensitive to partial pressures of oxygen and carbon dioxide[179]
2. Sensors in the upper airway responsive to negative pressure generated by the respiratory pump[150,151]
3. Cortical inputs directly related to state of consciousness or wakefulness[177]

Any of these inputs can restore respiratory muscle tone if the magnitude is sufficient. Cortical awakening from sleep, identified by EEG signs of wakefulness, is an adequate stimulus for ventilation. Importantly, obstructive apneas, such as upper airway collapse in OSA, can be terminated by increased drive to the respiratory muscles not involving cortical arousal.[180] For example, hypercarbia resulting from sustained hypopnea[179] and elevated upper airway negative pressure[150,151] can independently restore tone to the respiratory muscles. The level of drive provided to the respiratory muscles depends on the summation of stimuli in the central respiratory pattern generator output, including peripheral and central chemo-responsiveness, reflex responsiveness to the negative airway pressure, and strength of the wakefulness drive.

Treatment. Adequate treatment of OSA improves nocturnal oxygen saturation as well as duration and quality of sleep, which translates to reduced daytime sleepiness and associated functional daytime impairments, and improved quality of life. Successful treatment of OSA reduces cardiovascular risk, improves insulin sensitivity, and increases neurobehavioral performance.[181-184] Therefore all patients with a diagnosis of OSA should be offered a sufficient treatment of the disorder as soon as the diagnosis of OSA has been established and its severity has been

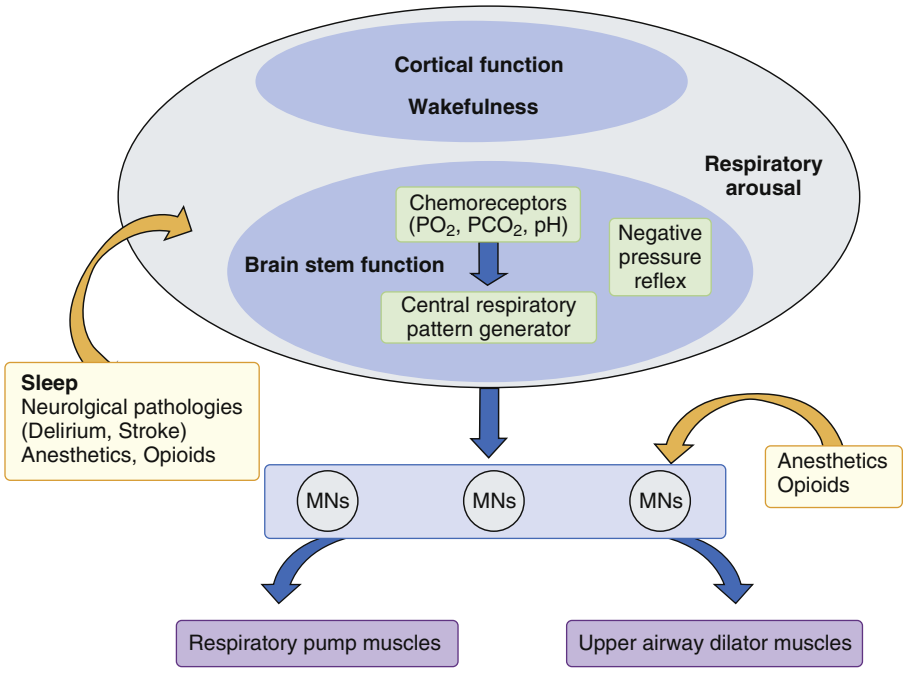

Figure 14-10. Effects of respiratory arousal on upper airway dilator and respiratory pump muscles. Respiratory arousal is composed of three primary inputs: central respiratory pattern generator processing peripheral and central chemoreceptor afferents, reflex responsiveness to the magnitude of negative pressure in the airway generated by the respiratory pump muscles, and strength of the wakefulness stimulus. Different factors can impair respiratory arousal, such as sleep and neurologic pathologies, anesthetics, and opioids. *Blue arrows* indicate excitatory effect; *yellow arrows* indicate inhibitory effect. *MN,* motor neuron. *(Modified from Sasaki N et al: Postoperative respiratory muscle dysfunction: pathophysiology and preventive strategies,* Anesthiology *118:961-978, 2013.)*

determined by objective testing (i.e., PSG).[28,31] Although different treatment options for OSA have been developed during the last decades (Table 14-6), noninvasive ventilation with positive airway pressure (PAP) is still the most effective treatment for OSA of all severities.[189,190]

Positive Airway Pressure Treatment. Noninvasive ventilation as a treatment for sleep disordered breathing is typically applied continuously (i.e., continuous positive airway pressure [CPAP]), which dose dependently reverses any sleep-associated upper airway obstruction, as outlined in Figure 14-11. The CPAP level needed for treatment of OSA varies between 5 and 20 cm H_2O and is different for every patient. An overnight study is necessary to titrate the airway pressure to a level sufficient to abolish airway obstruction in each patient. After titration, the prescribed treatment pressure is applied continuously throughout the night. Although this treatment is efficient in abolishing the underlying pathology and daytime functions, as well as the long-term consequences, the effect of PAP impact on outcome is limited by patient adherence,[42,129] mostly because of local side-effects at the nose or face, or discomfort caused by the mask.[186] When applied with high pressure, the amount of airflow can prevent the patient from falling asleep while using the treatment device. Some treatment devices offer a ramp or delay function that gradually increases treatment pressure from a low starting pressure to the prescribed pressure over a period of 5 to 45 minutes, allowing the patient to fall asleep more easily. Some patients report difficulties exhaling against high CPAP. To avoid this problem, bilevel treatment with reduced expiratory positive airway pressure (EPAP) and a sufficiently high inspiratory positive airway pressure (IPAP) can be combined.

In some cases, one CPAP pressure level is not sufficient to treat sleep apnea. PAP devices with dynamic pressure levels can improve treatment success, particularly in patients with a variable severity of sleep disordered breathing during different sleep stages. These automatic positive airway pressure or autotitrating devices measure different variables associated with hypopnea, such as oropharyngeal wall vibration, snoring, and inspiratory flow limitation and increase the airway pressure until these signs and symptoms of hypopnea disappear.

PAP treatment is recommended in patients with moderate to severe OSA, and it is the favored treatment for mild OSA. PAP is superior to all other OSA treatment options currently available, and it is recommended as the primary treatment of OSA by all major pulmonary and sleep medicine societies of Northern America and Europe, including the AASM,[27] the American Thoracic Society (ATS),[29] the American College of Chest Physicians, the European Respiratory Society,[29,186] the Canadian Thoracic Society,[31] the American Heart Association, and the American College of Cardiology.[32]

Although CPAP is sufficient in the treatment of patients with OSA, patients may need different treatment methods. For example, patients with mixed apneas (obstructive and central) or predominantly central apneas need a more controlled (frequency or time controlled),

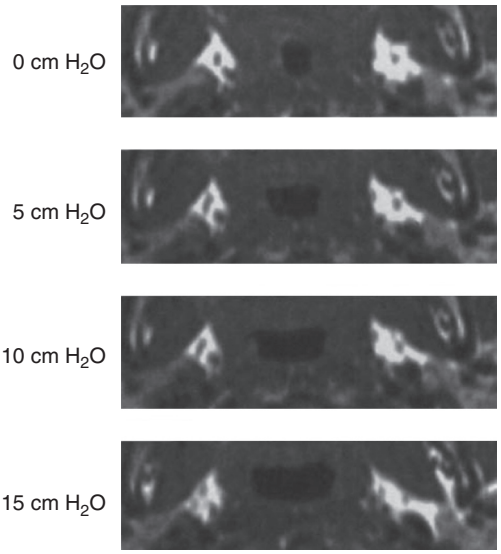

Figure 14-11. Magnetic resonance imaging of the human upper airway during different levels of continuous positive airway pressure. Magnetic resonance imaging of the upper airway during continuous positive airway pressure of 0, 5, 10 and 15 cm H_2O shows a dose-dependent increase in upper airway diameter. *(Obtained from Schwab RJ et al: Upper airway and soft tissue structural changes induced by CPAP in normal subjects,* Am J Respir Crit Care Med *154:1106-1116, 1996.)*

AT, Alternative treatment if positive airway pressure is not tolerated; *GS,* gold standard; *ID,* data not sufficient for recommendation; *MC,* may be concerned in carefully selected patients if conservative treatment fails; *NR,* not recommended; *SU,* supportive treatment.

noninvasive ventilation with predefined minimal respiratory frequency or respiratory timing that automatically induces the next inspiration (ventilation) if the patient does not induce the next breath within preset parameters.

Alternative Treatment Options. Oral appliances (OAs) are possible treatment options in patients with mild to moderate OSA who do not tolerate CPAP therapy. Two major designs are currently used in clinical practice: (1) mandibular repositioning appliance, which holds the mandible in an advanced position (a protrusion of at least 50% of the maximal possible extension is recommended for effective treatment),[186] and (2) tongue retaining devices leading to repositioning of the tongue into a forward position without any protrusion of the mandible. A multidisciplinary approach including a sleep physician and a dental technician experienced in oral appliances have been recommended for this purpose, because both factors are crucial for patient adherence and outcome from OA treatment.[121] OAs are recommended in patients with mild to moderate OSA who do not tolerate,[186] not respond to, fail, or are not appropriate candidates for PAP treatment.[28]

Historically, surgical treatment methods were the only approach to treatment of OSA, but the evidence of effectiveness of most of the nasopharyngeal surgical approaches to treatment of severe OSA is poor. However, tonsillectomy is beneficial in adult patients with OSA from tonsillar hypertrophy, and adenotonsillectomy is recommended in children with OSA and adenotonsillar hypertrophy[41] (see Chapter 93). Repeated sleep testing following surgery is recommended to assure sufficient long-lasting therapeutic effects.[28,186,191]

Electrical stimulation of the upper airway muscles has recently been postulated as a new approach to treatment of OSA. Hypoglossal nerve stimulation induces dose-related increases in airflow of sufficient magnitude to eliminate inspiratory flow limitation due to airway collapse during obstructive sleep apnea,[188] but this new therapeutic approach cannot be recommended as a first-line treatment of OSA.[172]

While pharyngeal fat deposits led to a decrease in pharyngeal patency, underlining the risk factor of obesity,[192,193] weight loss leads to a reduction in Pcrit and the severity of OSA[168,185,194] and is recommended as adjunctive treatment in all overweight patients with OSA.[195] Because long-term weight reduction is more effective when accompanied by weight loss surgery, bariatric surgery may be considered as an adjunctive therapy in very obese patients (body mass index [BMI] ≥ 40 k/m^2), as well as in those with important comorbidities and BMI of 35 kg/m^2 or greater and in whom dietary attempts at weight control have been ineffective.[28]

Oxygen is currently not recommended as primary treatment of OSA, but can be used as an adjunctive treatment in some patients.[28,187]

Although OSA is more common in the older population, it occurs in children with a peak in the incidence between 2 and 5 years of age (see Chapter 93). Obesity predicts snoring and other signs of obstructive respiratory events in children.[121] Tonsillar and adenoidal hypertrophy is another important cause of OSA in children and can be treated surgically.[196]

Central Sleep Apnea

Definition. Central sleep apnea (CSA) is defined as cessation of air flow without respiratory effort,[197] which separates it from OSA where respiratory effort is maintained during an apnea. In clinical sleep apnea, considerable overlap between OSA and CSA occur that need to be identified and subsequently treated.[198]

Epidemiology. Central sleep apnea can be found in older patients and in patients with severe comorbidities such as stroke and congestive heart failure (CHF). Two studies investigated the occurrence of CSA in the general population. In a southern Pennsylvania cohort, CSA (AHI ≥ 20/h) was found in 5% of men aged 65 years and older, but it was not found in younger men or in women of any age. For an AHI of 2.5 per hour and greater, the prevalence estimates in men younger than 45 years remains negligible, while CSA was found in 1.7% of men between 45 and 64 years, and 12% in men older than 65 years,[199,200] or 9% in individuals between 40 and 97 years, respectively.[201]

CSA mechanisms can be categorized into those with high loop gain and low loop gain. The most common subtype of CSA with an increased loop gain is CSR commonly seen in patients with CHF and left-ventricular systolic dysfunction. CSR is defined as a crescendo-decrescendo pattern of hyperventilation between 20 and 30 seconds in duration, followed by 10 to 40 seconds of hypopneas or apneas (Figure 14-12) usually occurring during NREM sleep stage 1 and 2.[202] Nevertheless, CSR can also occur

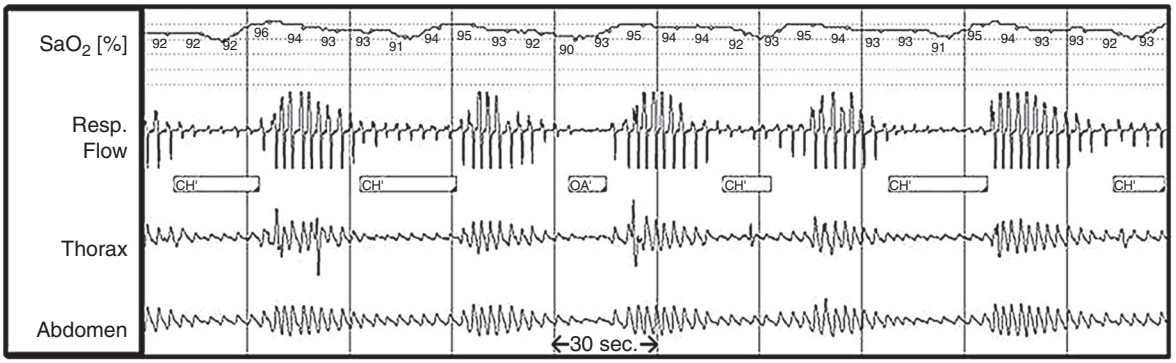

Figure 14-12. Polysomnographic recording of an episode of Cheyne-Stokes respiration. *CH,* Central hypopnea; *OA,* obstructive apnea.

during exercise or wakefulness. Almost one out of two patients with CHF shows Cheyne-Stokes respiration.[203] CSR is more common in men and worse in the supine body position.[204]

Consequences and Comorbidities. Central sleep apnea impairs quality of life[205] and is associated with adverse outcome in CHF patients,[206,207] but CSR by itself might not be just a marker of a "sicker" patient but an independent risk factor.[197,208]

Treatment. Potential respiratory therapies of CSR include oxygen, respiratory stimulants (e.g., CO_2, theophylline, and acetazolamide) and CPAP. It is difficult to quantify whether the hemodynamic or the respiratory effects of CPAP are the main mechanism of treatment success. A pilot study in 66 patients with CHF published by Sin and colleagues[209] showed a potential beneficial effect of CPAP treatment in patients with CHF with CSR on transplant-free survival. In these patients, cardiac function was improved after CPAP; however, this study is limited by the small number of subjects, lack of β-adrenergic blocker treatment in the majority of the subjects, as well as the absence of usage of intention-to-treat analytical technique. The Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure Trial (CANPAP) failed to corroborate these findings[210] and did not show improvement in outcome. In contrast, the data suggest a harmful effect of CPAP treatment in the short-term followed by a later improvement leading to an overall survival in this group equivalent to the survival in the control group. The improvements in morbidity also found in this study included left ventricular ejection fraction. The mechanism underlying the short-term worsening is unclear. It may relate to hypovolemia among CPAP-treated patients, which theoretically can decrease in cardiac output with nasal CPAP therapy (hypovolemic patients are pre-load dependent); whereas improved cardiac output with CPAP may be experienced in hypervolemic patients (more after-load dependent). A follow-up study of the CANPAP study population examined various subgroups, not prespecified in the initial study showing an improved outcome among the CPAP patients.[211] Follow-up trials investigating the effect of newer noninvasive ventilation devices in CHF are underway.[212,213] Because long-term data on the effect on mortality and morbidity of CPAP treatment are still missing, it is still not completely clear how CSR should be treated with noninvasive ventilation. Optimization of medical therapy is the optimal treatment, because CSR will often resolve with adequate treatment of CHF (cardiac resynchronization therapy and surgical treatment, such as heart transplant).[202,214]

Other Forms of Central Breathing Disorders. The term *periodic breathing* refers to altitude-induced breathing instability that can occur in most subjects transferred to a high altitude, whereas ambient hypoxia caused by low barometric pressure leads to an increased controller gain[108,215] or idiopathic central sleep apnea, which is a relatively uncommon disorder at sea level. This type of CSA occurs in individuals with an elevated hypercapnic ventilatory response (high controller gain) that leads to hypocapnia and respiratory control instability during sleep. Patients with idiopathic central sleep apnea tend to have low $PaCO_2$ levels, even during wakefulness.[216,217]

Obesity Hypoventilation Syndrome

Alveolar hypoventilation is defined as insufficient ventilation leading to hypercapnia (increased $PaCO_2$). Mechanisms of alveolar hypoventilation include central hypoventilation, chest wall deformities, neuromuscular disorders, chronic obstructive pulmonary disease, as well as severe obesity (obesity hypoventilation syndrome [OHS]). OHS is defined as the combination of nocturnal and daytime hypoventilation, usually leading to hypercapnia, in obese subjects (BMI ≥ 30 kg/m^2) in the absence of other causes of hypoventilation.

The prevalence of OHS is estimated to be up to 50% in obese patients with OSA (see Chapter 71). It is estimated to occur in up to 50% of patients with a BMI of 50 kg/m^2 and greater,[218] compared with 0.15% to 0.3% in the general adult population. Ninety percent of patients with OHS also suffer from OSA.[219,220] OHS often remains undiagnosed, and the true prevalence is unclear.

Severe obesity is associated with an increase in respiratory drive that helps to maintain eucapnia in the presence of the abnormal chest wall mechanics and high work of breathing.[221-223] In OHS, this compensatory mechanism is abolished,[223,224] which in part might be explained by leptin resistance.[225-228] Typically, OHS manifests as a reduced lung capacity, vital and functional residual capacity, expiratory reserve volume, respiratory system compliance, and inspiratory muscle strength, whereas response to CO_2 might be reduced or normal. In addition, there is an increase in serum bicarbonate and alveolar PCO_2, as well as in the work of breathing and leptin-levels.[228,229]

Impairment of the effectiveness of respiratory pump muscle function in patients with OHS can be explained by the effects of low lung volume because of central fat distribution, leading to a cranial displacement of the diaphragm during supine position.[229-234] In addition, diaphragmatic myopathy might be a contributing factor of OHS.[228] Treatment options include weight loss and noninvasive ventilation.[234,235]

SLEEP AND ANESTHESIA: TWO UNEQUAL TWINS INFLUENCING PERIOPERATIVE MEDICINE

CLINICAL PICTURE OF SLEEP AND ANESTHESIA

Although physiologic sleep and anesthesia share some clinical features (loss of consciousness and a modulation of brainstem autonomic function), major differences can be found when closer observations of both behavioral states are undertaken. In contrast to anesthesia, sleep shows spontaneous generation and termination, ready reversibility by noxious stimuli, and homeostatic regulation. Anesthesia does not share the stage-wise structure seen during physiologic sleep. Even the ether anesthesia derived stages of anesthesia, which do not apply to

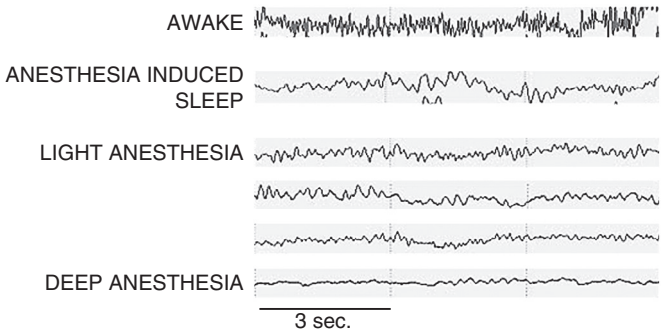

Figure 14-13. Electroencephalographic recording during sedation and loss of consciousness induced by anesthetics (i.e., propofol). Compared with physiologic sleep (see Figure 14-1), sedation shows electroencephalographic (EEG) traces comparable to slow wave sleep, indicating the sleep-inducing effect of anesthetics. Anesthesia-induced loss of consciousness *(lower four traces),* shows different EEG activity with reduced amplitudes and burst suppression. (Burst suppression is not shown in these traces.)

modern anesthesia, do not correspond to sleep stages (see Sleep Stages and Sleep Cycle). In addition, functional imaging studies underline the fundamental differences during onset of anesthesia and wakefulness-sleep transition.

Although there are similarities in the EEG patterns between slow-wave sleep and anesthesia-induced unconsciousness, the EEG patterns during sleep and anesthesia are different,[235] with different frequencies and types of activation in EEG recorded during physiologic sleep and the uniform EEG picture observed during anesthesia-induced unconsciousness (Figure 14-13).[41,237]

During anesthesia induction, the level of consciousness continuously decreases from fully awake through states of reduced response to external stimuli up to a completely unresponsive patient.[238] This is in contrast to the sharp alpha-theta EEG transitions seen while an individual proceeds from wakefulness to sleep without any transient stages. Individuals in a steady state of physiologic sleep can be aroused with sufficient stimulation, whereas drug-induced unconsciousness needs at least some drug elimination to occur before individuals can be aroused from this state.[239]

ACTIVATION OF SLEEP PROMOTING PATHWAYS DURING ANESTHESIA

The role of the endogenous sleep-promoting system in the mechanism of action of general anesthetics has recently received much attention. This hypothesis is attractive because of the similarities of sleep and anesthesia and some evidence that anesthetically induced sleep could meet some of the homeostatic need for sleep.[240a] (Tung 2004). It is even more attractive because, despite the large database of the molecular effects of anesthetics, how loss of consciousness occurs is still not explained. An important discovery was that some of the neurons that are active during sleep in the VLPO are also activated by certain anesthetics.[240-242] A second key observation was that inhibition of the arousal nuclei, the TMN, contributes to anesthesia.[241] This effect also implicates VPLO because it provides the major source of inhibition of the TMN. The idea has emerged that anesthesia-induced loss of consciousness is mediated by effects of the anesthetics on the flip-flop switch centered in the VLPO that is responsible for the sharp transition from wakefulness to sleep and back (see Sleep Promoting and Arousal Pathways).[239,243,244] There are a number of problems with this theory including, that rats and mice with complete lesions of the VLPO can still be anesthetized.[242,245]

Although lesions of VLPO lead to a transient resistance to volatile anesthetics,[242] if some time elapses following a VLPO lesion, the animals show increased sensitivity to isoflurane anesthesia attributable to increased homeostatic sleep drive.[242,245-247] Another problem with the VLPO-TMN circuit hypothesis of anesthesia is that direct inhibition of the TMN produces sedation but not produce anesthesia.[241]

Animals that have lost VLPO neurons have profound insomnia; however, they still sleep, indicating the existence of other sleep-promoting pathways.[93] Therefore, anesthesia might be the result of simultaneously driving all the endogenous sleep circuitry. This theoretical possibility is unlikely based on the key difference between anesthesia and sleep arousability. Sleep, but not anesthesia, is easily reversed or prevented by real or perceived environmental threats. This is the difference between the AAS being shut down by natural neural processes versus being shut off pharmacologically. Sleep promoting neurons work by inhibiting arousal pathways, but this inhibition does not and cannot prevent arousal to sufficient external stimuli. The unique property of anesthesia to do so has to be mediated by an additional mechanism. Nonetheless, the finding that GABAergic anesthetics engage sleep pathways is still important and meaningful; this is undoubtedly an important mechanism by which this class of anesthetics promotes sleep.

POSSIBLE MECHANISMS OF UNCONSCIOUSNESS

Defining the mechanism of anesthesia-induced loss of consciousness is a bold endeavor considering that the neurological substrate for consciousness is still unknown. However, the clinical characteristics of anesthesia as well as findings from basic science indicate that anesthetic drugs can induce unconsciousness mainly by altering neurotransmission in the cerebral cortex and possibly the thalamus.[248,249] Whether these effects are direct or occur via inhibition of brainstem ascending arousal pathways, or both, remains to be determined.[236,250] The GABA and NMDA receptors that are major targets of hypnotic drugs are found throughout the neuraxis.[251,252]

In anesthetized rodents, cortical neural activity is reduced.[253] These findings are in line with positron-emission tomographic studies in humans, which revealed a decrease in cortical metabolic activity under general anesthesia.[248,254]

Hypnotics have also been shown to inhibit brainstem arousal pathways.[236] Direct injection of a barbiturate into the mesopontine tegmental area has been shown to induce unconsciousness in rodents.[250] Such observations

are in line with brain-injury studies showing that brain stem unconsciousness typically involves the midbrain paramedian region and the lateral dorsal tegmental areas of the pons.[255]

PERIOPERATIVE INTERACTIONS BETWEEN ANESTHESIA AND SLEEP

Anesthesia and painful surgical procedures affect sleep and circadian rhythms[256-259] for as long as 6 months, depending on the complexity of the procedure performed.[260] A substantial decrease in REM sleep occurs on the first night after surgery and anesthesia, followed by a profound REM rebound phenomenon on the second to fourth postoperative night, when REM sleep increases in both intensity and amount.[256,258,259] Although most anesthetics can lead to an impairment of sleep architecture, such as REM depression and reduced sleep quality during postsurgical period, the extent of this impairment probably depends on the pharmacokinetics and pharmacodynamics of the anesthetic drug used, as well as the duration of administration. Opioids impair sleep quality[261,262] and the duration of REM sleep when given during anesthesia or for pain treatment.[263-266] These effects of opioids can be mediated in part by decreasing GABAergic transmission in the oral part of the pontine reticular nucleus.[267] GABAergic anesthetics, such as sevoflurane, also suppress REM sleep during the postanesthesia period.[268,269]

The effect of propofol on sleep architecture and REM sleep is complex and may be dose dependent. In long-term ventilated, critically ill patients, propofol sedation completely abolishes REM sleep and diminishes sleep quality,[270] whereas its lingering effects seem to have less intense effects on REM sleep.[247] The effects of ketamine sedation on sleep architecture have not been studied in detail yet, it may have rather mild effects on REM duration.[271]

Anesthetics can affect circadian rhythms. A recent trial in honeybees suggested an anesthetically induced circadian shift. Inside the laboratory with no outdoor cues, daytime anesthesia threw off the usual activity patterns in the hive for the next several days. In addition, cycles of clock gene activity showed a delay.[272,273] The mechanisms of these effects are unclear. More specifically, although circadian variation in drug metabolism may be linked to anesthetic drug efficacy, it is unknown whether anesthetics themselves can directly influence the regulation of the circadian clock. The psychotropic effects of anesthetics at subanesthetic doses cannot be isolated easily from anesthetic effects.[274] Of note, different psychotropic nonanesthetics, such as opioids, have been shown to affect melatonin secretion indirectly, independent of the behavioral state anesthesia.[275] Previous work in humans has shown that even 3 hours of anesthetic exposure in humans does not affect the circadian phase of the body temperature rhythm.[276]

In summary, the ability to distinguish between effects occurring directly on the circadian pacemaker and those occurring downstream from the pacemaker on other physiologic control systems requires extremely rigorous experimental conditions.

Surgical treatment itself impairs sleep, expressed as reduced REM sleep duration even in the absence of general anesthesia.[261,262] Pain, inflammation, stress immobility, and anxiety seem to be contributing factors.[277] After surgery, patients show a significant impairment of sleep quality and duration. Eventually, it will be known whether specific anesthetics are preferable to avoid the adverse effects of sleep deprivation.

SLEEP AND SEDATION IN THE INTENSIVE CARE UNIT

Sedation is frequently required in the intensive care unit (ICU) to treat excessive agitation or to fulfill specific therapeutic needs; however, heavy sedation is associated with prolonged ICU and hospital stays.[278] Pain is a common experience for most patients in the ICU,[279] and failure to recognize that pain can result in excessive administration of sedatives.[278] Accordingly, an aggressive approach to managing pain has been strongly recommended by published consensus opinions regarding sedation in the ICU.[280]

Impaired sleep is common in ICU patients,[11,281] and the mechanisms are intuitive: exposure to pain and anxiety, inflammation, noise, light, fluid, and nutrition without accounting for circadian considerations that induce a scenario comparable to an experimental "constant routine," in which effects produced by rhythmicity of habits and environmental stimuli are artificially abolished.

Sleep duration in the ICU shows a wide inter-individual variability among ICU patients depending on environmental conditions and the severity of the patient's disease.[282] Sleep fragmentation is seen in most ICU patients, especially during sedation and mechanical ventilation.[283,284] Deep NREM and REM sleep are severely reduced in ICU patients,[285-290] and variables reflecting circadian rhythm may be abolished.[291] Sedatives and pain medication, commonly applied during ICU treatment, can increase the severity of signs and symptoms of pathologic sleep.[270] Both noninvasive ventilation and ventilation via breathing tube impair sleep architecture and quality.[283,292] It is unclear how the issue of ICU-associated circadian disruption can be prevented or treated. Data suggest that some ventilator settings are less harmful than others; weaning procedures during daytime combined with a less activating ventilation mode during nighttime seem to improve sleep expressed as reduced numbers of arousal in patients requiring long-term ventilation.[288,289]

Studies on the use of melatonin for the treatment of sleep disturbances and delirium in ICU patients are too heterogeneous to recommend this treatment.[293] Nonpharmacologic treatments, such as earplugs and eye masks, have been shown consistently to improve sleep quality in ICU patients and possibly reduce the risk of delirium.[294-296] Additional research is needed to describe the biological consequences of ICU treatment-related impairment of circadian rhythms, and to develop protocols that successfully prevent severe disruption of the physiologic rhythmicity in critically ill patients.

SLEEP-DISORDERED BREATHING AND AIRWAY PATENCY DURING ANESTHESIA

Perioperative complications occur more often in patients with OSA than in healthy controls,[296,297] but the reasons

for this observation are unclear. It is challenging to isolate the effect of OSA from the known adverse effects on perioperative outcome of typical OSA comorbidities, such as hypertension, diabetes, coronary artery disease, neurovascular vulnerability, and obesity. Fortunately, severe postoperative complications are rare. As a consequence, large sample size trials (30,000 to 50,000 patients) need to be designed to isolate a cause-and-effect relationship between sleep-disordered breathing and meaningful perioperative complications, such as severe respiratory failure, thromboembolic complications, increased hospital length of stay, and mortality.

OSA is not (independently of obesity) associated with difficult tracheal intubation or mask ventilation.[298-302] However, a recent metaanalysis reported a significantly higher risk of postoperative cardiac events and acute postoperative respiratory failure, compared with control subjects.[303,304] These findings need to be confirmed in future trials with a larger sample size and a more homogenous population such that confounder control can be established. OSA is associated with postoperative delirium,[297,305] which is a meaningful perioperative complication associated with increased costs, morbidity, and mortality. However, it is currently unclear if this is due to repetitive hypoxia or sleep fragmentation. In contrast, a recent study using the Nationwide Inpatient Sample (NIS) database analyzed data from 1,058,710 patients undergoing elective surgeries. These authors showed that patients previously diagnosed with SDB had significantly higher rates of emergent mechanical ventilation, use of noninvasive ventilation, and CPAP, as well as increased rates of respiratory failure. Nevertheless, the study also showed that patients with SDB had better outcomes after emergent intubation and had lower care associated costs compared with their non-SDB counterparts.[306] Similar findings were reported by the same group for data from 91,028 patients undergoing bariatric surgery.[307] In this study patients with a previous diagnosis of SDB had shorter hospital length of stay and lower total costs compared with non-SDB patients. The reasons for the differences are unclear. Patients with a known history of sleep apnea may receive more sophisticated perioperative monitoring and more aggressive treatment of their respiratory disease, which might also explain the higher rate of postoperative reintubation in SDB patients reported by in the same group.[306] Another possible explanation relates to the consequences of chronic nocturnal desaturation, which can have preventive effects in terms of the consequences of perioperative acute hypoxia. Most importantly, these findings indicate that the association of SDB and perioperative outcome is likely to be more than a unidirectional relationship. More likely is that SDB could have a dual effect, leading to increased rates of perioperative respiratory complications in patients with SDB, but additionally protecting the same population from the fatal consequences of these complications. The mechanism of the potential link between OSA and postoperative respiratory failure, as well as postoperative delirium, is probably multifactorial. Frequent episodes of airway collapse in OSA lead to hypoxia, disrupted sleep, sleep inertia, daytime sleepiness, and increased arousal threshold from sleep, all of which can be considered as potential precipitating or augmenting factors of postoperative complications. It is intriguing to note that patients with OSA appear to be most vulnerable to hypoxia on postoperative night 2 or 3, the time interval during which postoperative delirium most typically manifests.

One population that might deserve additional attention in perioperative care is patients with OHS who, compared with obese patients, are more likely to be admitted to a hospital and require more healthcare resources.[306,308] In addition, higher rates of intensive care admission, lengthier long-term care requirements at discharge, and higher mechanical ventilation rates have been reported in patients with OHS compared to severe obese patients without OHS.[307-310]

In summary, patients with SDB are more vulnerable to developing severe perioperative complications. Nevertheless, it is currently unclear whether these complications translate to a poorer overall postoperative outcome for these patients.

PERIOPERATIVE MANAGEMENT IN PATIENTS WITH SLEEP DISORDERED BREATHING

The standard of care for perioperative management of patients with SDB depends on the severity of the disease, comorbidities, and the threat associated with the planned surgical procedure. It is probably neither feasible nor required to conduct a sleep study in all obese patients at risk for sleep apnea who are scheduled for surgery; however, high-risk patients need to be identified and treated perioperatively. Figure 14-14 shows an algorithm that is being developed at the Massachusetts General Hospital (MGH) in Boston. The algorithm is driven by the idea that patients who have been prescribed CPAP preoperatively should use CPAP perioperatively. In addition, the MGH algorithm indicates that patients characterized as double high-risk, in terms of surgical procedure and highly likelihood of meaningful sleep apnea, may need perioperative CPAP.

Preoperative Screening

Several strategies need to be considered to identify patients with SDB adequately.[39,309,310] Although clinical examination is the easiest and most cost-effective method of assessment using predisposing physical characteristics, it has a poor sensitivity and specificity of only 50% to 60% to diagnose OSA accurately.[311,312] However, the clinical value of using questionnaires relates to the fact that they help to identify a high-risk perioperative population, independently of the question of whether an individual patient has OSA. For example, the STOP-BANG questionnaire basically screens for comorbidities of OSA that we know increase the risk of perioperative complications (hypertension, obesity, male sex, older age) rather than direct breathing disorder–associated characteristics.

PSG is required to identify SDB specifically, but it cannot be used for preoperative screening of surgical patients. PSG is expensive, can delay surgery, and is inconvenient for the patient. A multistep approach of preoperative screening is required. Preoperative assessment should

include a screening for SDB and for the current use of noninvasive ventilation (NIV). OSA might not represent a meaningful risk in patients scheduled for low-risk procedures from a surgery and anesthesia point of view (e.g., hardware removal, ankle block). The authors believe that patients with no previously diagnosed SDB undergoing a low-risk surgical procedure should receive standard perioperative monitoring and treatment.

Patients undergoing high-risk surgical procedures should receive further work-up using a clinical examination combined with standardized and validated questionnaires (e.g., Berlin).[310,313] Although this diagnostic regimen might be a sufficient screening for OSA, it might be insufficient to detect OHS.[307,309] A blood gas analysis should be considered as a method to detect hypercapnia as a major symptom of OHS (criterion: awake daytime hypercapnia [$PaCO_2 \geq 45$ mm Hg]). Alternatively, a venous bicarbonate concentration of 27 mmol/L or greater is highly sensitive (92%) for an increased $PaCO_2$, which combined with hypoxemia (peripheral oxygen saturation [SpO_2] of 94%) indicates a high risk of OHS in these patients.[307,309,312,314] Of note, OHS is a diagnosis by exclusion. Severe obstructive airways disease, severe interstitial lung disease, severe chest wall disorders (e.g., kyphoscoliosis), severe hypothyroidism, neuromuscular disease, and congenital central hypoventilation syndrome need to be excluded, and further evaluation of sleep by a sleep medicine specialist before anesthesia should be considered. In these cases, the sleep specialist should determine the optimal diagnostic instruments in cooperation with the perioperative team, prescribe the perioperative autotitrating PAP device, and offer in collaboration with respiratory therapy specialists to improve tolerability of perioperative PAP therapy.

Perioperative Management of Patients With Possible Sleep-Disordered Breathing

Although the data on optimal intraoperative and perioperative management are still limited, the techniques and procedures summarized in Box 14-2 might be considered during the perioperative management of patients with SDB. Patients with a history of SDB who are undergoing surgery and anesthesia with high risk of morbidity should receive an "OSA anesthesia bundle," (see Box 14-2) that includes special procedures and preparations during intubation, extubation, pain therapy, and perioperative PAP and NIV treatment.

Endotracheal Intubation. Patients with OSA are frequently obese, and obesity is a risk factor for difficult intubation.[301,313-317] Patients should be preoxygenated efficiently before injection of the anesthetic drug. Sniffing and reverse Trendelenburg position are preferred before intubation, which improves maintenance of the passive (i.e., paralyzed) pharyngeal airway in patients with OSA[316,318] and increases functional residual capacity. To reduce the duration of paralysis, nondepolarizing NMDAs should be used with caution supported by quantitative neuromuscular transmission monitoring. Immediately after successful intubation, a lung recruitment maneuver and the application of postexpiratory positive airway pressure for maintaining lung volume during surgery might be considered.[317,319]

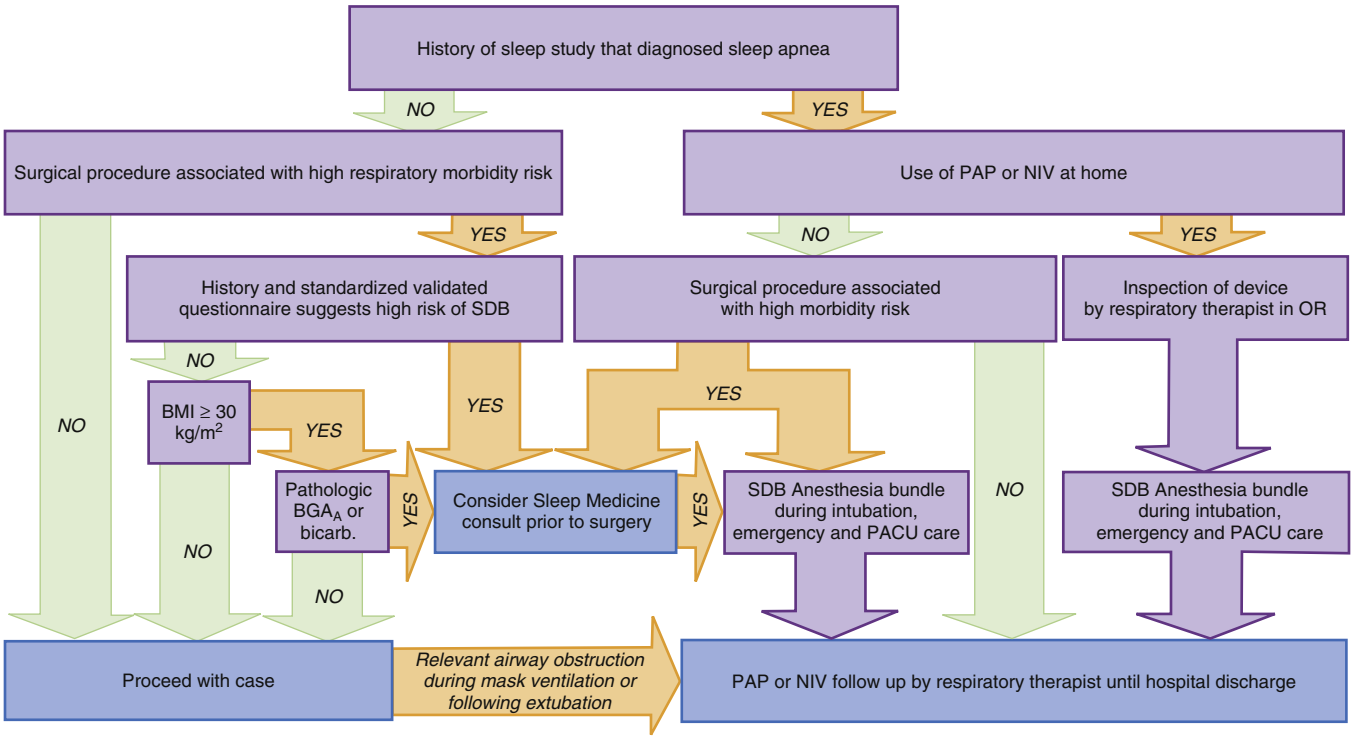

Figure 14-14. Clinical pathway for perioperative management of patients with sleep disordered breathing. *BGA_A,* Arterial blood gas analysis; *bicarb,* venous bicarbonate level; *BMI,* body mass index; *NIV,* non-invasive ventilation; *PACU,* post-anesthesia care unit; *PAP,* positive airway pressure.

BOX 14-2 ***Special Sleep-Disordered Breathing Anesthesia Bundle: Special Procedures Performed During Anesthesia in Patients With Diagnosed Sleep-Disordered Breathing and Positive Airway Pressure or Noninvasive Ventilation Treatment***

Preanesthesia Period

- Consider regional anesthetic techniques techniques that minimize the chance of postoperative sedation

Induction Strategy

- Monitoring: capnogram, tidal volume measurement
- Sniffing position
- Reverse Trendelenburg position
- Consider intubation without nondepolarizing NMBA, consider succinylcholine
- Triple airway maneuver with two hands
- Lung recruitment maneuvers immediately after intubation and apply PEEP for maintaining lung volume during surgery.
- PCV with PEEP
- Short-acting anesthetics and narcotics preferred
- Avoid high-dose steroidal NMBA
- Use neuromuscular transmission monitoring

Intraoperative Management

- Whenever possible, use of sedatives and narcotics should be reduced.
- Agents with reduced impairing effect on upper airway patency might be considered (e.g., ketamine, pentobarbital).
- Neuromuscular blockade should be monitored.
- Residual neuromuscular blockade should be reversed.

Extubation and Postanesthesia Care Unit

- Patient should be able to cooperate before extubation. Consider positioning of patients in PACU bed: upper body should be elevated by 45 degrees, lateral position preferred to minimize gravitational effects on the upper airway.
- In case of impaired respiratory function, a plan needs to be defined and documented for monitoring and treatment, including the consideration of noninvasive ventilation.
- Patients will be discharged to an unmonitored environment or home when they meet discharge criteria:
  - Vital signs within 20% from baseline
  - Adequate treatment of nausea
  - Pain score ≤ 40%
  - Aldrete-score ≥ 8
  - Passed room air challenge test

Pain Therapy

- Consider nonsteroidal antiinflammatory drugs to reduce opioid use whenever possible, if not contraindicated.
- Use caution when combining opioids with sedatives or hypnotics.

NMBA, Neuromuscular blocking agents; *PACU,* postanesthesia care unit; *PCV,* patient controlled ventilation; *PEEP,* postexpiratory positive airway pressure.

Intraoperative Treatment. Sedatives and anesthetic opioids,[318-321] as well as all GABAergic hypnotics and sedatives impair upper airway patency.[320-330] Recent preclinical data suggest that certain GABAergic anesthetics, including barbiturates[328-331] and isoflurane,[330,332] may be less harmful than others, such as propofol.[329-332] Ketamine abolishes the impairment of upper airway patency during loss of consciousness and sleep.[331,333] Short-acting anesthetics and narcotics are preferred in patients with OSA to reduce the risk of residual impairment of the upper airway after the end of anesthesia.

Nondepolarizing neuromuscular blocking drugs should be titrated optimally by quantitative neuromuscular transmission monitoring to avoid residual neuromuscular blockade, which increases the risk of postoperative respiratory complications.[332-337] The effects of neuromuscular blockade should be reversed only when present, because inappropriate reversal by cholinesterase inhibitors (e.g., neostigmine) can impair upper airway function in animals and humans[336-339] (see Chapters 34 and 35.)

Postoperative Care. Obstructive sleep apnea occurs during sleep and sedation[338,340]; therefore, extubation should be delayed until recovery of consciousness, expressed as a patient's ability to follow commands after emergence from anesthesia.

Patients should be positioned with the upper body elevated by 45 degrees, which improves airway patency[317,318] and functional residual capacity. The lateral body position is an alternative for patients who do not tolerate an elevated upper body position. Noninvasive ventilation is a viable treatment of postoperative respiratory failure and helps to prevent deoxygenation and the development of postoperative negative pressure pulmonary edema; it can also prevent the respiratory depressant effects of opioids.[339,341]

Before discharge from the postanesthesia care unit, vital signs should recover to values within 20% from preanesthesia baseline, and a room air-challenge test should be conducted. Adequate treatment of nausea and pain should be accomplished (pain score ≤ 40% max; Aldrete-score ≥ 8).

Pain Therapy. Pain treatment is of special concern during the postoperative period. Opioids can reduce respiratory function, and special caution is recommended when opioids are combined with sedatives or hypnotics. If not contraindicated, regional anesthesia and nonopioid analgesics should be considered to reduce opioid use for pain therapy whenever possible. The most important goal is maintenance of adequate respiratory drive, which can be accomplished under opioid therapy as long as the effects of pain stimulus and opioids on respiratory drive are in optimal balance. Pain intensity typically decreases over time following surgery. Decreasing opioid doses are typically required to maintain the balance of decreasing and increasing effects on respiratory drive.

Patients with SDB being treated with PAP or NIV at home should proceed with these treatments throughout the perioperative period. Sufficient functioning of the treatment device needs to be assured preoperatively by the respiratory technician or another clinician familiar with PAP and NIV devices and the treatment of SDB. These patients should receive the same care as patients with SDB who are not undergoing PAP or NIV treatment (see Box 14-2).

EFFECT OF OTHER SLEEP DISORDERS ON PERIOPERATIVE MANAGEMENT

Narcolepsy

Narcolepsy is a neurologic sleep disorder with a prevalence of 0.05% to 0.8% in most ethnic groups,[340-343] and it is characterized by excessive daytime sleepiness, involuntary daytime sleep episodes, and disturbed nocturnal sleep. It is accompanied by sleep-associated muscular hypotension. Narcolepsy is divided into narcolepsy with or without cataplexy (sudden loss of muscle tone without loss of consciousness).[342,344]

It has been suggested that an autoimmune pathology against hypothalamic hypocretin (orexin) (hcrt) neurons is involved in the pathogenesis of narcolepsy.[343,345] A mutation of the hcrt receptor 2 or loss of hcrt neurons have been shown to cause a narcolepsy-like state in dogs and mice,[344-347] and the deficiency of hcrt has been shown to be associated with narcolepsy in humans.[346-350] Hcrt is involved in control of several biological functions such as feeding, cardiovascular regulation, upper airway stability, pain, locomotion, stress, and addiction.[92,172,349,351] Environmental factors play a key role in the pathogenesis of the disorder, as the disease concordance rate between monozygotic twins is only 20% to 35%.[350-353]

Treatment of narcolepsy consists of (1) behavioral treatment, as well as pharmacologic treatment for (2) daytime sleepiness, and (3) cataplexies. Periodic and regular sleep times and scheduled daytime naps are recommended. Pharmaceutical treatments of daytime sleepiness include amphetamines, methylphenidate, modafinil, or selegiline (also effective for treatment of cataplexy), and cataplexies can be treated using tricyclic antidepressants, selective serotonin reuptake inhibitors, or γ-hydroxybutyrate/sodium oxybate. Medical treatment should always be accompanied by behavioral therapy.

Delayed emergence from anesthesia, postsurgical hypersomnia, and apneic episodes are in part related to an increased sensitivity to anesthetic drugs.[352-354] Medical treatment of narcolepsy should be maintained during the preoperative period.[354-357] The most commonly used treatment of daytime sleepiness is modafinil, which acts via dopaminergic pathways and accelerates emergence from anesthesia.[356-359] Some authors recommend not using sedative premedication[354-357] and to consider regional anesthesia.[358-361] Of note, narcoleptic or cataplectic events can also occur during regional anesthesia.[360-363]

Restless Legs Syndrome and Periodic Limb Movement Disorder

Restless legs syndrome, or Ekbom syndrome, is a neurologic disorder with a prevalence of 2% to 5% as defined by four cardinal features including: (1) the urge to move the limbs, usually associated with paresthesias or dysesthesias, (2) aggravating effects of rest, (3) ameliorating effects of physical activity, and (4) symptoms that worsen during the course of day, with a peak during the evening or at night. Patients with restless leg syndrome usually also complain about sensory symptoms in the legs.

Isolated periodic limb movements during sleep are a rare symptom, commonly referred to as *periodic limb movement disorder*. The characteristic periodic episodes of repetitive limb movements during sleep occur most often in the lower extremities, including the toes, ankles, knees, and hips, and occasionally in the upper extremities. These movements can be associated with frequent arousals leading to sleep disruption, causing excessive daytime sleepiness, which often is the only symptom reported by the patients themselves in the most cases.[12]

Symptomatic restless leg syndrome can occur in patients with iron deficiency and uremia, during pregnancy,[362,364] or during the use of neurotropic medications (dopamine antagonists, neuroleptics, selective serotonin reuptake inhibitors, tricyclic antidepressants, antihistamines, caffeine, alcohol, nicotine). Although daytime symptoms of restless leg syndrome can be sufficiently diagnosed clinically (clinical examination in combination with standardized questionnaires), a PSG is recommended to rule out SDB, especially in patients complaining of daytime sleepiness or sleep fragmentation.

According to the most recent guidelines of the AASM, the first-line treatment of restless leg syndrome should consist of dopamine agonists (i.e., ropinirole and pramipexole) in the evening (two or three times per day in some patients, at least 30 minutes before the usual time of symptom onset). Furthermore, gabapentin enacarbil, levodopa with dopa decarboxylase inhibitor, or opioids can be used. Medication impairing the dopaminergic system (dopamine antagonists, neuroleptics, selective serotonin reuptake inhibitor, and tricyclic antidepressants, antihistamines, caffeine, alcohol, and nicotine) should be avoided, if possible.

Exacerbation of restless leg syndrome symptoms can follow general anesthesia,[363,365] and the urge to move the limbs may be misinterpreted as agitation or delirium.[364,366] The first manifestation of restless leg syndrome can occur after spinal anesthesia[365,367] or general anesthesia,[366,368] and the prevalence of restless leg syndrome after surgery seems to be higher than expected in this population.[362,365]

To prevent perioperative exacerbation of symptoms, patients with restless leg syndrome should be scheduled for surgery early in the day, given the circadian character of the disorder. Restless leg syndrome medication should be continued until the day of surgery, whenever appropriate. Drugs that block the central dopamine transmission, such as neuroleptics, should be avoided. In contrast, ketamine might be the superior anesthetic drug for patients with restless leg syndrome.[367,369] In addition, intravenous or subcutaneous opioids and benzodiazepines during and after the surgery procedure might be beneficial in patients with restless leg syndrome. The best way to provide symptom release in patients restless leg syndrome might be early mobilization after surgery. In patients who are not eligible for mobilization, compression treatment[368,370] or intravenous administration of magnesium[369,371] and physiostigmine[370,372] have been shown to lead to relief of restless leg syndrome symptoms. Iron and ferritin blood levels should be monitored closely before, during, and after surgery, especially in surgical cases with iron loss (i.e., bleeding), to prevent symptomatic restless leg syndrome symptoms.

Chapter 15

Perioperative and Anesthesia Neurotoxicity

RODERIC ECKENHOFF • VESNA JEVTOVIC-TODOROVIC

Key Points

- General anesthetic exposure in both young and elderly patients can influence neuronal processes, which have the potential to influence later cognitive and behavioral states.
- Clinical studies at both extremes of life are, until now, largely retrospective and confounded, but consistently suggest an association between surgery and long-term cognitive outcomes.
- Potential mechanisms for anesthetic neurotoxicity are numerous, including calcium dysregulation, mitochondrial dysfunction, free-radical damage, amyloidopathy, and tauopathy. Important mechanisms in the developing brain are likely different from those in the aged brain (see also Chapter 80).
- The inflammatory response to surgery is important, especially with preexisting vulnerabilities such as aging or neurodegeneration. This conclusion implies that surgery and its response have a larger role in the elderly than in the young.
- Cognition and behavior are late manifestations of underlying toxicity and neurodegeneration; biochemical and imaging biomarkers enhance the ability of interventions to influence brain pathology and function.

Perioperative management decisions likely have consequences far beyond the perioperative period. Although cardiovascular and cerebrovascular abnormalities increase risk, a more subtle and delayed effect may occur from uncomplicated surgery on cognitive processes. First identified more than 50 years ago,[1] and anecdotally since, cognitive and behavioral disturbance after anesthesia and surgery at both extremes of age has now been largely validated (see also Chapters 80 and 93). This chapter recognizes the increased interest in the potential mechanisms of durable cognitive disturbances and how they relate to other better understood and defined entities, such as Alzheimer disease (AD) in the elderly and learning disabilities and attention deficit disorder in young patients. The authors make no assumptions regarding a relationship between these disorders and reversible postoperative cognitive decline (POCD), which is extensively discussed in Chapter 99, and caution the lumping together of these cognitive disorders. The underlying mechanisms of durable cognitive decline in the elderly and the young are likely fundamentally different. For example, perhaps neither fit neatly into the term *anesthetic toxicity,* but rather the observed disorders are the result of a series of off-pathway effects of perioperative management in general considering the extreme complexity of the perioperative period. Yet few evidence-based changes in practice can be offered at this point, and certainly more investigation is warranted.

DEVELOPMENTAL NEUROTOXICITY

As a result of skillful and sophisticated pediatric anesthesia management (see also Chapter 93), the exposure of very young children, including premature babies as young as 20 weeks postconception to general anesthesia is becoming common, resulting in the annual administration of more than 3 million anesthetics to children.[2] The frequency of surgery and anesthesia has increased exponentially, as has the length of stays in intensive care units (ICUs). Heroic attempts to save premature and very ill infants have resulted in prolonged, deep sedation, and repeated anesthesia during an extremely complex and delicate period of human development. We must question the safety of this practice.

In addition to many unique physiologic characteristics of young children, the human central nervous system (CNS) is not fully developed at birth; it continues to grow and develop for several years postnatally.[3,4] In utero, the CNS goes through extensive *neurogenesis,* which is almost completed by the end of the second trimester (see also Chapter 77). During the last trimester and the first 2 years or so of postnatal life, CNS development is marked by massive growth.[4] The human brain doubles in size during the first 6 months after birth and triples in size by 12 months of age, largely as a result of extensive dendritic branching, myelination, and glia proliferation. This is also the period of *synaptogenesis,* a process requiring several

key events to occur in a highly synchronized fashion. These events include neuronal migration, differentiation, and dendritic branching. The formation of synapses then leads to neuronal maturation and creation of circuitries via processes that are tightly controlled by the glial cells. Glia actively communicate with neurons while providing a nurturing milieu for neuron-neuron interactions.[5]

DEVELOPMENTAL APOPTOSIS

The transmitter glutamate promotes all key aspects of neuronal development.[6] The fine balance between γ-aminobutyric acid (GABA)-mediated versus glutamate-mediated neurotransmission is important for proper and timely formation of synapses and neuronal circuitries. Neurons that are not successful in making meaningful connections are somehow marked as redundant and undergo programmed cell death, or *apoptosis,* which is a normal occurrence during development of the CNS. Although normal, apoptosis during development is tightly controlled, resulting in the removal of only a small percentage of neurons.[7] However, a disturbance in the glutamatergic and GABAergic balance during this crucial stage of brain development may excessively signal developing neurons to self-destruct. The question becomes whether general anesthetics, at doses that almost certainly disrupt the glutamate and GABA signaling balance, could be promoting excessive activation of neuroapoptosis and the death of large populations of developing neurons.

General anesthetics do cause significant and widespread neuroapoptotic degeneration of developing neurons in various mammalian species, including mice,[8,9] rats,[7] guinea pigs,[10] piglets[11] and nonhuman primates[12-14] (Fig. 15-1). The peak of vulnerability to anesthesia-induced neuroapoptosis in each species coincides with its peak of synaptogenesis, with much less vulnerability observed during late stages of synaptogenesis.[10,15] The mechanisms of anesthesia-induced developmental neuroapoptosis are presently being intensely studied.

Mitochondria-Dependent Apoptotic Cascade

The mitochondria-dependent pathway of apoptotic activation, also termed the intrinsic pathway, involves down-regulation of antiapoptotic proteins from the bcl-2 family (e.g., Bcl-xL), increased mitochondrial membrane permeability, and increased release of cytochrome c into the cytoplasm. This, in turn, activates caspase-9 and caspase-3, resulting in apoptosis. Accordingly, general anesthesia administered at the peak of synaptogenesis activates the mitochondria-dependent cascade within 2 hours and is characterized by a decrease in Bcl-xL, a rise in cytochrome c, and activation of caspase-9.[15] Melatonin, a sleep hormone known to up-regulate Bcl-xL, offers some protection by partially inhibiting anesthesia-induced cytochrome c leakage and caspase-9 activation.[16]

Death Receptor–Dependent Apoptotic Cascade

Apoptosis can proceed via the extrinsic pathway, triggered by the activation of death receptors. This involves the formation of a death-inducing signaling complex (DISC), which results in the activation of caspase-8 and caspase-3, resulting in cell death. General anesthesia promotes DISC formation[15] and thereby apoptosis. Studies suggest that anesthesia-induced activation of the intrinsic pathway occurs before activation of the extrinsic pathway.[15]

Neurotrophic Factor–Dependent Apoptotic Cascade

The neurotrophins, a family of neuronal growth factors, support neuronal survival and differentiation and synaptic plasticity. Thus, they are important in synaptogenesis of the mammalian brain. Neurotrophins are synthesized and released by neurons; both their biosynthesis and secretion depend on neuronal activity. Extensive depression of neuronal activity can impair neurotrophin-regulated survival-promoting signals and consequently promote apoptosis. When clinically used general anesthetics were administered at the peak of synaptogenesis, the observed neuroapoptotic damage was mediated, at least in part, by a brain-derived neurotrophic factor (BDNF)-modulated apoptotic cascade.[17,18] Anesthesia-induced disturbances in BDNF-mediated neuronal survival pathways were rapid, and the underlying mechanisms may show region specificity. A sex hormone, β-estradiol, offers some protection against the anesthetic-induced neuroapoptosis by partially inhibiting anesthesia-induced caspase-3 activation.[17]

Anesthetic-Induced Neuroapoptosis Leads to Neuronal Depletion

An important question with potential functional implication is whether the observed anesthesia-induced apoptosis of developing neurons results in permanent neuronal deletion. Careful quantification of neuronal densities in the most vulnerable cortical and subcortical regions revealed that animals treated with general anesthesia had as much as a 50% decrease in neuronal densities in these brain regions in contrast to untreated animals.[10,19] Although physiologic "pruning" of redundant neurons commonly is observed in the developing mammalian brain, only approximately 1% to 2% do not survive normal synaptogenesis. Perhaps clinical doses of anesthetic jeopardizes the survival of such an excess of developing neurons.[10]

Neuroapoptosis: Anesthetic Versus Changes in Cardiovascular and Respiratory Homeostasis

Of prime importance in clinical anesthesia is the maintenance of adequate oxygenation and ventilation; tissue perfusion; and, ultimately, the stability of vital signs. Because of the technical limitations imposed by the small size of rodent pups, these important parameters cannot be monitored and controlled continuously in many of the preclinical studies that generated the previously mentioned data. Thus, some of the preclinical findings may be a result of inadequate maintenance of physiologic homeostasis. To address this concern, researchers have used guinea pigs[10] and primates,[12-14] species in which it is technically possible to more tightly control and monitor

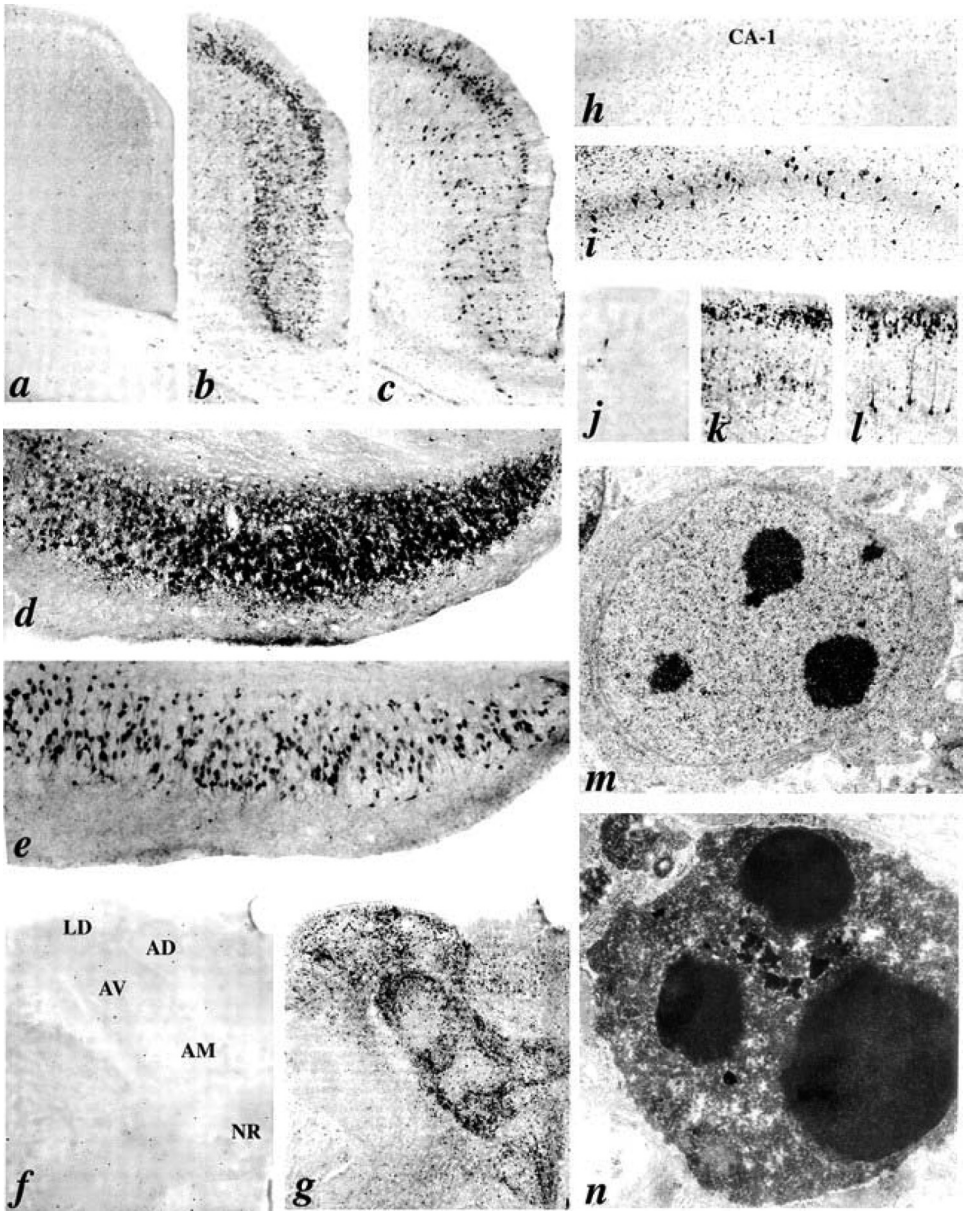

Figure 15-1. Anesthesia induces apoptotic neurodegeneration. Panels *a* to *l* are light micrographs of various brain regions of a control rat *(a, f, h, j)* and a rat exposed to isoflurane (0.75 vol%), midazolam 9 mg/kg subcutaneously, and nitrous oxide 75 vol% for 6 hours *(b* to *e, g, i, k, l).* Some sections were stained by the de Olmos silver method *(a, b, d, f, g, k);* the others were immunocytochemically stained to reveal caspase-3 activation *(c, e, h* to *j, l).* Regions are the posterior cingulate and retrosplenial cortex *(a* to *c),* subiculum *(d, e),* anterior thalamus *(f, g),* rostral CA1 hippocampus *(h, i),* and parietal cortex *(j* to *l).* The individual nuclei shown in the anterior thalamus *(f, g)* are laterodorsal *(LD),* anterodorsal *(AD),* anteroventral *(AV),* anteromedial *(AM),* and nucleus reuniens *(NR).* Panels *m* and *n* are electron micrographs of neurons undergoing apoptosis. The cell in *m* displays an early stage of apoptosis in which dense chromatin balls form in the nucleus while the nuclear membrane remains intact. The cell in *n* exhibits a much later stage of apoptosis in which the entire cell is condensed, the nuclear membrane is absent, and intermixing of nuclear and cytoplasmic constituents is seen. *(From Jevtovic-Todorovic V, Hartman RE, Izumi Y, et al: Early exposure to common anesthetic agents causes widespread neurodegeneration in the developing rat brain and persistent learning deficits,* J Neurosci *23:876-882, 2003.)*

the adequacy of ventilation, oxygenation, and tissue perfusion. These studies confirm the smaller animal studies, suggesting that the histomorphologic changes observed are caused by general anesthesia per se and not by hypoxia, hypercarbia, or metabolic imbalance. Moreover, neither hypoglycemia[9] nor hypercarbia[20] significantly worsens anesthesia-induced developmental neuroapoptosis, again implicating the anesthetic as opposed to the physiologic state.

MITOCHONDRIAL MECHANISMS FOR ANESTHESIA-RELATED DEVELOPMENTAL NEUROTOXICITY

In addition to jeopardizing the integrity of the mitochondrial membrane and activating the intrinsic apoptotic cascade, general anesthetics cause a significant and long-lasting disturbance in mitochondrial morphogenesis. Early exposure to general anesthesia causes mitochondrial

enlargement and disruption of the cristae and inner mitochondrial membrane.[21] Mitochondrial regeneration in neurons depends on a fine dynamic balance between mitochondrial fusion and fission.[22] Deranged fusion leads to mitochondrial fragmentation, whereas deranged fission leads to enlargement. Thus, general anesthetics may disturb this fine dynamic balance, favoring mitochondrial fusion. Such dysfunction may be the cause of anesthesia-induced developmental neurodegeneration,[21] especially because an imbalance that favors fusion may contribute to several adult neurodegenerative diseases.[23,24]

Anesthetic-induced mitochondrial enlargement may slow migration, delaying their delivery to highly arborized dendritic branches at a time when their presence is necessary for normal synapse formation and development.[25,26] Anesthesia reduces the number of mitochondria in these distal sites[21] and impairs plasticity of dendritic spines and the formation,[27,28] stability,[18] and function of developing synapses.[29]

The morphologic distortion and impairment of regional distribution is also accompanied by production of excessive reactive oxygen species (ROS) and peroxidation of lipids and proteins. ROS clearly contribute to the development and progression of several neuronal diseases associated with cognitive decline, including Parkinson disease,[30] AD,[31,32] and Huntington[33] disease. Neurons produce ROS as by-products of their high metabolic activity and yet are relatively deficient in oxidative defenses. This vulnerability, combined with a high polyunsaturated fatty acid content, makes them susceptible to excessive lipid peroxidation and cellular damage.[34] A functional link between anesthetic-induced mitochondrial dysfunction, ROS up-regulation, and cognitive decline may exist. Administration of either radical scavengers or mitochondrial permeability transition pore blockers with anesthetics at postnatal day 7 (the peak of synaptogenesis) prevented the development of learning and memory impairment as adolescents. Moreover, melatonin, a naturally occurring sleep hormone,[16] and carnitine, a nutritional supplement that protects mitochondrial integrity,[35] cause significant protection against neuronal apoptosis. Thus, preventing excessive lipid peroxidation and protecting mitochondria may be the key to safe use of general anesthesia during early stages of brain development.

ENDOPLASMIC RETICULUM MECHANISMS FOR ANESTHESIA-RELATED DEVELOPMENTAL NEUROTOXICITY

An upstream trigger for the mitochondrial and apoptotic observations discussed earlier could be the excessive release of calcium from the endoplasmic reticulum resulting in cytosolic and mitochondrial calcium overload. In turn, this causes cytochrome c leak,[36] further compromising mitochondrial function. Thus, the endoplasmic reticulum could be an important initial target organelle of anesthesia-induced developmental neurotoxicity. Indeed, isoflurane directly activates inositol 1,4,5-trisphosphate receptors ($InsP_3R$), producing an exaggerated and prolonged calcium release, and increases cytosolic calcium.[37] This increases mitochondrial permeability transition pore activity[38] and modulates mitochondrial Bcl-xL protein, events that promote apoptotic neuronal death in the immature rat brain. Desflurane and sevoflurane, but less so propofol, activate the $InsP_3R$ and with similar consequences.

Calcium dysregulation is not an all-or-none phenomenon. Moderate increases in endoplasmic reticulum calcium release may provide neuroprotection,[39] whereas excessive release may push calcium into the toxic range. As a second messenger, intracellular calcium regulates many aspects of neuronal development, including synapse formation and function, membrane excitability, protein synthesis, neuronal apoptosis, and autophagy—all important elements of neuronal survival.[36,40,41] Disturbances in calcium homeostasis underlie some forms of learning and memory deficits[42,43] and may play an important role in anesthetic-induced developmental dysfunction.

LYSOSOME AND AUTOPHAGY MECHANISMS IN ANESTHESIA-RELATED DEVELOPMENTAL NEUROTOXICITY

Anesthesia may produce an excess of defective organelles, often referred to as biologic "garbage" that must be degraded to ensure neuronal survival. The process for clearing this debris without causing damage to the neuron is the multistep process, autophagy (i.e., autophagocytosis). Autophagy is initiated by the formation of autophagosomes, double-membrane–bound cellular structures that enter lysosomes, the acidic vacuolar compartment that contains various lytic enzymes.[44-46] Defective organelles are autophagocytosed at a slow rate, resulting in lysosomal accumulation of an undegradable, polymeric, autofluorescent material termed lipofuscin. General anesthetics heighten the formation of autophagic bodies,[21] raising the possibility that anesthesia kills developing neurons in part by inducing autophagic stress, a form of self-cannibalism. Accordingly, a relationship between autophagy and neuroapoptosis may occur in other models of cell injury. However, whether autophagy is important for the initiation of apoptosis[47] or whether autophagy and apoptosis are independent of each other is not known.[48] Regardless, the neurotoxic effect of general anesthetics during early stages of development may involve the growth and demise of neuronal organelles (Fig. 15-2).

ANESTHESIA-RELATED IMPAIRMENT OF SYNAPTOGENESIS

Exposure of rodents to general anesthetics at the peak of synaptogenesis results in severe, long-lasting functional and ultrastructural abnormalities of synapses of the developing hippocampal complex[29] (Fig. 15-3). This observation agrees with a study showing that exposure of mice to general anesthesia during synaptogenesis results in significant reductions in dendritic filopodial spines and synapse formation both in vivo and in vitro.[18]

General anesthetics are powerful modulators of synaptogenesis not only in terms of causing significant deletion of neuronal synapses and neurons but also in causing

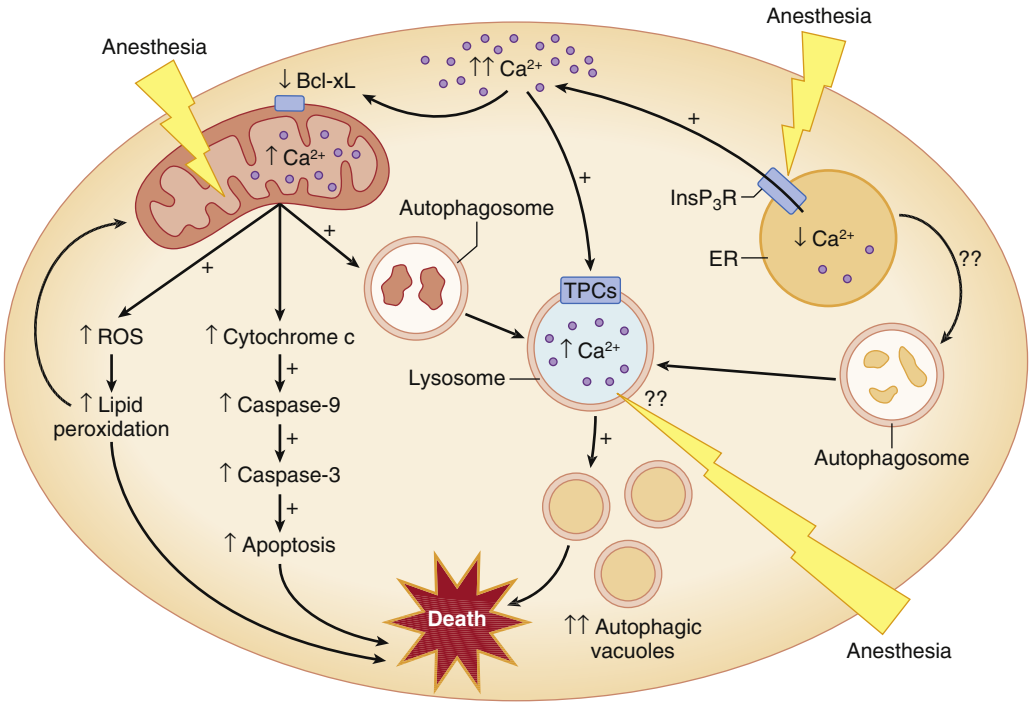

Figure 15-2. Anesthesia-induced pathways of developmental neurodegeneration. Three pathways are proposed: (1) The endothelial reticulum–dependent pathway involves anesthesia-induced activation of inositol 1,4,5-trisphosphate receptors *($InsP_3R$)* causing excessive calcium *(Ca^{2+})* release and acute elevation of cytosolic Ca^{2+}. This causes down-regulation of mitochondrial antiapoptotic protein, *Bcl-xL*, producing cytochrome c leak into the cytoplasm, which in turn activates apoptosis by activating caspase-9 and caspase-3. (2) The mitochondria-dependent pathway relies on anesthetic-induced up-regulation of reactive oxygen species *(ROS),* leading to the excessive lipid peroxidation of mitochondrial and endoplasmic reticulum *(ER)* membranes. Damaged mitochondrial and ER are sources of more ROS, cytochrome c, and calcium, so these cells have to be removed by apoptosis or autophagy. (3) The lysosome-dependent pathway involves lysosome activation by nicotinic acid adenine dinucleotide phosphate–gated two-pore channels *(TPCs),* which control Ca^{2+} uptake into the lysosomes. An increase in lysosomal calcium increases proteolytic activity, which in turn promotes the formation of autophagic vacuoles and autophagy. It is unclear whether anesthesia causes lysosomal activation indirectly by an increase in cytosolic Ca^{2+} from the ER or directly via lysosomal activation. *(From Jevtovic-Todorovic V, Boscolo A, Sanchez V, Lundari N: Anesthesia-induced developmental neurodegeneration: the role of neuronal organelles,* Front Neurol *3:141, 2012.)*

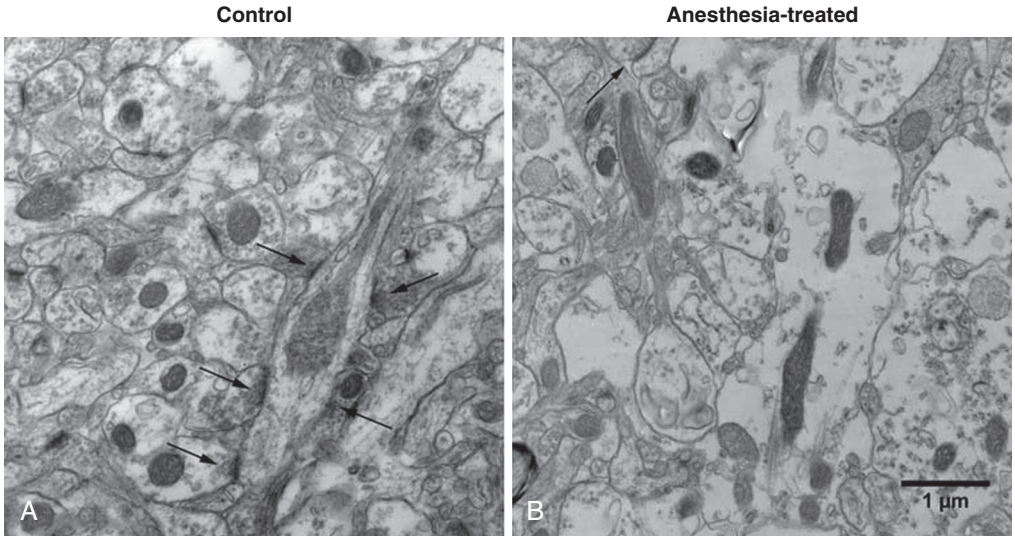

Figure 15-3. Anesthesia-treated animals had scarce multiple synaptic boutons (MSBs). **A,** The abundance of MSBs *(arrows)* on the neuronal profile of a control subiculum. In contrast, anesthesia (**B**) produces a reduction of synaptic contacts (magnification 12,000×). *(From Lunardi N, Ori C, Erisir A, et al: General anesthesia causes long-lasting disturbances in the ultrastructural properties of developing synapses in young rats,* Neurotox Res *17:179-188, 2010.)*

Figure 15-4. undue up-regulation of synaptic contacts when the exposure occurs at the later stages of synaptogenesis[27,28] (Fig. 15-4). Of course, the functional outcomes of either morphologic phenomenon remain to be deciphered.

LONG-TERM COGNITIVE OUTCOME IN ANIMALS AFTER EARLY ANESTHETIC EXPOSURE

The pathomorphologic findings discussed earlier make it clear that anesthesia exposure results in neuronal deletion[10,19] and long-lasting impairment of synapses in vulnerable brain regions.[18,29] The question now is whether these observations translate to lasting effects on behavior.

The answer, at least in animals, is yes. The development of cognitive abilities of animals exposed to general anesthetics at the peak of synaptogenesis lagged behind those of controls, with the gap widening into adulthood (Fig. 15-5). Even intravenously administrated general anesthetics such as propofol or thiopental in combination with ketamine (but not singly) at postnatal day 10 alter mouse behavior later in young adulthood.[49] Similar adult behavioral deficits were noted when mice were exposed at postnatal day 10 to a cocktail containing ketamine and diazepam.[50]

Although anesthesia cocktails seem to be most detrimental, ketamine given alone during early stages of brain development in rats also caused later deficits in habituation, learning, and memory.[50] When anesthetic drugs with GABAergic and *N*-methyl-D-aspartate antagonist properties are combined, which is done frequently in the clinical setting (e.g., nitrous oxide [N_2O] and volatile anesthetics or propofol and ketamine), cognitive deficits are more profound.[7,49,50] Although causality is difficult to establish, anesthesia-induced neuroapoptosis (discussed previously) is at least in part responsible for the observed cognitive deficits. Whether multiple, longer-lasting exposures to anesthesia cocktails during vulnerable periods have more effects than predicted on neurocognitive development is not known.

General anesthesia is rarely administered in the absence of surgery and its associated pain and tissue injury. Thus, the reported neurotoxic potential of general anesthesia during brain development needs to be confirmed in the setting of surgical stimulation. Using clinically relevant concentrations of N_2O and isoflurane, Shu and colleagues[51] found that nociception enhanced neuroapoptosis and worsened long-term cognitive impairments in contrast to anesthesia alone (Fig. 15-6). On the other hand, Liu and colleagues[52] found that noxious stimulation attenuated the apoptotic effect of ketamine anesthesia. Resolution is needed in these conflicting results in the combined effects of surgery and anesthesia in the neonate.

Results from rodent studies usually translate poorly to humans, but newly emerging behavioral studies with nonhuman primates suggest that translation is likely. Paule and colleagues[53] examined the effects of continuous neonatal (age 5 or 6 days) ketamine infusion (24 hours) sufficient to maintain a light surgical plane of anesthesia on behavioral development in primates. They observed that ketamine-treated primates exhibit long-term disturbances in all important aspects of cognitive development, such as learning, psychomotor speed, concept formation, and motivation. These effects occurred despite an absence of physiologic or metabolic trespass. Although 24 hours of anesthetic exposure would be considered unusual, it certainly occurs, especially in critically ill patients of all ages.

LONG-TERM COGNITIVE AND BEHAVIORAL DEFICITS IN HUMANS AFTER CHILDHOOD SURGERY

The effects of perioperative events on the psychological and emotional development of children have been known for decades. In 1945, Levy's retrospective study[54] was the first to make an association between relatively short surgical procedures, such as tonsillectomy, adenoidectomy, or appendectomy, in otherwise healthy children and the development of new behavioral problems such as terrors, dependency, destructiveness, and disobedience within the first 6 postoperative months. Most of the sensitive children were in the youngest age group; 33% to 58% of them were between 0 and 2 years of age. We now know

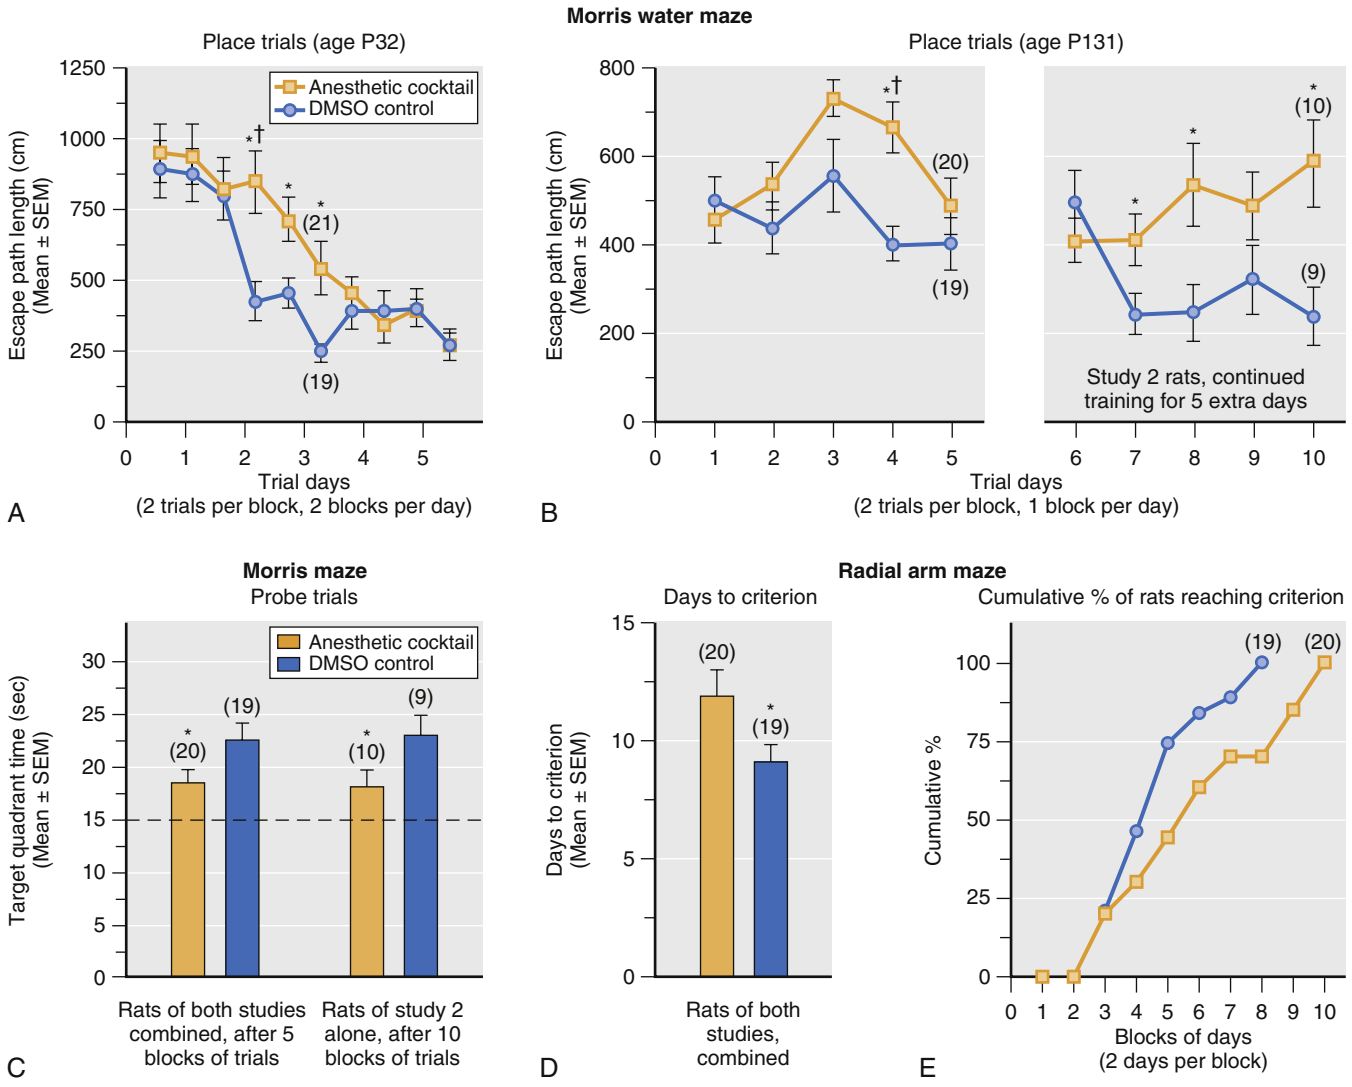

Figure 15-5. Effects of neonatal anesthetic cocktail treatment on spatial learning. Typical cognitive studies demonstrate durable anesthetic-induced defects. **A,** Rats were tested at P32 for their ability to learn the location of a submerged (not visible) platform. ANOVA analysis of data on the length of escape paths yielded a significant main effect of treatment ($P = 0.032$) and a significant treatment by blocks of trials interaction ($P = 0.024$). These results indicated that the place-training performance of rats given an anesthetic cocktail (0.75-vol% isoflurane with midazolam at 9 mg/kg, s.c., and nitrous oxide at 75-vol% for 6 hrs) was significantly inferior to that of control rats. Subsequent pairwise comparisons indicated that differences were greatest during blocks 4, 5, and 6 ($P = 0.003$, 0.012, and 0.019, respectively). However, rats given the anesthetic cocktail improved their performance to control-like levels during the last four blocks of trials. **B,** Rats were retested as adults (P131) for their ability to learn a different location of the submerged platform. The graph *on the left* shows the path-length data from the first five place trials when all rats were tested. ANOVA analysis of these data yielded a significant main effect of treatment ($P = 0.013$), indicating that the control rats, in general, used significantly shorter paths in swimming to the platform than did rats treated with the anesthetic cocktail. Subsequent pairwise comparisons showed that differences were greatest during block 4 ($P = 0.001$). The graph *on the right* shows the data from rats given 5 additional training days as adults. During these trials, rats in the control group improved their performance and appeared to reach asymptotic levels, whereas the rats given the anesthetic cocktail showed no improvement. ANOVA analysis of these data yielded a significant main effect of treatment ($P = 0.045$), as well as a significant treatment by blocks of trials interaction ($P = 0.001$). Additional pairwise comparisons showed that group differences were greatest during blocks 7, 8, and 10 (P = 0.032, 0.013, and 0.017, respectively). **C,** Probe trial performance of rats given the anesthetic cocktail and control rats during adult testing. Search behavior of the rats was quantified when the submerged platform was removed from the pool after the last place trials in blocks 5 and 10. The histogram *on the left* presents data for rats in both studies 1 and 2 combined after five blocks of place trials were completed. The histogram *on the right* presents data for rats in study 2 alone, after 10 blocks of place trials were completed. The *dotted line* represents the amount of time that animals would be expected to spend in the target quadrant based on chance alone. Both histograms show that the control rats spent significantly more time in the target quadrant than did the anesthesia-exposed rats, regardless of whether the probe tests were done on both study groups after five blocks or only on the study 2 rats after 10 trials. **D** and **E,** Data are shown from the radial arm maze test done on P53 to evaluate spatial working memory capabilities. The histogram in **D** shows that rats given the anesthetic cocktail rats required significantly more days to reach a criterion demonstrating learning (8 correct responses out of the first 9 responses for 4 consecutive days) compared with controls. The plot in **E** shows the days to criterion data as the cumulative percentage of rats reaching criterion in each group as a function of blocks of training days. The acquisition rate of rats given the anesthetic cocktail began to slow around the fourth block of trials and remained slower throughout the rest of the experiment. Numbers in parentheses in each graph indicate sample sizes. *$P < 0.05$; Bonferroni corrected level: $P < 0.005$ in a; $P < 0.01$ in b. *(From Jevtovic-Todorovic V, Hartman RE, Izumi Y, et al: Early exposure to common anesthetic agents causes widespread neurodegeneration in the developing rat brain and persistent learning deficits,* J Neurosci *23:876-882, 2003.)*

that the incidence of surgery-associated psychological disturbances ranged from 9% to 20% and that children younger than 2 years of age were at most risk. Furthermore, the risk was independent of the anesthetic drug used,[55-58] and in some cases the behavioral disturbances persisted for months and even years. In a prospective multicenter survey of 551 children, Campbell and associates[59] found a 47% overall incidence of new behavioral problems, including anxiety, nightmares, and attention seeking, and again noted a relatively more frequent risk in those having procedures in the first 2 years of life.

Because the behavioral changes were independent of drug or technique, the emotional shocks of hospitalization, separation from family, and the physical traumas of surgical intervention, including pain, fluid imbalance, nutritional changes, and blood loss, were thought to cause the regressive behavioral changes. However, the relationship between anesthesia and acute personality changes was suggested in 1953, when Eckenhoff[56] published a retrospective study of 612 patients younger than 12 years of age who had either a tonsillectomy or appendectomy while anesthetized with a variety of anesthetics (cyclopropane, N_2O, morphine, and pentobarbital). Behavioral changes and new-onset bedwetting occurred on average 2 months after surgery, with the most frequent incidence (57%) in those younger than 3 years and lowest incidence (8%) in those older than 8 years.

Backman and Kopf[58] were the first to suggest a relationship between anesthesia and long-term cognitive delay. In this report, children were anesthetized with ketamine and halothane for removal of congenital nevocytic nevi, a fairly minor procedure. Nevertheless, the authors reported an increased incidence of cognitive impairment, described as regressive behavioral changes, lasting up to 18 months after the procedure. Again, children younger than 3 years of age were the most sensitive. These authors clearly voiced concern that general anesthetics may cause long-term cognitive effects.

Clinical investigations are still at an early stage, but the evidence that has emerged over the last few years consistently points to detrimental effects of anesthetic exposure in young children on subsequent behavioral and cognitive development.

In a population-based retrospective birth-cohort study of 5357 children, Wilder and associates[60] found that children who received two or more general anesthetics before the age of 4 years were at increased risk for learning disability as adolescents (Fig. 15-7). Moreover, the

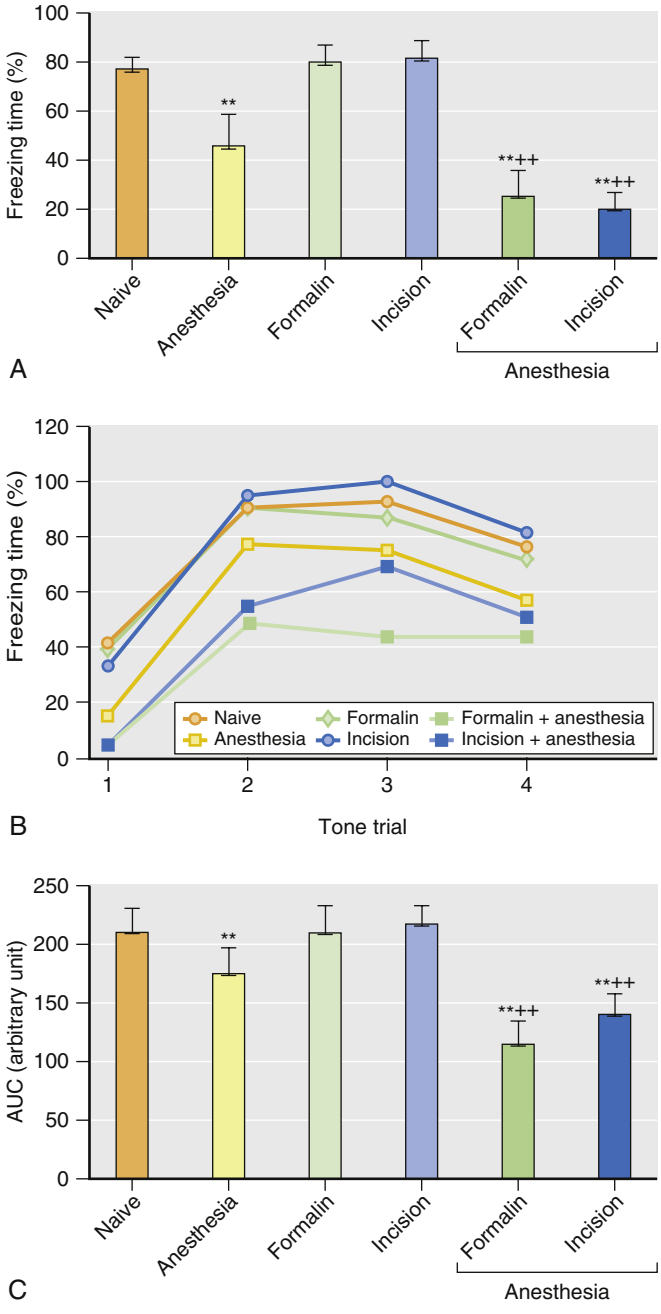

Figure 15-6. Cognitive function assessed with trace fear conditioning. To test the combined effect of noxious stimulation and anesthesia, P7 rats received 70% nitrous oxide plus 0.75% isoflurane with or without noxious stimulation (formalin paw injection or skin incision). At 40 days of age, the rats were tested with a fear-conditioning assay, in which longer freezing times reflect better memory. **A-C** show that the addition of noxious stimulation to the anesthetic at P7 actually further reduces cognitive performance as young adults. *(From Shu Y, Zhou Z, Wan Y, et al: Nociceptive stimuli enhance anesthetic-induced neuroapoptosis in the rat developing brain,* Neurobiol Dis *45:743-750, 2012.)*

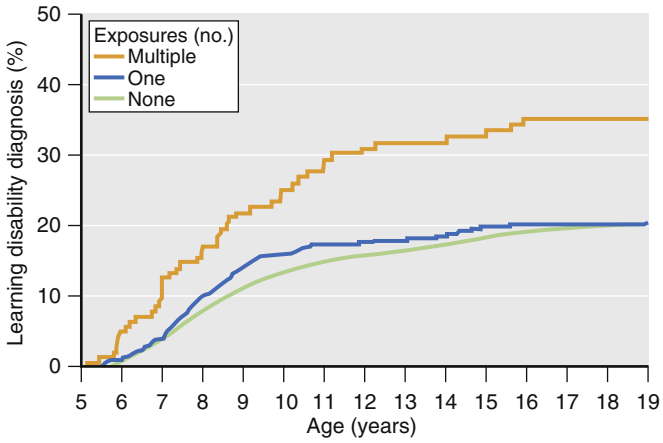

Figure 15-7. Learning disabilities in children having surgery before 4 years of age. Only multiple surgical procedures before age 4 had a significant effect on the cumulative incidence of learning disability. *(From Wilder RT, Flick RP, Sprung J, et al: Early exposure to anesthesia and learning disabilities in a population-based birth cohort,* Anesthesiology *2009;110:796-804.)*

risk increased with longer cumulative exposure duration (>2 hours). Of particular concern is their finding that the cohort exposed to anesthesia before 4 years of age had cognitive scores that were 2 standard deviations below predicted. This implies that early exposure to general anesthesia may have prevented achievement of full cognitive potential. In an even larger population study, Sun and co-workers[61] assessed learning disabilities in 228,961 individuals. Children who had procedures requiring anesthesia before 3 years of age required more Medicaid services for learning disability than did children not having these procedures. Kalkman and associates[62] also found more learning deficits in a similarly exposed but smaller population of children in the Netherlands. Procedures in premature infants have also been associated with an excess of behavioral disabilities later in life. For example, surgically treated premature infants with patent ductus arteriosus[63] or necrotizing enterocolitis[64] had worse neurologic outcomes than did premature infants who were treated medically.

A recent retrospective clinical study examined the association between procedures requiring general anesthesia before the age of 2 years and the occurrence of attention deficit/hyperactivity disorder (ADHD) up to the age of 19 years.[65] As found in the prior Wilder study,[60] only the cohort having two or more exposures before 2 years of age was associated with ADHD; the lack of association in single exposures was not explained by anesthetic type or comorbidities (Fig. 15-8).

Despite the limitations inherent in retrospective clinical studies, such as lack of randomization, unmatched controls, and numerous uncontrolled (and unknown) variables, this study points to yet another behavioral impairment that could be associated with early exposure to anesthesia. But association does not imply causality. A measure of caution is advisable because the effects of surgery or the illness requiring surgery cannot be clearly separated from the effects of anesthesia in retrospective clinical studies. However, the complex issues associated with the design of randomized, double-blinded prospective clinical studies of very young patients cannot be underestimated. These issues include, but are not limited to, ethical considerations; the lack of biomarkers of apoptosis that can be used safely in a living organism; the complexity and significance of various clinical outcomes, especially neurocognitive ones; and the lack of appropriate controls.

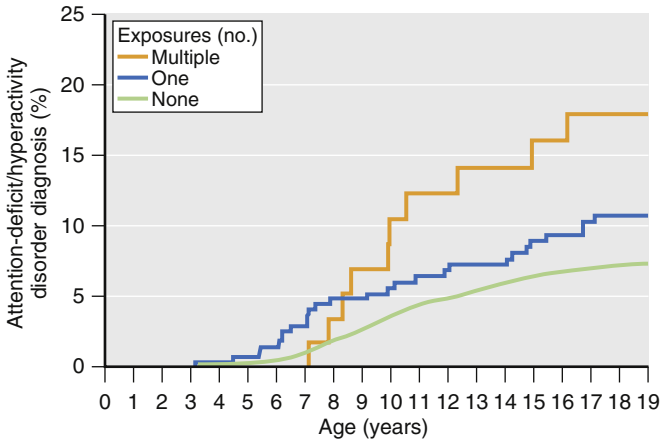

Figure 15-8. Attention-deficit/hyperactivity disorder (ADHD) in children having surgery before 2 years of age. Similar to the data on learning disability (see Fig. 15-7), the largest effect on ADHD incidence of prior surgery occurred in the cohort having multiple procedures before 2 years of age. *(From Sprung J, Flick RP, Katusic SK, et al: Attention-deficit/hyperactivity disorder after early exposure to procedures requiring general anesthesia,* Mayo Clin Proc *87:120-129, 2012.)*

PRACTICE GUIDELINES AND RECOMMENDATIONS

Although appreciation of anesthesia-induced developmental neurotoxicity is rapidly emerging, it is premature to draw definite conclusions regarding the human risk in anesthesia in the developing brain. However, if developmental events (e.g., synaptogenesis) present distinct vulnerabilities, the timing and duration of anesthesia exposure might be considered in the decision whether to operate. The most vulnerable age group is younger than 4 years, but whether a specific anesthetic technique, surgical procedure, comorbidity, or genotype presents additional vulnerability is unknown and requires further study. A reasonable recommendation is to avoid anesthesia until most of the synaptogenesis has been completed and/or to limit the duration of exposure to less than 2 hours whenever possible. Ultimately, however, general anesthesia cannot be avoided in cases in which life-threatening conditions make frequent surgical interventions and prolonged stays in ICUs a necessity.

NEUROTOXICITY IN THE ELDERLY

See also Chapter 80.

ANESTHETICS

While they are in the central nervous system (CNS), general anesthetics alter cognitive states. Depending on the drug and the duration and magnitude of exposure, the altered cognitive state can outlast the surgery itself for a considerable period, but rarely for more than a day or two. Thus, anesthetic drugs should be considered as candidates for more durable cognitive influences. Clinical studies of POCD, however, have not been able to find differences attributable to the anesthetic or the anesthetic approach, except for the initial International Study on Postoperative Cognitive Dysfunction, which detected anesthetic duration as a significant risk factor. Because anesthesia and surgery are inextricably linked in human studies, the possibility that the anesthetic per se is causing the cognitive deficits has been studied in cell culture and in animal models. Culley and associates first established a model of POCD in elderly rats after anesthesia alone by showing that isoflurane and N_2O exposure caused memory and learning deficits that lasted at least 3 weeks,[66] but not in younger rats.[67] A later study implicated isoflurane as the probable cause[68] rather than N_2O. This was confirmed by work in elderly mice in which Bianchi and colleagues[69] also provided evidence for an isoflurane-induced cognitive decline in a wild-type strain in the absence of surgery. Few studies have rigorously compared different

anesthetics, but desflurane may be less provocative than isoflurane and the injectable anesthetics, such as propofol, even less. In general, however, all of the preclinical investigations of anesthetic exposure alone have revealed only a modest and transient cognitive disturbance. This is consistent with the multitude of small human trials (see later discussion) that have not detected an association of POCD risk with any particular feature of anesthetic management. Yet, perhaps small vulnerable populations exist that have ongoing neuropathology and in which the anesthetic alone might have a deleterious effect.

Amyloid-β and Anesthesia

Strongly implicated in the pathogenesis of AD is amyloid-β, a small proteolytic fragment of a larger membrane protein (amyloid precursor protein [APP]) of synaptic origin but still unknown function. All known familial forms of AD involve mutations directly in the *APP* gene or its interactors, and the only mutation found to protect against AD is also in this gene.[70] Excessive amyloid-β accumulates extracellularly and, through poorly understood mechanisms, begins to form oligomers and ultimately plaques (Fig. 15-9). Currently, the amyloid plaques are considered to be a form of inert material that has been sequestered, and the smaller oligomers are capable of causing both direct neuronal toxicity and an inflammatory response by interacting with the brain's primary immune surveillance cell, the microglia. The smoldering neurotoxic and inflammatory insult gradually depletes both synapses and neurons, which at some point, cross a threshold after which cognitive consequences emerge. Most mouse models of AD involve alterations in the *APP* gene. For example, the Tg2576 model incorporates the human *APP* gene containing the "Swedish" mutation, which results in excessive proteolysis and release of the amyloid-β peptide. The mice develop an age-related decline in cognition and demonstrate amyloid-β plaque in similar areas of the brain, as seen in humans (subiculum, hippocampus, and cortex) (Fig. 15-10). Interestingly, exposure of elderly, symptomatic Tg2576 mice to anesthetics *did not* result in a further decline in their cognition.[69] The investigators attributed these counterintuitive results to a "floor-effect"; in other words, the mice were already so compromised that an incremental effect from the anesthetic was undetectable. In support of this notion, it is known that cognitive decline in humans, once detectable, proceeds along a relatively relentless trajectory that might not respond to perturbants in either direction[71] (Fig. 15-11). This may be the primary reason for the multitude of failed therapeutic trials in AD, because improvement in already symptomatic individuals has been the most common end point. Thus, cognitive measures alone might be relatively insensitive to these incremental effects, but biomarkers of the actual pathologic process have been more revealing.

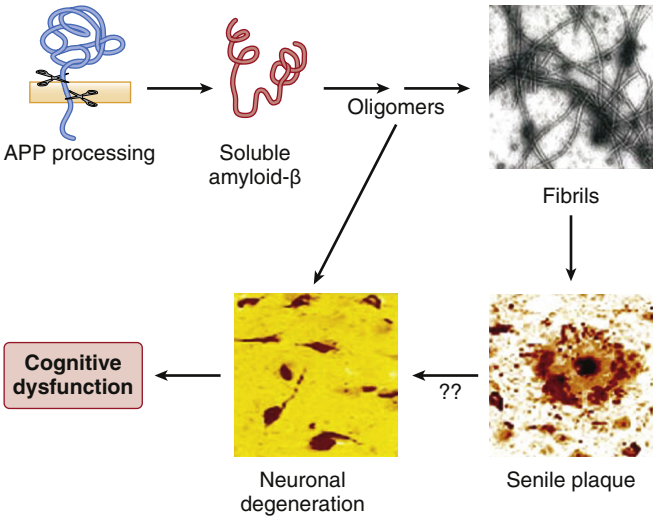

Figure 15-9. Amyloid-β cascade hypothesis. Amyloid precursor protein *(APP)* is cleaved by secretase and other enzymes to produce a variety of fragments, among which is soluble amyloid-β peptide. Once a critical but variable concentration threshold is reached, these monomers begin to aggregate into oligomers of 2 to 20 monomers. These oligomers, through poorly understood mechanisms cause direct cellular toxicity or inflammation, which ultimately leads to cell death and cognitive dysfunction. In addition to causing direct toxicity, these oligomers also reorganize into fibrils, which in turn attract other extracellular components to form the hallmark lesion of Alzheimer disease, the senile plaque. Whether these plaques actually contribute to neurodegeneration, or simply serve as a bystander marker of it, is not yet clear.

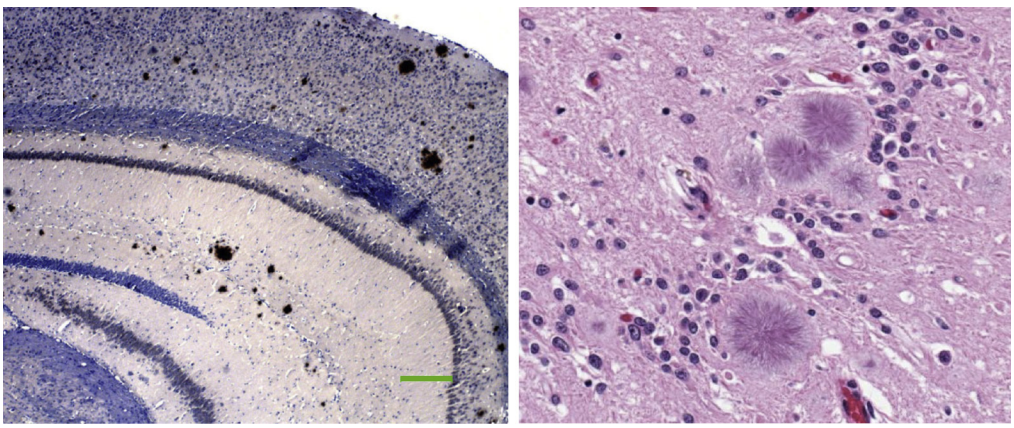

Figure 15-10. Brain amyloidopathy. Both sections show extracellular amyloid plaque. The left section (magnification 30×) is from an Alzheimer mouse model stained with an anti–amyloid antibody, and the right (magnification 150×) is from human brain stained with hematoxylin and eosin only.

Halothane exposure in the Tg2576 mouse caused significant increases in amyloid plaque, a hallmark biomarker of AD pathologic findings.[69] This was the first study to link anesthetic exposure to AD pathologic findings in vivo, and a host of other studies have now appeared. For example, in vitro and in cell culture, the inhaled anesthetics promote amyloid-β production[72] and aggregation[73] (see Fig. 15-9), events that accelerate the onset of AD.[74] If and how these provocative in vitro effects translate to humans is not known, but it is clear that other factors are necessary. For example, the equivalent anesthetic exposures in *young* transgenic mice failed to produce a change in amyloid burden and in fact produced an *improvement* in learning and memory.[75] Perhaps, then, multiple susceptibility factors may be necessary to transduce anesthetic exposure to a change in pathologic factors and cognition.

Tau and Anesthesia

The other hallmark lesion of dementia of the AD-type is the neurofibrillary tangle (NFT), composed largely of phosphorylated and aggregated (fibrillar) τ protein. The τ protein is microtubule associated and regulates microtubule stability and dynamics. When phosphorylated, it detaches from microtubules, and, if excessive, can stay unattached and form aggregates that eventually become fibrillar and cytotoxic (Fig. 15-12). This is in addition to leaving microtubules, essential for many cellular functions, destabilized and perhaps dysfunctional. Thus, small molecules that stabilize microtubules have been shown to improve pathogenesis and behavior in animals and are currently in clinical trials in patients. Anesthetics have not been directly implicated in the τ aggregation process as they have for amyloid-β, but features of the anesthetic *state* have been implicated in τ phosphorylation and detachment. For example, the enzymes responsible for dephosphorylating τ (phosphatases) are very temperature-sensitive, and thus even the temperature decline of 2° to 3°C that is common in modern anesthetic practice can increase populations of phospho-τ, at least transiently. The clinical implication of transient changes in τ populations is unclear, but it appears that populations also can be shifted on a more permanent basis by repeated exposures. Le Freche and colleagues[76] found that repeated sevoflurane exposures increased phospho-τ, whereas single exposures did not. Similarly, Tang and colleagues[75] found that multiple midlife isoflurane and halothane exposures also increased phospho-τ durably. In addition to the inhaled anesthetics, propofol may modulate τ populations.[77] The mechanistic basis for these less transient effects may be changes in the activity of the underlying kinases as opposed to phosphatases.[78] Thus, the second hallmark lesion of AD, tauopathy, is also influenced by general anesthetics or physiologic states that commonly accompany general anesthesia, providing

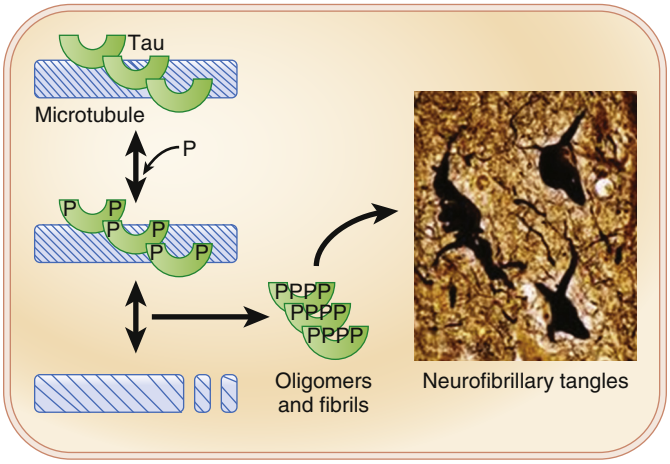

Figure 15-12. Tauopathy pathways. The τ protein is attached reversibly to microtubules, an interaction thought to stabilize the microtubule polymer. It has multiple phosphorylation sites, which modulate microtubule binding affinity. Hyperphosphorylation not only releases τ from microtubules but also facilitates τ aggregation into oligomers; fibrils; and ultimately, large intracellular deposits termed neurofibrillary tangles (NFTs). Depletion of functional τ is thought to leave microtubules destabilized. It is not clear whether cellular dysfunction associated with tauopathy is caused by a loss of function (microtubules) or gain of toxic function (NFTs). *P,* Phosphorylation site.

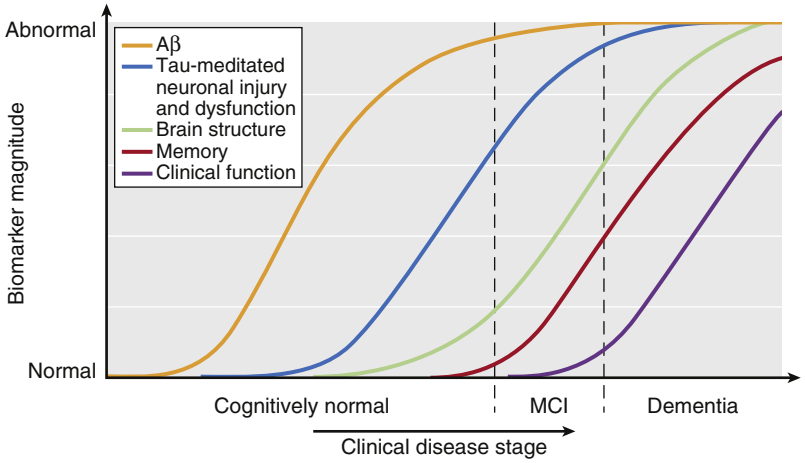

Figure 15-11. Correlation of pathologic processes and disease stage. This figure emphasizes that amyloidopathy, tauopathy, and structural loss are well advanced before the ability to detect significant cognitive consequences. In addition, it is not clear to what degree pathologic processes and degeneration are reversible once cognitive decline is detected. This recent understanding makes cognitive markers of neurodegeneration of questionable value in judging the effect of interventions, both positive and negative. *MCI,* Mild cognitive impairment.

additional rationale that an interaction between anesthesia and AD pathogenesis might underlie postoperative cognitive decline.

Calcium and Anesthesia

A third major mechanism thought to underlie dementia of the AD type is calcium dysregulation and is one mechanism that might be shared with neurotoxicity of the young (see earlier discussion). That anesthetics cause changes in calcium regulation is widely known, and this is likely to occur through interactions with several types of channels[79] (Fig. 15-13). Implicated in AD is one group of receptor channels that control calcium release from the endoplasmic reticulum, specifically the ryanodine and the IP_3 receptors. The neuronal endoplasmic reticulum is a normal cellular store of calcium that is released in a highly regulated fashion through these channels. It is now thought that mutations in either of these channels, or exposure to drugs that interact with either, may lead to an exaggerated release of calcium that could trigger apoptosis.[80] General volatile anesthetics such as halothane and isoflurane are known to trigger a syndrome termed malignant hyperpyrexia in susceptible individuals by actions on the muscle-type ryanodine receptor (see also Chapter 43); thus, it is feasible that similar but less dramatic effects may happen in the neuronal subtypes. Recent in vitro and cell culture work have also implicated the IP_3 receptor as a direct target for the general volatile anesthetics, which results in an excessive dumping of calcium into the cytosol.[81] In vivo, calcium dysregulation induced by anesthetics may require other susceptibility factors (phospho-τ, amyloid-β) that prime the $InsP_3R$ for excessive calcium release. Propofol appears to be much less provocative.

If endoplasmic reticulum calcium release contributes to AD pathogenesis or anesthetic-induced apoptosis, drugs that inhibit these channels may be useful not only during surgery but also as a delaying tactic for AD itself. Initial studies of this premise in animals using the ryanodine receptor inhibitor dantrolene are inconsistent, perhaps because of difficulty in getting this drug across the blood-brain barrier. Further work with this and related drugs seems warranted.

Mitochondria and Anesthesia

These small organelles are the powerhouses of cells, and their function is tightly integrated with most cellular functions. Not surprisingly, mitochondrial dysfunction has been implicated in aging, in AD,[82] and as a target for the general anesthetics. For example, anesthetics decrease activity of the respiratory chain,[83] influence K_{ATP} channels, and directly bind to a wide variety of mitochondrial proteins, including those responsible for initiating apoptosis.[84,85] Mitochondrial mechanisms for initiating apoptosis are covered in the earlier discussion on developmental neurotoxicity, so discussion will not be repeated here, because the underlying mechanisms are likely to be similar.

Neuroinflammation and Anesthesia

That inflammation contributes to cognitive decline is well known. This may be transduced through the release of peripheral proinflammatory cytokines, such as interleukin-6 (IL-6) and tumor necrosis factor–α (TNF-α), or through vagal afferents. That inflammatory pathways contribute to the dementing diseases such as AD was first recognized by the robust protection afforded by years of nonsteroidal antiinflammatory drug (NSAID) use by patients with arthritis.[86] The literature on inflammation in dementia, especially in AD, has subsequently increased. Inflammatory cascades clearly play at least a

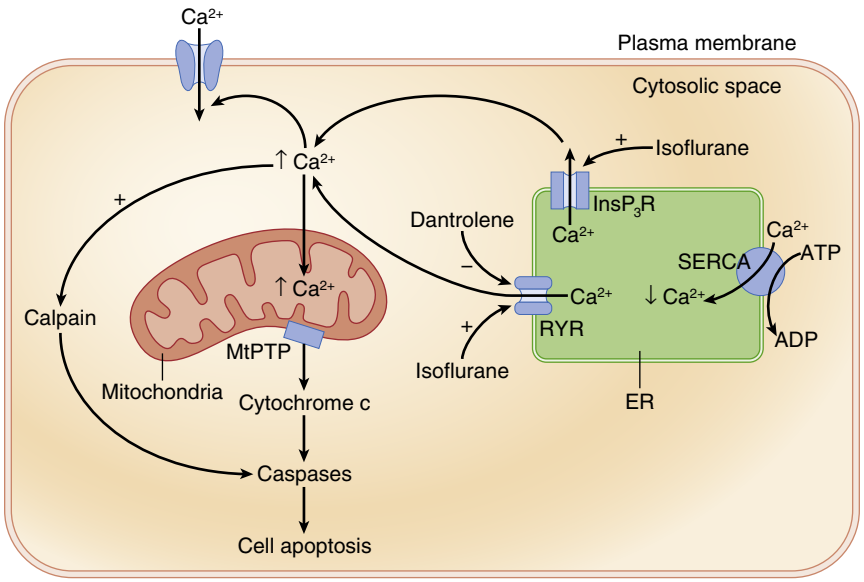

Figure 15-13. Cellular calcium dynamics. In this much simplified scheme, anesthetics (isoflurane shown) activate both the $InsP_3R$ and RyR calcium release channels on the endoplasmic reticulum (ER), elevating cytosolic calcium level. This initiates several processes. First, it activates calcium channels on the plasma membrane to allow further calcium entry. Second, it activates proteases (e.g., calpain) to activate caspase enzymes that initiate cell apoptosis. Third, excess cytosolic calcium is buffered by mitochondrial uptake, although when excessive the mitochondrial permeability transition pore (MtPTP) is activated. The MtPTP then releases cytochrome C, causing further activation of caspase activity and amplifying apoptosis. A role for dantrolene mitigation is suggested via its known actions on the ER RyR.

modulatory role; microglia are activated by amyloid-β, proinflammatory cytokines are up-regulated, and peripheral monocytes are recruited.[87] Although the role for neuroinflammation is clear, prospective trials of NSAIDs have not duplicated these results, perhaps because of timing. Perioperative management frequently includes drugs capable of modulating inflammatory cascades (e.g., lidocaine, dexamethasone, ketorolac), but whether this is being done by anesthetics is not clear. Inhaled anesthetics such as isoflurane and sevoflurane are not likely antiinflammatory, but literature in favor of propofol being antiinflammatory has increased. Certainly, propofol is a radical scavenger, but whether this is responsible for any salutary effects is not yet clear. Studies examining POCD have not yet exonerated propofol.

Summary

The durable effects of anesthetics alone on cognition and on the pathologic factors that underlie some of the known cognitive disorders such as AD suggests an unfavorable contribution, the magnitude of which is not clear. In general, however, it appears from anesthetic-only studies, especially those that examined long-term effects, that anesthetics produce few to no cognitive effects and only small and often reversible pathologic effects.

SURGERY

Animal Studies

Anesthesia is indicated for the ablation of consciousness and pain during surgery, endoscopy, and percutaneous catheter procedures and is rarely used by itself. Given that many of these procedures elicit inflammation, they may contribute to cognitive problems, especially in vulnerable populations. That surgery itself can contribute to short-term cognitive loss was first shown in mice exposed to either an injectable anesthetic alone or combined with an orthopedic operation.[88,89] Substantial cognitive decline was detected, but only in the surgery group. Further, they were able to attribute this to neuroinflammation provoked by the peripheral inflammatory response, most notably the cytokine TNF-α.[90] However, the surgery-induced cognitive effects were, like the anesthetic effects mentioned earlier, fully reversible in less than a week. Moreover, these animals were healthy and young, a group at infrequent risk for cognitive complications and hardly representative of most of our patients. The question of whether the cognitive consequences of surgery are more pronounced in vulnerable populations has been recently tested in a somewhat different transgenic model of AD, but it is still one that acquires an AD phenotype and pathologic findings at 10 to 12 months of age. In this case, desflurane anesthesia alone produced only a transient cognitive consequence whereas the addition of surgery caused a much larger decrement that lasted—essentially unchanged—for at least 3 months.[91] Again, the evidence supported that surgery-induced peripheral inflammation provoked a neuroinflammatory response that interacted with the AD pathologic factors to produce an irreversible acceleration in damage (Fig. 15-14). Such a mechanism may explain why everyone does not suffer cognitive decline after surgery. First, patients arrive for surgery with vastly different vulnerabilities, most of which are unknown. Second, the inflammatory response to an intervention such as surgery is known to be enormously variable. Understanding both of these features may, in the future, allow us to predict and prevent cognitive decline.

Patient Studies

As mentioned earlier, patient studies invariably combine both anesthesia and surgery, but serve as the ultimate test of whether the notions described dictate a change in perioperative management. With respect to long-term cognitive problems, several small retrospective studies addressed the question of whether anesthesia and surgery alter the incidence, age of onset, or trajectory of AD. In one study of approximately 250 subjects, the authors found that anesthesia and surgery significantly reduced the age of diagnosis but that the overall odds ratio for an ultimate diagnosis of AD of 1.5 was not statistically significant.[92] A similar pattern was seen in two other studies, suggesting that perhaps the negative results were the result of a lack of power.[93,94] In an examination of cardiac surgery patients, two studies had conflicting results. One compared coronary artery bypass graft (CABG) surgery under general anesthesia with percutaneous transluminal coronary angioplasty under sedation and found a significantly higher rate of AD in the CABG group.[94] Looking at this question somewhat differently, Knopman and colleagues[95] found that the rate of having had CABG surgery was no more frequent in patients

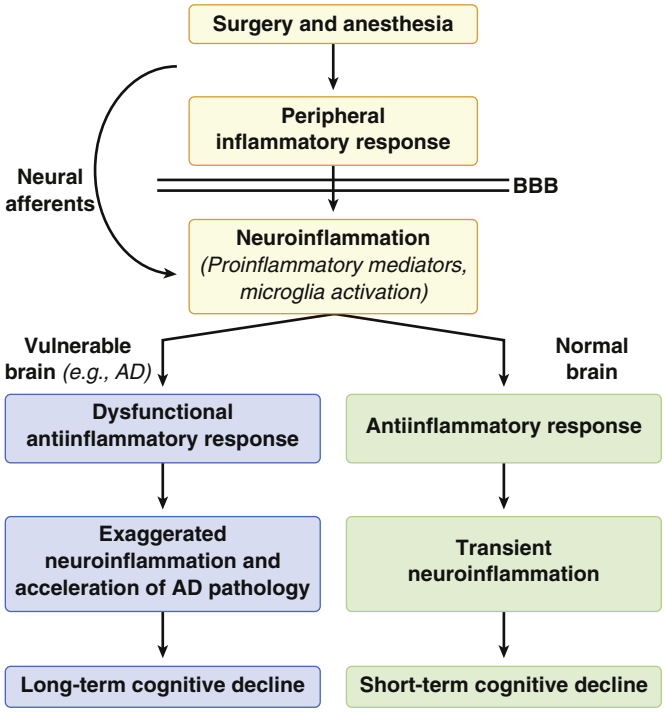

Figure 15-14. The "vulnerable" brain. Because cognitive dysfunction does not occur in everyone, we propose in this model that the combination of surgery-induced neuroinflammation and a preexisting dysfunctional immune response resulting from ongoing neuropathology (such as aging or Alzheimer disease [AD]) conspire to produce exaggerated neuroinflammation (analogous to autoimmunity) and a persistent cognitive consequence. *BBB,* Blood-brain barrier; *FDG,* fluorodeoxyglucose; *PIB,* Pittsburg compound B.

From Shaw LM, Vanderstichele H, Knapik-Czajka M, et al: Cerebrospinal fluid biomarker signature in Alzheimer's disease neuroimaging initiative subjects. *Ann Neurol* 65:403-413, 2009.

Through the Alzheimer Disease NeuroImaging (ADNI) study (Shaw and colleagues), it has been found that levels of both amyloid-$\beta_{(1-42)}$ and τ (both phosphorylated and total) are associated with progressive cognitive decline characteristic of AD. These biomarkers, especially the ratio of τ to amyloid-β, are now being used to both establish a diagnosis of AD and to stratify patients for interventional trials.

AD, Alzheimer disease; *MCI,* mild cognitive impairment; *SD,* standard deviation.

with already diagnosed AD than in age-matched controls. More recently, a meta-analysis of 15 case-control studies was conducted, concluding that an association between prior anesthesia and surgery and the risk for AD could not be detected.[96] These authors also concluded "there are few high quality studies in this area" and "Prospective cohort studies with long-term follow-up or randomized controlled trials are required to further understand the association between general anesthesia and Alzheimer's disease."

Investigators have begun to leverage the work taking place in Alzheimer disease centers across the world to study the impact of surgery and anesthesia, despite the fact that few of these centers have been systematically collecting data on surgery or anesthesia. In these centers, elderly patients with and without cognitive symptoms are recruited and studied extensively with a variety of tests, including cognition, imaging, and biomarker assays. They are then followed longitudinally for many years to seek associations between cognitive decline and the various biomarkers. In a recently published study, the patients from the centers were retrospectively examined for associations between their cognitive trajectory and the occurrence of either a surgical procedure or a serious illness (requiring hospitalization). The small number of surgical procedures in these patients limited power, but the authors were able to conclude an absence of any relationship between cognitive trajectory and either surgery or serious illness.[97] In a similar but larger study that examined primarily hospitalization for serious illness, a significant association with subsequent cognitive trajectory was detected.[98] In a subsequent study again using patients from Alzheimer disease centers, surgery and anesthesia were associated with cognitive decline approximately 6 months later in contrast to a control group of matched patients. Most interestingly, larger losses of hippocampal and cortical gray matter volume were detected in the surgical group, suggesting a brain structural correlate to the cognitive defect. This work is one of the first to use biomarkers in establishing an effect of surgery and anesthesia on the brain.

Biomarkers

Especially in disorders with a very long presymptomatic phase, biomarkers are important to understand the linkage between interventions and outcomes. Neurodegeneration begins decades before the first memory complaints, and yet it is likely that this presymptomatic phase is a period of vulnerability, both to therapy and to acceleration by interventions such as surgery. Thus, biomarkers can have a two-pronged benefit. First, to establish this vulnerability preoperatively to tailor perioperative management (when we know how) and, second, to understand the impact of perioperative management on the trajectory of the pathology. In addition to the retrospective imaging study mentioned previously, several perioperative cerebrospinal fluid (CSF) biomarker studies have begun to appear. Specific CSF biomarkers are currently a cornerstone of AD diagnosis. These are amyloid-β_{42}, total τ, and phosphorylated τ (Table 15-1). In AD, the CSF amyloid-β_{42} is low and both forms of τ are high. The ratio of total τ to amyloid-β_{42} is a very sensitive and specific predictor of AD. In a study of patients who have undergone CABG, Palotas and coworkers[99] found only small changes in the early postoperative period but significant and striking changes in an AD-like direction at 6 months postoperatively. In another study, CSF assayed before and at 24 hours after CABG surgery revealed large increases in proinflammatory cytokines but only small changes in amyloid-β_{42} (99). In the authors' work, CSF proinflammatory cytokines and total and phospho-τ were significantly elevated in patients 24 to 48 hours after endoscopic nasal surgery, with no change in amyloid-β_{42}.[100] Although one of these studies suggested that total intravenous anesthesia evoked a smaller CSF IL-6 response than sevoflurane,[100] rigorous, prospective comparisons of perioperative management on CSF biomarker outcomes have not yet been reported. The unique skills and opportunity that the anesthesiologist has with respect to lumbar puncture should greatly facilitate generation of the necessary data.

Other biomarker modalities that might reflect perioperative neurotoxicity include plasma (e.g., S100β) and imaging. Plasma biomarkers of neuronal injury are in their infancy and not yet rigorously validated,[101] but significant advances in imaging have occurred. In particular, positron emission tomography (PET) imaging for either glucose usage or one of the characteristic lesions of AD, the amyloid plaque, has dramatically enhanced the ability to diagnose AD, stratify patients for therapeutic trials, and follow the course of disease after interventions[102,103] (Fig. 15-15). No perioperative

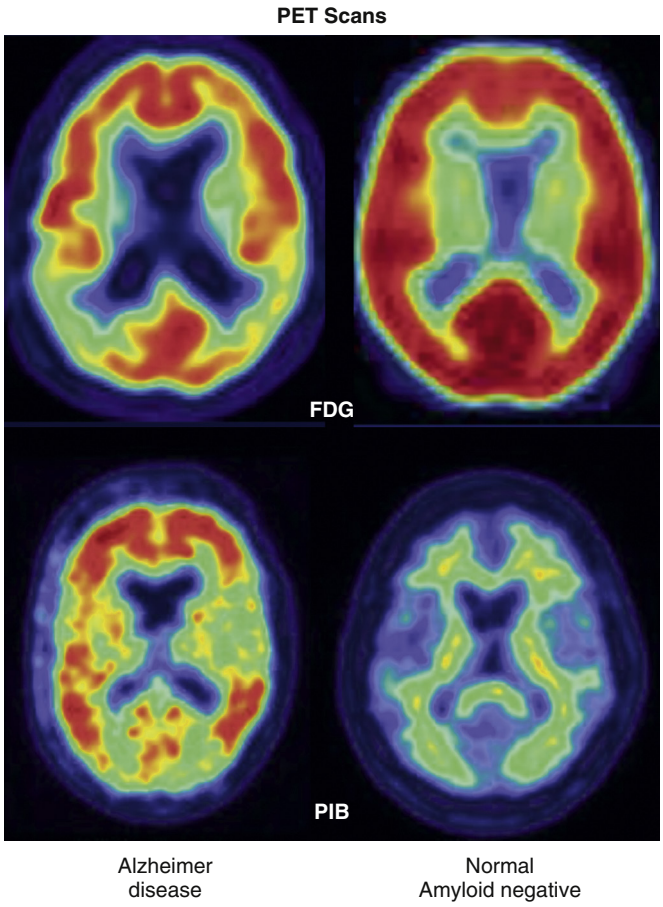

Figure 15-15. Positron emission tomography (PET) imaging. This form of "biomarker" has proved useful for evaluating brain vulnerability. Fluorodeoxyglucose (FDG) imaging reports brain areas undergoing active glucose uptake and usage. Thus, the Alzheimer brain (*left*) shows a much lower global signal than the normal brain (*right*), presumably as a result of both neuron loss and neuronal dysfunction. The Pittsburgh compound B (PIB) is a small carbon-13–containing radioligand with high affinity for fibrillar amyloid deposits (mostly plaque); thus, the signal is much higher in the Alzheimer brain than in the normal brain. These imaging biomarkers hold promise for determining vulnerability and the response to therapy (or surgery). *AD-BSL,* Alzheimer disease—baseline; *CI,* confidence interval; *MCI-BSL,* mild cognitive impairment—baseline; *NL-BSL,* normal—baseline.

studies using PET imaging have appeared, and this represents an opportunity for perioperative practitioners. Similarly, magnetic resonance imaging (MRI), either functional or structural, is being increasingly used to document neurodegenerative changes.[104,105] The functional MRI (e.g., blood-O_2 level–dependent [BOLD], or arterial spin labeling [ASL]) is thought to reflect early events in neurodegenerative diseases, whereas the structural imaging would reflect very late events, such as neuronal and glial depletion. Only a single study has retrospectively examined structural MRI in patients after surgery.[106] These investigators found a small but significant decline in hippocampal and cortical gray matter volume an average of 6 months after surgery in contrast to a matched control group that did not have surgery (Fig. 15-16).

A final "biomarker" used to establish vulnerability is genetic testing. Specific genetic mutations (e.g., *APPswe, PS1,* trisomy-21) that lead to very-high-penetrance "familial" neurodegeneration are rare and are responsible for a small minority of disease, but no information on optimal perioperative management of these patients is available. Two susceptibility genes for late-onset, or sporadic, AD have been identified: *TOMM40* and *apoEε4*.[107] Similarly, whether perioperative management should be altered when faced with these patients (some patients are acquiring their own genetic data from private companies) is not known. Until such time that this information is available, the cost of routine genetic testing cannot be justified, unless these patients are enrolled in studies.

SUMMARY OF ADULT NEUROTOXICITY

In contrast to the case in the neonate, general anesthetics may be neurotoxic in the adult or elderly brain at conventional clinical concentrations. On the other hand, the potential impact of surgery itself, via inflammatory pathways, is more compelling and supported by both preclinical and clinical data. The neuropathologic and behavioral outcome of surgery in the elderly is likely to be strongly modulated by many patient vulnerability factors, in addition to perioperative management decisions.

PRACTICE GUIDELINES AND RECOMMENDATIONS

As stated at the outset, few evidence-based changes in practice can be recommended except for the most obvious—not to have surgery. This will require, of course, careful balancing of the risks for cognitive decline against the risk for not receiving needed surgery. In most cases, the latter risk would be higher; thus, elements of perioperative management contributing to cognitive decline need to be identified and managed. The evidence at this point implicates inflammatory pathways and also suggests that anesthetic choice matters. Nothing has been confirmed in prospective clinical trials that strongly emphasizes this need. Finally, reliable biomarkers are needed to stratify patients and follow the effects of interventions.

SUMMARY AND CONCLUSIONS

The complexity of our patients and their disorders combined with the complexity and perceived chaos of the perioperative period make it extremely difficult to prove what feature, if any, of the perioperative period is responsible for long-term cognitive decline in the young or in the old. However, significant progress in the laboratory has made a compelling case that anesthesia and surgery may indeed be the cause of durable cognitive problems—at both extremes of age. These preclinical studies have allowed more focused clinical studies, many of which are under way. It is too early to make recommendations for detailed changes in perioperative management, but it is not too early to call for more investigation into the causes and prevention of perioperative neurotoxicity.

Chapter 16

The Autonomic Nervous System

DAVID B. GLICK

Key Points

- The autonomic nervous system works in concert with renin, cortisone, and other hormones to respond to internal and external stresses.
- The hallmark of the sympathetic nervous system is amplification; the hallmark of the parasympathetic nervous system is a limited targeted response.
- Inhaled and intravenous anesthetics can alter hemodynamics by influencing autonomic function.
- β-Adrenergic blockade has emerged as important prophylaxis for ischemia and as therapy for hypertension, myocardial infarction, and congestive heart failure.
- The sympathetic nervous system demonstrates acute and chronic adaptation to stress presynaptically and postsynaptically (e.g., biosynthesis, receptor regulation).
- Presynaptic α receptors play an important role in regulating sympathetic release.
- Many therapies for the treatment of hypertension are based on direct or indirect effects on sympathetic function.
- The vagus nerve is the superhighway of parasympathetic function; it accommodates 75% of parasympathetic traffic.
- Aging and many disease states (e.g., diabetes, spinal cord injury) are accompanied by important changes in autonomic function.

The autonomic nervous system (ANS) controls involuntary activities of the body outside consciousness. It is at once the most primitive and among the most essential of control systems—primitive in that its characteristics are largely preserved across all mammalian species and essential in that it oversees responses to immediate life-threatening challenges and the body's vital maintenance needs (including cardiovascular, gastrointestinal, and thermal homeostasis). The ANS is divided into two subsystems, the sympathetic nervous system and the parasympathetic nervous system. A third subsystem, the enteric nervous system, has been added to the original characterization of the ANS. Activation of the sympathetic nervous system elicits what is traditionally called the fight-or-flight response, typically including redistribution of blood flow from the viscera to skeletal muscle, increased cardiac function, sweating, and pupillary dilation. The parasympathetic system governs activities of the body more closely associated with maintenance needs, such as digestive and genitourinary function. A major goal of administration of anesthetics is maintaining optimum homeostasis in patients despite powerful challenges to the contrary. Safe administration of anesthetic care to patients requires knowledge of ANS pharmacology to achieve desirable interactions of anesthetics with the involuntary control system and to avoid responses or interactions that produce deleterious effects. Furthermore, disease states may impair ANS function and thereby alter the expected responses to surgery and anesthesia. In addition, the human stress response may be harmful. Modification or ablation of the stress response may actually improve perioperative outcome.

HISTORY AND DEFINITIONS

Initially, nerves were thought to be connected in a giant syncytium. Claude Bernard, a student of Magendie, postulated the theory of transmission by synapses through the release of chemical mediators. Later, Sherrington initiated a systematic study of reflexes and described some characteristics of reflex function. A chemist, J.J. Abel, first synthesized epinephrine in 1899, and his student Langley demonstrated that it caused effects similar to those produced by stimulating postganglionic sympathetic neurons. Furthermore, Langley found that when the nerve was cut and epinephrine was injected, a more profound effect was produced, thus demonstrating denervation supersensitivity. From these observations, the concept of chemical transmission in the ANS developed. Sir Henry Dale isolated choline and subsequently studied acetylcholine in animals, in which he demonstrated that acetylcholine causes vasodilation and hypotension.

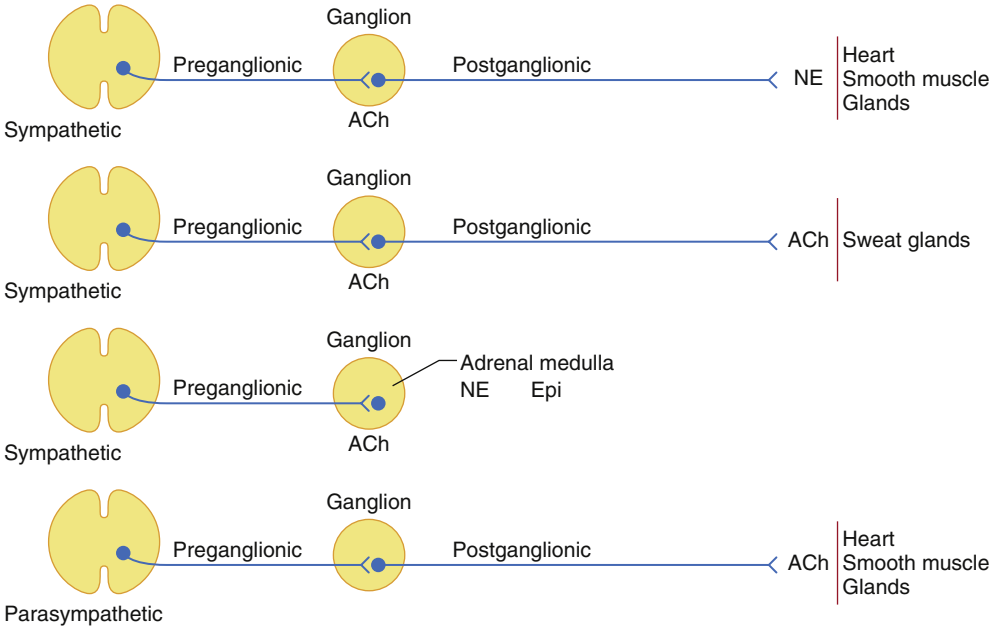

Figure 16-1. Autonomic nervous system neurotransmission. *ACh,* Acetylcholine; *Epi,* epinephrine; *NE,* norepinephrine.

Nerves that operate by acetylcholine are called *cholinergic*, whereas those using norepinephrine are called *adrenergic*. In addition to classifying nerves, the term cholinergic refers to other structures or functions that relate in some way to acetylcholine. For instance, cholinergic receptors (i.e., cholinoceptors) are proteins in cell membranes that interact with acetylcholine and cause the cell to respond in a characteristic way (e.g., muscles contract, glands secrete). Cholinergic agonists are drugs that act like acetylcholine on cholinoceptors to cause the cell to react in its characteristic way. They are sometimes referred to as cholinomimetic drugs. Cholinergic antagonists are drugs that react with cholinoceptors to block access by acetylcholine and thereby prevent its action. These drugs may also be referred to as cholinolytic, cholinergic-blocking, or anticholinergic drugs.

Because muscarine, a chemical isolated from a mushroom, causes effects similar to those produced by activation of the parasympathetic nervous system, it was thought to be the endogenous parasympathetic transmitter. Thus, drugs that mimic the effects of muscarine on parasympathetically innervated structures, including the heart, smooth muscles, and glands, have been called *muscarinic* drugs.

In the early 1900s, nicotine was found to interact with ganglionic and skeletal muscle synapses and on nerve membranes and sensory endings. Accordingly, drugs that act on these parts of the cholinergic system are called *nicotinic* drugs. Nicotinic drugs that are more specific in their action have been discovered and are referred to by the name of the system that they affect, such as ganglionic drugs, neuromuscular drugs, and drugs affecting nicotinic transmission with the central nervous system (CNS). For the purposes of this chapter, cholinergic nerves include the following (Fig. 16-1):

1. All the motor nerves that innervate skeletal muscle
2. All postganglionic parasympathetic neurons
3. All preganglionic parasympathetic and sympathetic neurons
4. Some postganglionic sympathetic neurons, such as those that innervate the sweat glands and certain blood vessels
5. Preganglionic sympathetic neurons that arise from the greater splanchnic nerve and innervate the adrenal medulla
6. Central cholinergic neurons

Drugs mimicking the action of norepinephrine are referred to as *sympathomimetic*, whereas drugs inhibiting the effects of norepinephrine are called *sympatholytic*. Adrenergic nerves release norepinephrine at the neuroeffector junction, whereas epinephrine and norepinephrine are released by the adrenal medulla.

Adrenergic receptors have been identified and subdivided into α and β receptors and further subdivided into α_1, α_2, β_1, β_2, and other types. α_2-Adrenergic receptors are primarily located on the presynaptic membrane and modulate release of norepinephrine, whereas postsynaptic α_1-adrenergic receptors mediate smooth muscle vasoconstriction (Fig. 16-2). β_1-Adrenergic receptors are found primarily on cardiac tissue, and β_2-adrenergic receptors mediate smooth muscle relaxation in some organs. Adrenergic neurons include the following (see Fig. 16-1):

1. Postganglionic sympathetic neurons
2. Some interneurons
3. Certain central neurons

FUNCTIONAL ANATOMY

Each branch of the ANS exhibits a different anatomic motif that is recapitulated on a cellular and molecular level. The underlying theme of the sympathetic nervous system is an amplification response, whereas that of the parasympathetic nervous system is a discrete and narrowly targeted response. The enteric nervous system is arranged nontopographically and relies on the mechanism of chemical coding to differentiate among nerves serving different functions.

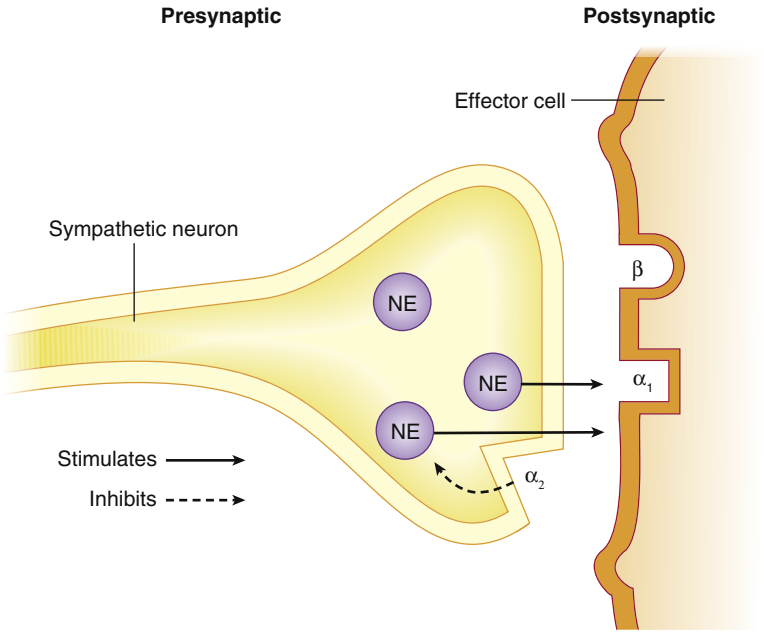

Figure 16-2. Preganglionic and postganglionic α receptors of the sympathetic nervous system. α_1 Receptors and β receptors are located postsynaptically on the membrane of the effector cell, whereas α_2 receptors are located presynaptically on the cell membrane of the sympathetic nerve innervating the effector cell. *NE,* Norepinephrine.

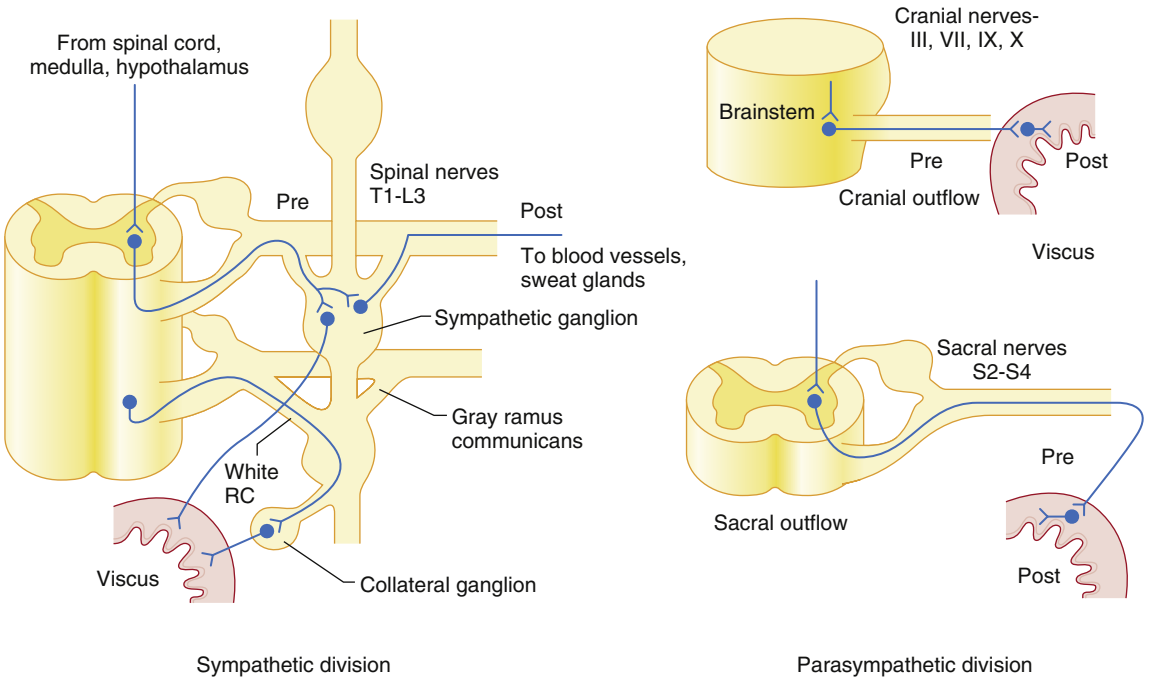

Figure 16-3. Autonomic nervous system. *Pre,* Preganglionic neuron; *Post,* postganglionic neuron; *RC,* ramus communicans. *(From Ganong W: The autonomic nervous system. In Ganong W, editor:* Review of medical physiology, *ed 15. Norwalk, Conn, 1991, Appleton & Lange, p 210.)*

SYMPATHETIC NERVOUS SYSTEM

The sympathetic nervous system originates from the spinal cord in the thoracolumbar region, from the first thoracic through the second or third lumbar segment. The preganglionic sympathetic neurons have cell bodies within the horns of the spinal gray matter (i.e., the intermediolateral columns). Nerve fibers from these cell bodies extend to three types of ganglia grouped as paired sympathetic chains, various unpaired distal plexuses, or terminal or collateral ganglia near the target organ.

The 22 paired ganglia lie along either side of the vertebral column. Nerve trunks connect these ganglia to each other, and gray rami communicantes connect the ganglia to the spinal nerves. The preganglionic fibers leave the spinal cord in the anterior nerve roots, join the spinal nerve trunks, and enter the ganglia at their respective level through the white (myelinated) ramus. Leaving the ganglion, postsynaptic fibers reenter the spinal nerve through the gray (unmyelinated) ramus and then innervate the pilomotor and sudomotor (sweat gland) effectors and blood vessels of the skeletal muscle and skin (Fig. 16-3). Sympathetic postganglionic fibers innervate the trunk and limbs through the spinal nerves.

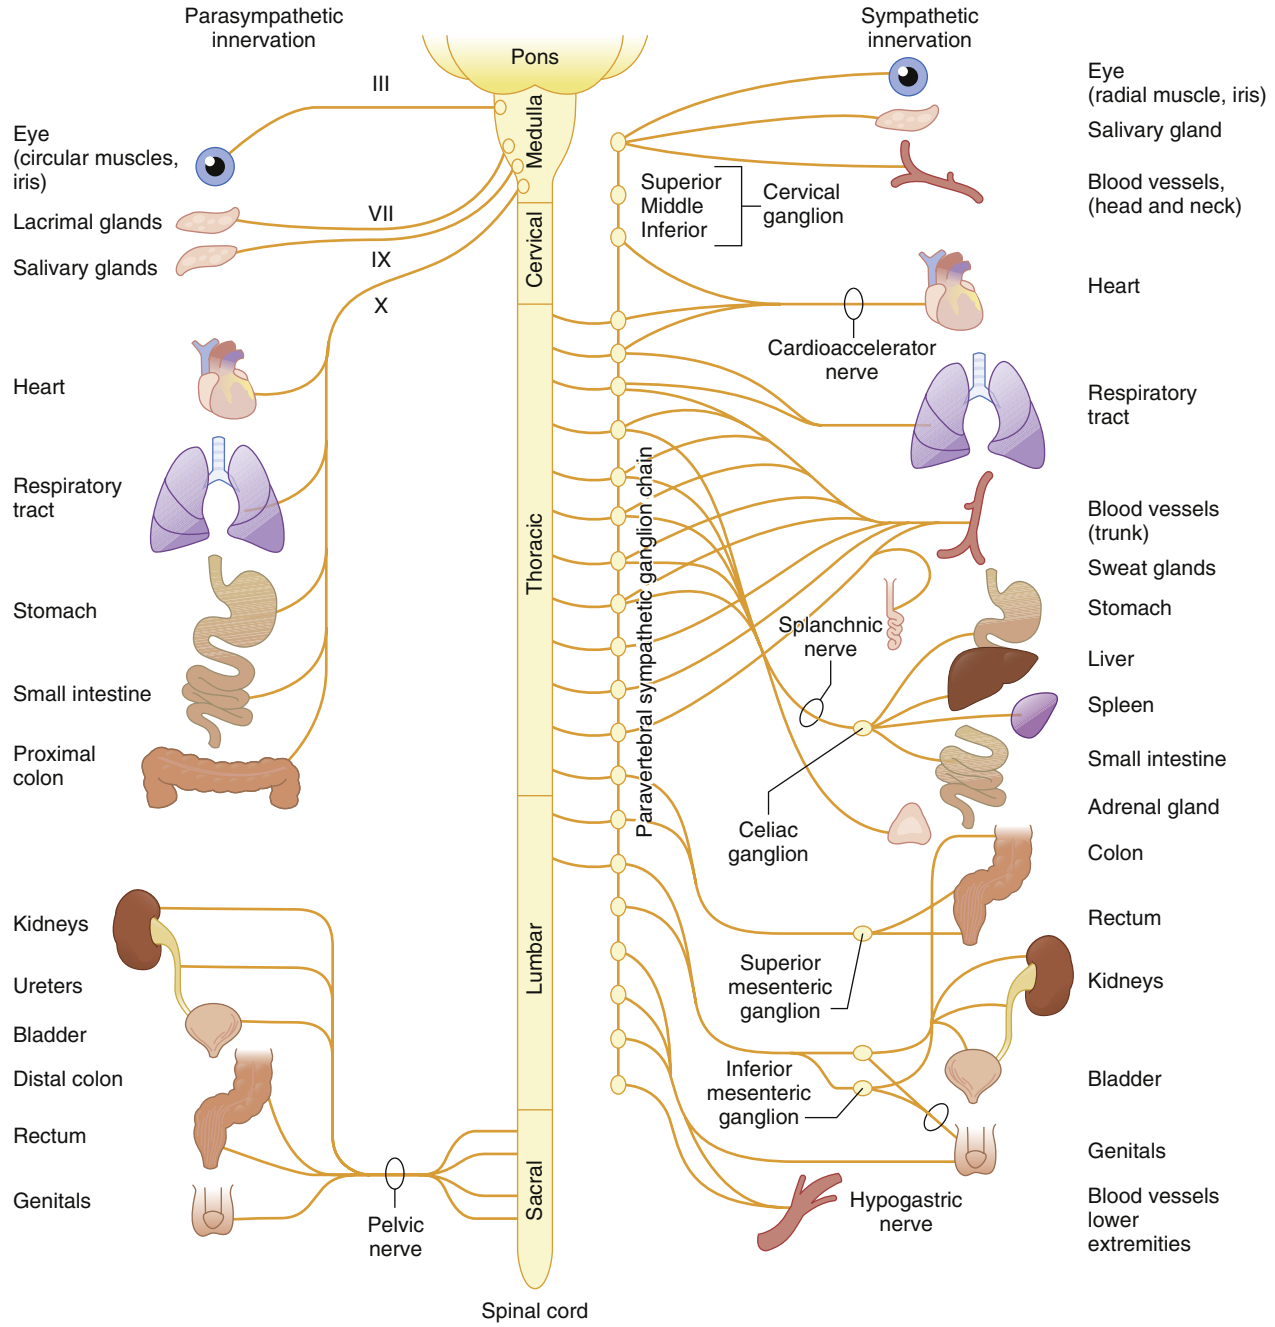

Figure 16-4. Schema of the autonomic nervous system depicting the functional innervation of peripheral effector organs and the anatomic origin of peripheral autonomic nerves from the spinal cord. The Roman numerals on nerves originating in the tectal region of the brainstem refer to the cranial nerves that provide parasympathetic outflow to the effector organs of the head, neck, and trunk. *(From Bylund, DB: Introduction to the autonomic nervous system. In Wecker L, Crespo L, Dunaway G, et al, editors:* Brody's human pharmacology: molecular to clinical, *ed 5. Philadelphia, 2010, Mosby, p 95.)*

The sympathetic distribution to the head and neck that enables and mediates vasomotor, pupillodilator, secretory, and pilomotor function comes from the three ganglia of the cervical sympathetic chain. Preganglionic fibers of these cervical structures originate in the upper thoracic segments. In 80% of people, the stellate ganglion is formed by fusion of the inferior cervical ganglion with the first thoracic ganglion on each side.

The unpaired prevertebral ganglia reside in the abdomen and pelvis anterior to the vertebral column and are the celiac, superior mesenteric, aorticorenal, and inferior mesenteric ganglia. Postganglionic fibers arising from synaptic links of the upper thoracic sympathetic fibers in the paravertebral ganglia form the terminal cardiac, esophageal, and pulmonary plexuses. The postganglionic fibers from the celiac, superior, and inferior mesenteric plexuses innervate the viscera of the abdomen and pelvis (Fig. 16-4).

Ganglia of the third type, the terminal or collateral ganglia, are small, few in number, and near their target

organs (e.g., the adrenal medulla). The adrenal medulla and other chromaffin tissues are homologous to the sympathetic ganglia, and all are derived embryonically from neural crest cells. Unlike sympathetic postganglionic fibers, however, the adrenal medulla releases epinephrine and norepinephrine.

Sympathetic preganglionic fibers are relatively short because sympathetic ganglia are generally close to the CNS, but they are distant from the effector organs; therefore, postganglionic fibers run a long course before innervating effector organs. Preganglionic sympathetic fibers may pass through multiple ganglia before synapsing, and their terminal fibers may contact large numbers of postganglionic neurons. Thus, preganglionic sympathetic fibers not only synapse at the ganglion of the level of their origin in the spinal cord but also can course up and down the paired ganglia. Because sympathetic response is not confined to the segment from which the stimulus originates, an amplified, diffuse discharge is allowed.

PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system arises from cranial nerves III, VII, IX, and X, as well as from sacral segments. Unlike in the sympathetic nervous system, ganglia of the parasympathetic nervous system are in close proximity to or within the innervated organ. This location of ganglia makes the parasympathetic nervous system more targeted and less robust than the sympathetic nervous system.

Preganglionic fibers of the parasympathetic nervous system originate in three areas of the CNS: the midbrain, the medulla oblongata, and the sacral part of the spinal cord. Fibers arising in the Edinger-Westphal nucleus of the oculomotor nerve course in the midbrain to synapse in the ciliary ganglion. This pathway innervates the smooth muscle of the iris and the ciliary muscle. In the medulla oblongata lie parasympathetic components of the facial (lacrimatory nucleus), glossopharyngeal, and vagus (dorsal nucleus) nerves. The facial nerve gives off parasympathetic fibers to the chorda tympani, which subsequently synapses in ganglia of the submaxillary or sublingual glands, and to the greater superficial petrosal nerve, which synapses in the sphenopalatine ganglion. The glossopharyngeal nerve synapses in the otic ganglion. The postganglionic fibers innervate the mucous, salivary, and lacrimal glands; they also carry vasodilator fibers.

The vagus is the most important of the parasympathetic nerves and transmits fully 75% of the traffic of the parasympathetic nervous system. It supplies the heart, tracheobronchial tree, liver, spleen, kidney, and entire gastrointestinal tract except for the distal part of the colon. The preganglionic fibers of the vagus are long, whereas the postganglionic fibers are short. Most vagal fibers do not synapse until they arrive at small ganglia on and about the thoracic and abdominal viscera. Although the parasympathetic nerves may synapse with a 1:1 ratio of nerve to effector cell, the vagal innervation of the Auerbach plexus may connect 1 nerve fiber to 8000 cells.

The second through fourth sacral segments contribute the nervi erigentes, or the pelvic splanchnic nerves. They synapse in terminal ganglia associated with the rectum and genitourinary organs.

ENTERIC NERVOUS SYSTEM

Given the importance of clinical phenomena such as nausea, vomiting, and alterations in bowel function associated with anesthesia, the third branch of the ANS is not well understood. The enteric nervous system is the network of neurons and their supporting cells found within the walls of the gastrointestinal tract, including neurons within the pancreas and gallbladder. It is derived from neuroblasts of the neural crest that migrate to the gastrointestinal tract along the vagus nerve. Notably, the enteric nervous system contains as many nerve cells as the spinal cord.

One major difference between the enteric nervous system and the sympathetic and parasympathetic branches of the ANS is its extraordinary degree of local autonomy. Digestion and peristalsis occur even after spinal cord transection or during spinal anesthesia, although sphincter function may be impaired.

Although functionally discrete, the gut is influenced by sympathetic and parasympathetic activity. The sympathetic preganglionic fibers from T8 through L3 inhibit gut action through the celiac, superior, and inferior mesenteric ganglia; a spinal or epidural anesthetic covering the midthoracic levels removes this inhibition and yields a contracted, small intestine that may afford superior surgical conditions in combination with the profound muscle relaxation of a spinal anesthetic. The sphincters are relaxed, and peristalsis is normally active.

Norepinephrine within the gut is the transmitter of postganglionic sympathetic neurons to the gut. For example, if the contents of the upper intestine become overly acidic or hypertonic, an adrenergically mediated enterogastric reflex reduces the rate of gastric emptying. The adrenergic neurons, which run to the myenteric ganglia of the gastrointestinal tract from the thoracic and lumbar spinal segments, are usually inactive in resting individuals. Reflex pathways within and external to the alimentary tract cause discharge of these neurons. When the viscera are handled during abdominal surgery, reflex firing of the adrenergic nerves inhibits motor activity of the intestine for an extended period. This adrenergic inhibition is thought to be the basis of the common condition known as postoperative ileus. Loss of parasympathetic nervous control usually decreases bowel tone and peristalsis, but over time, the increased activity of the enteric plexus compensates for the loss. Spinal cord lesions may remove sacral parasympathetic input, but cranial parasympathetic signals may still be carried by branches of the vagus nerve down to the end-organ ganglia. Thus, colonic dilation and fecal impaction (which may precipitate hypertension in patients with autonomic dysreflexia) occur more often than small intestinal dysfunction.

Enteric neurons can be sensory and monitor tension in the wall of the intestine or its chemical contents; associative and act like interneurons; or motor and contract intestinal muscles, dilate vessels, or transport water and electrolytes. Motor neurons in the enteric nervous system may be excitatory or inhibitory.

Certain plexuses play important roles in the enteric nervous system. The myenteric plexus, also called the Auerbach plexus, is a network of nerve strands and small ganglia lying in the plane between the external

longitudinal and circular muscle layers of the intestine. The submucous plexus (Meissner plexus) consists of nerve cell bodies, glial cells, and glial and neuronal processes, but it does not contain connective tissue or blood vessels. Within the ganglia, many neuronal processes contain vesicles that store neurotransmitters.

Unlike the sympathetic and parasympathetic nervous systems, in which geographic location can confer selective action, this is anatomically impossible in the gut, and an alternative pattern of chemical coding for function assumes an important organizational role. The combination of amines and peptides and their relative concentrations within the enteric neuron determine its function.

Acetylcholine, the principal excitatory trigger of the nonsphincteric portion of the enteric nervous system, causes muscle contraction. Cholinergic neurons have several roles in the enteric nervous system, including excitation of external muscle, activation of motor neurons augmenting secretion of water and electrolytes, and stimulation of gastric cells. Neural control of gastrointestinal motility is mediated through two types of motor neurons: excitatory and inhibitory. These neurons act in concert on the circular smooth muscle layer in sphincteric and nonsphincteric regions throughout the digestive tract and supply muscles of the biliary tree and the muscularis mucosae. Enteric motor neurons to the circular muscle of the small and large intestine are activated by local reflex pathways contained within the wall of the intestine. Distention evokes polarized reflexes, including contraction proximally and relaxation distally, which in synchrony constitute peristalsis. Nicotinic antagonists abolish enteric reflexes, thus suggesting that the sensory neurons or interneurons in the pathway are cholinergic. In cases of cholinergic overload, such as insecticide poisoning or an excess of neostigmine when reversing a nondepolarizing muscle relaxant (see Chapter 35), the gut (in which cholinesterase is inhibited) has a tendency to become hyperactive.

Many neuroactive compounds other than norepinephrine and acetylcholine participate in the autonomic control of intestinal function. Predominant among these nonadrenergic noncholinergic (NANC) neurotransmitters appears to be nitric oxide (NO), a primary intrinsic inhibitor, but other NANC neurotransmitters such as substance P, a variety of opiate peptides, vasoactive intestinal polypeptide (VIP), and a growing population of peptide hormones are also present (Table 16-1) (see Chapter 104).

TABLE 16-1 NEUROPEPTIDES AND THEIR ACTIONS IN THE GASTROINTESTINAL TRACT

Peptide	Action(s)
Bombesin	Multiple stimulatory effects (including gastrin release)
Calcitonin gene–related peptide	Gastric acid secretion, muscle constriction
Cholecystokinin	Unknown
Dynorphin	Opiate effects
Endothelin-1	Vasoconstriction
Galanin	Muscle constriction
Leu-enkephalin	Opiate effects
Met-enkephalin	Opiate effects
Neuromedin U	Muscle constriction, vasoconstriction
Neuropeptide Y	Vasoconstriction
Pituitary adenylate cyclase	Adenylate cyclase activation
Peptide histidine methionine	Muscle relaxation, secretion
Somatostatin	Multiple inhibitory effects (including gastrin inhibition)
Substance P	Vasodilation, muscle constriction
Vasoactive intestinal polypeptide	Vasodilation, muscle relaxation, secretion

FUNCTION

ORGANIZATION AND INTEGRATION

The sympathetic system, in response to internal or external challenges, acts to increase the heart rate, arterial pressure, and cardiac output; dilate the bronchial tree; and shunt blood away from the intestines and other viscera to voluntary muscles. Parasympathetic nervous input acts primarily to conserve energy and maintain organ function and to support vegetative processes.

Most organs of the body exhibit dual innervation, with input from the sympathetic and parasympathetic systems frequently mediating opposing effects (Table 16-2).[1] Stimulation of one system may have an excitatory effect on the end organ, whereas stimulation of the other system may have an inhibitory effect. For example, sympathetic stimulation acts on the heart to increase the rate and vigor of contraction and enhance conduction through the atrioventricular (AV) node, whereas parasympathetic stimulation acts to decrease the heart rate, atrial contractility, and conduction through the AV node. One of the two systems normally dominates a particular organ function, thus providing its "resting tone." In a few organs, the sympathetic system alone provides innervation; most blood vessels, the spleen, and piloerector muscles are examples.

To predict the effects of drugs, the interaction of the sympathetic and parasympathetic system in different organs must be understood. Blockade of sympathetic function unmasks preexisting parasympathetic activity, and the converse relationship is also true. For example, administration of atropine blocks the resting muscarinic tone of the parasympathetically dominated heart, and the unopposed sympathetic tone then causes tachycardia. Clinically, cardiac autonomic denervation occurs with cardiac transplantation; it may also occur with neuraxial anesthesia, diabetes, and myocardial infarction (MI); and it can be assessed by changes in the time interval between successive heartbeats (i.e., beat-to-beat or heart rate variability) as a measure of sympathovagal balance.[2]

ADRENERGIC FUNCTION

Overview of the Effects of Sympathetic Mediators

Adrenergic neurons influence and adjust body functions, and their effects on circulation and respiration are among the most important (Table 16-3).

The endogenous catecholamines norepinephrine and epinephrine possess α- and β-receptor agonist activity. Norepinephrine has minimal β_2-receptor activity, whereas epinephrine stimulates β_1 and β_2 receptors (Table 16-4). α-Receptor–mediated activity is responsible for most of the sympathetically induced smooth muscle contraction throughout the body, including the ciliary muscle of the eye and vascular, bronchial, and ureteral smooth muscle. The gastrointestinal and genitourinary sphincter mechanisms are stimulated by α-adrenergic receptors. α-Receptor agonism also mediates sympathetic nervous system control of pancreatic insulin secretion, with stimulation of α_2 receptors leading to decreased release of insulin from pancreatic

TABLE 16-2 RESPONSES ELICITED IN EFFECTOR ORGANS BY STIMULATION OF SYMPATHETIC AND PARASYMPATHETIC NERVES

Effector Organ	Adrenergic Response	Receptor Involved	Cholinergic Response	Receptor Involved	Dominant Response (A or C)

TABLE 16-3 EFFECTS OF ACTIVATION OF THE SYMPATHETIC NERVOUS SYSTEM

Site of Action	Stimulation	Inhibition
Heart	Rate, conduction, contractility	
Blood vessels	Vasoconstriction (skin, gut, liver, heart, kidney)	Vasodilation (skeletal muscle, heart, brain)
Respiration	Respiratory center (increased drive to breath) Bronchodilation	
Gastrointestinal tract	Sphincters (increased tone)	Smooth muscle peristalsis
Genitourinary tract	Sphincters (increased tone)	Ureteral and uterine muscle contraction
Metabolic and endocrine effects	Glycogenolysis (muscle, liver) Gluconeogenesis Insulin release Renin release ADH release	Insulin release (α stimulation or β_1 antagonism) Lipolysis

ADH, Antidiuretic hormone or arginine vasopressin.

β cells. In the peripheral vasculature, α_1 and α_2 receptors modulate vascular tone in response to humorally borne neurotransmitters and exogenously administered drugs.

β-Receptor agonism is primarily responsible for sympathetic stimulation of the heart, relaxation of vascular and bronchial smooth muscle, stimulation of renin secretion by the kidney, and several metabolic consequences, including lipolysis and glycogenolysis. The β_1 receptor is thought to primarily be involved in cardiac effects[3] and release of fatty acids and renin, whereas β_2 receptors are primarily responsible for smooth muscle relaxation and hyperglycemia. In specialized circumstances, however, β_2 receptors may also mediate cardiac activity. Although acute changes in arterial pressure and heart rate can be caused by norepinephrine or epinephrine, chronic hypertension does not appear to be related to circulating levels of these hormones.[4] Notably, 85% of resting arterial pressure is determined by the level of renin activity (Fig. 16-5**)**. An additional important effect of epinephrine is to increase gap junctions in bone and thereby cause an increase in circulating blood elements.[5]

Psychological and physical stimuli may evoke different sympathetic compensatory responses. Public speaking activates the adrenal gland with a disproportionate rise in serum epinephrine, whereas physical exercise elicits primarily a marked rise in serum norepinephrine.[6] Thus, the stress response should not be thought of as a uniform response; it can vary in mechanism, intensity, and manifestations.

TABLE 16-4 ADRENERGIC RECEPTOR DIFFERENTIATION

Receptor	Stimulation	Inhibition

(1), Mediated by β_1 receptors; *(2),* mediated by β_2 receptors; *(?),* controversial.

Blood Glucose

Sympathetic nervous stimulation of β receptors increases glycogenolysis in liver and muscle and liberates free fatty acids from adipose tissue, thereby ultimately increasing blood glucose levels. In neonates, epinephrine plays an additional role in the exothermic breakdown of brown fat to maintain body temperature (i.e., nonshivering thermogenesis).

Also present in the pancreas are α_2 and β_2 receptors. α_2-Receptor activation suppresses insulin secretion by pancreatic islet cells; blockade of these receptors may increase release of insulin and thus could be associated with significant lowering of blood glucose levels. β_2-Receptor stimulation increases glucagon and insulin secretion and decreases peripheral sensitivity to insulin.[7]

Potassium Shift

Plasma epinephrine also takes part in regulation of the serum potassium concentration. β-Adrenergic activity can initiate transient hyperkalemia as potassium shifts out of hepatic cells with the glucose efflux produced by β_2-adrenergic stimulation. This effect is followed by a more prolonged hypokalemia as β_2-adrenergic stimulation drives potassium into red blood cells and muscle cells. Stimulation of the β_2 receptors of red blood cells by exogenously administered or endogenously released epinephrine activates adenylate cyclase and sodium-potassium adenosine triphosphatase (ATPase) and drives potassium into cells. Serum potassium concentrations are then reduced and may contribute to the cardiac arrhythmias accompanying MI and other stresses. Selective β_2-adrenergic blockade has the theoretic advantage of inhibiting this potassium shift. However, selective and nonselective β-blockers are equivalent in protecting the postinfarcted heart against arrhythmias.[8-12]

CHOLINERGIC FUNCTION

Overview of the Effects of Acetylcholine

In contrast to the diffuse discharge of the sympathetic nervous system that constitutes the fight-or-flight response, the parasympathetic system is anatomically and functionally more localized in its effects. Parasympathetic activation conserves energy and maintains organ function. A massive parasympathetic response would prostrate the organism and leave it helplessly salivating, weeping, wheezing, vomiting, urinating, defecating, and seizing. Although the sympathetic system is needed for the emergency response to stressful situations, it is not necessary for day-to-day survival; the parasympathetic system is, however, essential for maintenance of life.

Release of acetylcholine is the hallmark of parasympathetic activation. The actions of acetylcholine are almost diametrically opposed to those of norepinephrine and epinephrine. In general, the muscarinic effects of acetylcholine are qualitatively the same as the effects of vagal stimulation.

Acetylcholine decreases the heart rate, the velocity of conduction in the sinoatrial and AV nodes, and atrial contractility (although this decrease is not as marked as the increase in contractility produced by sympathetic stimulation). In the sinoatrial node, acetylcholine causes membrane hyperpolarization, which delays attainment of the threshold potential and the ability to generate another action potential, thereby slowing the heart rate. In the AV node, acetylcholine decreases conduction velocity and increases the effective refractory period. This decrease in AV nodal conduction accounts for the complete heart block seen when large amounts of cholinergic agonists are given. In the ventricle, acetylcholine decreases automaticity in the Purkinje system and thus increases the fibrillation threshold (see also Chapters 20 and 47). Cardiac presynaptic and postsynaptic muscarinic receptors are involved in these effects. Acetylcholine inhibits adrenergic stimulation of the heart presynaptically by inhibiting the release of norepinephrine from sympathetic nerve endings and postsynaptically by opposing the effects of catecholamines on the myocardium.

Parasympathetic activation has many effects outside the cardiovascular system. Cholinergic stimulation causes smooth muscle constriction, including that of the bronchial walls. In the gastrointestinal and genitourinary tracts, smooth muscle in the walls constricts, but the sphincter muscles relax, which results in incontinence. Topically administered acetylcholine constricts the smooth muscle of the iris and causes miosis.

The signs and symptoms of cholinergic overload reflect all these effects, as well as nausea and vomiting, intestinal cramps, belching, urination, and urgent defecation. All glands innervated by the parasympathetic nervous system are stimulated to produce secretions, including the lacrimal, tracheobronchial, salivary, digestive, and exocrine glands.

Local Control of Vascular Tone

In addition to the pharmacologic effects of acetylcholine that are mediated by the parasympathetic nervous system, bloodborne acetylcholine has a significant effect on blood vessels in that it dilates virtually all vessels in vivo. Endothelial cells respond to acetylcholine stimulation by producing one or more endothelium-derived relaxing factors (EDRFs).[13] It now appears that endothelial cells have receptors for numerous agonists, including serotonin, adenosine, histamine, and catecholamines (Fig. 16-6).

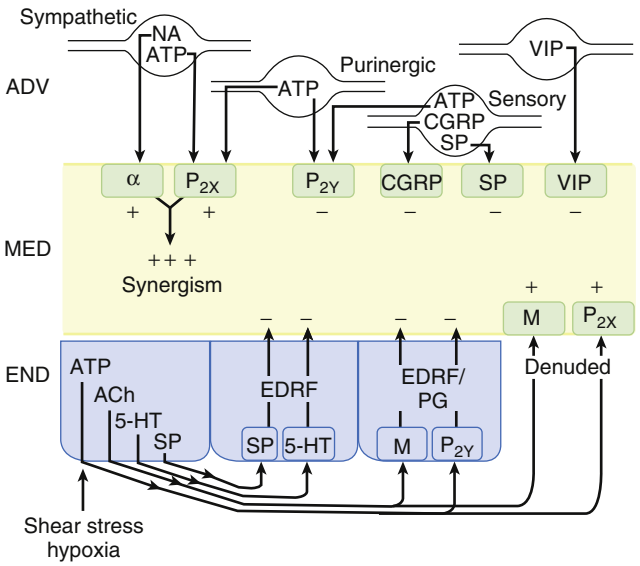

Figure 16-6. Schematic representation of potential modes of regulation of vascular tone by endothelial cell–related mechanisms. Norepinephrine (NA), adenosine triphosphate (ATP), calcitonin gene–related peptide (CGRP), substance P (SP), and vasoactive intestinal polypeptide (VIP) can be released from nerves in the adventitia (ADV) to act on their respective receptors in the media (MED) and cause vasoconstriction or vasodilation. ATP, acetylcholine (ACh), 5-hydroxytryptamine (5-HT), and SP released from endothelial cells (END) by shear stress or hypoxia act on their receptors on endothelial cells to cause release of endothelium-derived relaxing factors (EDRF) or prostaglandins (PG), which act on smooth muscle to cause relaxation. In areas denuded of endothelial cells, opposite effects may be produced by receptors on smooth muscle. *α,* Norepinephrine receptor; *M,* muscarinic receptor; P_{2X}, P2X purinoceptor; P_{2Y}, P2Y purinoceptor. *(From Lincoln J, Burnstock G: Neural-endothelial interactions in control of local blood flow. In Warren J, editor:* The endothelium: an introduction to current research. *New York, 1990, Wiley-Liss, p 21.)*

The radical NO was the first identified EDRF (see Chapter 104 for details). When the endothelium is damaged, as in atherosclerosis, production of EDRF diminishes and constriction increases. This change explains why patients with damaged or diseased vessels react differently.

An understanding of the biology of NO is fundamental to an appreciation of many vital body functions (see Chapter 104).[14] Endothelial cells play a role in control of the circulation in addition to the production of NO. Endothelial cells metabolize many vasoactive amines, convert angiotensin I to angiotensin II, and secrete prostacyclin and the vasoconstrictive peptide endothelin-1 (ET-1). NO, ET-1, and prostacyclin are local hormones released by endothelial cells to influence their immediate microenvironment. Prostacyclin and NO relax vascular smooth muscle, whereas in the lumen, they act separately or in concert to prevent platelets from clumping onto the endothelium.

NO, prostacyclin, and ET-1 appear to be operative in local control of the circulation. The prostacyclin system may be a redundant mechanism that reinforces the NO system in the presence of endothelial damage. Acting together, these two dilators are also a strong defense mechanism against intravascular thrombosis. ET-1 can be produced locally in response to trauma, such as wounds to the vessel wall, and it perhaps decreases blood loss. The long-term functions of these local hormones are of considerable interest in the pathophysiology of many disease states, including septic shock, pulmonary hypertension, and renal failure.[15,16] For more information on NO biology, see Chapter 104.

PHARMACOLOGY

ADRENERGIC PHARMACOLOGY

Synthesis of Norepinephrine

Norepinephrine is synthesized from tyrosine, which is actively transported into the varicosity of the postganglionic sympathetic nerve ending (Fig. 16-7). Tyrosine is synthesized from phenylalanine. Precursors are taken up in greater amounts in shock and may have beneficial effects on the effort of the sympathetic nervous system to maintain perfusion pressure.

A series of steps results in conversion of tyrosine to norepinephrine and epinephrine (in the adrenal medulla). The first of these steps involves the rate-limiting

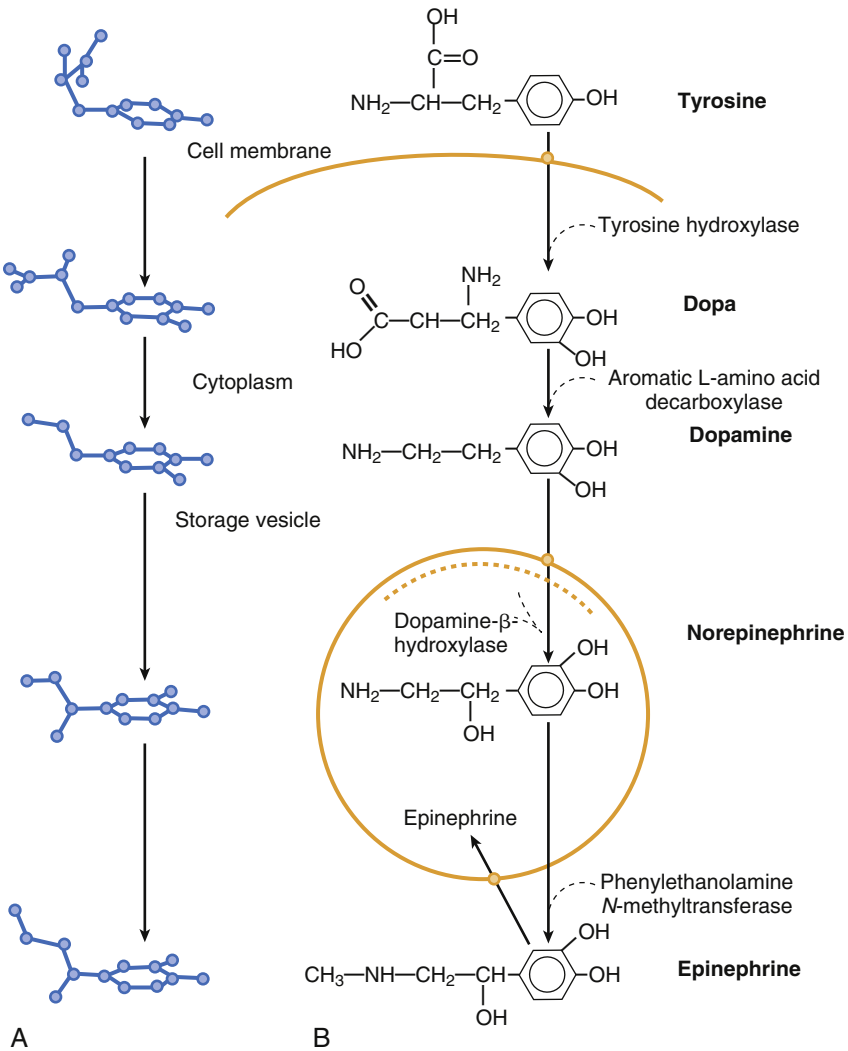

Figure 16-7. Biosynthesis of norepinephrine and epinephrine in sympathetic nerve terminal (and the adrenal medulla). **A,** Perspective view of molecules. **B,** Enzymatic processes. *(From Tollenaeré JP:* Atlas of the three-dimensional structure of drugs. *Amsterdam, 1979, Elsevier North-Holland, as modified by Vanhoutte PM: Adrenergic neuroeffector interaction in the blood vessel wall,* Fed Proc *37:181, 1978.)*

cytoplasmic enzyme tyrosine hydroxylase (TH). High levels of norepinephrine inhibit TH, and low levels stimulate the enzyme. During stimulation of the sympathetic nervous system, an increased supply of tyrosine also increases the synthesis of norepinephrine. TH activity is modified by phosphorylation. TH depends on a pteridine cofactor and the presence of molecular oxygen. When the quantity of molecular oxygen is reduced, synthesis of norepinephrine may be decreased significantly, a condition that could account for changes in wakefulness. Whereas acute control of TH occurs by altering enzyme activity, chronic stress can elevate TH levels by stimulating the synthesis of new enzyme. Under the influence of TH, tyrosine is converted to dihydroxyphenylalanine (DOPA), which is decarboxylated to dopamine by an aromatic amino acid decarboxylase (DOPA decarboxylase), a relatively promiscuous enzyme in its substrate specificity.

Dopamine acts as a neurotransmitter in some cells, but most of the dopamine produced is β-hydroxylated within the vesicles to norepinephrine by the enzyme dopamine β-hydroxylase (DβH). In the adrenal medulla and to a limited extent in discrete regions of the brain, another enzyme, phenylethanolamine *N*-methyltransferase (PNMT), methylates approximately 85% of the norepinephrine to epinephrine. Glucocorticoids from the adrenal cortex pass through the adrenal medulla and can activate the system, and stress-induced steroid release can increase the production of epinephrine. This local circulation amplifies the effects of glucocorticoid release.[17]

Storage of Norepinephrine

Norepinephrine is stored within large, dense-core vesicles where dense cores in these vesicles are filled not only with norepinephrine but also with binding proteins. In addition, the vesicles contain calcium, a variety of peptides, and adenosine 5′-triphosphate (ATP). Depending on the nature and frequency of physiologic stimuli, the ATP can be released selectively for an immediate postsynaptic effect through purinoreceptors, yet norepinephrine is the predominant neurotransmitter at sympathetic nerve endings.

Synaptic vesicles are heterogeneous and exist within functionally defined compartments. An actively recycling population of synaptic vesicles has been defined, together with a reserve population of vesicles that are mobilized only upon extensive stimulation. Functionally, norepinephrine is stored in compartments, and 10% of it is readily releasable. In general, 1% of the stored norepinephrine is released with each depolarization, thus implying a significant functional reserve.

Release of Norepinephrine

The contents of the vesicle enter the synaptic cleft by several different processes. The dominant physiologic mechanism of release is exocytosis, during which the vesicle responds to the entry of calcium by initiating vesicular docking, fusion, release of vesicular contents, and ultimately, endocytosis (the process by which the vesicular membrane and proteins are recaptured) (Fig. 16-8). The entire contents of the vesicle are liberated by stimulation of the nerve. The biology of vesicular release is not a random event, but a highly differentiated process. The finding that exocytosis is so highly conserved from species to species indicates its biologic importance. Angiotensin II, prostacyclin, and histamine potentiate release, whereas acetylcholine and prostaglandin E inhibit release. Further details on neurotransmitter release are discussed in Chapter 28.

Although chromaffin cells in the adrenal medulla synthesize epinephrine and norepinephrine, the two compounds are stored in and secreted from distinct

Figure 16-8. chromaffin cell subtypes. Pharmacologic differences between cells containing norepinephrine and those containing epinephrine have been described, and data suggest possible preferential release from one or another form of chromaffin cell contingent on the nature of the stimulus. Nicotinic agonists or depolarizing agents cause the preferential release of norepinephrine, whereas histamine elicits predominantly epinephrine release.[18-20] Protein kinase C plays an important role in regulating the secretion of catecholamines from norepinephrine-containing chromaffin cells.[21]

Inactivation

Most of the norepinephrine released is rapidly removed from the synaptic cleft by an amine mechanism (i.e., uptake-1 mechanism) or by nonneuronal tissue (i.e., uptake-2 mechanism). The uptake-1 mechanism represents the first and most important step in the inactivation of released norepinephrine. Most of the norepinephrine released is transported into storage vesicles for reuse. This uptake of neurotransmitter into synaptic vesicles is driven by an electrochemical proton gradient across the synaptic vesicle membrane. The vacuolar proton pump is a large, hetero-oligomeric complex that contains eight to nine different subunits. After reuptake, the small amounts of norepinephrine not taken up into the vesicle are deaminated by cytoplasmic monoamine oxidase (MAO). Several organ-specific forms of this enzyme exist.

Since the isolation and cloning in 1991 of the human norepinephrine transporter, considerable information has accumulated.[22,23] The pharmacologic characteristics of this binding protein identify it as the cocaine binding site, although tricyclic antidepressants (i.e., desipramine and nortriptyline) are also potent antagonists.

Uptake of norepinephrine into the nerve varicosity and its return to the storage vesicle, albeit efficient, are not specific for the neurotransmitter. Some compounds structurally similar to norepinephrine may enter the nerve by the same mechanism and result in depletion of the neurotransmitter. These false transmitters can be of great clinical importance. Moreover, some drugs that block reuptake into the vesicle or into the synaptic ending itself may enhance the response to catecholamines (i.e., more norepinephrine is available to receptors). Such drugs include cocaine and tricyclic antidepressants (Table 16-5).

Activity of the uptake-1 system varies greatly among different tissues. Because of anatomic barriers, peripheral blood vessels exhibit almost no reuptake of norepinephrine; consequently, rapid rates of norepinephrine synthesis are needed in peripheral blood vessels to modulate vascular tone. The highest rate of reuptake is found in the heart. Drugs or disease states that alter biosynthesis or storage (e.g., methyldopa decreases storage) have a more profound effect on blood pressure; those that affect reuptake would be expected to affect cardiac rate and rhythm.

Typically, the lungs remove 25% of the norepinephrine that passes through the pulmonary circulation, whereas epinephrine and dopamine pass through unchanged. Pulmonary uptake of norepinephrine appears to be a sodium-dependent, facilitated transport process in the endothelial cells of precapillary and postcapillary vessels and pulmonary veins. Significant uptake by nerve endings occurs. Primary or secondary pulmonary hypertension diminishes uptake of norepinephrine, presumably because of concomitant thickening of the pulmonary vasculature. Although the functional significance of the endothelial uptake mechanism of the pulmonary vascular wall is unknown, uptake of other powerful vasoactive compounds suggests that the pulmonary endothelium functions to protect the left side of the heart.

Defects in the ANS are common in patients with congestive heart failure (CHF). Acute stress-induced (takotsubo) cardiomyopathy has been linked to abnormal cardiac sympathetic activity.[24] In chronic heart failure, the heart is depleted of catecholamines, and reuptake of norepinephrine is decreased.[25] Sustained sympathoexcitation results in increased neuronal release of norepinephrine.[26] Cardiac norepinephrine spillover rates differ widely, even among patients with end-stage heart failure who are awaiting cardiac transplantation, but some studies suggest that elevated plasma catecholamine levels portend a poorer prognosis than can be anticipated with traditional cardiovascular indices.[27,28] Because augmentation of catecholamine release is markedly impaired in patients with CHF, compensation for further decreases in systemic vascular resistance requires activation of the renin-angiotensin system. Together, these events result in increased adrenergic drive, desensitization of β receptors, and depletion of norepinephrine stores, all of which contribute to insufficient inotropic function.[29,30]

Metabolism

During storage and reuptake, a small amount of norepinephrine escapes uptake into the nerve ending and enters the circulation, where it is metabolized by MAO,

TABLE 16-5 COMPARISON OF DIRECT- AND INDIRECT-ACTING SYMPATHOMIMETICS

	Response of Effector Organ to	
Pretreatment	**Direct Sympathomimetics (e.g., Epinephrine): Acts at the Receptor**	**Indirect Sympathomimetics (e.g., Tyramine): Causes Release of NE After Its Uptake by Uptake-1**
Denervation Loss of uptake-1 sites Receptor up-regulation	Increased	Reduced
Reserpine Blocks vesicular uptake Depletes NE May cause up-regulation	Slightly increased	Reduced
Cocaine Blocks uptake-1 Depletes NE	Increased	Reduced

NE, Norepinephrine.

catechol-*O*-methyltransferase (COMT), or both in the blood, liver, and kidney.

Epinephrine, which is released by the adrenal medulla, is inactivated by the same enzymes. The final metabolic product of inactivation is vanillylmandelic acid (VMA). Because of its rapid clearance, the half-life of norepinephrine (and most biogenic amines) in plasma is short, less than 1 minute. This short half-life necessitates administration of these drugs by infusion. Another consequence of their short half-life is that a more ideal measure of catecholamine production may be metabolic products rather than the catecholamines themselves. For example, screening for a norepinephrine-producing pheochromocytoma is best performed by measuring the level of plasma free metanephrines.[31]

Inhibition of MAO has a large impact on the sympathetic function of a patient. MAO inhibitors (MAOIs) are generally well tolerated, but the stability of the patient belies the fact that amine handling is fundamentally changed. Clinically important, life-threatening drug interactions are discussed later in the section on drugs and the ANS.

Other compounds can be metabolized by catabolic enzymes to produce false transmitters. Although not used therapeutically, tyramine is the prototypical drug studied. Tyramine is present in many foods, particularly aged cheese and wine, and it can be synthesized from tyrosine. Tyramine enters the sympathetic nerve terminal through the uptake-1 mechanism and displaces norepinephrine from the vesicles into the cytoplasm. The released norepinephrine leaks out of the cytoplasm and is responsible for the hypertensive effect of tyramine. However, a secondary effect can occur. In the vesicle, tyramine is converted by DβH to octopamine, which is eventually released as a false transmitter in place of norepinephrine, but without the hypertensive effect because it has only 10% of the potency of norepinephrine.

Adrenergic Receptors

Initially, α-adrenergic receptors were distinguished from β-adrenergic receptors by their greater response to epinephrine and norepinephrine than to isoproterenol. The development of α- and β-antagonists further supported the existence of separate α receptors. Traditionally, adrenergic receptors have been classified as α or β and more recently as α_1, α_2, β_1, or β_2 based on responses to specific drugs. With technologic advances in molecular biology, classification evolved to three major subtypes and nine sub-subtypes (Fig. 16-9).[32] Table 16-6 describes the distribution, response, typical agonists, and antagonists of the α_1, α_2, β_1, and β_2 receptors.

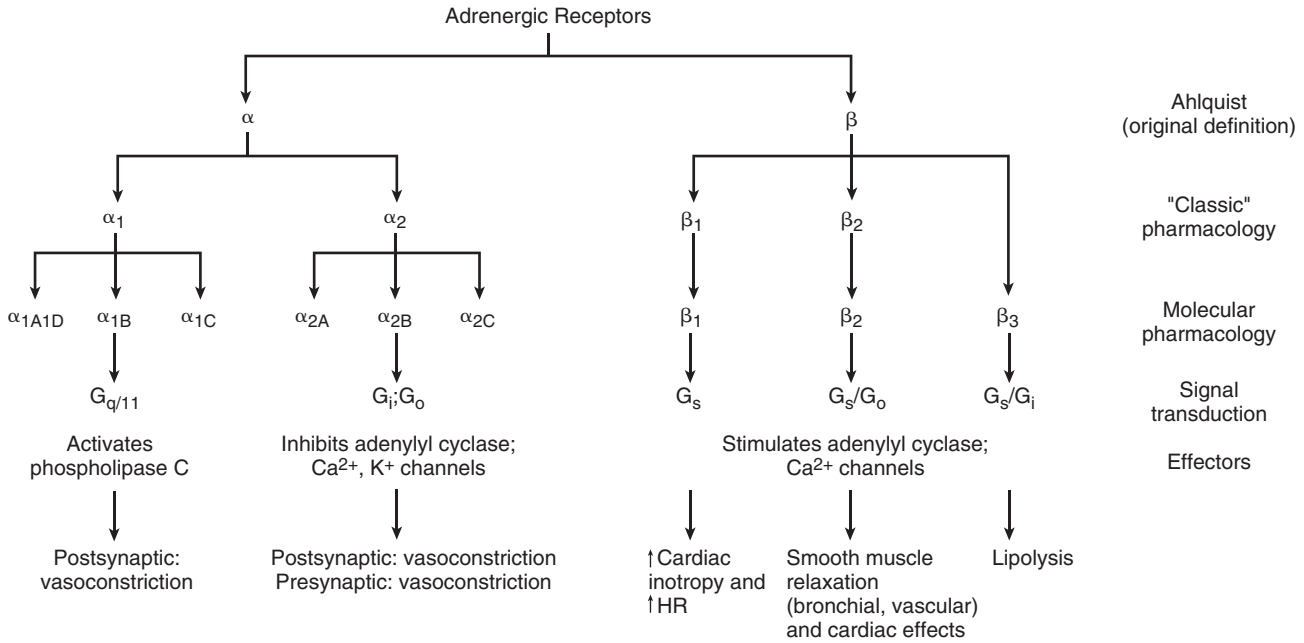

Figure 16-9. Classification of adrenergic receptors. *Ca^{2+}, Calcium; HR,* heart rate; *K^+*, potassium.

TABLE 16-6 **DISTRIBUTION OF α AND β RECEPTORS**

Receptor	Distribution	Response	Agonist	Antagonist

α-Adrenergic Receptors. Functional and binding assays and molecular biologic methods have unequivocally confirmed the classification of α adrenoceptors into subtypes.[33] Within α_1-adrenergic receptors, $\alpha_{1a/d}$, α_{1b}, and α_{1c} receptors have been characterized. Several α_2 isoreceptors (α_{2a}, α_{2b}, and α_{2c}) have also been described. α_2 Receptors are usually expressed presynaptically or even in nonneuronal tissue. α_2 Receptors are found in the peripheral nervous system, in the CNS, and in a variety of organs, including platelets, liver, pancreas, kidney, and eyes, where specific physiologic functions have been identified.[34] The predominant α_2 receptor of the human spinal cord is the α_{2a} subtype.[32,35] Mammalian genomes probably contain two sets of at least three unique genes encoding the α adrenoceptors. Genes encoding α_2 receptors have been localized to chromosomes 2, 4, and 10. There is more than theoretic relevance in the subclassification of receptors,[36] in that mutations that decrease α_{2c} presynaptic function and enhance β_1-receptor linkage cause adrenergic hyperactivity and predispose to CHF.[37]

Amino acid sequence comparisons indicate that α receptors are members of the 7–transmembrane segment gene superfamily, which uses G protein for signal transduction. A core of 175 amino acids constitutes the 7 transmembrane regions and is highly conserved among different family members. The plethora of receptor subtypes remains incompletely explained, although the observation that different signal transduction mechanisms are used suggests finer control and physiologic significance. Considerable variability in α-adrenergic receptor subtypes exists among species.[38]

Receptors can be presynaptic as well as postsynaptic. Presynaptic receptors may act as heteroreceptors or autoreceptors. An *autoreceptor* is a presynaptic receptor that reacts with the neurotransmitter released from its own nerve terminal to provide feedback regulation. A *heteroreceptor* is a presynaptic receptor that responds to substances other than the neurotransmitter released from that specific nerve terminal. This regulatory scheme is present throughout the nervous system but is particularly important in the sympathetic nervous system.[39]

Although several presynaptic receptors have been identified, the α_2 receptor may have the greatest clinical import. Presynaptic α_2 receptors regulate the release of norepinephrine and ATP through a negative-feedback mechanism.[40] Activation of presynaptic α_2 receptors by norepinephrine inhibits subsequent release of norepinephrine in response to nerve stimulation. A similar inhibitory response is produced by attachment of acetylcholine to presynaptic cholinergic receptors within the ANS. In the human brain, ligand studies reveal a high density of α_2 receptors, particularly in the cerebral cortex and medulla.[41] This latter distribution may account for the bradycardic and hypotensive responses to α_2-agonist drugs.

β-Adrenergic Receptors. Like the α receptor, the β receptor is one of the superfamily of proteins that have seven helices passing through the cell membrane. These transmembrane domains are labeled M_1 through M_7; antagonists have specific binding sites, whereas agonists are more diffusely attached to hydrophobic membrane-spanning domains (Fig. 16-10). The extracellular portion of the receptor ends in an amino group. A carboxyl group occupies the intracellular terminal, where phosphorylation occurs. At the cytoplasmic domains, G proteins and kinases, including β-adrenergic receptor kinase, interact. The β receptor has mechanistic and structural similarities with muscarinic but not nicotinic receptors, primarily in the transmembrane sections.

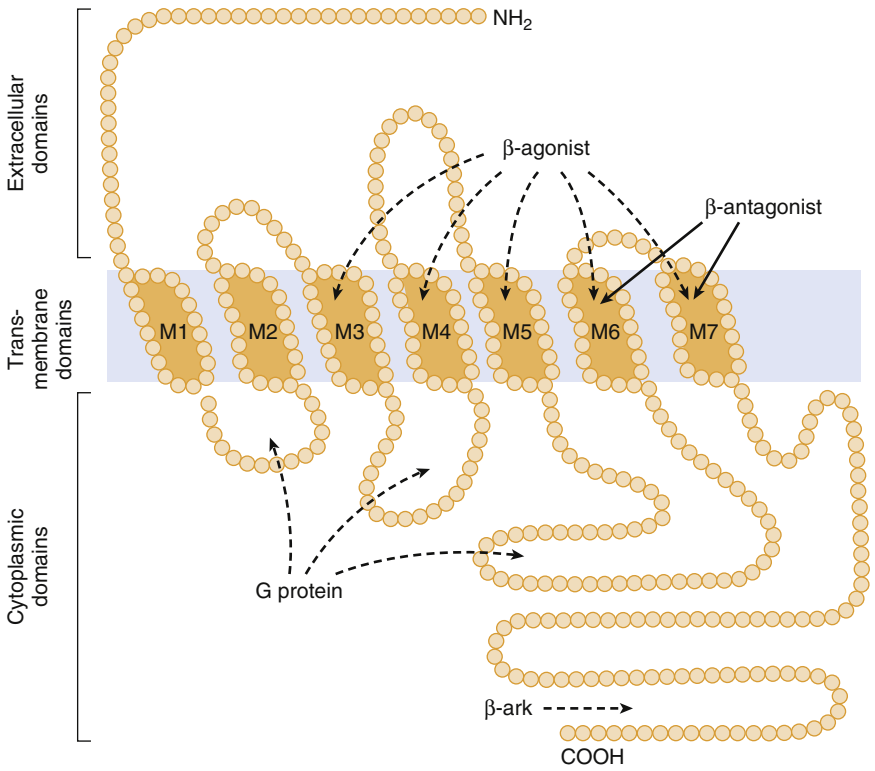

Figure 16-10. Molecular structure of the classic G-protein–coupled β-adrenergic receptor. Notice the three domains. The transmembrane domains act as a ligand-binding pocket. Cytoplasmic domains can interact with G proteins and kinases such as β-adrenergic receptor kinase (β-ark). The latter can phosphorylate and desensitize the receptor. *COOH,* Carboxyl; *NH_2,* amine. *(From Opie L: Receptors and signal transduction. In Opie LH, editor:* Heart physiology: from cell to circulation, *ed 4. Philadelphia, 2004, Lippincott Williams & Wilkins, 2004, p 194.)*

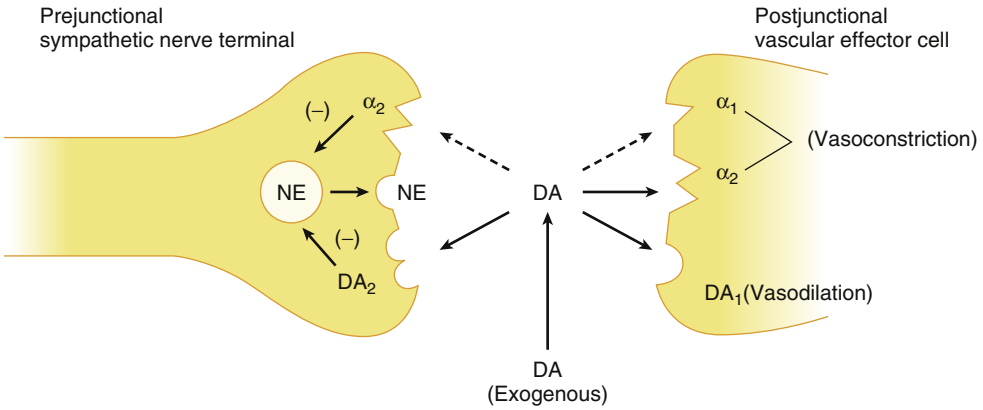

Figure 16-11. Location of dopamine type 1 (DA_1) receptors and α_1 and α_2 adrenoceptors on postganglionic vascular effector cells and DA_2 receptors and α_2 adrenoceptors on the prejunctional sympathetic nerve terminal. When dopamine is administered, activation of DA_1 receptors causes vasodilation, whereas activation of DA_2 receptors causes inhibition (–) of release of norepinephrine (NE) from storage granules. A larger dose of dopamine activates α_1 and α_2 adrenoceptors on the postjunctional effector cells to cause vasoconstriction and α_2 adrenoceptors on the prejunctional sympathetic terminal to inhibit release of NE. NE released from the prejunctional sympathetic terminal also acts on α_1 and α_2 adrenoceptors. *(From Goldberg LI, Rajfer SI: Dopamine receptors: applications in clinical cardiology,* Circulation *72:245, 1985.)*

β Receptors have been further divided into β_1, β_2, and β_3 subtypes, all of which increase cyclic adenosine monophosphate (cAMP) through adenylate cyclase and the mediation of G proteins.[42] Although β_1 receptors were traditionally thought to be isolated to cardiac tissue and β_2 receptors were believed to be restricted to vascular and bronchial smooth muscle, we now know that the β_2-receptor population in human cardiac tissue is substantial and accounts for 15% of β receptors in the ventricles and 30% to 40% in the atria.[43] β_2 Receptors may help compensate for disease by maintaining response to catecholamine stimulation when β_1 receptors are down-regulated during chronic catecholamine stimulation and in CHF.[44] The β_2-receptor population is almost unaffected in end-stage congestive cardiomyopathy.[45] In addition to positive inotropic effects, β_2 receptors in the human atria participate in regulation of the heart rate. Generation of cAMP in the human heart appears to be mediated primarily by β_2 receptors, although this may be an artifact related to the lability of β_1 receptors.[45] Localization of β_3 receptors to fat cells suggests a new therapy for obesity.[46] Polymorphism of this β-receptor subtype is associated with obesity and the potential for the development of diabetes.[47-49] Similarly, point mutations in genes encoding β_2 receptors are correlated with decreased down-regulation of β receptors and nocturnal asthma.[50,51]

Dopamine Receptors

Dopamine exists as an intermediate in the biosynthesis of norepinephrine, and in addition, exogenous dopamine exerts α- or β-adrenergic effects (depending on the dose administered). Goldberg and Rajfer demonstrated physiologically distinct dopamine type 1 (DA_1) and dopamine type 2 (DA_2) receptors,[52] and these remain the most important of the five dopamine receptors cloned (Fig. 16-11). DA_1 receptors are postsynaptic and act on renal, mesenteric, splenic, and coronary vascular smooth muscle to mediate vasodilation through stimulation of adenylate cyclase and increased production of cAMP. The vasodilatory effect tends to be strongest in the renal arteries. It is for this action, particularly the redistribution of blood flow to the kidneys, that dopamine is most frequently used. Additional renal DA_1 receptors located in the tubules modulate natriuresis through the sodium-potassium ATPase pump and the sodium-hydrogen exchanger.[52-55] DA_2 receptors are presynaptic; they may inhibit release of norepinephrine and perhaps acetylcholine. In addition, central DA_2 receptors may mediate nausea and vomiting, a finding that may explain why the antiemetic activity of droperidol is thought to be related to its DA_2 activity.

Guanosine Triphosphate–Binding Regulatory Proteins (G Proteins)

After adrenergic receptor stimulation, the extracellular signal is transformed into an intracellular signal by a process known as signal transduction in which α_1 and β receptors are coupled to G proteins. When activated, G proteins can modulate the synthesis or availability of intracellular second messengers (Fig. 16-12). The activated second messenger diffuses through the cytoplasm and stimulates an enzymatic cascade. The sequence of first messenger → receptor → G protein → effector → second messenger → enzymatic cascade is found in a wide variety of cells; the specific entities that fulfill the separate roles vary from cell to cell.[56] G proteins located on the inner surface of the cell membrane can also directly modify the activity of transmembrane ion channels.

G proteins are heterotrimeric compounds composed of three subunits labeled α, β, and γ. The β and γ subunits form a stable complex, and the α subunit associates with them in a reversible fashion. The β and γ subunits show little variation in their structure. In contrast, 20 different α subunits have been identified. The structure of the attached α subunit defines the function of the G protein. Four classes of α subunits have been defined: α_s, α_i, α_q, and α_{12}. The corresponding G-protein complexes formed when these α subunits bind to the βγ structure are called G_s, G_i, G_q, and G_o.[57]

Each class of adrenergic receptor couples to a different major subfamily of G proteins, which are linked to different effectors. The major subtypes of α_1, α_2, and β receptors are linked to G_q, G_i, and G_s, respectively, which

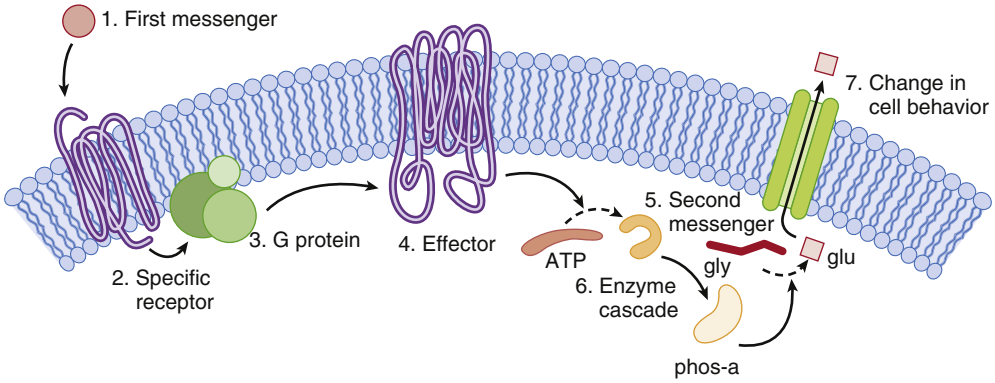

Figure 16-12. Epinephrine-stimulated glycogenolysis in a liver cell demonstrates the role of G proteins in cellular function. The first messenger (epinephrine) binds to its specific receptor and stimulates the G protein (in this case, G_s) to activate the effector adenylyl cyclase. This enzyme converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate, the second messenger, which then triggers a cascade of enzymatic reactions that stimulates the enzyme phosphorylase (phos-a) to convert glycogen (gly) into glucose (glu), which the cell extrudes. *(From Linder ME, Gilman AG: G Proteins,* Sci Am *267:56, 1992.)*

are linked to activation of phospholipase C (α_1), inhibition of adenylyl cyclase (α_2), or stimulation of adenylyl cyclase (β) (see Fig. 16-9). In its resting state, the G protein is bound to guanosine diphosphate (GDP) and is not in contact with the receptor. When the receptor is activated by the first messenger, it stimulates the G protein to release GDP and bind guanosine triphosphate (GTP) to its α subunit, thereby activating itself. The bound GTP signals the G protein to split into two parts consisting of the α-GTP structure and the βγ subunit. The released α subunit binds to the effector, activates it, and then converts its attached GTP to GDP, thereby returning itself to the resting state. The α subunit joins with the βγ unit, and the reconstructed G protein again waits at the inner membrane.

β-Receptor stimulation of G proteins enhances the activity of adenylate cyclase and the formation of cAMP. The briefest encounter of plasma membrane β-adrenergic receptors with epinephrine or norepinephrine results in profound increases (≤400-fold higher than the basal level within minutes) in intracellular levels of cAMP. Increased cAMP synthesis activates protein kinases, which phosphorylate target proteins to elicit various cellular responses that complete the path between receptor and effect. Stimulation of α_2 receptors results in G_i inhibition of adenylate cyclase. The relative abundance of G proteins results in amplification of receptor agonism at the signal transduction step. The number of G-protein molecules greatly exceeds the number of β-adrenergic receptors and adenylate cyclase molecules. The receptor concentration and ultimately adenylate cyclase activity limit the response to catecholamines, and this perhaps explains the efficacy of phosphodiesterase inhibitors.[58,59]

Myocardial cells respond to receptor stimulation differently, depending on the identity of the first messenger. Two opposing effects, inhibition and stimulation of contractility, are both produced by the sequence of receptor → G protein → effector → enzymatic cascade. However, the identity of the chemicals in the sequence differs.[60] Norepinephrine causes myocardial cells to contract with more vigor when the α subunit of the stimulatory protein (G_s) activates adenylate cyclase. The α subunits of this protein cause potassium channels to open and permit efflux of potassium ion. The force of contraction is diminished when acetylcholine acts as a first messenger and stimulates its receptor to activate the inhibitory protein G_i or G_o. Clinically important, second-to-second changes in heart rate can be explained by the simultaneous activation of G_s and G_o. The current caused by G_o is larger than that caused by G_s, and this finding explains the clinical impression that vagal inhibition of heart rate predominates in the presence of sympathetic stimulation, such as may occur in unpremedicated patients.[60]

Up-regulation and Down-regulation

β-Adrenergic receptors are not fixed; they change significantly in dynamic response to the amount of norepinephrine present in the synaptic cleft or in plasma. For β-adrenergic receptors, this response is fast; within 30 minutes of denervation or adrenergic blockade, the number of receptors increases. Such up-regulation may explain why sudden discontinuation of β-adrenergic receptor blocking drugs causes rebound tachycardia and increases the incidence of MI and ischemia. Many chronic phenomena, such as varicose veins[61] or aging, can decrease adrenergic receptor number or responsiveness systemically.

Clinically and at the cellular level, responses to many hormones and neurotransmitters wane rapidly despite continuous exposure to adrenergic agonists.[62] This phenomenon, called desensitization, has been particularly well studied for the stimulation of cAMP levels by plasma membrane β-adrenergic receptors. Mechanisms postulated for desensitization include receptor uncoupling (e.g., phosphorylation), sequestration, and down-regulation. The molecular mechanisms underlying rapid β-adrenergic receptor desensitization do not appear to require internalization of the receptors, but rather an alteration in the functioning of β receptors themselves that uncouples the receptors from the stimulatory G_s protein. Agonist-induced desensitization involves phosphorylation of G-protein–coupled receptors by two classes of serine-threonine kinases. One of these classes initiates receptor-specific or homologous desensitization. The other works through second messenger–dependent kinases and mediates a general cellular hyporesponsiveness called

heterologous desensitization. Ultimately, an inhibitory arrestin protein binds to the phosphorylated receptor and causes desensitization by blocking signal transduction. Because enzymatic phosphorylation occurs only in the activated state, transient β blockade has been used in states of receptor desensitization such as CHF or cardiopulmonary bypass to achieve a "receptor holiday."[63] Regeneration of a functional β-adrenergic receptor is contingent on sequestration of the receptor, with dephosphorylation and presumed recycling. Some evidence indicates that the arrestins contribute to desensitization by uncoupling signal transduction and by contributing to the process of receptor internalization.[64,65] Receptor populations can change rapidly with such sequestration, which does not require protein synthesis.

Down-regulation may be distinguished from these rapid mechanisms in that it occurs after hours of exposure to an agonist (as in chronic stress or CHF), and receptors are destroyed. New receptors must be synthesized before return to a baseline state is possible.

Chronic CHF is one of the most important and best-studied pathophysiologic situations in which tolerance or down-regulation occurs (see Chapter 20). It was initially observed that the density of cardiac β receptors decreases markedly in patients with terminal heart failure in response to the elevated plasma catecholamine levels. This finding explained why administration of exogenous β-agonists was relatively ineffectual in this syndrome. With the demonstration that β_1 and β_2 receptors coexist in human ventricles,[66] Bristow and co-workers, using radioligand techniques, documented that β_1-receptor density decreases without change in the density of β_2 receptors in human ventricles affected by CHF. Consequently, β_2 agonism accounted for 60% of the total inotropic response stimulated by isoproterenol in the failing heart as compared with 40% in a nonfailing heart.[67]

The activity of the thyroid gland influences receptor density; hyperthyroidism increases density, and hypothyroidism decreases density. Clinically, β-receptor blockade is important in the acute treatment of hyperthyroidism. Some evidence indicates that corticosteroids decrease receptor density. Consequently, the reaction of the body to well-characterized sympathetic agonists may be considerably different, depending on the pathologic and environmental circumstances. However, the structural similarity of thyroid hormone and tyrosine suggests that false transmitters may play a role (see Chapters 84 and 85).[68]

CHOLINERGIC PHARMACOLOGY

Acetylcholine Synthesis

Many of our assumptions about cholinergic pharmacology are drawn from our understanding of the prototypical nicotinic cholinergic receptor at the neuromuscular junction. The chemistry of cholinergic synthesis and metabolism is covered in detail in Chapter 18.

Cholinergic Receptors

Traditionally, cholinergic receptors have been organized into two major subdivisions, nicotinic and muscarinic. Muscarinic receptors belong to the G-protein–coupled superfamily and are present mostly in peripheral visceral organs. Nicotinic receptors are ligand-gated ion channels typically found on parasympathetic and sympathetic ganglia (neuronal subtypes) and on the neuromuscular junctions of skeletal muscle (neuronal and muscle subtypes).

Although these two structurally and functionally distinct classes of receptors have significantly different responses to acetylcholine, the chemical itself exhibits no specificity. However, specific antagonists can exploit the difference between muscarinic and nicotinic receptors. As a result, structure-activity relationships have emerged. All cholinergic agonists need a quaternary ammonium group, as well as an atom capable of forming a hydrogen bond through an unshared pair of electrons. The distance between the two sites may determine whether the agonism is nicotinic or muscarinic. With muscarinic agonists, the distance appears to be approximately 4.4Å, whereas for nicotinic agonists, the distance is 5.9Å.

The neuronal and muscle subtypes of nicotinic receptors on ganglia and motor end plates, respectively, differ. Nondepolarizing neuromuscular blocking drugs block neuronal nicotinic acetylcholine receptors present in ganglia, in the carotid body,[69] and at the neuromuscular junction (see Chapter 18),[70] whereas hexamethonium blocks the ganglionic receptors.

Ganglionic nicotinic receptors are likely more sensitive to anesthetics than receptors at the neuromuscular junction.[71]

The nicotinic receptors on ganglia and motor end plates are discussed in detail in Chapter 18. In brief, they are pentameric membrane proteins that form nonselective cation channels. There are two α units (each 40 kDa) and one each of the β, ε, and δ units. These five subunits surround each ion channel through which sodium or calcium enters the cell or potassium exits. Each ion has its own separate channel. For the channel to open, acetylcholine must occupy a receptor site on each of the two α subunits.

In contrast to ligand-gated ion channel nicotinic receptors, muscarinic receptors have greater homology to α- and β-adrenergic receptors than to nicotinic receptors. Like the other members of the family of receptors with seven helices (i.e., α_2, β_1, β_2, serotonin, rhodopsin, and opsin), muscarinic receptors use G proteins for signal transduction. Five muscarinic receptors (i.e., M_1 through M_5) exist, with the primary structural variability residing in a huge cytoplasmic loop between the fifth and sixth membrane-spanning domains. Although molecular studies have described five forms, four of which are defined pharmacologically (i.e., M_1, M_2, M_3, and M_4), selective muscarinic drugs are not available. The M_2 cholinergic postjunctional receptor predominates in visceral organs. M_2 and M_3 receptors have been identified in the airway smooth muscle of many species. In vitro studies reveal that the M_3 receptor mediates the contractile and secretory response. However, the excess of M_2 receptors could explain the relative ineffectiveness of β-adrenergic agonists in reversing cholinergic bronchoconstriction.[72]

The muscarinic receptors have diverse signal transduction mechanisms. The odd-numbered receptors (i.e., M_1, M_3, and M_5) work predominantly through hydrolysis of polyphosphoinositide, whereas the even-numbered receptors work primarily to regulate adenylate cyclase.[73]

When the M_3 muscarinic receptor is activated, G_q activates phospholipase C, which catalyzes the hydrolysis of phosphatidylinositol bisphosphate into diacylglycerol and inositol triphosphate. Receptors in the muscarinic series are coupled to second messenger systems, such as cyclic nucleotides or phosphoinositides. These are coupled to ion channels. In other cases, influx of a cation is the trigger for cellular response. For example, the influx of calcium ions can act as a messenger that reacts with and opens other ion channels. In addition to affecting ion channels, the messenger calcium can stimulate various intracellular proteins to alter cell activity. In cardiac atria, activation of muscarinic receptors leads to the efflux of potassium and hyperpolarization of the cell membrane. This hyperpolarization slows conduction and slows or stops atrial pacemakers. In glands, an influx of calcium or sodium, or both, activates intracellular events and causes the cells to secrete. Similarly, influx of these ions into smooth muscle cells causes them to contract.

Muscarinic receptors are found on central and peripheral neurons; a single neuron may have muscarinic receptors with excitatory as well as inhibitory effects. Prejunctional autoreceptors are not as well studied in the parasympathetic nervous system as in the sympathetic nervous system. Presynaptic muscarinic receptors may inhibit the release of acetylcholine from postganglionic parasympathetic neurons; prejunctional nicotinic receptors may increase its release.

Because of the complex coupling, the response of the muscarinic system is sluggish; no response is seen for seconds to minutes after the application of acetylcholine. Similarly, the effect long outlives the presence of the agonist. Even though the transmitter is destroyed rapidly, the train of events that it initiates causes the cellular response to continue for many minutes. Muscarinic receptors are desensitized through agonist-dependent phosphorylation in a mechanism similar to that described earlier for β-adrenergic receptors.

NONADRENERGIC NONCHOLINERGIC NEUROTRANSMISSION IN THE AUTONOMIC NERVOUS SYSTEM

NANC components such as monoamines, purines, amino acids, and polypeptides are part of the ANS. Other transmitter candidates demonstrated in perivascular nerves by histochemical and immunohistochemical techniques include ATP, adenosine, VIP, substance P, 5-hydroxytryptamine (5-HT), neuropeptide Y (NPY), and calcitonin gene–related peptide (CGRP). Immunocytochemical studies show that more than one transmitter or putative transmitter may be colocalized in the same nerve. The most common combinations of transmitters in perivascular nerves are norepinephrine, ATP, and NPY in sympathetic nerves (Fig. 16-13); acetylcholine and VIP in parasympathetic nerves (Fig. 16-14); and substance P, CGRP, and ATP in sensorimotor nerves. Many of these putative transmitters act through cotransmission, which comprises the synthesis, storage, and release of more than one transmitter by a nerve. Initially, the multiplicity of transmitters released in various combinations appeared random and bewildering, but a pattern is emerging that clarifies the situation. Autonomic nerves exhibit chemical coding—individual neurons serving a specific physiologic function contain distinct combinations of transmitter substances.[74]

The concepts of cotransmission and neuromodulation are accepted mechanisms in autonomic nervous control. To establish that transmitters coexisting in the same nerves act as cotransmitters, each substance must act postjunctionally on its own specific receptor to produce a response.

For many perivascular sympathetic nerves, norepinephrine and ATP act as cotransmitters and are released from the same nerves but act on α_1 adrenoceptors and P_2 purinoceptors, respectively, to produce vasoconstriction (see Fig. 16-13).[75,76] ATP probably mediates contraction

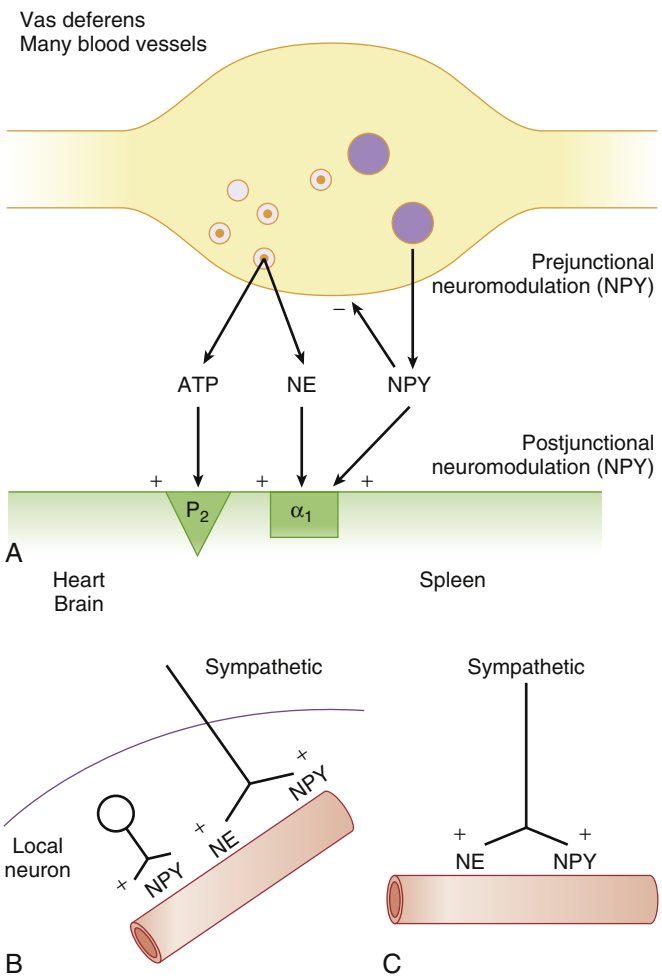

Figure 16-13. Schematic representation of different interactions that occur between neuropeptide Y (NPY) and adenosine triphosphate (ATP) and the norepinephrine (NE) released from single sympathetic nerve varicosities. **A,** Diagram showing what occurs in the vas deferens and many blood vessels, where NE and ATP, probably released from small granular vesicles, act synergistically to contract (+) the smooth muscle through α_1 adrenoceptors and P_2 purinoceptors, respectively. **B** and **C,** Sympathetic neurotransmission in the heart and brain (**B**) and the spleen (**C**). *(From Lincoln J, Burnstock G: Neural-endothelial interactions in control of local blood flow. In Warren J, editor:* The endothelium: an introduction to current research. *New York, 1990, Wiley-Liss, p 21.)*

through P_2 receptors by voltage-dependent calcium channels.[77] The fast component of contraction is mediated by these purinoceptors, whereas norepinephrine sustains contraction of muscle by acting on the α_1 adrenoreceptor through receptor-operated calcium channels. ATP is stored in vesicles along nerve varicosities. It is released into the synaptic cleft by exocytosis and then binds to postsynaptic purinergic receptors. ATP is then degraded to adenosine by membrane-bound ATPases and 5′-nucleotidases. Adenosine is subsequently taken up into the presynaptic neuron, where ATP is resynthesized and incorporated into vesicles for later release.[78]

Purinergic receptors are categorized as P_1 or P_2 receptors. P_1 receptors bind adenosine, whereas P_2 receptors bind ATP. Four subtypes of P_1 receptors have been identified (A_1, A_{2A}, A_{2B}, and A_3). All the P_1 receptors are coupled to membrane-bound G proteins. The two subclasses of P_2 receptors are P2X and P2Y. P2X receptors bind ATP and open ligand-gated ion channels. In contrast, P2Y receptors are coupled to G proteins and their associated secondary messenger systems. Seven P2X subtypes ($P2X_{1\text{-}7}$) and eight P2Y subtypes ($P2Y_{1,2,4,6,11,12,13,14}$) have been identified. Some P2Y receptors are preferentially activated by adenosine diphosphate rather than ATP, and some can be activated by pyrimidine nucleosides (uridine triphosphate), as well as by purinergic agonists.

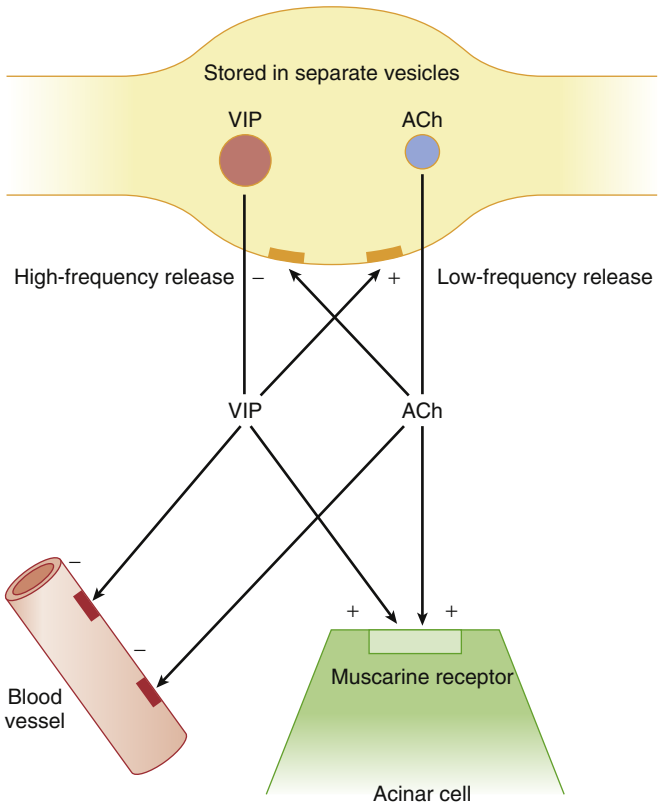

Figure 16-14. The classic transmitter acetylcholine (ACh) coexists with vasoactive intestinal polypeptide (VIP) in parasympathetic nerves supplying the cat salivary gland. ACh and VIP are stored in separate vesicles; they can be released differentially at different stimulation frequencies to act on acinar cells and glandular blood vessels. Cooperation is achieved by the selected release of ACh at low impulse frequencies and VIP at high frequencies. Prejunctional and postjunctional modulation is indicated. *(From Burnstock G: Local mechanisms of blood flow control by perivascular nerves and endothelium,* J Hypertens Suppl *8:S95, 1990.)*

ATP released at nerve endings in the setting of hypertension leads to marked decreases in arterial pressure. ATP bound to magnesium chloride ($MgCl_2$) is a potent pulmonary vasodilator used to treat patients with pulmonary hypertension secondary to congenital heart disease. In addition, it is used to treat postischemic renal injury. Purinergic cotransmission is also seen in the gastrointestinal tract, where ATP (and NO) receptor stimulation inhibits peristalsis.

Neuromodulators modify the process of neurotransmission. They may be circulating neurohormones, local agents, or neurotransmitter substances released from the same nerves or from others nearby. Neuromodulation can occur prejunctionally by decreasing or increasing the amount of transmitter released during transmission or postjunctionally by altering the extent or time course of the neurotransmitter's effect. In all known examples in which prejunctional and postjunctional neuromodulation occurs, these substances act in concert to attenuate or augment effective transmission. The rationale for such effects may reflect the variable geometry of the autonomic neuroeffector junction.[79,80] Unlike the neuromuscular junction, the autonomic neuroeffector junction exists in a dynamic state and manifests only modest postjunctional specialization. Biogenic amines often must traverse wide distances. Given the short half-lives of these chemicals, neuromodulation provides a biologic mechanism for augmentation and prolongation of their action.[81]

NPY is also colocalized with norepinephrine and ATP. However, in some vessels, NPY has little or no direct action; instead, it acts as a neuromodulator prejunctionally to inhibit the release of norepinephrine from the nerve or postjunctionally to enhance the action of norepinephrine (see Fig. 16-13, *A*).[82,83] In other vessels, notably those of the spleen, skeletal muscle, and cerebral and coronary vasculature, NPY has direct vasoconstrictor actions. In the heart and brain, local intrinsic (nonsympathetic) neurons use NPY as the principal transmitter (see Fig. 16-13, *B*). In the spleen, NPY appears to act as a genuine cotransmitter with norepinephrine in perivascular sympathetic nerves (see Fig. 16-13, *C*).[84] The frequency of stimulation determines which vesicles are mobilized to release their transmitters.

A classic transmitter such as acetylcholine coexists with VIP in the parasympathetic nerves of many organs, but in this instance, the two transmitters are stored in separate vesicles. They can be released differentially at different stimulation frequencies, depending on where they are located.[85,86] For example, in the salivary gland, they can act independently on acinar cells and glandular blood vessels (see Fig. 16-14).[76] Cooperation is achieved by the selective release of acetylcholine at low frequencies and VIP at high frequencies of stimulation. Elements of prejunctional and postjunctional modulation have also been described. In many biologic states, including pregnancy[87] (see Chapter 77), hypertension, and aging (see Chapter 80), the relationships among cotransmitters may be an important determinant of a compensatory response to allow finer control of important physiologic function. Additionally, the large number of different receptors may provide targets for potential pharmacologic interventions.

GANGLIONIC PHARMACOLOGY

Ganglia serve far more complex functions than simply being a link between the nerve process of one cell and the cell body of its next connection. Integrative and processing functions contribute to the subtlety of response and organization of the ANS. The electrophysiology of ganglionic stimulation is complex, with at least four different types of responses to electrical stimulation, based on their characteristic excitatory postsynaptic potential (EPSP) or inhibitory postsynaptic potential (IPSP).[88]

The central event at the ganglion is the EPSP when acetylcholine interacts with a neuronal-type nicotinic receptor to depolarize the postsynaptic membrane. Depolarization results primarily from the influx of sodium ions through the nicotinic receptor channel, and it is sensitive to nondepolarizing nicotinic blocking drugs such as hexamethonium. The other changes in electrical potential are related to secondary or subsidiary pathways that augment or suppress; these pathways are insensitive to classic nicotinic antagonists.

Secondary pathways are indicated by the following changes in potential elicited by electrical stimulation of the ganglia: (1) slow EPSP, (2) late slow EPSP, and (3) IPSP.

Autonomic ganglia may be stimulated by two groups of drugs: nicotinic and muscarinic agonists. Nicotinic agonists cause a rapid onset of excitatory effects, mimic the initial EPSP, and are blocked by classic nondepolarizing ganglionic blocking drugs. Muscarinic agonists delay onset of the excitatory effects and are blocked by atropine.

Blockade of ganglionic transmission results primarily from action at the nicotinic receptor to stop or inhibit transmission. Two groups of drugs block ganglionic transmission. The first group is classically represented by nicotine and initially stimulates the receptor but then blocks it. This action is similar to the action of persistent depolarization. The second group does not cause initial stimulation or a change in ganglionic potentials. This group includes the drugs hexamethonium, trimethaphan, and mecamylamine. Trimethaphan acts by competing with acetylcholine at cholinergic receptor sites on the ganglia; hexamethonium blocks the channel when it is open. Either mechanism blocks the initial EPSP and ganglionic transmission.

Muscarinic antagonists and α-agonists are incapable of completely blocking transmission, but they may inhibit normal modulation of the nerve impulse. β-Adrenergic stimulation facilitates nicotinic and muscarinic transmission, whereas α-adrenergic stimulation inhibits it. 5-HT is mostly facilitative, but it can be inhibitory in certain areas. Dopamine may also be inhibitory through stimulation of the IPSP. The adrenal medulla is a specialized ganglionic synapse and is therefore under influences similar to those arising on the autonomic ganglia.

DRUGS AND THE AUTONOMIC NERVOUS SYSTEM

The structure and function of the sympathetic and parasympathetic systems are discussed in the preceding sections. Pharmacologic manipulation of autonomic function is the basis of therapy for many acute and chronic illnesses. The complex physiology allows many points for intervention, including enhancement or inhibition of synthesis, storage, or receptor-mediated activity. In the following sections, specific autonomic drugs of interest to anesthesiologists and the mechanisms by which they work are discussed.

DRUGS AFFECTING ADRENERGIC TRANSMISSION

Endogenous Catecholamines

The endogenous sympathetic transmitters norepinephrine, epinephrine, and dopamine are catecholamines, an important subclass of the sympathomimetic drugs (Fig. 16-15). The parent compound of this sympathomimetic group is β-phenylethylamine, the structure of which includes a benzene ring and an ethylamine side chain. Substitution of hydroxyl groups at the 3 and 4 positions of the benzene ring converts benzene to catechol, and these compounds are known as catecholamines. Although synthetic, isoproterenol and dobutamine are also catecholamines. In addition, noncatecholamine drugs may act as sympathomimetics and have a similar structure.

The catecholamines are primarily metabolized by COMT. The loss of either hydroxyl group enhances oral

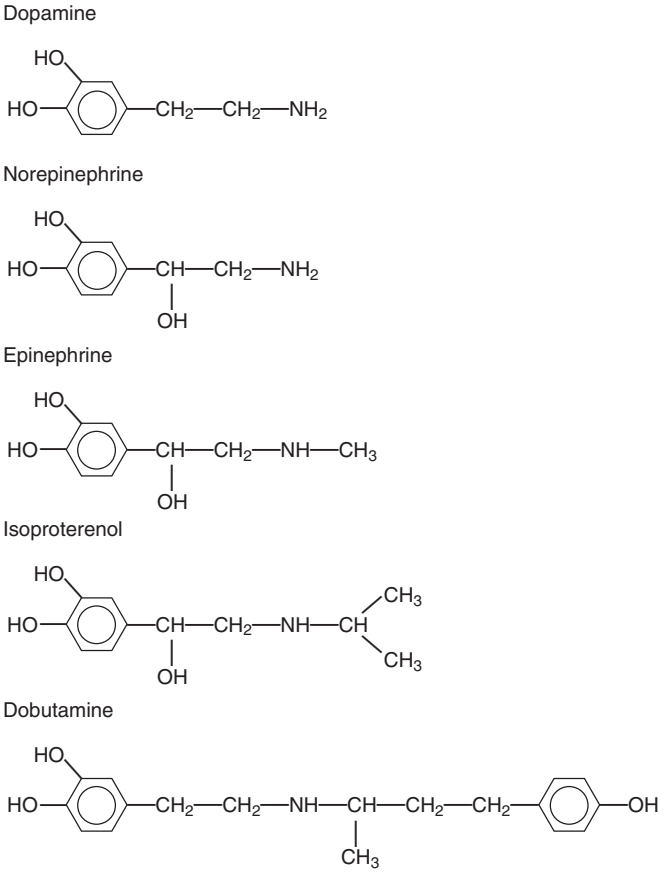

Figure 16-15. Catecholamine structures. A benzene ring with two adjacent hydroxyl groups forms the catechol nucleus.

effectiveness and duration of action because the drug is no longer metabolized by COMT. Noncatecholamine sympathomimetics are primarily metabolized by MAO. The noncatecholamines that have a substituted α-carbon have a longer duration of action because they are not metabolized by COMT or MAO.

Epinephrine. Epinephrine is used intravenously in life-threatening circumstances, including the treatment of cardiac arrest, circulatory collapse, and anaphylaxis, but it is also commonly used locally to limit the spread of local anesthetics or to reduce blood loss. The systemic effects of epinephrine are variable and are related to blood levels. The choice of dosing and the route of administration are determined by the indication for use and its urgency.

Epinephrine activates all adrenergic receptors: α_1, α_2, β_1, β_2, and β_3. Potential therapeutic effects of epinephrine include the following: positive inotropy, chronotropy, and enhanced conduction in the heart (β_1); smooth muscle relaxation in the vasculature and bronchial tree (β_2); and vasoconstriction (α_1). With vasoconstriction, aortic diastolic pressure is increased, thereby promoting coronary flow during cardiac arrest, which may be the single most important determinant of survival.[89] Endocrine and metabolic effects of epinephrine include increased levels of glucose, lactate, and free fatty acids.

Epinephrine may be given intravenously as a bolus or by infusion. The usual bolus doses for pressure support begin at 2 to 8 μg given intravenously; 0.02 mg/kg or approximately 1.0 mg is given for cardiovascular collapse, asystole, ventricular fibrillation, electromechanical dissociation, or anaphylactic shock[90] (see also Chapter 108). The larger dose range is recommended in these critical situations to maintain myocardial and cerebral perfusion through peripheral vasoconstriction. High-dose epinephrine (0.1 to 0.2 mg/kg) has been studied in resuscitation from cardiac arrest; rates of survival in adults are not improved. In pediatric patients, outcome after asystole and pulseless cardiac arrest is abysmal, and the current recommendation is an initial dose of 0.01 mg/kg repeated every 3 to 5 minutes throughout resuscitative attempts[42,91] (see Chapter 95). In unusual circumstances, larger doses may be given, and doses as large as 0.2 mg/kg may be effective.[92] Patients vary tremendously in their response to epinephrine, and given rates of infusion cannot guarantee the expected serum levels in all patients; the "pressors" should therefore be carefully titrated, and measures to monitor renal, cerebral, and myocardial perfusion are more critical than adherence to a rigid dosing scheme (Table 16-7). A rate of 1 to 2 μg/minute, although rarely used, should predominantly activate β_2 receptors, with resulting vascular and bronchial smooth muscle relaxation. A rate of 2 to 10 μg/minute (25 to 120 ng/kg/minute) increases heart rate, contractility, and conduction through the AV node and decreases the refractory period. Doses in excess of 10 μg/minute (100 ng/kg/minute) cause marked α-adrenergic stimulation with resultant generalized vasoconstriction. Epinephrine is a potent renal vasoconstrictor that acts directly by α-receptor stimulation and indirectly by stimulation of renin release. Although low-dose epinephrine increases the heart rate by direct β_1-adrenergic stimulation, reflex bradycardia is seen with higher doses because of the marked elevation in blood pressure resulting from peripheral vasoconstriction.

TABLE 16-7 DOSE-DEPENDENT ACTIONS OF INOTROPES AND CHRONOTROPES

Drug*	Receptors	Usual Infusion Rate
Epinephrine	β_2	1-2 μg/min
	$\beta_1 + \beta_2$	2-10 μg/min
	α_1	≥10 μg/min† (bolus: 2-10 μg; 0.5-1.0 mg‡)
Norepinephrine	α_1, $\beta_1 >> \beta_2$	4-12 μg/min†
Dopamine	Dopaminergic	0-3 μg/kg/min
	β	3-10 μg/kg/min
	α	>10 μg/kg/min†
Dobutamine	$\beta_1 >> \beta_2$, α	2.5-10 μg/kg/min†
Isoproterenol	$\beta_1 > \beta_2$	0.5-10 g/min

Data from Hoffman BB, Lefkowitz RJ: Catecholamines and sympathetic drugs. In Goodman A, Rall T, Nies A, et al, editors: Goodman and Gilman's the pharmacological basis of therapeutics, *ed 8. New York, 1990, Pergamon Press, p 187.*

*All drugs have elimination half-lives of a few minutes except amrinone (half-life, 3.6 hours; 5.8 hours in congestive heart failure).

†Much larger doses have been used in clinical practice.

‡With anaphylaxis or cardiac arrest.

Racemic epinephrine (i.e., mixture of the levorotary and dextrorotary isomers) constricts edematous mucosa and is used for the treatment of severe croup,[93] as well as for postextubation and traumatic airway edema. A 2.25% solution is diluted with water or saline in a 1:8 ratio and is nebulized. Treatments may be given as frequently as every 2 hours, with effects lasting 30 to 60 minutes; the patient should remain under observation for at least 2 hours because initial improvement may be followed by rebound swelling up to 2 hours after administration. Although it is common clinical practice to use the racemic form of epinephrine for these clinical applications, data show that L-epinephrine is 15 to 30 times more potent than the mixture,[94] and it is equally effective and less expensive for treating these clinical complications.[95]

Bronchospasm may also be treated by subcutaneous administration of epinephrine in doses of 300 μg every 20 minutes with a maximum of three doses. In addition to its direct bronchodilatory effects, epinephrine may decrease antigen-induced release of endogenous bronchospastic substances from mast cells and is particularly useful in anaphylactic reactions.[96] Relative contraindications include advanced age, significant tachycardia, hypertension, and coronary occlusive disease. Absorption of subcutaneous epinephrine is extremely slow because of intense local vasoconstriction, and the effect of a very large subcutaneous dose of 0.5 to 1.5 mg is roughly equivalent to an intravenous infusion of 10 to 30 μg/minute. Intravenous injection of epinephrine in a dose appropriate for subcutaneous administration can result in life-threatening ventricular arrhythmias, hypertension, and cerebral hemorrhage. Epinephrine is often applied locally to mucosal surfaces to decrease bleeding at an operative site. It is mixed with local anesthetics for infiltration into tissues or intrathecal injection. The α-mediated

vasoconstriction decreases bleeding in the area and slows vascular uptake of local anesthetic, thereby prolonging the duration of effect and decreasing the peak serum level of the local anesthetic. Although clinicians express concern about the possible systemic effects of such injections, the increases in plasma levels from vascular uptake are relatively modest and are substantially less than levels seen during psychological stress.[97] This conclusion assumes the absence of overt intravenous injection.

Drug interactions with epinephrine are often predictable. Cocaine and other uptake inhibitors enhance the effect and duration of exogenous epinephrine. Preexisting α_1 blockade can cause the paradoxical phenomenon of epinephrine reversal (a hypotensive and tachycardic response) as the β_2-vasodilating effects are unmasked. Patients receiving nonselective β-blockers may demonstrate unopposed α responses. Cardioselective (β_1) blockade does not have this effect.[98]

Halothane (which is still used in some countries) sensitizes the heart to catecholamines and can cause arrhythmias during light levels of anesthesia. Epinephrine decreases the refractory period and thus renders the heart more susceptible to arrhythmias. In adults, the epinephrine dose required to produce three premature ventricular contractions in 50% of patients (ED_{50}) at 1.25 minimum alveolar concentration (MAC) was 2.1 μg/kg for halothane, 6.7 μg/kg for isoflurane, and 10.9 μg/kg for enflurane.[99] Children tolerate larger doses than do adults (see Chapter 93). In addition, children undergoing halothane anesthesia may receive a maximum of 10 to 15 μg/kg of epinephrine subcutaneously every 10 minutes.[92] Hypocapnia potentiates this drug interaction.

Norepinephrine. Norepinephrine differs structurally from epinephrine only in its lack of a methyl group. Like epinephrine, norepinephrine acts at α and β receptors, but it is typically used for its potent α agonism. It is frequently the pressor of last resort in supporting systemic vascular resistance. Because of its short half-life of 2.5 minutes, continuous infusion is preferred. Whereas less than 2 μg/minute (30 ng/kg/minute) may uncover the effects of β_1-adrenergic stimulation, the usual infusion rates of greater than 3 μg/minute (50 ng/kg/minute) elicit peripheral vasoconstriction from α-adrenergic stimulation.

Peripheral vasoconstriction increases arterial blood pressure and may cause reflex bradycardia. Venous return is increased by the powerful venoconstriction. Cardiac output is frequently unchanged or decreased; oxygen consumption is markedly increased. Because pulmonary vascular resistance may be increased, norepinephrine should be used with caution in patients with pulmonary hypertension.[100]

Like epinephrine, norepinephrine is a potent constrictor of the renal and mesenteric vascular beds and can cause renal failure, mesenteric infarction, and peripheral hypoperfusion. The decrease in hepatic flow is of clinical relevance because plasma levels of hepatically metabolized drugs (e.g., lidocaine) are markedly increased. To ameliorate the renal effects, a low-dose dopamine infusion may be added to norepinephrine.[101] Extravasation of norepinephrine can cause tissue necrosis and may be treated by local infiltration of phentolamine. Prolonged infusion has caused gangrene of the digits. The potential for profound vasoconstriction makes careful patient selection and close monitoring mandatory.

Dopamine. Dopamine acts at α-adrenergic, β-adrenergic, and dopaminergic receptors; it also acts to release norepinephrine and therefore has mixed direct and indirect effects. Although dopamine is a precursor of norepinephrine, its most important ANS effect in the periphery may be to cause peripheral vasodilation. Improvement of blood flow through the renal and mesenteric beds in shocklike states is expected through its action at dopamine receptors on the postjunctional membrane. It is rapidly metabolized by MAO and COMT and has a half-life of approximately 1 minute. Like other endogenous catecholamines, dopamine is given as a continuous intravenous infusion without a loading dose. At low doses (0.5 to 2.0 μg/kg/minute), DA_1 receptors are stimulated, and renal and mesenteric vascular beds dilate.[102] In addition to an improvement in renal blood flow, the glomerular filtration rate and sodium excretion increase. With an infusion rate of 2 to 10 μg/kg/minute, β_1 receptors are stimulated, and cardiac contractility and output are increased. Rates higher than 5 μg/kg/minute stimulate the release of endogenous norepinephrine, which contributes to cardiac stimulation. In larger doses (10 to 20 μg/kg/minute), α and β_1 receptors are stimulated, the α-adrenergic vasoconstrictive effect predominates, and the benefit to renal perfusion may be lost.[103]

In the past, dopamine was frequently used for the treatment of shock (especially in vasodilated states such as sepsis). Infusions of dopamine, by increasing renal blood flow, may protect the kidney and aid in diuresis.[104] However, dopamine may not have a beneficial effect on renal function in shock states, and its routine use in these patients is questionable (see Chapters 102 and 107).[105,106]

Dopexamine hydrochloride, an inotropic vasodilator, is a synthetic parenteral dopamine analogue that may be of use in CHF. Dopexamine is approximately 60 times more potent at β_2-adrenergic receptors than dopamine is, one third as potent at DA_1 receptors, and one seventh as potent at DA_2 receptors.[107,108] Unlike dopamine, it shows no α-adrenergic effects and negligible β_1-adrenergic effects and is consequently devoid of vasoconstrictive activity.[107,109] Dopexamine has a reported half-life of 3 to 7 minutes in healthy patients and approximately 11 minutes in patients with low cardiac output.[110] β_2 Agonism produces systemic vasodilation and indirect inotropic activity (through inhibition of neuronal uptake of norepinephrine).[107-109,111,112] Stimulation of dopaminergic receptors produces selective vasodilation of renal and splanchnic vessels and increases the glomerular filtration rate, diuresis, and natriuresis.[108,113-116]

The use of dopexamine is preferable when vascular resistance is high. Within the dose range of 1 to 6 μg/kg/minute, the combined inotropic, vasodilative, diuretic, and natriuretic effects have shown benefit in the management of CHF,[117-120] but an indeterminate outcome in the treatment of septic shock.[119,121-125] Use of this agent has been limited by dose-dependent tachycardia, mainly at doses higher than 4 μg/kg/minute.[126,127] The effects of dopexamine on intestinal mucosal and hepatic perfusion

remain controversial.[128-133] In general, systemic vasodilation is more pronounced with dopexamine, and positive inotropic effects appear more marked with dopamine[134] and dobutamine.[135]

Fenoldopam is a selective DA_1 agonist and potent vasodilator (i.e., six to nine times as potent as dopamine) that enhances natriuresis, diuresis, and renal blood flow.[136-140] Because of its poor bioavailability and varied results in clinical trials, fenoldopam is no longer being investigated as a candidate for the treatment of chronic hypertension or CHF. Instead, intravenous fenoldopam, given by infusion at rates of 0.1 to 0.8 μg/kg/minute with incremental titration at 0.1 μg/kg/minute, has been approved to treat severe hypertension. It is an alternative to sodium nitroprusside, with potentially fewer side effects (i.e., no thiocyanate toxicity, rebound effect, or coronary steal) and improved renal function. The peak effects of fenoldopam occur within 15 minutes.[141,142]

Noncatecholamine Sympathomimetic Amines

The β-agonist isoproterenol and the α-agonists phenylephrine and methoxamine act predominantly at only one type of receptor, but most noncatecholamine sympathomimetic amines act at α and β receptors because they have two mechanisms of action: directly at a receptor and indirectly by releasing endogenous norepinephrine.

Mephentermine, ephedrine, and metaraminol are mixed-acting drugs. Ephedrine increases arterial blood pressure and has a positive inotropic effect. Because uterine blood flow is not decreased, ephedrine is widely used as a pressor in hypotensive parturient patients (see Chapter 77), although more recent evidence suggests that phenylephrine may be as safe or safer in this setting.[143] As a result of its β_1-adrenergic–stimulating effects, ephedrine is helpful in treating moderate hypotension, particularly if accompanied by bradycardia. It also has some direct β_2-adrenergic–stimulating effects and has been used orally as a bronchodilator. The usual dose is 2.5 to 25 mg given intravenously or 25 to 50 mg administered intramuscularly. Mephentermine is similar to ephedrine in its effects, whereas metaraminol has relatively stronger direct α_1-adrenergic–stimulating effects and may be associated with reflex bradycardia.

Tachyphylaxis to the indirect effect may develop through depletion of norepinephrine stores. Although all sympathomimetic amines are capable of producing tolerance or tachyphylaxis, the mechanism has been studied best with metaraminol. Metaraminol is taken up into the sympathetic nerve ending, where it displaces norepinephrine and produces its sympathomimetic effect. However, after some time, the drug acts as a false transmitter, and subsequent sympathetic nerve stimulation results in much less effect. Consequently, metaraminol probably should not be used when other, more effective drugs are available. Its indirect action is attenuated in the presence of long-term reserpine or cocaine use, but it may still be efficacious at larger doses. Although indirect-acting drugs are widely used as a first-line therapy for intraoperative hypotension, epidemiologic studies of adverse reactions under anesthesia suggest that dependence on these agents in life-threatening events may contribute to morbidity if they delay the administration of epinephrine.[144]

α-Receptor Agonists

Phenylephrine and methoxamine are selective α_1-agonists. These drugs are commonly used when peripheral vasoconstriction is needed and cardiac output is adequate, as in the hypotension that may accompany spinal anesthesia, as well as in patients with coronary artery disease or aortic stenosis to increase coronary perfusion pressure without chronotropic side effects. Phenylephrine has a rapid onset and relatively short duration of action (5 to 10 minutes) when given intravenously. It may be given in bolus doses of 40 to 100 μg or by infusion at a starting rate of 10 to 20 μg/minute. Larger doses of up to 1 mg are used to slow supraventricular tachycardia through reflex action. Phenylephrine is also used as a mydriatic and nasal decongestant. In anesthetic practice, it is applied topically, alone or mixed with local anesthetic gel, to prepare the nostril for nasotracheal intubation. It is also added to local anesthetic to prolong subarachnoid blockade. In contrast, methoxamine is a much longer-acting drug (30 to 60 minutes).[145] In larger doses, methoxamine possesses some membrane-stabilizing and β-blocking properties.

α_2-Agonists are assuming greater importance as anesthetic adjuvants and analgesics. Their primary effect is sympatholytic. They reduce peripheral norepinephrine release by stimulation of prejunctional inhibitory α_2 adrenoreceptors. They inhibit central neural transmission in the dorsal horn by presynaptic and postsynaptic mechanisms and also have direct sympatholytic effects on spinal preganglionic sympathetic neurons. Traditionally, they have been used as antihypertensive drugs, but applications based on their sedative, anxiolytic, and analgesic properties are being developed.

Clonidine, the prototypic drug of this class, is a selective partial agonist for α_2 adrenoreceptors, with a ratio of approximately 200:1 (α_2 to α_1). Its antihypertensive effects are caused by central and peripheral attenuation of sympathetic outflow and central activation of nonadrenergic imidazoline-preferring receptors.[146-148] The decrease in central sympathetic outflow reduces activity in peripheral sympathetic neurons without affecting baroreceptor reflexes.[149] Arterial blood pressure is thereby decreased without the accompanying orthostatic hypotension produced by many antihypertensive drugs.[150] Because clonidine is lipid soluble, it penetrates the blood-brain barrier to reach the hypothalamus and medulla, and unlike methyldopa, it does not require transformation into another substance.[151] Clonidine withdrawal may precipitate hypertensive crises, so the drug should be continued throughout the perioperative period or at the least be replaced by close monitoring of arterial blood pressure and ready ability to treat hypertension. The administration of nonselective β-blockers during clonidine withdrawal can worsen hypertension by leaving α_1-receptor–mediated vasoconstriction unopposed. Labetalol can be used to treat this withdrawal syndrome.

Although experience with α_2-agonists as sole anesthetics is limited,[152] these drugs reduce anesthetic requirement and provide a more stable cardiovascular course, presumably because of their sympatholytic effect

and the need for lower doses of cardioactive anesthetics.[153,154] Oral, intravenous, epidural, or intrathecal administration of clonidine potentiates the anesthetic action of other volatile or intravenous anesthetics and reduces general and regional anesthetic requirements with correspondingly fewer side effects.[153,155-162] Additionally, a meta-analysis of the perioperative use of clonidine and the other α_2-agonists dexmedetomidine and mivazerol indicated a decrease in MI and perioperative mortality in patients undergoing vascular surgery (see Chapter 69).[163]

Dexmedetomidine has a 1600:1 preference for α_2 receptors relative to α_1 receptors.[164] This drug was introduced into clinical practice as an adjunct to regional, local, and general anesthetics.[165] Dexmedetomidine has a half-life of 2.3 hours, although its context-specific half-life is less than 5 minutes,[166] thus making its clinical effect short.

In healthy volunteers, dexmedetomidine increases sedation, analgesia, and amnesia and decreases heart rate, cardiac output, and circulating catecholamines in a dose-dependent fashion.[164] The purported MAC-reducing sedative and analgesic effects demonstrated in preclinical and volunteer studies have largely been borne out in clinical practice. Although dexmedetomidine infusions attenuate the hemodynamic lability of induction, maintenance, and emergence, the dose of other anesthetics must be carefully reduced[167,168] because requirements for other anesthetics may decrease. Another use for this drug is to provide sedation for mechanically ventilated patients during weaning from the ventilator (see Chapter 103).[169]

In addition to their use in the operative setting, α_2-agonists provide effective analgesia for acute and chronic pain, particularly as adjuncts to local anesthetics and opioids. The addition of clonidine increases the duration of analgesia and reduces dose requirements for local and narcotic pain medications.[159,170-184] Epidural clonidine is indicated for the treatment of intractable pain; that is, patients unresponsive to maximum doses of oral or epidural opioids may benefit from oral, patch, intramuscular, or neuraxial administration of clonidine,[185-188] as do patients with reflex sympathetic dystrophy[189] and neuropathic pain.[190] The intrinsic analgesic effects of α_2-agonists have been demonstrated with large doses of clonidine alone administered intrathecally (as much as 450 μg) or epidurally (1 to 2 μg/kg/hour) to control intraoperative and postoperative pain. Clonidine decreases postoperative oxygen consumption and the adrenergic stress response.[191,192] Although dose-dependent adverse effects such as hypotension and sedation and idiosyncratic adverse effects such as bradycardia do occur, clonidine seems to have limited effects on respiratory control and only mildly potentiates opiate-induced respiratory depression.[193,194] The impact of α_2-induced sedation on respiratory function combined with the short duration of action of dexmedetomidine led to several reports of the use of dexmedetomidine for awake fiberoptic intubation.[195,196] The authors of these reports emphasize the ability to maintain spontaneous ventilation in the context of adequate sedation for the procedure as the reason for selecting the short-acting α_2-agonist for sedation in patients with difficult or at-risk airways. For similar reasons, dexmedetomidine infusions have been used for the perioperative management of obese patients with obstructive sleep apnea to minimize their narcotic needs while providing adequate analgesia.[197]

Aside from its role as an anesthetic adjuvant and antihypertensive agent, clonidine has been used to treat the following: panic disorder[198]; symptoms of opiate, benzodiazepine, and ethanol withdrawal[199]; cigarette craving after smoking cessation[200]; emesis in cancer chemotherapeutic regimens; and diabetic diarrhea. Experimental data also suggest that α_2-agonists have protective effects against anesthetic neurotoxicity in the developing brain.[201]

Clonidine may increase blood glucose concentrations by inhibiting release of insulin.[202] Unlike spinal opioids, clonidine does not cause urinary retention and may hasten the time to first micturition after spinal anesthesia.[203,204] The breadth of experience with dexmedetomidine is much less than with clonidine. Nevertheless, infusions of the short-acting intravenous α_2-agonist have been used for sedation after extubation at the intensive care unit (ICU),[205] during neurosurgical cases (to facilitate intraoperative wake-ups and to improve signal quality during neuromonitoring)[206] (see Chapters 49 and 70), and as part of a postoperative pain management regimen.[207] Patients in the ICU who are sedated with dexmedetomidine appear to have a lower incidence of delirium and/or coma.[208,209] An important characteristic of dexmedetomidine that makes it an attractive choice in these settings is the "rousable" sedation that it creates (see also Chapter 102). Specifically, patients awaken from apparently deep states of sedation to verbal commands or light tactile stimulation.

β-Receptor Agonists

Nonselective β-Receptor Agonists

Dobutamine. Although at clinical doses it can act at β_2 and α_1 receptors, dobutamine, a synthetic analogue of dopamine, has predominantly β_1-adrenergic effects. When compared with isoproterenol, it is reported to affect inotropy more than chronotropy, but it increases conduction velocity through nodal tissue to the same extent. Dobutamine exerts less of a β_2-type effect than does isoproterenol and less of an α_1-type effect than does norepinephrine. Unlike dopamine, dobutamine does not directly release endogenous norepinephrine, nor does it act at dopaminergic receptors.

Dobutamine may be useful in CHF and MI complicated by a low cardiac output state, although in cases of severe hypotension, it may not be effective because it lacks a significant α_1-pressor effect. It is relatively safe to use in patients with myocardial ischemia without increasing the size of the infarct or causing arrhythmias. Doses lower than 20 μg/kg/minute do not produce tachycardia, but in especially severe CHF, significant tachycardia is the primary adverse effect. Because dobutamine directly stimulates β_1 receptors, it does not rely on norepinephrine stores and may still be effective in catecholamine-depleted states such as chronic CHF. However, in severe chronic CHF, the down-regulation of β-adrenergic receptors may hamper the drug's effectiveness.

The β_2-vasodilating effects of dobutamine are almost exactly offset by its α_1-constricting effects, which can be revealed experimentally by administering a nonselective β-blocking drug. Its modest ability to dilate the

peripheral vasculature is probably more closely connected with its ability to relieve the high-adrenergic state of decompensated CHF than with specific β_2-mediated vasodilation.[210] Clinical situations that call for distinct afterload reduction may be better served by an agent such as nitroprusside.

Prolonged treatment with dobutamine causes downregulation of β receptors; tolerance to its hemodynamic effects is significant after 3 days and may be temporarily offset by increasing the rate of infusion. [211] Intermittent infusions of dobutamine have been used in the long-term treatment of heart failure and have improved exercise tolerance,[212] although not survival.[213]

Isoproterenol. Isoproterenol provides relatively pure nonselective β-adrenergic stimulation with no significant effect at α receptors. Its β_1-adrenergic stimulation is significantly stronger than its β_2 stimulation, but it still causes more β_2-adrenergic activity than does dobutamine. Since the development of other inotropes, the popularity of isoproterenol has declined because of its adverse effects of tachycardia and arrhythmias. Isoproterenol was historically used for bradycardia or heart block resistant to atropine (see Chapter 108). Its primary use at this time is as a chronotropic agent in patients after heart transplantation. These patients are unable to generate an endogenous sympathetic response to challenges because the sympathetic fibers are divided when the native heart is removed. The availability of superior pharmacologic options for most clinical indications has led to removal of isoproterenol from many hospital formularies. Infusion rates start at 0.5 to 5 μg/minute for adults. Because isoproterenol is not taken up into adrenergic nerve endings, its duration of action is slightly longer than that of the natural catecholamines.

Selective β_2-Receptor Agonists. In the past, isoproterenol was used in the treatment of bronchospasm for its β_2-adrenergic–stimulating properties, but unpleasant and dangerous β_1-mediated adverse effects limited its use. The development of β_2-selective agents made β stimulants a cornerstone of the treatment of bronchospasm. However, this β_2 selectivity is only relative, and it may be lost at higher doses; in addition, β_2 receptors in the sinoatrial node may cause tachycardia when stimulated. The structures of these drugs have been modified to slow their metabolism, thereby prolonging their therapeutic benefit and enabling oral administration. In particular, the addition of bulky structures on the catecholamine amino group increases β_2 selectivity, decreases affinity for α receptors, and protects against metabolism by COMT. These drugs are aerosolized and given by inhaler for rapid onset and to minimize systemic drug levels and adverse effects.

An increase in the annual number of deaths from asthma has been well documented, and investigators have suggested that this increase may be related to β_2-agonist use.[214-216] Susceptibility to arrhythmia by direct cardiac stimulation or by β_2-induced hypokalemia is a suggested mechanism of these effects. It has also been hypothesized that long-term use of these drugs may increase airway hyperreactivity. Nonetheless, their safe use in many thousands of patients is well documented.

Commonly used drugs include metaproterenol, terbutaline, and albuterol. Metaproterenol is probably less β_2 selective than albuterol or terbutaline. Terbutaline is the only β_2-selective agent that can be given subcutaneously and may therefore have particular use in status asthmaticus. The normal subcutaneous dose is 0.25 mg, which may be repeated after 15 to 30 minutes.

β_2-Agonists are also used to treat premature labor (see Chapter 77). β_1-Adrenergic adverse effects are common, particularly when the drugs are administered intravenously. As a consequence, their use for the purpose of tocolysis has been questioned.[217]

α-Receptor Antagonists

α_1-Antagonists have long been used clinically as antihypertensives, but they have become less popular over the years. α_1 Blockade vasodilates by blocking the arterial and venous constriction caused by endogenous catecholamines. The effects are potentiated when standing or in the presence of hypovolemia. Reflex tachycardia and fluid retention can ensue.

Phenoxybenzamine is the prototypic α_1-antagonist, although it irreversibly binds to α_1 and α_2 receptors. New receptors must be synthesized before complete offset of its effects occurs. Its half-life after oral administration is unknown, but after an intravenous dose its half-life is approximately 24 hours. Phenoxybenzamine decreases peripheral resistance and increases cardiac output, and blood flow to the skin and viscera is increased. As expected, the primary adverse effect of phenoxybenzamine is orthostatic hypotension; nasal stuffiness may also occur. In addition to receptor blockade, phenoxybenzamine inhibits neuronal and extraneuronal uptake of catecholamines. Phenoxybenzamine is used for the treatment of pheochromocytoma; with extended use, it establishes a "chemical sympathectomy" preoperatively that aids in blood pressure control, permits correction of the contracted plasma volume, and protects against catecholamine-induced cardiac damage. Thus, phenoxybenzamine treatment allows a smoother perioperative course for patients undergoing removal of a pheochromocytoma. When exogenous sympathomimetics are administered after α_1-receptor blockade, their vasoconstrictive effects are inhibited. The effect of phenylephrine is completely blocked, whereas that of norepinephrine is limited to its β_1-adrenergic effect of cardiac stimulation. Epinephrine reversal caused by unopposed β_2 agonism when exogenous epinephrine is given is manifested as severe hypotension and tachycardia. Despite phenoxybenzamine's irreversible binding to the receptor, the recommended treatment of phenoxybenzamine overdosage is norepinephrine infusion because some receptors remain free of the drug.[218]

Phentolamine is a shorter-acting drug that blocks α_1 and α_2 receptors. Historically used to treat pulmonary hypertension, it has largely been supplanted by epoprostenol (prostaglandin I_2). It is also used to treat the hypertension associated with clonidine withdrawal or with tyramine ingestion during MAOI therapy, but few data have been collected on its efficacy and safety for these indications. Phentolamine has also been infiltrated

into affected tissues after extravasation of agents such as norepinephrine in an attempt to relax vasoconstriction; for this purpose, 5 to 10 mg is diluted in 10 mL of saline. Adverse effects of phentolamine include hypotension and gastrointestinal distress; reflex tachycardia and arrhythmias may result from action at α_2 receptors. Coronary artery disease and peptic ulcer disease are relative contraindications to its use. As in phenoxybenzamine overdosage, severe hypotension may require treatment with norepinephrine rather than epinephrine.

Prazosin is a potent selective α_1-adrenergic blocker often used as a prototypic antagonist in pharmacologic experiments. It antagonizes the vasoconstrictor effects of norepinephrine and epinephrine, thereby causing a decline in peripheral vascular resistance and venous return to the heart. Although the heart rate does not normally increase, orthostatic hypotension is a major problem. Unlike other antihypertensive drugs, prazosin improves lipid profiles by lowering low-density lipid levels while raising the level of high-density lipids. It is primarily used to treat hypertension. It has also been used in patients with CHF, but unlike the angiotensin-converting enzyme inhibitors (ACEIs), prazosin does not prolong life. It is metabolized by the liver. Supplied as 1-, 2-, and 5-mg tablets, its starting dose is usually 0.5 to 1 mg given at bedtime because of the orthostatic hypotension. Eventually, it can be taken twice daily.

α_2-Antagonists such as yohimbine increase sympathetic outflow by enhancing release of norepinephrine. These drugs have proved to be of little clinical utility in anesthesia, although they are used in urology.

β-Receptor Antagonists

Pharmacology. β-Adrenergic receptor antagonists (i.e., β-blockers) are among the most commonly prescribed drugs and are frequently taken by patients about to undergo surgery. Current indications for the use of β blockade include ischemic heart disease, postinfarction management, arrhythmias, hypertrophic cardiomyopathy, hypertension, heart failure, and prophylaxis for migraine headache. Concern that patients treated with β-blockers would be hemodynamically unstable under anesthesia has proved to be largely unjustified. These drugs are an important part of the armamentarium of the anesthesiologist in the ongoing attempt to limit stress responses perioperatively and to protect the cardiovascular system. A comprehensive analysis found that the use of β-blockers perioperatively reduces morbidity and mortality in noncardiac surgery for patients at risk.[219] Several well-known clinical trials,[220-224] as well as the widespread use and safety of these drugs in heart failure,[225] have made β blockade an evolving standard (see Chapter 38).

A wide spectrum of β-adrenergic blockers is available to the clinician. The most important properties to consider when choosing a β-blocker for long-term use are cardioselectivity, intrinsic sympathomimetic activity (ISA), and lipid solubility. In anesthetic practice, cardioselectivity, duration of action, and a formulation suitable for intravenous use are crucial factors (Table 16-8). β-Antagonists resemble isoproterenol in structure and bind competitively to the β receptor, thereby blocking access by more potent β-agonists (Fig. 16-16). Competitive inhibition at the β receptor can be overcome by increasing the available concentration of β-agonist. The potency of a β-blocker is often determined by its ability to inhibit induction of tachycardia by isoproterenol. Propranolol is assigned a potency of 1, and the other drugs are evaluated in relation to it.

Nonselective β-adrenergic blockers act at the β_1 and β_2 receptors and include propranolol, nadolol, pindolol, sotalol, oxprenolol, penbutolol, and timolol. Cardioselective β-blockers have stronger affinity for β_1-adrenergic receptors than for β_2-adrenergic receptors, and the predominant effects are therefore cardiac. With β_1-selective blockade, AV conduction velocity, heart rate, and cardiac contractility are decreased, as are release of renin by the juxtaglomerular apparatus and lipolysis at adipocytes. At larger doses, the relative selectivity for β_1-adrenergic receptors is lost and β_2 receptors are also blocked, with

the potential for bronchoconstriction, peripheral vasoconstriction, and decreased glycogenolysis.

Cardioselective drugs include atenolol, betaxolol, bevantolol, esmolol, and metoprolol. These drugs may be preferable for patients with obstructive pulmonary disease, peripheral vascular disease, Raynaud phenomenon, and diabetes mellitus. Although previously a matter of controversy, a meta-analysis concluded that cardioselective β-blockers can be given safely to patients with chronic obstructive pulmonary disease.[226] Nevertheless, because the selectivity is only relative and may be lost at conventional clinical doses, extreme care should be taken when administering a β-blocker in the presence of pulmonary disease. Some β-antagonists also have vasodilatory effects, thus making them particularly useful in the treatment of hypertension and CHF.[227,228] Labetalol vasodilates by blocking α_1 receptors and by direct β_2-receptor agonism.

β-Blockers exerting a partial agonist effect at the receptor while blocking access by more potent agonists possess ISA. Drugs with ISA include acebutolol, carteolol, celiprolol, dilevalol, oxprenolol, penbutolol, and pindolol. These drugs primarily decrease arterial blood pressure and, to a lesser extent, heart rate and left ventricular function. When sympathetic activity is high, such as during exercise, these drugs behave more like conventional β-blockers. The partial β_2 agonism of pindolol induces bronchodilation. ISA may therefore be useful if β blockade is required in a patient with bradycardia, peripheral vascular disease, or very mild hyperreactive airway disease. Drugs with ISA may not be as effective in controlling symptoms in severe angina or in reducing mortality after MI.[229] ISA may protect against β-blocker withdrawal syndrome.[230]

Propranolol and acebutolol possess membrane-stabilizing activity (MSA), also referred to as the quinidine-like or local anesthetic effect. This effect reduces the rate of rise in cardiac action potential. The MSA of propranolol may explain the decrease in the oxygen affinity of hemoglobin when the drug is administered. However, MSA is seen only at concentrations 10 times those required for blockade of β receptors and is probably of little clinical consequence. Overdose with drugs that exhibit MSA is associated with a higher incidence of fatality.[231]

Indications for Use

Perioperative β Blockade. In the late 1990s, two important studies established the value of perioperative β blockade in patients at risk for coronary ischemia who were undergoing noncardiac operations (see Chapters 38 and 39). Patients were labeled as "at risk" if they fit into one of two categories: they were undergoing high-risk vascular surgery and had no evidence of inducible coronary ischemia, or they were undergoing a nonvascular procedure but had traditional risk factors for coronary artery disease (older age, high cholesterol, hypertension, cigarette smoking, family history of coronary disease, or diabetes).[232] The Multicenter Study of Perioperative Ischemia Research Group enrolled 200 patients about to undergo surgery who had risk factors for coronary artery disease and randomized these patients to receive placebo or atenolol before and after surgery.[221] The results of the study demonstrated that although no improvement occurred in in-hospital outcomes (cardiac death or MI) in the atenolol-treated group, the treated group did have a lower incidence of cardiac events at the 6- to 8-month follow-up and a marked decrease in all-cause mortality that persisted at 2-year follow-up (survival rate at 2 years: 68% in the placebo group and 83% in the atenolol-treated group). The second study enrolled patients with known ischemic disease demonstrated on preoperative stress echocardiography.[222] The treatment group in this study was given bisoprolol, and the dose was titrated to achieve a heart rate less than the patients' ischemic threshold. The results of this study, whose participants were at much higher risk for ischemic events than were the patients in the previous study, demonstrated a 10-fold decrease in perioperative cardiac death and MI (3.4% versus 34%). These powerful demonstrations that β blockade could decrease perioperative cardiac risk and improve survival out to 2 years led to tremendous political and administrative pressure to increase the use of β-blockers perioperatively.[233] Unfortunately, the value of routine perioperative β blockade is now questionable.

The Perioperative Beta-Blockade (POBBLE) study results showed no reduction in 30-day cardiovascular morbidity in patients undergoing vascular surgery (one of the "at-risk" groups from previous studies).[234] Similarly, the Diabetic Postoperative Mortality and Morbidity (DIPOM) study showed no benefit of β blockade in diabetic patients (another "at-risk" group) undergoing major noncardiac operations.[235] Finally, a large retrospective study looking at in-hospital mortality in more than 780,000 patients demonstrated a neutral or even negative effect of perioperative β blockade in patients without clear-cut coronary artery disease. β Blockade was associated with a reduced mortality rate in only the 3% of patients who had three or more risk factors (based on the revised Cardiac Risk Index) for coronary ischemia.[236] Thus, until larger studies are completed, the only strong indications for initiating β blockade preoperatively are for patients undergoing vascular or intermediate-risk surgical procedures who are at high cardiac risk as a result of multiple risk factors or the finding of ischemia on preoperative testing.[233] These more stringent standards for initiating preoperative β blockade have led to a decrease in the perioperative use of these drugs.[237]

When perioperative β-blocker therapy is initiated, it should be titrated to a non–ischemia-inducing heart rate (usually 60 to 70 beats/minute) and not given as a standard fixed dose to all patients. β-blockers should be continued in patients who are already taking them as treatment for their angina, symptomatic arrhythmia, or hypertension.

The safety of continuing long-term β blockade perioperatively is well established, and initial concerns regarding interaction with general anesthesia have not been confirmed. Attempts to discontinue β-blockers increase the risk for rebound tachycardia (with or without atrial fibrillation) and myocardial ischemia in patients with coronary disease. These drugs should be given up to the time of surgery, and intravenous forms in appropriate dosages should be used whenever gastrointestinal absorption may be in question. If β-blockers have been omitted from the preoperative regimen, esmolol or labetalol may be used acutely to blunt tachycardia and hypertension. Cardioselective and nonselective β-blockers are effective in blocking the chronotropic effects of endotracheal intubation and surgical stress.[238]

Myocardial Ischemia. Propranolol was initially introduced for the treatment of myocardial ischemia in the 1960s, and β-adrenergic blocking drugs remain an important part of drug therapy for myocardial ischemia (see Chapter 39). This class of drugs reduces oxygen demand by decreasing the heart rate and cardiac contractility. Although initially there was concern that β_2-receptor blockade could worsen ischemia through unopposed α-mediated vasoconstriction, this phenomenon is rarely seen, even in patients with variant (Prinzmetal) angina. β-Antagonists are used to treat acute MI and on a long-term basis to reduce reinfarction and mortality in patients after infarction.[239-242] Early administration of intravenous β-blocking agents to patients receiving thrombolytic therapy appears to lower the incidence of ischemia and reinfarction,[243] and it may reduce the incidence of serious ventricular arrhythmias.[244] Long-term use of β-blockers (i.e., timolol, propranolol, metoprolol, and atenolol) has been shown to decrease mortality after MI. In usual clinical practice, the dose is increased until the heart rate is 60 to 80 beats/minute at rest and no tachycardia occurs with exercise.

Congestive Heart Failure. Since the 1990s, β-blockers have become first-line agents for the treatment of CHF of ischemic and nonischemic origin. Clinicians had been disinclined to use β-blockers for heart failure patients because of the drugs' negative inotropic effects. These effects have not turned out to be a significant concern in clinical practice. Early studies demonstrated a significant decrease in all-cause mortality for patients with heart failure who were treated with metoprolol or bisoprolol. Several large studies were stopped because the decrease in mortality in treated patients with moderate to severe heart failure was so pronounced.[245,246] The benefits of β-blockers in patients with heart failure have been attributed to the following: normalization and remodeling of the ventricle, which begin after 1 month of β blockade[247]; reduced norepinephrine-related cardiomyocyte apoptosis in the presence of β_1 blockade[248]; decreased sudden cardiac death because of the β-blockers' antiarrhythmic activity; and, most recently, altered expression of genes in the myocardium that regulate contractility and pathologic hypertrophy.[249] To avoid worsening a patient's heart failure symptoms and to minimize negative inotropic effects, β-blockers are started at very low doses and are titrated to the target dose.[250] If decompensation occurs with the β-blocker, phosphodiesterase inhibitors are the inotropes of choice because their effects are not antagonized by β blockade.[251]

Hypertension. The mechanisms by which β-antagonists treat hypertension are incompletely understood. Arterial blood pressure is specifically decreased in hypertensive patients because long-term treatment of normotensive individuals does not decrease blood pressure. Reduced cardiac output and renin release have been suggested as mechanisms. In hypertensive patients, β-antagonists without ISA may cause a 15% to 20% reduction in cardiac output and a 60% reduction in renin release. However, pindolol, which has ISA and minimal effect on renin, is also successful in treating hypertension.[252] Maximum renin suppression precedes significant changes in arterial blood pressure.[253] Initially, β blockade increases peripheral vascular resistance and then over time lowers it.[254] The decrease in cardiac output and eventual lowering of peripheral resistance may account for much of the antihypertensive efficacy of these drugs. However, this too is an incomplete explanation because labetalol is an effective antihypertensive despite its lack of effect on cardiac output. A primary CNS effect is not likely to be a major mechanism because the antihypertensive efficacy of lipophilic and hydrophilic compounds is similar. Generally, β blockade is ineffective as monotherapy in hypertensive African American patients who are older than 60 years.

Cardiac Arrhythmias. β-Blockers are widely used in the treatment of tachyarrhythmias as class II agents (see Chapters 38, 67, and 68). Two possible mechanisms of action are blockade of catecholamine effects and MSA, although MSA is most likely not clinically significant because antiarrhythmic effects are present in agents without MSA.[255] β-Antagonists slow the rate of depolarization of the sinus node and any ectopic pacemakers, slow conduction through atrial tissue and the AV node, and increase the refractory period of the AV node. These drugs can convert atrial arrhythmias to sinus rhythm,[256] but β blockade is primarily used to slow the ventricular response. Reentrant tachyarrhythmias and those associated with Wolff-Parkinson-White syndrome, mitral valve prolapse, and a prolonged QT interval may also respond to these drugs. Care should be exercised if AV block is present, as in digitalis toxicity, although these drugs are useful in the treatment of digitalis-associated tachyarrhythmias. Sotalol, a β-blocker with added class III activity, is effective against ventricular tachyarrhythmias; however, in a trial comparing racemic sotalol with D-sotalol in post-MI patients, mortality increased with D-sotalol.[257] The trial was terminated when patients at lowest risk for arrhythmic events after MI had an increased mortality rate with this drug.[258]

Tachycardia. β-Antagonists are frequently used as adjuvants to moderate the reflex tachycardia associated with vasodilators (see Chapter 68). In addition to potentiating a reduction in blood pressure, β blockade also reduces the velocity of left ventricular ejection (dP/dt) and attenuates the shearing force associated with the increased velocity

of ventricular contraction when afterload is reduced with nitroprusside without concomitant β blockade.[259] This is important in the management of aortic dissections, in which increased dP/dt can extend the tear. Labetalol has been particularly useful in this situation.[260]

Thyrotoxicosis. Cardiac complications are a primary cause of morbidity in thyrotoxicosis (see Chapter 85). β Blockade can suppress the tachycardia and rhythm disturbances, although very large doses may be required. β-Antagonists also may be combined with digitalis for their synergistic effect on AV node conduction. Propranolol inhibits conversion of thyroxine to the active form triiodothyronine in the periphery.[261]

Miscellaneous Conditions. Timolol and betaxolol are β-blocking drugs used topically in the eye to treat glaucoma. They reduce the production of aqueous humor. Even topical use of these agents has been associated with significant systemic effects of β blockade. β-Blockers are used in patients with idiopathic hypertrophic subaortic stenosis to reduce the dynamic obstruction to left ventricular outflow. These drugs are also effective in the prophylaxis, but not the treatment, of migraine headaches and in controlling acute panic symptoms and essential tremor.

Adverse Effects. The adverse effects of most concern are those involving cardiopulmonary function. Severe noncardiopulmonary reactions such as cutaneous reactions or anaphylaxis are rare. Life-threatening bradycardia, even asystole, may occur, and decreased contractility may precipitate CHF in vulnerable individuals. In patients with bronchospastic lung disease, β_2 blockade may be fatal. CNS effects, although an appropriate consideration with long-term therapy, are not a concern with the usual anesthetic use of β-receptor antagonists. Diabetes mellitus is a relative contraindication to the long-term use of β-antagonists because hypoglycemia in the presence of sympathetic blockade is not accompanied by warning signs such as tachycardia and tremor and because compensatory glycogenolysis is blunted. However, most non–insulin-dependent diabetic patients can tolerate these drugs, although β blockade may cause insulin resistance in rare cases. In addition to the potential worsening of peripheral perfusion by β_2 blockade in patients with peripheral vascular disease, Raynaud phenomenon may be triggered in susceptible patients. Sudden withdrawal of β-blockers may cause myocardial ischemia and possibly infarction, but this is less of a problem with β-blockers that have ISA, such as pindolol.[262] Even though β-antagonists may reduce renal blood flow and the glomerular filtration rate, these agents can be used in renal failure. For such patients, the doses of lipid-insoluble drugs should be reduced. To avoid worsening of hypertension, use in pheochromocytoma should be avoided unless α receptors have previously been blocked. Nonselective agents may elicit hypertensive responses in cases of high sympathetic stimulation.[263]

Undesirable drug interactions are possible with β-blockers. The rate and contractility effects of verapamil are additive to those of β-blockers.[264,265] When combining these drugs, caution should be taken in acute situations such as supraventricular tachycardia. The combination of digoxin and β-blockers can have powerful effects on heart rate and conduction. Pharmacokinetic interactions are predictable from the degree of lipid solubility of the drug. Cimetidine and hydralazine may reduce hepatic perfusion, thereby increasing plasma levels and half-lives of the lipid-soluble β-antagonists. Barbiturates, phenytoin, rifampin, and smoking may induce hepatic enzymes and enhance metabolism. Propranolol may reduce hepatic clearance of lidocaine and increase the risk for toxicity.

Overdose of β-blocking drugs may be treated with atropine, but isoproterenol, dobutamine, or glucagon infusions (or some combination) may be required along with cardiac pacing to ensure an adequate rate of contraction.

Specific Drugs. The drugs propranolol, metoprolol, labetalol, and esmolol are particularly useful in anesthetic practice because they are widely available in intravenous formulations and have well-characterized effects. If the drug that the patient has taken on a long-term basis is propranolol, metoprolol, or labetalol, it may be continued in intravenous form. In deciding which intravenous β-blocker to substitute in a patient taking a β-blocker on a long-term basis, the need for cardioselectivity is a primary consideration. Cardioselectivity is provided by metoprolol or esmolol. If the long-term agent has ISA, oxprenolol and acebutolol have intravenous forms, but they are not readily available. In many situations, esmolol may be substituted and titrated to effect, with the expectation that its effects will fade relatively rapidly if it is not well tolerated.

Propranolol. Propranolol (Inderal, Ipran), the prototypic β-blocker, is a nonselective β-blocking drug with MSA but no ISA. It readily penetrates the CNS. Because of its high lipid solubility, it is extensively metabolized in the liver, but metabolism varies greatly from patient to patient. Its effective dose is extremely variable: 10 mg to as much as 320 mg may be given orally each day. Clearance of the drug can be affected by liver disease or altered hepatic blood flow, which may result in markedly increased plasma concentrations during continuous intravenous administration if the dose regimen is not adjusted. Renal impairment does not require adjustment of dosing. Despite its half-life of 4 hours, its antihypertensive effect persists long enough to permit dosing once or twice daily. Propranolol is available in an intravenous form and was initially given as either a bolus or an infusion. Infusions of propranolol have largely been supplanted by esmolol. For bolus administration, doses of 0.1 mg/kg may be given, although most practitioners initiate therapy with much smaller doses, typically 0.25 to 0.5 mg, and titrate to effect. Propranolol shifts the oxyhemoglobin dissociation curve to the right, an effect that perhaps accounts for its efficacy in vasospastic disorders.[266]

Metoprolol. Metoprolol (Lopressor) is approved for the treatment of angina pectoris and acute MI. It is cardioselective and lacks ISA and MSA. Because it is metabolized in the liver by the monooxygenase system, doses need not be adjusted in the presence of liver failure. The usual oral dose is 100 to 200 mg/day given once or twice daily for hypertension and twice daily for angina pectoris. It may be administered intravenously in doses of 2.5 to 5 mg every 2 to 5 minutes up to 15 mg, with titration to heart rate and blood pressure.

Labetalol. Labetalol is representative of a class of drugs that act as competitive antagonists at the α_1- and

β-adrenergic receptors. Labetalol consists of four isomers that block the α_1, β_1, and β_2 receptors, inhibit neuronal uptake of norepinephrine (uptake-1), act as a partial agonist at β_2 receptors, and possibly have some direct dilating ability. The potency of the mixture for β blockade is 5- to 10-fold that for α blockade. The usual oral dose of labetalol is 200 to 400 mg twice daily, although much larger doses have been used. It is metabolized by the liver, and clearance is affected by hepatic perfusion. The dose need not be adjusted for renal dysfunction. Labetalol may be given intravenously every 5 minutes in 5- to 10-mg doses or up to a 2 mg/minute infusion. It significantly blunts cardiovascular responses to tracheal intubation.[267] This drug can be effective in the treatment of aortic dissection,[259] hypertensive emergencies,[268,269] and postoperative cardiac surgical patients,[270] particularly because vasodilation is not accompanied by tachycardia. It may be used in pregnancy to treat hypertension on a long-term basis and in more urgent situations.[271] Uterine blood flow is not affected, even with a significant reduction in blood pressure (see Chapter 77).[272]

Carvedilol. Carvedilol, a mixed α- and β-antagonist, has been introduced as therapy for mild or moderate hypertension,[273-281] for the management of stable or unstable angina, and after acute MI.[282-286] Clinical trials of carvedilol for the treatment of controlled CHF (New York Heart Association class II to IV) suggest a significant reduction in mortality,[244,245,287,288] especially for patients with diabetes.[289]

Esmolol. Because of its hydrolysis by esterases, esmolol has a uniquely short half-life of 9 to 10 minutes that makes it particularly useful in anesthetic practice. It is administered when β blockade of short duration is desired or in critically ill patients for whom the adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. The peak effects of a loading dose are seen within 5 to 10 minutes and diminish rapidly (within 20 to 30 minutes). Esmolol is cardioselective and may be given as a bolus of 0.5 mg/kg to blunt cardiovascular responses to tracheal intubation. If it is used as an infusion for the treatment of supraventricular tachycardia, 500 μg/kg is given over a 1-minute period, followed by an infusion of 50 μg/kg/minute for 4 minutes. If the rate is not controlled, a repeat loading dose followed by a 4-minute infusion of 100 μg/kg/minute is given, and this sequence is repeated with the infusion increased in 50 μg/kg/minute increments up to 200 or 300 μg/kg/minute if needed. The effect may persist for 20 to 30 minutes after discontinuation of the infusion. When compared with verapamil, esmolol is more likely to convert atrial fibrillation to sinus rhythm.[255] Esmolol is safe and effective for the treatment of intraoperative and postoperative hypertension and tachycardia.[290-292] If continuous use is required, esmolol may reasonably be replaced by a longer-lasting cardioselective drug such as intravenous metoprolol. Esmolol has been used safely even in patients with compromised left ventricular function.[293,294]

Drugs that Inhibit Synthesis, Storage, or Release of Norepinephrine

Some early antihypertensive drugs acted by replacing norepinephrine in the nerve ending with a much less potent false transmitter. Methyldopa is such a drug and was the most popular nondiuretic antihypertensive used before the development of β-blockers.[219] Like DOPA, methyldopa enters the biosynthetic pathway for norepinephrine (see Fig. 16-7). It is then decarboxylated to α-methylnorepinephrine. Initially, this chemical was thought to act as a false transmitter, but it was found to be almost as potent as norepinephrine. In the CNS, methyldopa may be further metabolized to α-methylepinephrine, and it acts at α_2 receptors to decrease sympathetic outflow, which reduces blood pressure. Because of its sedating qualities, fluid retention, postural hypotension, and occasional reports of hepatic necrosis, methyldopa is now used much less often.

Methylparatyrosine is a potent inhibitor of TH, which catalyzes the formation of DOPA from tyrosine (see Fig. 16-7). Because this is the rate-limiting step in the biosynthesis of norepinephrine, the drug significantly decreases levels of endogenous catecholamines and is useful in treating inoperable or malignant pheochromocytomas.

Reserpine affects the uptake of norepinephrine, not at the neuronal membrane but at the vesicular membrane, thereby inhibiting transport and storage of norepinephrine and dopamine. However, this drug is rarely used in modern medicine.

Guanethidine acts initially by blocking the release of norepinephrine, and then it is taken up into adrenergic nerve endings by the uptake-1 mechanism and depletes norepinephrine stores. This drug is used to treat hypertension, usually after many other drugs have been tried. Its inability to cross the blood-brain barrier accounts for its lack of sedative effects. Guanadrel is similar to guanethidine, but it has a faster onset and shorter duration of action.

Bretylium, a class III antiarrhythmic used parenterally to treat life-threatening ventricular tachyarrhythmias, is now largely of historical interest. Like guanethidine, it is taken up into adrenergic nerve terminals, but its mechanism of action is otherwise quite different. Bretylium initially causes release of norepinephrine and subsequently blocks that release by decreasing sympathetic nerve excitability. Unlike guanethidine, bretylium does not deplete norepinephrine stores. The initial catecholamine release may cause marked hypertension and worsen some arrhythmias, such as those associated with digitalis toxicity and myocardial ischemia.[241] As a consequence, bretylium, which had been part of the advanced cardiac life support protocols for treating ventricular arrhythmias, has been dropped from the algorithms.

MAO and COMT are enzymes important in degradation of the catecholamines. MAOIs bind irreversibly to the enzyme and increase the amine concentration within the presynaptic terminal. Long-term MAOI use is associated with antihypertensive, antidepressant, and antinarcoleptic effects. MAOIs are thought to exert their antihypertensive effect through a false transmitter mechanism. Tyramine is usually oxidatively deaminated in the gut by MAO. With administration of an MAOI, tyramine levels rise. When tyramine is taken up into the sympathetic nerve terminal by the uptake-1 mechanism, it enters the varicosities and is transformed by DβH into octopamine. On its subsequent release in place of norepinephrine, octopamine is only weakly reactive at sympathetic

receptors, thereby resulting in lowering of blood pressure. The MAOIs are no longer used as antihypertensives because many other drugs with better risk-to-benefit profiles have been developed.

MAOIs are primarily used in psychiatric practice. The use of MAOIs as antidepressants is based on the theory that depression is caused by decreased amine in the synapses of the CNS. Inhibition of MAO makes more amine available for release. MAOIs available for the treatment of depression include isocarboxazid, phenelzine sulfate, and tranylcypromine sulfate.

Based on substrate specificity, at least two forms of MAO exist. MAO-A acts on 5-HT, epinephrine, norepinephrine, tyramine, and dopamine, whereas MAO-B is specific for tyramine and dopamine. A specific MAO-B inhibitor, selegiline hydrochloride, has been developed for the treatment of Parkinson disease in the hope that by blocking central dopamine breakdown, more dopamine will be preserved in the affected areas.[295]

Drug and food reactions have been of great concern in patients taking MAOIs. Tyramine-containing foods such as red wine and aged cheese must be avoided by patients taking these drugs. Consumption delivers a huge amount of tyramine to the adrenergic nerve terminal, with subsequent massive release of norepinephrine. This release is manifested clinically as a hypertensive crisis with the potential for MI, cerebral hemorrhage, and death. Any intake of biogenic amine precursors can be expected to increase catecholamine levels greatly, as seen with the concurrent administration of levodopa with MAOIs. The effects of sympathomimetic amines, particularly the indirectly acting drugs, are enhanced. Narcotics, most notably meperidine, have been associated with hyperpyrexic coma and death in patients treated with MAOIs. The depressant effects of agents such as sedatives, alcohol, and general anesthetics are enhanced in these patients. Anesthetic interactions with deprenyl have not been reported, but experience with this drug is limited. Great concern has been expressed that patients receiving long-term therapy with an MAOI risk life-threatening drug interactions during anesthesia. Emergency surgery in patients given an MAOI can be punctuated by marked hemodynamic instability. Severe reactions to narcotics and indirect-acting sympathomimetics, as well as altered metabolism of endogenous and exogenous catecholamines, make these patients potentially difficult to manage. Because of the possibly dangerous interactions of many drugs with MAOIs, controversy exists about the best way to anesthetize these patients.[296,297] The level of concern expressed over the years may be excessive. Although prudence and custom dictate discontinuation of MAOIs at least 2 weeks in advance of elective procedures, there appear to be rational anesthetic choices based on pharmacology and risk-to-benefit considerations for patients to continue their MAOIs when surgery cannot be delayed or no effective alternative psychiatric medications are available.

DRUGS AFFECTING THE RENIN-ANGIOTENSIN SYSTEM

The renin-angiotensin system maintains blood pressure and fluid balance. The major end product of the system, angiotensin II, is a potent vasoconstrictor that also stimulates release of aldosterone from the adrenal cortex, which causes salt and water retention by the kidney. The juxtaglomerular cells of the renal cortex secrete the proteolytic enzyme renin, which cleaves angiotensinogen, a protein synthesized in the liver, and produces the decapeptide angiotensin I. Angiotensin I is converted almost immediately to angiotensin II by angiotensin-converting enzyme (ACE). This converting enzyme is located predominantly in the endothelial tissue of the lung. In addition to its direct vasoconstrictive activity, angiotensin II enhances the prejunctional release of norepinephrine from adrenergic nerve endings and increases efferent sympathetic nerve activity. Angiotensin II also affects sodium and water homeostasis by directly decreasing tubular reabsorption of sodium, increasing antidiuretic and adrenocorticotropic hormone secretion, and stimulating the secretion of aldosterone. ACE is also a kinase that degrades the vasodilator bradykinin. ACE inhibition blocks angiotensin II formation and delays the breakdown of bradykinin, along with effects on associated prostaglandins.[298]

Although only a few hypertensive patients have high circulating plasma renin levels, 70% of patients will respond to the antihypertensive effects of ACEIs. In patients who have elevated plasma renin levels (e.g., patients with CHF or salt depletion states), ACEI therapy must be initiated at lower doses because these patients are extremely sensitive to the effects of ACEIs, and significant hypotension can follow the administration of a standard starting dose of these drugs.[219]

ACEIs have proved useful in the treatment of hypertension and CHF and have decreased mortality after MI.[299] Captopril was the first active oral agent available, followed by enalapril and lisinopril. ACEIs affect the renin-angiotensin-aldosterone system by inhibiting ACE activity.[300,301] Enalapril is the only ACEI available as an intravenous preparation at this time. Lisinopril offers once-daily dosing, which is convenient for long-term use, but the drug can lead to troublesome hypotension if it is not held on the day of surgery and significant intraoperative blood loss occurs.

All the ACEIs are approved for the treatment of hypertension. Captopril, enalapril, ramipril, and trandolapril all decrease morbidity and mortality in patients with CHF. Captopril is associated with more frequent adverse effects than the other agents, may have a few more drug interactions, and has a dosing regimen of two or three times daily, in contrast to the other ACEIs, which have a dosing regimen of once or twice daily.

Some adverse effects observed with ACEIs are common to the entire class, such as cough, angioedema, acute renal failure, and hyperkalemia. Angioedema, especially after the first dose, affects the face, extremities, lips, mucous membranes, tongue, glottis, or larynx.[302,303] Some occurrences may be fatal.[298,304] Rash and taste disturbances are more frequent with captopril than with the other ACEIs. Because impairment of renal function with an ACEI is usually reversible after withdrawal of the drug, renal function must be monitored, and because hyperkalemia may result from inhibition of aldosterone secretion, serum potassium levels should be monitored. ACEIs can cause fetal morbidity and mortality in humans.

These agents should not be used at all during the second or third trimester of pregnancy.[300] The adverse effect profile of the ACEIs led to the development of angiotensin II receptor blockers (ARBs). Losartan was the first of this newer class of antihypertensive agents, which now includes six other ARBs. Initial trials did not demonstrate ARBs to be superior to ACEIs; however, the addition of these agents during long-term ACEI therapy reduced all-cause mortality and hospitalization in patients with heart failure.[305]

CHOLINERGIC DRUGS

Overview of Mechanisms of Action

Cholinergic drugs act by mimicking, amplifying, or inhibiting the effects of acetylcholine. Cholinergic drugs do not behave exactly like acetylcholine. Their drug action is more specific, with fewer sites affected than with acetylcholine, and their duration of action is generally longer than that of acetylcholine.

Unlike adrenergic pharmacology, in which the clinician can select from a wide choice of drugs, relatively few drugs influence parasympathetic function. In general, drugs that affect the parasympathetic system act in one of four ways:

1. As an agonist by stimulating cholinergic receptors
2. As an antagonist by blocking or inhibiting the actions mediated by the cholinergic receptor
3. By blocking or stimulating receptors on autonomic ganglia
4. By inhibiting the enzymatic breakdown of acetylcholine and thereby causing an increased and prolonged effect

No effective clinically used drugs act through mechanisms affecting the synthesis of acetylcholine (by inhibiting choline acetyltransferase) or by causing indirect release of acetylcholine. Hemicholinium, which interferes with choline uptake and could deplete acetylcholine stores, is not used clinically. Adenosine may inhibit the release of acetylcholine by decreasing the affinity of binding sites for calcium ions; aminoglycoside antibiotics compete with calcium for membrane calcium channels, as does magnesium. Exocytotic release of acetylcholine is inhibited by botulinum toxin. This toxin is sometimes given by local injection to treat strabismus and blepharospasm and has also been used for trigger point injections in pain clinics and to treat age lines. The popularity of off-label uses of this toxin increases the chance of botulism poisoning. In a full-blown botulism poisoning syndrome, fatalities may result from muscle weakness and respiratory failure.

Cholinergic Agonists

Cholinergic agonists have limited therapeutic use because of their detrimental effects. As a result of its diffuse, nonselective actions and rapid hydrolysis by acetylcholinesterase and butyrylcholinesterase, acetylcholine has had almost no therapeutic use other than as an intraocular medication for transient constriction of the pupil during ophthalmic surgery.

Cholinergic agonists in clinical use have been derived from acetylcholine, but they resist hydrolysis by cholinesterase, which permits a useful duration of action. The different systemic effects of the cholinergic agonists are more quantitative than qualitative, although some limited organ selectivity is useful therapeutically, as seen with the synthetic choline esters bethanechol and carbachol. Methacholine and bethanechol are primarily muscarinic agonists; carbachol has significant nicotinic and muscarinic effects. Adding a methyl group to the β position of the choline in acetylcholine produces methacholine, which is almost purely muscarinic and nearly totally resistant to hydrolysis by either of the cholinesterases. An intravenous infusion of methacholine causes hypotension and bradycardia; a small subcutaneous dose causes transient hypotension with a reflex increase in heart rate. The sole current use of methacholine is as a provocative agent in diagnosing hyperreactive airways, thereby making positive use of the deleterious bronchoconstrictive effect of muscarinic agonists. It is administered only by inhalation; serious adverse effects include gastrointestinal symptoms, chest pain, hypotension, loss of consciousness, and complete heart block when the drug is given orally or parenterally. An excessive bronchoconstrictive response should be treated by an inhaled β-agonist; coexisting β blockade is considered a contraindication to the use of methacholine.

The carbamate derivative of methacholine, bethanechol, is occasionally used postoperatively to reinstitute peristaltic activity in the gut or to force the extrusion of urine from an atonic bladder. Bethanechol shows preferential activity at intestinal and urinary receptors relative to cardiac sites, so stimulation of the gastrointestinal tract and bladder is achieved with minimal cardiovascular effects. Bethanechol is usually given orally, but if gastrointestinal function is not adequate to permit absorption of an oral dose, the drug can be given subcutaneously as well.

Carbachol is used topically or intraocularly to constrict the pupil for the long-term treatment of wide-angle glaucoma. When used topically, this drug is often better tolerated than the ophthalmic anticholinesterase agents, and it may be effective in patients resistant to pilocarpine and physostigmine. The rapid pupillary constriction is caused by the combination of ganglionic blockade and muscarinic effects. Another natural alkaloid, pilocarpine, was used to treat glaucoma until the advent of more modern drugs.

Muscarinic Antagonists

Muscarinic antagonists are the active ingredients in some common plants used since antiquity for medicinal and poisonous effects. Despite their age, muscarinic antagonists still represent important drugs in anesthesia and critical care.

Muscarinic antagonists compete with neurally released acetylcholine for access to muscarinic cholinoceptors and block its effects. They also antagonize the actions of muscarinic agonists at noninnervated, muscarinic cholinoceptors. Presynaptic muscarinic receptors on the adrenergic nerve terminal may inhibit release of norepinephrine, and muscarinic antagonists may enhance sympathetic activity. With the exception of quaternary ammonium compounds that do not readily cross the blood-brain barrier and have few CNS actions, no significant specificity of

TABLE 16-9 MUSCARINIC ANTICHOLINERGIC DRUGS

Drug	Duration	Central Nervous System*	Antisialagogue	Heart Rate
Atropine	Short	Stimulation	+	++
Glycopyrrolate	Long	0	++	+
Scopolamine	Short	Sedation	++	0/+

0, No effect; +, mild effect; ++, moderate effect.
* The effects of atropine are limited with the usual clinical doses, but they can be significant in older patients.

action exists among these drugs; they block all muscarinic effects with equal efficacy, although some quantitative differences in effect may be seen (Table 16-9). Research has revealed several subtypes of muscarinic receptors, and agonists and antagonists have been synthesized that bind preferentially to one or another of these subtypes. Pirenzepine preferentially blocks the M_1 receptor, tripitramine shows highest affinity for the M_2 receptor, and darifenacin binds preferentially to the M_3 receptor. The distinctive pharmacology of the various antimuscarinic agents has played a major role in the development of new treatments of overactive bladder disorders. Oxybutynin, tolterodine, darifenacin, solifenacin, and trospium have all been developed to optimize the relief of bladder symptoms while minimizing effects on muscarinic receptors outside the bladder.

Historically, muscarinic antagonists were used to treat peptic ulcer disease, various forms of spastic bowel syndrome, upper respiratory illness, and asthma. However, with the availability of specific histamine (H_2)–blocking drugs and proton pump inhibitors to treat peptic ulcer disease, these uses have markedly decreased. Atropine, once used to treat bronchospasm, was displaced with the introduction of β_2-agonist drugs that did not dry secretions or diminish ciliary motility. Topical use of atropine analogues in ophthalmologic practice to dilate the pupil is still common.

The addition of a muscarinic anticholinergic drug to anesthetic premedication for decreasing secretions and preventing harmful vagal reflexes was mandatory in the era of ether anesthesia, but it is less important with modern inhaled agents. Routine preoperative use of these drugs as antisialagogues continues in some pediatric and otorhinolaryngologic cases or when fiberoptic intubation is planned.

Atropine has a tertiary structure that easily crosses the blood-brain barrier (Fig. 16-17). CNS effects have been seen with the relatively large doses (1 to 2 mg) given to block the adverse muscarinic effects of the anticholinesterase drugs that reverse neuromuscular blockade (see Chapter 35). In contrast, one of the synthetic antimuscarinic drugs, glycopyrrolate, does not cross the blood-brain barrier because of its quaternary structure and has gained popularity for this use. Glycopyrrolate has a longer duration of action than does atropine.

Scopolamine, which resembles the others of this class in peripheral actions, has pronounced CNS effects. It is the active ingredient in most over-the-counter preparations sold as soporifics, and it is effective in preventing motion

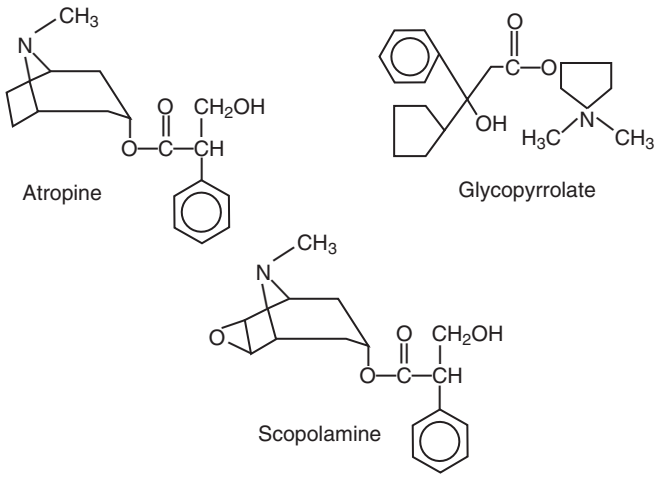

Figure 16-17. Structural formulas of clinically useful antimuscarinic drugs.

sickness. The patch preparation of scopolamine can be used prophylactically for motion sickness and for postoperative nausea and vomiting, but like the oral and parenteral forms, it may be associated with adverse eye, bladder, skin, and cognitive and psychological effects.[306,307]

The development of ipratropium reestablished antimuscarinic drugs for the treatment of asthma and bronchospastic disorders.[308] Although ipratropium is structurally similar to atropine and has essentially the same effects when administered parenterally, an important difference is that ipratropium is a quaternary ammonium compound. It is very poorly absorbed when inhaled and has few extrapulmonary effects, even in extremely large doses by this route. Ninety percent of the inhaled drug is swallowed, but only 1% of the total dose is absorbed systemically.

When administered to normal volunteers, ipratropium provides almost complete protection against bronchospasm induced by a variety of provocative agents. However, in asthmatic patients, results vary. The bronchospastic effects of some agents, such as methacholine or sulfur dioxide, are completely blocked, whereas ipratropium has little effect on leukotriene-induced bronchoconstriction. The onset of bronchodilation is slow, and the maximum effect is less than that seen with β-agonists. Unlike atropine, ipratropium has no negative effect on ciliary clearance. In general, the therapeutic effect of antimuscarinics, including ipratropium, is greater in patients with chronic obstructive pulmonary disease than in asthmatic patients.[305] Ipratropium is supplied as a metered-dose inhaler that dispenses 18 μg per puff. Two puffs are taken orally four times each day. Maximum bronchodilation occurs in 30 to 90 minutes and may last 4 hours.

The toxic effects of muscarinic antagonists come from the blockade of muscarinic cholinoceptors in the periphery and the CNS. The peripheral effects (e.g., dry mouth) may be irritating but are not life-threatening in healthy adults. However, children depend more than adults on sweating for thermoregulation and can become dangerously hyperthermic when they are given these agents. Moreover, older individuals may not be able to

tolerate the cardiac, ocular, or urinary effects of muscarinic blockade.

Increasing doses of atropine or scopolamine cause greater distortions of mentation that progress from thought disorders to hallucinations, delusions, delirium, and severe psychoses. These effects are reversible, but the mental dysfunction can persist for weeks. Small doses of atropine (0.05 mg) can evoke bradycardia, a finding that has led some clinicians to increase the dose in children. It was thought that a CNS effect of atropine could be responsible, but the time course and the fact that bradycardia occurred in animals without vagal function cast doubt on this explanation. Whether this paradoxical bradycardia is a central or peripheral effect, or both, and the role of muscarinic subtypes are still subjects of debate.[309]

Atropine or scopolamine toxicity (the central anticholinergic syndrome) has been treated for decades with the naturally occurring alkaloid physostigmine, which is an anticholinesterase that penetrates the blood-brain barrier. Use of this drug in doses of 1 to 2 mg given intravenously to treat the postoperative CNS effects of intravenous atropine or scopolamine has been successful. Physostigmine may also reverse the CNS effects of other compounds with anticholinergic activity, including the tricyclic antidepressants, several major tranquilizers, and antihistamine drugs. Physostigmine may also antagonize the sedative effects of the benzodiazepines, but a specific benzodiazepine antagonist, flumazenil, has supplanted physostigmine for this use.[310] Physostigmine must be administered with care because of its potentially lethal nicotinic effects, which are not prevented by the muscarinic antagonists, and because its half-life rarely matches that of the intoxicant.

Cholinesterase Inhibitors

Anticholinesterase drugs are a common means of producing sustained, systemic cholinergic agonism. These drugs are used to reverse neuromuscular blockade and to treat myasthenia gravis and certain tachyarrhythmias.

Three chemical classes of compounds are used as cholinesterase inhibitors: carbamates, organophosphates, and quaternary ammonium alcohols. Physostigmine, neostigmine, and pyridostigmine are carbamates, whereas edrophonium is a quaternary ammonium alcohol. The cholinesterase enzyme is inhibited as long as the esteratic site is bound to an acetate, carbamate, or phosphate. Carbamate and phosphate bonds are much more resistant to attack by hydroxyl groups than are acetate bonds. The acetylated form lasts for only microseconds, whereas the carbamylated form lasts for 15 to 20 minutes. Organophosphates include diisopropyl fluorophosphate, parathion, malathion, soman, sarin, VX, and a variety of other compounds used as insecticides. Although the toxicity of the organophosphate insecticides is primarily related to their anticholinesterase activity, the mechanism of this effect is different from the clinically used anticholinesterase drugs (see Chapter 83). The organophosphates produce irreversible enzyme inhibition and have CNS effects. Consequently, treatment of organophosphate insecticide poisoning relies on chemical compounds capable of displacing the insecticides from the enzyme to reactivate the cholinesterase activity. The best documented of these chemicals is pralidoxime (2-PAM). Physostigmine and most of the organophosphates are not quaternary ammonium compounds and have major effects on cholinergic functions in the CNS (see Chapter 83).

Because these compounds can increase the effect and duration of neurally released acetylcholine, they are useful in situations in which such release is deficient, such as myasthenia gravis. Anticholinesterase drugs are occasionally used to stimulate intestinal function and are applied topically in the eye as a miotic. An irreversible organophosphate anticholinesterase that is used clinically is echothiophate iodide, which is available as topical drops for the treatment of glaucoma. Its major advantage over other topical agents is its prolonged duration of action. Because this chemical also inactivates plasma cholinesterase, it may prolong the action of succinylcholine. Although prudence dictates discontinuation of echothiophate for 1 week before surgery, numerous case reports exist of successful anesthesia performed under emergency conditions and without discontinuation of echothiophate.

GANGLIONIC DRUGS

Ganglionic Agonists

Ganglionic agonists are essential for analyzing the mechanism of ganglionic function, but they have no therapeutic use. Nicotine is the classic ganglionic agonist, and its effects have been well described.

Parasympathetic drugs stimulate ganglia, but this action is usually masked by the other parasympathomimetic effects of these drugs. Experimentally, relatively large doses of acetylcholine administered intravenously after blockade of muscarinic receptors by atropine cause ganglionic stimulation and release of epinephrine by the adrenal medulla.

Ganglionic Antagonists

Ganglionic antagonists were the first effective therapy for the management of hypertension and were used extensively during the 1950s and 1960s. However, because of interference with transmission through sympathetic and parasympathetic ganglia, their antihypertensive action was accompanied by numerous undesirable effects. Hexamethonium, the prototypic drug of this class, has minimal neuromuscular and muscarinic activity. The systemic effects of ganglionic blockade are determined by the resting tone of a specific body system before the initiation of ganglionic blockade (see Table 16-2). With the disappearance of trimethaphan from clinical use, these drugs are largely of historical interest.

AUTONOMIC DYSFUNCTION

ASSESSMENT OF AUTONOMIC FUNCTION

The increased operative risk for patients with autonomic dysfunction that may occur with aging and diabetes[311] makes the diagnosis of autonomic neuropathy extremely important. A panel of five tests of cardiovascular function was developed to evaluate autonomic function in

diabetic patients (see Chapter 39).[312] The tests include heart rate responses to the Valsalva maneuver, standing up, and deep breathing and blood pressure responses to standing up and sustained handgrip. The tests involving changes in heart rate measure injury to the parasympathetic system, which precedes changes in the measures of blood pressure that reflect sympathetic injury. *Early autonomic dysfunction* is defined as a single abnormal or two borderline-abnormal results on the tests involving changes in heart rate. *Definite involvement* is diagnosed when the results are abnormal on two of the tests of changes in heart rate. *Severe dysfunction* is defined as abnormality in blood pressure assessments. Application of these standards requires that the investigator understand the proper techniques for performing the five tests and the expected results in patients without autonomic neuropathy (Table 16-10). The simplicity and effectiveness of this clinical assessment led to its use in the evaluation of patients with nondiabetic causes of autonomic dysfunction as well. The validity of the tests in the "nonstandardized" setting of a preoperative clinic was also demonstrated, a finding suggesting that the tests can be used in preoperative screening for surgical patients at risk for autonomic dysfunction.[313]

TABLE 16-10 **NONINVASIVE TESTS FOR ASSESSING THE AUTONOMIC NERVOUS SYSTEM**

Clinical Examination	Technique	Normal Value
Parasympathetic		
HR response to a Valsalva maneuver	The seated subject blows into a mouthpiece (while maintaining a pressure of 40 mm Hg) for 15 sec; the Valsalva ratio is the ratio of the longest R-R interval (which comes shortly after release) to the shortest R-R interval (which occurs during the maneuver)	Ratio of >1.21
HR response to standing	HR is measured as the subject moves from a resting supine position to standing; a normal tachycardic response is maximal around the fifteenth beat after rising; a relative bradycardia follows that is most marked around the thirtieth beat after standing; the response to standing is expressed as a 30:15 ratio and is the ratio of the longest R-R interval around the thirtieth beat to the shortest R-R interval around the fifteenth beat	Ratio of >1.04
HR response to deep breathing	The subject takes six deep breaths in 1 min; the maximum and minimum heart rates during each cycle are measured, and the mean of the differences (maximum HR – minimum HR) during three successive breathing cycles is taken as the maximum-minimum HR	Mean difference >15 beats/min
Sympathetic		
BP response to standing	The subject moves from resting supine to standing, and standing SBP is subtracted from supine SBP	Difference <10 mm Hg
BP response to sustained handgrip	The subject maintains a handgrip of 30% of the maximum handgrip squeeze for up to 5 min; BP is measured every minute, and the initial DBP is subtracted from the DBP just before release	Difference >16 mm Hg

BP, Blood pressure; *DBP,* diastolic blood pressure; *HR,* heart rate; *SBP,* systolic blood pressure.

PLASMA CATECHOLAMINES

Accurate and sensitive techniques for measuring plasma catecholamines have existed since the 1970s, but interpretation of the data that they yield has been controversial. Normal plasma epinephrine and norepinephrine levels are typically in the range of 100 to 400 pg/mL, and they can increase sixfold or more with stress.

Plasma concentrations of epinephrine, which reflect adrenal medullary activity if not overall sympathetic activity, are labile. Significant isolated adrenal medullary secretion results from certain stressful situations, such as public speaking.[5] Moreover, venous samples may reflect epinephrine kinetics in the organ being sampled rather than in the whole body, so arterial samples may be more reliable.

The significance of the norepinephrine concentration in plasma is even more controversial. Even though the adrenal medulla secretes some norepinephrine, levels in plasma generally reflect spillover from sympathetic stimulation that was not taken up again by the nerve terminal. Although reuptake may be tissue specific and markedly influenced by alterations in physiology or diseases, spillover in humans is 10% to 20% of the synthesis rate of norepinephrine at baseline and may be greatly enhanced in periods of sympathetic activation.[314] The most compelling argument for the use of plasma norepinephrine as a marker of sympathetic activity comes from animal studies in which plasma norepinephrine levels directly mirrored nerve stimulation. Many important studies correlated increases in plasma catecholamines with acute and chronic stress, which led to the concept of stress-free anesthesia. A striking relationship between mortality rates for patients with CHF and elevated plasma norepinephrine levels resulted in the use of β-adrenergic antagonists to treat ventricular dysfunction.[315,316]

The development of experimental radiotracer techniques to assess the in vivo kinetics of catecholamines provided additional information that is of clinical importance, particularly in relation to regional kinetics. For example, studies relying only on arterial and venous catecholamines suggested that the hepatomesenteric bed contributes significantly to total-body clearance of catecholamines but only minimally (<8%) to spillover. However, later studies of regional norepinephrine kinetics demonstrated that release of norepinephrine from the gut (≤25% of the total body) was largely obscured by efficient

extraction (>80%) in the liver. Similarly, selective elevations in release of norepinephrine from the heart, which may be associated with ischemia, early onset of CHF, and tachyarrhythmias, may not be apparent in measured arterial or venous levels.[317] Observations involving regional spillover led to the realization that although stress may activate a generalized sympathetic response, there may be different patterns contingent on the stimulus. It is possible that the lack of consistency of plasma norepinephrine levels in the presence of clinically significant sympathetic activation may be a function of the measurement technique or the particular stressor.

On balance, given the effects of age, posture, and hydration, small changes in plasma catecholamine levels correlate poorly with hemodynamic changes and merit cautious interpretation, whereas significant increases (>1000 pg/mL) in levels are good markers of activation of the sympathetic nervous system.

CLINICAL SYNDROMES

Surgical Stress Response

Surgical stress, particularly that associated with major operations, results in profound metabolic and endocrine responses. The combination of autonomic, hormonal, and catabolic changes that accompany surgery has been called the surgical stress response.[318] Despite widespread clinical intuition that attenuation of the stress response is beneficial, there has been long-standing debate about whether such a strategy affects outcome. Three separate lines of evidence suggest that attenuation of the surgical stress response can lead to improved outcomes. In a series of studies, interruption of the sympathetic response to surgery markedly reduced surgical stress intraoperatively and postoperatively. The use of continuous thoracic epidural infusions of local anesthetics minimized the rise in plasma catecholamines, cortisol, and glucagon and improved outcomes. Improved outcome was independent of the patient's level of pain because metabolic and endocrine responses to surgery were not similarly reduced in patients receiving other methods of pain relief, including nonsteroidal anti inflammatory drugs and opioids.[319] Continuation of epidural infusions well into the postoperative period was regarded as essential to improving outcome. Inflammatory and immunologic responses, which are necessary for infection control and wound healing, appear to be unaffected. With the use of similar techniques and other stress-reducing maneuvers, faster and more complete recovery was achieved in older patients undergoing colon resection.[320]

A separate line of evidence supporting the hypothesis that long-term attenuation of the stress response alters surgical outcomes comes from the pediatric literature. When neonates with complex congenital heart disease underwent cardiac surgery, those who received high-dose sufentanil infusions intraoperatively and for the first 24 hours postoperatively to reduce the stress response had lower β-endorphin, norepinephrine, epinephrine, glucagon, aldosterone, and cortisol levels than did controls.[318] The mortality rate in the high-dose opiate group was significantly lower than in the study or historical controls, a finding suggesting that anesthetic techniques can have profound effects on the metabolic and endocrine responses to surgery and that effective management of these reflexes can alter outcomes.

A third line of evidence involves results from the multicenter study of the Perioperative Ischemia Research Group (see the earlier discussion of perioperative β blockade).[221] The ability to alter overall survival at 2 years with a perioperative regimen of β blockade provided compelling evidence of the benefit of attenuating the stress response,[222,223,225] and it changed clinical practice in patients at risk for cardiac morbidity. Similar results were achieved when perioperative α_2-agonists were given to "at-risk" patients as well.[321] Presumably, the decrease in sympathetic tone that accompanied administration of the β-blocker or the α_2-agonist suppressed the stress response and improved outcomes.

Diabetes Mellitus

Diabetic autonomic neuropathy is the most common form of autonomic neuropathy and the most extensively investigated (see Chapter 39). It occurs in 20% to 40% of all insulin-dependent diabetic patients. The symptoms associated with diabetic autonomic neuropathy confer an increased risk during anesthesia and surgery by direct and secondary mechanisms. Common manifestations of diabetic autonomic neuropathy include impotence, postural hypotension, gastroparesis, diarrhea, and sweating abnormalities. Early small-fiber damage is revealed by loss or impairment of vagally controlled normal heart rate variability, decreased peripheral sympathetic tone with a subsequent increase in blood flow, and diminished sweating. In a diabetic neuropathic foot, the senses of pain and temperature are lost before touch or vibration is affected. With sympathetic denervation, the sympathetic nerves normally found supplying small arterioles are entirely absent or are abnormally distant from their effector sites. When impotence or diarrhea is the sole manifestation, little effect is seen on survival; however, with postural hypotension or gastroparesis, 5-year mortality rates are greater than 50%.

Most clinicians recognize that diabetic patients with autonomic neuropathy may be at additional risk during general anesthesia.[322] Gastroparesis is probably caused by vagal degeneration and is of clinical relevance because awake or rapid-sequence intubation may be required. Systemic injury to the vasa vasorum in patients with postural hypotension increases the risk for hemodynamic instability and cardiovascular collapse in the perioperative period. Mechanisms that maintain normal standing blood pressure are altered, and normal precapillary vasoconstriction in the foot on standing may be diminished. Baroreceptors in the carotid sinus and aortic arch are compromised by diabetic neuropathy. Diabetic patients with orthostatic hypotension usually have lower norepinephrine levels.

Even in seemingly minor surgery, diabetic autonomic neuropathy can lead to significant complications.

Diabetic patients with autonomic neuropathy may have a significantly greater decline in blood pressure with induction and a greater need for vasopressors than do diabetic patients without autonomic dysfunction.[322] Page

and Watkins reported five cases of unexpected cardiorespiratory arrest in young diabetic patients, all of whom had symptoms of autonomic neuropathy.[323] In a large, prospective study of diabetic autonomic neuropathy involving use of the five evocative clinical tests discussed earlier, parasympathetic dysfunction preceded sympathetic failure in 96% of the patients.[324] This battery of autonomic tests identifies patients with autonomic neuropathy and is highly predictive of mortality and perioperative risk.[311]

AUTONOMIC CHANGES WITH AGING

Aging is associated with alterations in vascular reactivity manifested clinically as exaggerated changes in blood pressure—hypertension and orthostatic hypotension (see Chapter 80). Orthostatic hypotension is quite common (≈20%) in older persons and may result largely from diminished baroreceptor responsiveness. Heart rate responses to changes in blood pressure, the Valsalva maneuver, and the respiratory cycle are blunted with aging.[325]

Resting and exercise-induced norepinephrine levels increase with age in healthy subjects (by ≈13% per decade), in part because of decreased clearance.[326] Previously a matter of controversy, it now appears that besides the well-documented reduction in vagal function associated with aging,[327] the primary autonomic defect in aging is an impairment in reuptake of norepinephrine, perhaps as a function of decreased nerve density. Although no apparent age-dependent decrement in nerve firing rates from sympathetic efferents in skeletal muscle occurs,[328] kinetic studies reveal selective and dramatic increases in cardiac norepinephrine spillover attributable to the decreased reuptake in older patients subjected to mental stress or exercise. [314] This situation can precipitate clinical complications (i.e., arrhythmogenesis and sudden cardiac death) in patients with cardiac disease. However, end-organ responsiveness is blunted by compensatory down-regulation of β_1 adrenoreceptors (i.e., decreased receptor density and affinity) and uncoupling of β_2 adrenoreceptors through decreased G_s activity.[329] Despite increased cardiac spillover, cardiac oxygen consumption is not altered.[330]

Attenuation of presynaptic α_2-adrenoreceptor–mediated inhibition of neuronal norepinephrine release also accounts for the increased norepinephrine levels observed with age.[331-333] Reduced postsynaptic α-adrenoreceptor activity decreases contractile responses and further attenuates vasoconstrictor tone. In a seemingly vicious cycle, the increase in circulating norepinephrine levels is associated with down-regulation of platelet α_2-adrenoreceptor density and responsiveness. The loss of adrenergic control through the reduction of α_2- and β-receptor–mediated responses with age causes a decrease in the sympathetic nervous system's ability to maintain cardiovascular homeostasis, thus implying a relationship with or an explanation for the increased incidence of cardiovascular disorders such as CHF in older adults.

AUTONOMIC CHANGES IN SPINAL CORD TRANSECTION

The most drastic alteration in the ANS that an anesthesiologist may encounter is in patients with complete spinal cord transection (see Chapters 52, 70, and 81). Spinal cord transection affects motor and sensory function, and it may also result in profound changes in autonomic activity that can alter anesthetic care. Spinal cord injuries or transection can cause various degrees of autonomic dysfunction, depending on the site, extent, and timing of the lesion. Many autonomic reflexes are inhibited by the supraspinal feedback that is lost after spinal cord transection. Thus, in paraplegic patients, small stimuli can evoke exaggerated sympathetic discharges.

In patients with cervical spinal cord transection, sympathetic and parasympathetic outflow is detached from central control mechanisms. In addition to the expected motor and sensory changes, profound abnormalities alter the cardiovascular, thermoregulatory, gastrointestinal, and urinary systems. The autonomic consequences of transection are not always apparent because the distal portion of the spinal cord may retain some function and thereby result in unanticipated autonomic abnormalities.

Fundamental differences exist between the acute and chronic effects of spinal cord transection. Initially, a transient state of decreased excitability occurs. This phenomenon, known as spinal shock, usually takes place immediately after the lesion and may last for days to weeks. In these patients, the periphery is generally atonic, and the peripheral vascular bed is dilated. In patients with high thoracic lesions who have sustained recent injury, basal supine blood pressure is usually low and is accompanied by plasma catecholamine levels that are approximately 35% of normal.[334] Patients with recent low spinal injuries may exhibit compensatory tachycardia from intact parts of the ANS.

Patients with chronic high spinal lesions may fail to respond to hypovolemia with an increased heart rate and may exhibit bradycardia. The only intact efferent component of the baroreflex pathways in quadriplegic patients is the vagus. Bradycardia occurs with changes in position and with Valsalva maneuvers or increased intrathoracic pressure.[335]

One aspect of care that is frequently overlooked is the effect of tracheal suctioning on patients with high spinal transection. Given that many of these patients depend on artificial respiration because of their respiratory muscle paralysis, unopposed vagal stimuli may contribute to profound bradycardia. This vagal response is accentuated by hypoxemia.

Because the sympathetic nervous system may be dysfunctional in these patients, the renin-angiotensin-aldosterone system compensates for the maintenance of blood pressure. Patients with spinal cord transection may be exquisitely sensitive to ACEIs, even with modest changes in intravascular volume or posture. The release of renin may be independent of sympathetic stimulation and may be caused by the renal baroreceptor stimulation that accompanies the decline in renal perfusion pressure.

Although pressure stimuli above the lesion do not usually change arterial blood pressure, the phenomenon of autonomic dysreflexia can occur with stimulation below the lesion. Bladder or bowel distention can elicit the so-called mass reflex. This autonomic reflex includes a dramatic rise in blood pressure, a marked reduction in flow to the periphery, and flushing and sweating in areas

above the lesion. In addition, contraction of the bladder and rectum, skeletal muscle spasms, and penile erection often occur.

The heart rate may decline as a reflex. Surprisingly, evidence from microneurography studies indicates only a modest rise in sympathetic nerve activity during activation of the mass reflex,[336] as well as a modest increase in plasma norepinephrine levels. Speculation has arisen that the exaggerated blood pressure response may be caused by supersensitivity of adrenoreceptors. As anticipated, quadriplegic patients exhibit an increase in sensitivity to exogenously administered pressors.[334] Blood pressure in quadriplegic patients may increase dramatically in response to the exogenous administration of angiotensin and to catecholamines. Impairment of the descending inhibitory reflex pathways that are activated during hypertension may contribute to the supersensitivity. This hypothesis is supported by the finding that sensitivity is rarely increased when the lesion is below T5. These patients with lower spinal lesions, even those patients with long-standing quadriplegia, apparently have a normal level of adrenoceptors.

Management of autonomic dysreflexia is of clinical importance. Although the anesthesiologist may be tempted to opt for minimal anesthesia in a patient without sensory or motor function, significant visceral reflexes can be evoked. The anesthesiologist may use spinal anesthesia, general anesthesia, or a vasodilator such as nitroprusside or nitroglycerin to attenuate this reflex, even if pain is not appreciated. There has been some enthusiasm for using clonidine prophylactically to diminish this response.

An additional problem arising from the autonomic denervation of spinal cord transection is thermogenesis. In these patients, hypothermia may result from cutaneous vasodilation and the inability to shiver. Similarly, hyperthermia can occur because the normal sweating mechanism is impaired. It is therefore important to monitor temperature assiduously in these patients during the course of anesthesia.

NEW CONCEPTS IN AUTONOMIC ACTIVITY

GENETIC CONTRIBUTORS TO AUTONOMIC FUNCTION AND DRUG RESPONSIVENESS

As this chapter is being written, an explosion of scientific research is taking place to identify single nucleotide polymorphisms (SNPs) in β-adrenergic receptor genes and to relate them to autonomic pathophysiology.[337] In general, these studies are statistical, associating the incidence of SNPs with disease entities, including hypertension, asthma, CHF, and arrhythmias. However, in some instances, the underlying biologic links have been more intensively explored, and therapeutic implications are beginning to emerge. A U.S. Food and Drug Administration conference on genomics summarized the first recommendations for genetic testing before initiating drug therapies. At this time, the recommendations are limited to chemotherapeutic agents, and work with drugs affecting the ANS is labeled as purely informational.

Although the association between asthma susceptibility and β-adrenergic polymorphisms in the general population has not been confirmed, asthma phenotypes, including severity of asthma and bronchial hyperresponsiveness, have been associated with β_2-receptor polymorphisms. Most notably, changes in the coding region may alter response to short-acting and long-acting agonists, a finding suggesting the possibility of a different therapeutic response contingent upon the underlying genetic makeup. Similarly, increasing interest has been shown in the extent to which adrenergic receptor polymorphisms play a role in hypertension, heart failure,[338] sudden death, and response to β-adrenergic antagonists. Whereas intensive studies of β-receptor polymorphisms have led to a greater understanding of important clinical syndromes such as postural tachycardia syndrome[339] and sudden death, specific changes in clinical management have lagged considerably. Nowhere has this been more evident than in heart failure, in which receptor function has been studied for decades[340] but for which investigators remain unable to translate pharmacogenetic insights into therapeutic recommendations.[341]

More recently, however, emerging data have suggested that differences in the underlying signaling and recovery mechanism beyond receptors may play a role in autonomic pathophysiology.[342] It has been proposed that variability in the genetics of the arrestin system, which not only participates in the regeneration of adrenergic function but also can act as a second messenger, could account for differences in therapeutic efficacy of various cardiac drugs.

Therefore, although the ANS could fairly be called primitive (it is largely preserved across all mammalian species), its incredible complexity leaves it incompletely understood. As the understanding of the genetic determinants of autonomic activity and of the functional and cellular interactions of the ANS grows, the ability to interrupt or augment various autonomic effects with greater and greater precision will increase. This, in turn, will allow for improvements in both the long-term health and the acute perioperative safety of our patients.

Chapter 17

Cerebral Physiology and the Effects of Anesthetic Drugs

PIYUSH M. PATEL • JOHN C. DRUMMOND • BRIAN P. LEMKUIL

Key Points

- The brain has a high metabolic rate and receives approximately 15% of cardiac output. Under normal circumstances, cerebral blood flow (CBF) is approximately 50 mL/100 g/min. Gray matter receives 80% and white matter receives 20% of this blood flow.
- Approximately 60% of the brain's energy consumption supports electrophysiologic function. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities.
- CBF is tightly coupled to local cerebral metabolism. When cerebral activity in a particular region of the brain increases, a corresponding increase in blood flow to that region takes place. Conversely, suppression of cerebral metabolism leads to a reduction in blood flow.
- CBF is autoregulated and remains constant over a mean arterial pressure (MAP) range estimated at 65 to 150 mm Hg, given normal venous pressure. Appreciable intersubject variability exists. CBF becomes pressure passive when MAP is either less than the lower limit or more than the upper limit of autoregulation.
- CBF is also under chemical regulation. CBF varies directly with arterial carbon dioxide tension in the arterial partial pressure of carbon dioxide ($Paco_2$) range of 25 to 70 mm Hg. When arterial partial pressure of oxygen (Pao_2) decreases to less than 60 mm Hg, CBF dramatically increases. Reductions in body temperature influence CBF primarily by suppression of cerebral metabolism.
- Systemic vasodilators (e.g., nitroglycerin, nitroprusside, hydralazine, calcium channel blockers) vasodilate the cerebral circulation and can, depending on the MAP, increase CBF. Vasopressors such as phenylephrine, norepinephrine, ephedrine, and dopamine do not have direct effects on the cerebral circulation. Their effect on CBF is via their effect on arterial blood pressure. When the MAP is less than the lower limit of autoregulation, vasopressors increase the MAP and thereby increase CBF. If the MAP is within the limits of autoregulation, then vasopressor-induced increases in systemic pressure have little effect on CBF.
- All volatile anesthetics suppress the cerebral metabolic rate (CMR) and, with the exception of halothane, can produce burst suppression of the electroencephalogram. At that level, the CMR is reduced by approximately 60%. Volatile anesthetics have dose-dependent effects on CBF. In doses less than the minimal alveolar concentration (MAC), CBF is modestly decreased. In doses larger than 1 MAC, direct cerebral vasodilation results in an increase in CBF and cerebral blood volume.
- Barbiturates, etomidate, and propofol decrease the CMR and can produce burst suppression of the electroencephalogram. At that level, the CMR is reduced by approximately 60%. Because blood flow and metabolism coupling are preserved, CBF is decreased. Opiates and benzodiazepines effect minor decreases in CBF and CMR. In contrast, ketamine can significantly increase the CMR with a corresponding increase in blood flow.
- Brain stores of oxygen and substrates are limited, and the brain is extremely sensitive to decreases in CBF. Severe decreases in CBF (less than 6 to 10 mL/100 g/min) lead to rapid neuronal death. Ischemic injury is characterized by early excitotoxicity and delayed apoptosis.

KEY POINTS—cont'd

- Barbiturates, propofol, ketamine, volatile anesthetics, and xenon have neuroprotective efficacy and can reduce ischemic cerebral injury in experimental models. This anesthetic neuroprotection is sustained only when the severity of the ischemic insult is mild; with moderate-to-severe injury, long-term neuroprotection is not achieved. The neuroprotective efficacy of anesthetics in humans is limited. Administration of etomidate can decrease regional blood flow, which can exacerbate ischemic brain injury.

This chapter reviews the effects of anesthetic drugs and techniques on cerebral physiology, in particular, their effects on cerebral blood flow (CBF) and metabolism. The final section presents a brief discussion of pathophysiologic states, including cerebral ischemia and cerebral protection. Prime attention is directed to the immediate relevance of the rationale for use of the anesthetic and the intensive care management of patients with intracranial pathologic conditions. Chapter 70 presents the clinical management of these patients in detail. Neurologic monitoring, including the effects of anesthetics on the electroencephalogram (EEG) and evoked responses, is reviewed in Chapter 49.

ANATOMY OF THE CEREBRAL CIRCULATION

The arterial blood supply to the brain is composed of paired right and left internal carotid arteries, which give rise to the anterior circulation, and paired right and left vertebral arteries, which give rise to the posterior circulation. The connection of the two vertebral arteries forms the basilar artery. The internal carotid arteries and the basilar artery connect to form a vascular loop called the circle of Willis that permits collateral circulation between both the right and left and the anterior and posterior perfusing arteries. Three paired arteries that originate from the circle of Willis perfuse the brain: anterior, middle, and posterior cerebral arteries. The posterior communicating arteries and the anterior communicating artery complete the loop. The anterior and the posterior circulations contribute equally to the circle of Willis.

Under normal circumstances, blood from the anterior and posterior circulations does not admix because the pressures in the two systems are equal. Similarly, side-to-side admixing of blood across the circle is limited. The vessels that originate from the circle provide blood flow to well-delineated regions of the brain. However, in pathologic circumstances during which occlusion of one of the arterial branches occurs, the circle of Willis can act as an anteroposterior or side-to-side shunt to increase collateral blood flow to the region of the brain with reduced perfusion.

A complete circle of Willis is shown in Figure 17-1, *A*. However, substantial variability exists in the anatomy of the circle of Willis, and a significant proportion of individuals may have an incomplete circular loop.[1] The variations in the circle and their prevalence are shown in Figure 17-1, *B*.

Three sets of veins drain blood from the brain. The superficial cortical veins are within the pia mater on the brain surface. Deep cortical veins drain the deeper structures of the brain. These veins drain into dural sinuses, of which the superior and inferior sagittal sinuses and the straight, transverse and sigmoid sinuses are the major dural sinuses. These ultimately drain into the right and left internal jugular veins. A schematic representation of the cerebral venous circulation is shown in Figure 17-1, *C*.

REGULATION OF CEREBRAL BLOOD FLOW

Anesthetic drugs cause dose-related and reversible alterations in many aspects of cerebral physiology, including CBF, cerebral metabolic rate (CMR), and electrophysiologic function (EEG, evoked responses). The effects of anesthetic drugs and techniques have the potential to adversely affect the diseased brain and are thus of clinical importance in patients with neurosurgical disease. Conversely, the effects of general anesthesia on CBF and CMR can be altered to improve both the surgical course and the clinical outcome of patients with neurologic disorders.

The adult human brain weighs approximately 1350 g and therefore represents approximately 2% of total body weight. However, it receives 12% to 15% of cardiac output. This high flow rate is a reflection of the brain's high metabolic rate. At rest, the brain consumes oxygen at an average rate of approximately 3.5 mL of oxygen per 100 g of brain tissue per minute. Whole-brain oxygen consumption (50 mL/min) represents approximately 20% of total body oxygen utilization. Normal values for CBF, CMR, and other physiologic variables are provided in Box 17-1.

Approximately 60% of the brain's energy consumption supports electrophysiologic function. The depolarization-repolarization activity that occurs, reflected in the EEG, requires expenditure of energy for the maintenance and restoration of ionic gradients and for the synthesis, transport, and reuptake of neurotransmitters. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities. Local CBF and CMR within the brain are very heterogeneous, and both are approximately four times greater in gray matter than in white matter. The cell population of the brain is also heterogeneous in its oxygen requirements. Glial cells make up approximately one half of the brain's volume and require less energy than neurons. Besides providing a physically supportive latticework for the brain, glial cells are important in the reuptake of neurotransmitters, in the delivery

and removal of metabolic substrates and wastes, and in blood-brain barrier (BBB) function.

The brain's substantial demand for substrate must be met by adequate delivery of oxygen and glucose. However, the space constraints imposed by the noncompliant cranium and meninges require that blood flow not be excessive. Not surprisingly, elaborate mechanisms regulate CBF. These mechanisms, which include chemical, myogenic, and neurogenic factors, are listed in Table 17-1.

CHEMICAL REGULATION OF CEREBRAL BLOOD FLOW

Several factors, including changes in CMR, arterial partial pressure of carbon dioxide ($Paco_2$), and arterial partial

BOX 17-1 *Normal Cerebral Physiologic Values*

CBF	
Global	45-55 mL/100 g/min

pressure of oxygen (Pao_2), cause alterations in the cerebral biochemical environment that result in adjustments in CBF.

Cerebral Metabolic Rate

Increased neuronal activity results in increased local brain metabolism, and this increase in the CMR is associated with a proportional change in CBF that is referred to as *flow-metabolism coupling*. The traditional view of this coupling is that it is a positive feedback mechanism wherein increased neuronal activity results in a demand for energy; this demand is met by an increase in CBF. More recent data indicate that coupling is based on a feed-forward mechanism wherein neuronal activity directly increases CBF, thereby increasing energy supply.[2] Although the precise mechanisms that mediate flow-metabolism coupling have not been defined, the data available implicate local by-products of metabolism (potassium ion [K^+], hydrogen ion [H^+], lactate, adenosine, and adenosine triphosphate [ATP]). Increased synaptic activity with the attendant release of glutamate leads to the downstream generation of a variety of mediators that affect vascular tone (Fig. 17-2). Glutamate, released with increased neuronal activity, results in the synthesis and release of nitric oxide (NO), a potent cerebral vasodilator that plays an important role in coupling of flow and metabolism. Glia play an important role in flow-metabolism coupling, and their processes make contact with neurons. These processes may serve as conduits for the coupling of increased neuronal activity to increases in blood flow. Glutamate activation of metabotropic glutamate receptors (mGluR) in astrocytes leads to arachidonic acid (AA) metabolism and the subsequent generation of prostaglandins and epoxyeicosatrienoic acids (EETs). Local by-products of metabolism (K^+, H^+, lactate, adenosine, and ATP) can also directly modulate vascular tone. Oxygen modulates the relative contribution of these pathways, and in the setting of reduced oxygen tension at the tissue level, the release of adenosine can contribute to vascular dilation. The net result therefore on vascular tone is determined by the relative contribution of multiple signaling pathways. In addition, nerves that innervate cerebral vessels release peptide neurotransmitters such as vasoactive intestinal peptide (VIP), substance P, cholecystokinin, somatostatin, and calcitonin gene–related peptide. These neurotransmitters may also potentially be involved in neurovascular coupling. Flow-metabolism coupling within the brain is a complex physiologic process that is regulated, not by a single mechanism, but by a combination of metabolic, glial, neural, and vascular factors.

CMR is influenced by several phenomena in the neurosurgical environment, including the functional state of the nervous system, anesthetic drugs, and temperature.

Functional State. CMR decreases during sleep and increases during sensory stimulation, mental tasks, or arousal of any cause. During epileptic activity, increases in the CMR may be extreme, whereas regionally after brain injury and globally with coma, the CMR may be substantially reduced.

Anesthetic Drugs. The effect of individual anesthetic drugs on the CMR is presented in greater detail in the second section of this chapter. In general, anesthetic drugs suppress the CMR, with the exception of ketamine and nitrous oxide (N_2O). The component of the CMR on which they act is electrophysiologic function. With several anesthetics, including barbiturates, isoflurane, sevoflurane, desflurane, propofol, and etomidate, increasing plasma concentrations cause progressive suppression of EEG activity and a concomitant reduction in the CMR. However, increasing the plasma level beyond what is required to first achieve suppression of the EEG results in no further depression of the CMR. The component of the CMR required for the maintenance of cellular integrity, the "housekeeping" component, is unaltered by anesthetic drugs (Fig. 17-3).

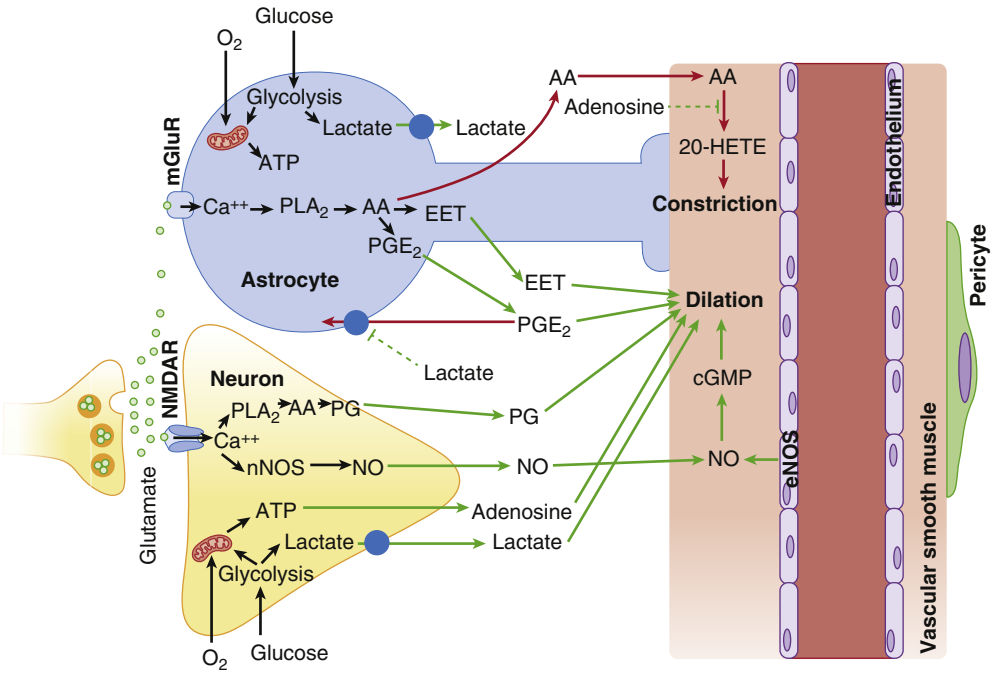

Figure 17-2. Cerebral flow-metabolism coupling. Synaptic activity leads to glutamate release, activation of glutamatergic receptors, and calcium entry in neurons. This results in a release of arachidonic acid (AA), prostaglandins (PGs), and nitric oxide (NO). Adenosine and lactate are generated from metabolic activity. These factors all lead to vascular dilation. Glutamate also activates metabotropic glutamate receptors (mGluR) in astrocytes, causing intracellular calcium entry, phospholipase A_2 (PLA_2) activation, release of AA and epoxyeicosatrienoic (EET) acid and prostaglandin E_2 (PGE_2). The latter two AA metabolites contribute to dilation. By contrast, AA can also be metabolized to 20-hydroxyl-eicosatetraenoic acid (20-HETE) in vascular smooth muscle. 20-HETE is a potent vascular constrictor. *cGMP,* Cyclic guanosine monophosphate; *eNOS,* endothelial nitric oxide synthase; *NMDAR, N*-methyl D-aspartate glutamate receptor; *nNOS,* neuronal nitric oxide synthase. *(Modified from Attwell D, Buchan AM, Charpak S, et al: Glial and neuronal control of brain blood flow,* Nature *468(7321):232-243, 2010.)*

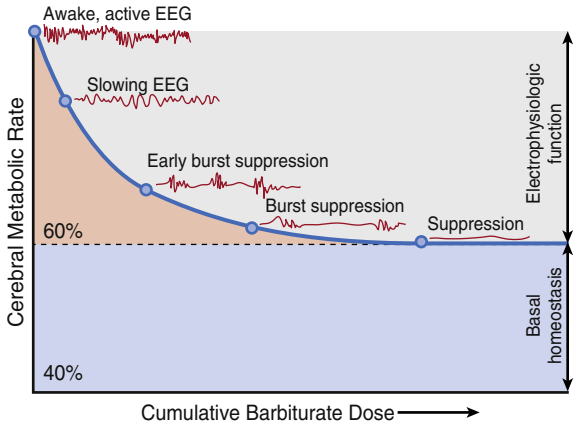

Figure 17-3. Interdependency of cerebral electrophysiologic function and cerebral metabolic rate (CMR). Administration of various anesthetics, including barbiturates, results in a dose-related reduction in the CMR of oxygen ($CMRO_2$) and cerebral blood flow (CBF). The maximum reduction occurs with the dose that results in electrophysiologic silence. At this point, the energy utilization associated with electrophysiologic activity has been reduced to zero, but the energy utilization for cellular homeostasis persists unchanged. Additional barbiturates cause no further decrease in CBF or $CMRO_2$. *EEG,* Electroencephalogram.

When complete suppression of EEG is achieved, the cerebral metabolic rate of oxygen ($CMRO_2$) is similar irrespective of the anesthetic agent used to achieve EEG suppression. Yet, anesthetic-induced EEG suppression is not a single physiologic state and is influenced by the drug that is used to produce suppression. When barbiturates are administered to the point of EEG suppression, a uniform depression in the CBF and CMR occurs throughout the brain. When suppression occurs during the administration of isoflurane and sevoflurane, the relative reductions in the CMR and CBF are more intense in the neocortex than in other portions of the cerebrum. Electrophysiologic responsiveness also varies. Cortical somatosensory-evoked responses to median nerve stimulation can be readily recorded at doses of thiopental far in excess of those required to cause complete suppression of the EEG but are difficult to elicit at concentrations of isoflurane associated with a burst-suppression pattern (~1.5 MAC) (Fig. 17-4[3,4]). In addition, the EEG characteristics of the burst-suppression states that occur just before complete suppression differ among anesthetic drugs. These differences may be of some relevance to discussions of differences in the neuroprotective potential of drugs that can produce EEG suppression.

Temperature. The effects of hypothermia on the brain have been reviewed in detail[5] (also see Chapter 54). The CMR decreases by 6% to 7% per degree Celsius of temperature reduction. In addition to anesthetic drugs, hypothermia can also cause complete suppression of the EEG (at approximately 18° C to 20° C). However, in contrast to anesthetic drugs, temperature reduction beyond that at which EEG suppression first occurs *does* produce a further decrease in the CMR (Fig. 17-5). This decrease occurs because anesthetic drugs reduce only the component

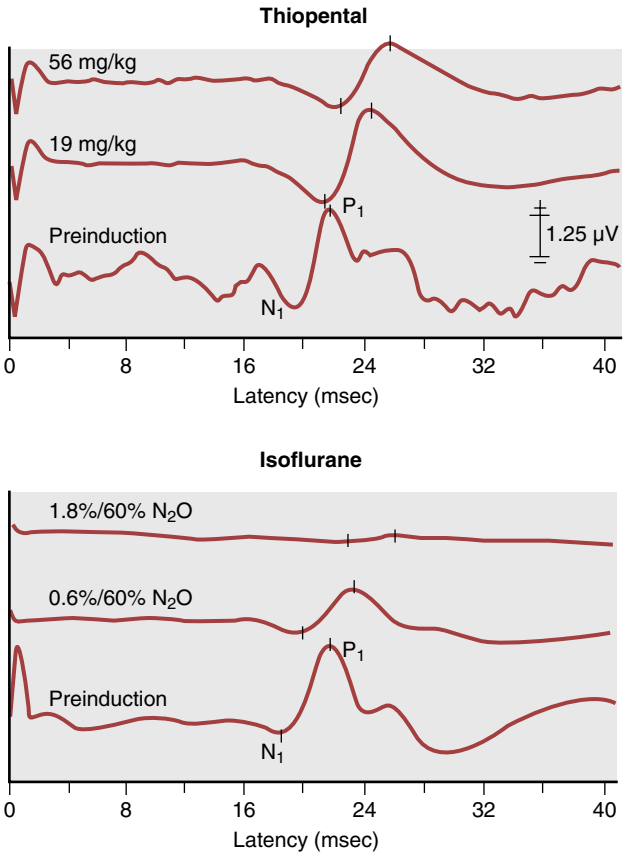

Figure 17-4. Cortical somatosensory-evoked responses to median nerve stimulation in humans before induction and during anesthesia with thiopental–nitrous oxide (N_2O) and isoflurane-N_2O. Despite an equivalent or greater degree of reduction in the cerebral metabolic rate with thiopental, cortical evoked responses are better preserved[3] than during anesthesia with isoflurane,[4] which suggests that the electroencephalographic suppression achieved with different anesthetic drugs should not be assumed to be equivalent electrophysiologic states. The cumulative thiopental doses and expired concentrations of isoflurane and N_2O are indicated in this figure.

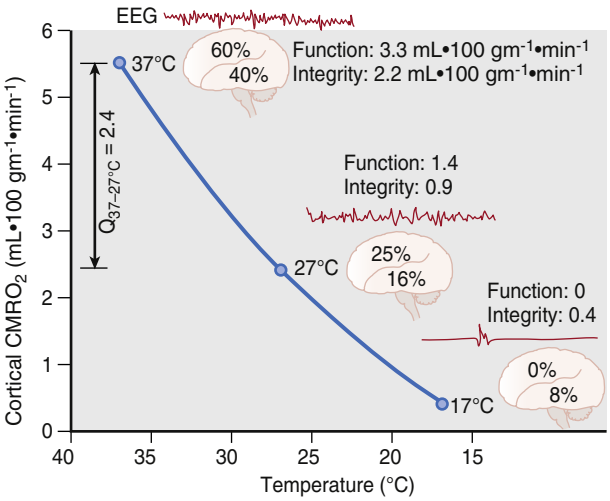

Figure 17-5. Effect of temperature reduction on the cerebral metabolic rate of oxygen ($CMRO_2$) in the cortex. Hypothermia reduces both of the components of cerebral metabolic activity identified in Figure 17-3—that associated with neuronal electrophysiologic activity (Function) and that associated with the maintenance of cellular homeostasis (Integrity). This is in contrast to anesthetics that alter only the functional component. The ratio of cerebral metabolic rate (CMR) at 37° C to that at 27° C, the Q10 ratio, is shown in the graph. Note that the $CMRO_2$ in the cortex (grey matter) is greater than global $CMRO_2$, considering the lower metabolic rate in white matter. *(Modified from Michenfelder JD:* Anesthesia and the brain: clinical, functional, metabolic, and vascular correlates. *New York, 1988, Churchill Livingstone.)*

of the CMR associated with neuronal function, whereas hypothermia decreases the rate of energy utilization associated with both electrophysiologic function and the basal component associated with the maintenance of cellular integrity. Mild hypothermia preferentially suppresses the basal component of the CMR. The $CMRO_2$ at 18° C is less than 10% of normothermic control values, which may explain the brain's tolerance for moderate periods of circulatory arrest at these and cooler temperatures.

Hyperthermia has an opposite influence on cerebral physiologic function. Between 37° C and 42° C, CBF and CMR increase. However, above 42° C, a dramatic reduction in cerebral oxygen consumption occurs, an indication of a threshold for a toxic effect of hyperthermia that may occur as a result of protein (enzyme) denaturation.

$Paco_2$. CBF varies directly with $Paco_2$ (Fig. 17-6), especially within the range of physiologic variation of $Paco_2$. CBF changes 1 to 2 mL/100 g/min for each 1 mm Hg change in $Paco_2$ around normal $Paco_2$ values. This response is attenuated at a $Paco_2$ less than 25 mm Hg. Under normal circumstances, the sensitivity of CBF to changes in $Paco_2$ ($\Delta CBF/\Delta Paco_2$) is positively correlated with resting levels of CBF. Accordingly, anesthetic drugs that alter resting CBF cause changes in the response of the cerebral circulation to carbon dioxide (CO_2). The magnitude of the reduction in CBF caused by hypocapnia is more intense when resting CBF is rapid (as might occur during anesthesia with volatile agents). Conversely, when resting CBF is slow, the magnitude of the hypocapnia-induced reduction in CBF is decreased. However, CO_2 responsiveness has been observed in normal brain during anesthesia with all of the anesthetic drugs that have been studied.

The changes in CBF caused by $Paco_2$ are dependent on pH alterations in the extracellular fluid of the brain. NO, in particular NO of neuronal origin, is an important although not exclusive mediator of CO_2-induced vasodilation.[6] The vasodilatory response to hypercapnia is also mediated in part by prostaglandins. The changes in extracellular pH and CBF rapidly occur after $Paco_2$ adjustments because CO_2 freely diffuses across the cerebrovascular endothelium. In contrast with *respiratory* acidosis, acute systemic *metabolic* acidosis has little immediate effect on CBF because the BBB excludes H^+ from the perivascular space. The CBF changes in response to alterations in $Paco_2$ rapidly occur, but they are not sustained. Despite the maintenance of an increased arterial pH, CBF returns toward normal over a period of 6 to 8 hours because the pH of cerebrospinal fluid (CSF) gradually returns to normal levels as a result of extrusion of bicarbonate (see Fig. 70-6). Consequently, a patient who has had a sustained period of hyperventilation or hypoventilation deserves special consideration. Acute restoration of a

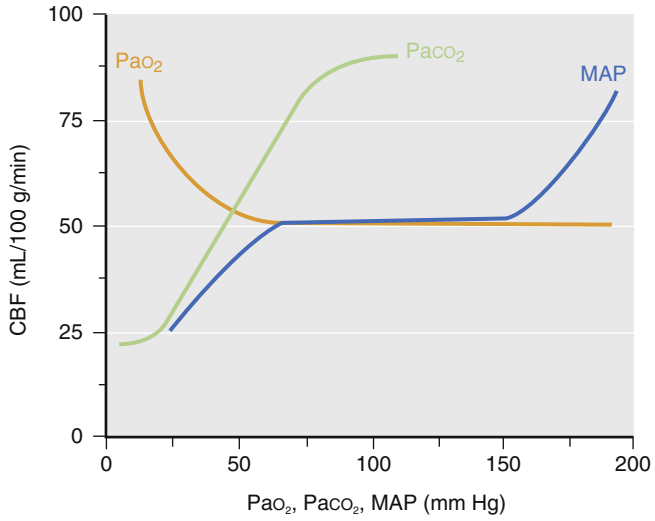

Figure 17-6. Changes in cerebral blood flow (CBF) caused by independent alterations in arterial partial pressure of carbon dioxide ($Paco_2$), partial pressure of oxygen (Pao_2), and mean arterial pressure (MAP).

normal $Paco_2$ value will result in a significant CSF acidosis (after hypocapnia) or alkalosis (after hypercapnia). The former results in increased CBF with a concomitant increase in intracranial pressure (ICP) that depends on the prevailing intracranial compliance. The latter conveys a theoretic risk for ischemia.

Pao_2. Changes in Pao_2 from 60 to more than 300 mm Hg have little influence on CBF. Less than a Pao_2 of 60 mm Hg rapidly increases CBF (see Fig. 17-6). The mechanisms mediating cerebral vasodilation during hypoxia may include neurogenic effects initiated by peripheral and neuraxial chemoreceptors, as well as local humoral influences. At least part of the hyperemic response to hypoxia is mediated by NO of neuronal origin. Hypoxia-induced opening of ATP-dependent K^+ channels in vascular smooth muscle also leads to hyperpolarization and vasodilation. The rostral ventrolateral medulla (RVM) serves as an oxygen sensor within the brain. Stimulation of the RVM by hypoxia results in an increase in CBF (but not the CMR), and lesions of the RVM suppress the magnitude of the CBF response to hypoxia. The response to hypoxia is synergistic with the hyperemia produced by hypercapnia and acidosis. At high Pao_2 values, CBF modestly decreases. At 1 atmosphere of oxygen, CBF is reduced by 12%.

MYOGENIC REGULATION (AUTOREGULATION) OF CEREBRAL BLOOD FLOW

Autoregulation refers to the capacity of the cerebral circulation to adjust its resistance to maintain CBF constant over a wide range of mean arterial pressure (MAP) values. In normal *human* subjects, the limits of autoregulation likely occur at MAP values of approximately 70 and 150 mm Hg (see Fig. 17-6). The lower limit of autoregulation (LLA) may be a MAP value of 50 mm Hg. Although this number was derived from animal studies, the LLA is likely higher in humans.[7] The units used on the *x* axis of autoregulation curves will influence the correct inflection points of the curve. When the *x* axis is the MAP, the normal average LLA is not less than 70 mm Hg (with considerable interindividual variation). Because ICP is not usually measured in normal subjects, cerebral perfusion pressure (CPP) (MAP – ICP) is rarely available. Assuming a normal ICP of 5 to 10 mm Hg in a supine subject, an LLA of 65 mm Hg expressed as MAP corresponds to an LLA of 55 to 60 mm Hg expressed as CPP.

Above and below the autoregulatory plateau, CBF is pressure dependent (pressure passive) and linearly varies with CPP. Autoregulation is influenced by various pathologic processes, as well as the time course over which the changes in CPP occur. Even within the range over which autoregulation normally occurs, a rapid change in arterial pressure will result in a transient (i.e., 3 to 4 minutes) alteration in CBF.

The *limits of autoregulation* are conceptual constructs for the purpose of analysis. They do not represent physiologic "all-or-none" responses. A continuum of vascular responsiveness in both the lower and upper limits probably exists as the ability of the arteriolar bed to dilate or constrict is exhausted. Furthermore, the morphologic form of the autoregulation is strongly influenced by the background level of vasodilation or vasoconstriction (e.g., $Paco_2$ or anesthetic conditions).

The precise mechanisms, by which autoregulation is accomplished and its overlap with flow-metabolism coupling are not known. According to the myogenic hypothesis, changes in CPP lead to direct changes in the tone of vascular smooth muscle; this process appears to be passive. NO may participate in the vasodilation associated with hypotension (also see Chapter 104). Autonomic innervation of cerebral blood vessels may also contribute to the autoregulation of blood flow (discussed in the next section).

NEUROGENIC REGULATION OF CEREBRAL BLOOD FLOW

The cerebral vasculature is extensively innervated.[8] The density of innervation declines with vessel size, and the greatest neurogenic influence appears to be exerted on larger cerebral arteries. This innervation includes cholinergic (parasympathetic and nonparasympathetic), adrenergic (sympathetic and nonsympathetic), serotoninergic, and VIPergic systems of extraaxial and intraaxial origin. An extracranial sympathetic influence via the superior cervical ganglion, as well as parasympathetic innervation via the sphenopalatine ganglion, certainly exists in animals. The intraaxial pathways likely result from innervation arising from several nuclei in animals, including the locus coeruleus, the fastigial nucleus, the dorsal raphe nucleus, and the basal magnocellular nucleus of Meynert. Evidence of the functional significance of neurogenic influences has been derived from studies of CBF autoregulation and ischemic injury. Hemorrhagic shock, a state of high sympathetic tone, results in less CBF at a given MAP than occurs when hypotension is produced with sympatholytic drugs. During shock, a sympathetically mediated vasoconstrictive effect shifts the lower end of

the *autoregulatory* plateau to the right. It is not clear what the relative contributions of humoral and neural mechanisms are to this phenomenon; however, a neurogenic component certainly exists because sympathetic denervation increases CBF during hemorrhagic shock. Moreover, sympathetic denervation produced by a blockade of the stellate ganglion can increase CBF in humans.[9] Activation of cerebral sympathetic innervation also shifts the upper limit of autoregulation to the right and offers some protection against hypertensive breakthrough of the BBB. Experimental interventions that alter these neurogenic control pathways influence outcome after standardized ischemic insults, presumably by influences on vascular tone and therefore CBF. The nature and influence of such pathways in humans are not known, and their manipulation for the purposes of clinical management remains to be systematically investigated.

EFFECTS OF BLOOD VISCOSITY ON CEREBRAL BLOOD FLOW

Blood viscosity can influence CBF. Hematocrit is the single most important determinant of blood viscosity.[10] In healthy humans, variation of the hematocrit within the normal range (33% to 45%) probably results in only modest alterations in CBF. Beyond this range, changes are more substantial. In anemia, cerebral vascular resistance is reduced and CBF increases. However, this may result not only from a reduction in viscosity but also as a compensatory response to reduced oxygen delivery.[11] The effect of a reduction in viscosity on CBF is more important with focal cerebral ischemia, a condition in which vasodilation in response to impaired oxygen delivery is probably already maximal. In this situation, reducing viscosity by hemodilution increases CBF in the ischemic territory. In patients with focal cerebral ischemia, a hematocrit of 30% to 34% will result in optimal delivery of oxygen. However, manipulation of viscosity in patients with acute ischemic stroke is not of benefit in reducing the extent of cerebral injury.[12] Therefore viscosity is not a target of manipulation in patients at risk as a result of cerebral ischemia, with the possible exception of those with hematocrit values higher than 55%.

VASOACTIVE DRUGS

Many drugs with intrinsic vascular effects are used in contemporary anesthetic practice, including both anesthetic drugs and numerous vasoactive drugs specifically used for hemodynamic manipulation. This section deals with the latter. The actions of anesthetics are discussed in the section, "Effects of Anesthetics on Cerebral Blood Flow and Cerebral Metabolic Rate."

Systemic Vasodilators

Most drugs used to induce hypotension, including sodium nitroprusside, nitroglycerin, hydralazine, adenosine, and calcium channel blockers, also cause cerebral vasodilation. As a result, CBF either increases or is maintained at prehypotensive levels. In addition, when hypotension is induced with a cerebral vasodilator, CBF is maintained at lower MAP values than when induced by either hemorrhage or a noncerebral vasodilator. In contrast to direct vasodilators, the angiotensin-converting enzyme (ACE) inhibitor enalapril does not have any significant impact on CBF.[13] Anesthetics that simultaneously vasodilate the cerebral circulation cause increases in cerebral blood volume (CBV) with the potential to increase ICP. The effects of these anesthetics on ICP are less dramatic when hypotension is slowly induced, which probably reflects the more effective interplay of compensatory mechanisms (i.e., shifts in CSF and venous blood) when changes occur more slowly.

Catecholamine Agonists and Antagonists

Numerous drugs with agonist and antagonist activity at catecholamine receptors (α_1, α_2, β_1, β_2, and dopamine) are in common use. The effects of these vasoactive drugs on cerebral physiology are dependent on basal arterial blood pressure, the magnitude of the drug-induced arterial blood pressure changes, the status of the autoregulation mechanism, and the status of the BBB. A drug may have direct effects on cerebral vascular smooth muscle or indirect effects mediated by the cerebral autoregulatory response to changes in systemic blood pressure (or both types of effects). When autoregulation is preserved, increases in systemic pressure should increase CBF if basal blood pressure is outside the limits of autoregulation. When basal pressure is within the normal autoregulation range, an increase in systemic pressure does not significantly affect CBF because the normal autoregulatory response to a rising MAP entails cerebral vasoconstriction (i.e., an increase in cerebral vascular resistance) to maintain a constant CBF. When autoregulation is defective, CBF will vary in direct relation to arterial pressure. The information in the following paragraphs and in Table 17-2 emphasizes data obtained from investigations of vasopressors in intact preparations and gives priority to the results obtained in humans and higher primates.

TABLE 17-2 BEST ESTIMATES OF THE INFLUENCE OF PURE CATECHOLAMINE RECEPTOR AGONISTS AND SPECIFIC PRESSOR SUBSTANCES ON CEREBRAL BLOOD FLOW AND CEREBRAL METABOLIC RATE*

The number of symbols indicates the magnitude of the effect.

α_1-Agonists. Will the administration of α_1-agonists (phenylephrine, norepinephrine) reduce CBF?

Studies in humans and nonhuman primates do not confirm this concern. Intracarotid infusions of norepinephrine in doses that significantly increase the MAP result in no change in CBF. Administration of phenylephrine to patients undergoing cardiopulmonary bypass does not decrease CBF.[14] There are, however, some species differences with regard to the CBF response to α-agonists. α_1-Agonists also do not cause cerebral vasoconstriction in rats but do produce modest decreases in CBF in dogs and goats; this decrease in CBF can be blocked by α_1-antagonists (also see Chapter 16).

Norepinephrine can increase CBF. Such increases might occur if autoregulation were defective or its limit exceeded. In some instances the increases may be the result of abnormalities in the BBB. β-Mimetic drugs (norepinephrine has β_1 activity) may cause activation of cerebral metabolism[15] with a coupled increase in CBF. This effect is more apparent when these drugs can gain greater access to the brain parenchyma via a defective BBB (see Table 17-2).

The traditional view that CBF can be maintained by the administration of α_1-agonists without any adverse effect on cerebral oxygenation has been challenged. In anesthetized patients,[16-18] phenylephrine administration by bolus modestly reduced cerebral oxygen saturation (S_{CO_2}), measured by near-infrared oximetry. Ephedrine, although increasing arterial blood pressure to a similar extent as phenylephrine, did not reduce S_{CO_2}, presumably because of its ability to maintain cardiac output. In human volunteers, a norepinephrine-induced increase in arterial blood pressure slightly reduced middle cerebral artery (MCA) flow velocity and S_{CO_2} and jugular venous oxygen saturation (SjV_{O_2}).[19] By contrast, although phenylephrine decreased S_{CO_2}, MCA flow velocity was increased and SjV_{O_2} was unchanged.[20] Do phenylephrine and norepinephrine administration negatively impact cerebral oxygenation? Several factors argue against this possibility. The first concern is methodology. Near-infrared spectroscopy (NIRS) measures oxygenated and deoxygenated blood in a defined region of brain and is a composite of arterial, capillary, and venous blood. Vasopressors affect both arterial and venous tone. Even a minor change in the volume of arterial and venous volumes within the region of the brain can affect the S_{CO_2} measurement. Moreover, extracranial contamination is a significant component of the S_{CO_2} values reported by the currently available NIRS monitors.[21] This contamination is more important than the slight reduction in S_{CO_2} observed in these investigations. In the absence of direct measurement of brain tissue oxygenation, a modest reduction in S_{CO_2} in the face of increasing arterial blood pressure cannot be taken as evidence of impairment of cerebral oxygenation. In addition, phenylephrine did not decrease SjV_{O_2}, a more global measurement of cerebral oxygenation. Although norepinephrine decreased SjV_{O_2} by approximately 3% (a mild reduction at best), its administration has been previously shown to increase the $CMRO_2$. Finally, the minor reduction in S_{CO_2} effected by phenylephrine is no longer apparent when an increase in the $CMRO_2$ is concurrent. Phenylephrine apparently does not prevent an increase in CBF when such an increase is warranted by increased brain metabolism.

These studies were conducted in patients with a normal central nervous system (CNS). Although unlikely, the concern is that α_1-agonists might reduce cerebral perfusion in the injured brain. For example, in patients with a head injury, the administration of phenylephrine increased CPP and did not reduce regional CBF.[22] Transient changes may occur in CBF and S_{CO_2} (on the order of 2 to 5 minutes) in response to bolus doses of phenylephrine; however, with a continuous infusion, α_1-agonists have little direct influence on CBF and cerebral oxygenation in humans.[23] Thus maintenance of CPP with these vasopressors does not have an adverse effect on the brain.

α_2-Agonists. α_2-Agonists have both analgesic and sedative effects. This class of drugs includes dexmedetomidine and clonidine, with the latter being a significantly less specific and less potent α_2-agonist. Two investigations in human volunteers have confirmed the ability of dexmedetomidine to decrease CBF. Dexmedetomidine dose-dependently decreased MCA flow velocity, with the maximum reduction being approximately 25%.[24] Dexmedetomidine (1-μg/kg loading dose and infusion at either 0.2 or 0.6 μg/kg/hr) decreased CBF by approximately 30%[25] in healthy human volunteers. In both these investigations, the CMR was not measured; whether the reduction in CBF was due to a direct vasoconstrictor activity of dexmedetomidine or to suppression of the CMR with a corresponding reduction in CBF is not clear. In a more recent study of dexmedetomidine during which both MCA flow velocity and the CMR were measured in healthy humans, dexmedetomidine decreased MCA flow velocity in parallel with a reduction in the CMR.[26] The effects of dexmedetomidine on CBF were primarily mediated by its ability to suppress the CMR. The well-known effect of dexmedetomidine to decrease arterial blood pressure merits careful consideration if used in patients who are critically dependent on collateral perfusion pressure, especially in the recovery phase of an anesthetic.

β-Agonists. β-Receptor agonists, in small doses, have little direct effect on the cerebral vasculature. In larger doses and in association with physiologic stress, they can cause an increase in the CMR with an accompanying increase in CBF.[27] The β_1-receptor is probably the mediator of these effects. In doses that do not result in substantial changes in the MAP, intracarotid epinephrine does not change CBF in unanesthetized humans. However, with larger doses that lead to an increase in the MAP, both CBF and $CMRO_2$ can increase by approximately 20%.

Evidence suggests that a defect in the BBB enhances the effect of β-agonists.[28] Intracarotid norepinephrine, which does not normally affect CBF and CMR, increases CBF and CMR when BBB permeability is increased with hypertonic drugs. Epinephrine caused an elevation in the $CMRO_2$, but only when the BBB was made permeable.[28] These observations beg the interpretation that β-agonists will increase CBF and CMR *only* when the BBB is injured. However, when epinephrine was given in doses that did not significantly increase the MAP, increases in CBF and CMR occurred.[29] Accordingly, BBB injury may exaggerate

but not be a necessary condition in humans for the occurrence of β-mediated increases in CBF and CMR.

β-Blockers. β-Adrenergic blockers either reduce or have no effect on CBF and CMR. In two investigations in humans, propranolol, 5 mg intravenously,[30] and labetalol, 0.75 mg/kg intravenously,[31] had no effect on CBF and cerebral blood flow velocity (CBFV), respectively. Modest reductions in CBF occur after the administration of labetalol to patients undergoing craniotomy who become hypertensive during emergence from anesthesia. Esmolol shortens seizures induced by electroconvulsive therapy (ECT), which suggests that esmolol does cross the normal BBB. Catecholamine levels at the time of β-blocker administration or the status of the BBB (or both) may influence the effect of these drugs. β-Adrenergic blockers are unlikely to have adverse effects on patients with intracranial pathologic abnormalities, other than effects secondary to changes in perfusion pressure.

Dopamine. Dopamine can treat hemodynamic dysfunction. It also augments the function of the normal cardiovascular system when an increase in the MAP is desired as an adjunct to the treatment of focal cerebral ischemia, especially in the setting of vasospasm. Nonetheless, its effects on CBF and CMR have not been defined with certainty. The likely predominant effect of dopamine in the normal cerebral vasculature, when administered in small doses, is probably slight vasodilation with a minimal change in the CMR.[32] Increased CMR in discrete regions of the brain, such as the choroid plexus and basal ganglia, can occur. However, overall cortical blood flow is not influenced.[33] Vasoconstriction of the cerebral circulation is not observed even when dopamine is administered in doses of up to 100 μg/kg/min. In that same investigation, dobutamine increased CBF and CMR by 20% and 30%, respectively.[32] Fenoldopam is a dopamine agonist with activity at the DA_1-receptor and α_2-receptor. The administration of fenoldopam leads to systemic vasodilation and a decrease in arterial blood pressure. In humans, fenoldopam decreased systemic blood pressure to a level that was above the LLA; however, a modest (≈15%) reduction was observed in CBF that did not increase to normal levels when systemic blood pressure was supported.[34] This reduction in CBF was attributed to the α_2 activity of fenoldopam; its effect on the injured brain is not known.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Antagonists. Both ACE inhibitors and angiotensin-receptor antagonists (ARAs) are commonly used to treat hypertension. In the surgical setting and in the neurocritical care unit, these drugs are administered to control arterial blood pressure acutely. ACE inhibitors and ARAs reduce arterial blood pressure when hypertension is present. However, they do not affect resting CBF, and autoregulation is maintained.[35] In patients with acute stroke, ACE inhibitors and ARAs reduce arterial blood pressure but do not acutely affect CBF.[36-38] Apparently, these drugs did not reduce CBF when arterial blood pressure modestly decreased (also see Chapter 16).

AGE

The loss of neurons is progressive in the normally aging brain from young adulthood to advanced age. Initial studies showed a reduction in neuronal density of as much as 60%.[39] More recent investigations reveal neuronal loss of approximately 10%.[40] The loss of myelinated fibers results in reduced white matter volume.[41] By contrast, the loss of synapses in the aged brain is considerably greater. The majority of excitatory synapses in the brain are on dendritic spines. Dendrite branching and volume progressively decrease, and the number of dendritic spines is reduced by approximately 25% to 35%.[41] Attendant with the loss of neuropil, both CBF and $CMRO_2$ decrease by 15% to 20% at the age of 80 years[42] (also see Chapters 80 and 93).

EFFECTS OF ANESTHETICS ON CEREBRAL BLOOD FLOW AND CEREBRAL METABOLIC RATE

This section discusses the effects of anesthetic drugs on CBF and CMR. It includes limited mentions of the influences on autoregulation, CO_2 responsiveness, and CBV. Effects on CSF dynamics, the BBB, and epileptogenesis are discussed in the section, "Epileptogenesis."

In neuroanesthesia, the manner in which anesthetic drugs and techniques influence CBF receives prime attention. The rationale is twofold. First, the delivery of energy substrates is dependent on CBF, and modest alterations in CBF can substantially influence neuronal outcome in the setting of ischemia. Second, control and manipulation of CBF are central to the management of ICP because as CBF varies in response to vasoconstrictor-vasodilator influences, CBV varies with it.[43] With respect to ICP, CBV is the more critical variable. In the normal brain, CBV is approximately 5 mL/100 g of brain,[44] and over a $Paco_2$ range of approximately 25 to 70 mm Hg, CBV changes by approximately 0.049 mL/100 g for each 1 mm Hg change in $Paco_2$. In an adult brain weighing approximately 1400 g, this change can amount to 20 mL in total CBV for a $Paco_2$ range of 25 to 55 mm Hg. Because CBV is more difficult to measure than CBF few data exist, especially in humans.

Although CBV and CBF usually vary in parallel, the magnitude of change in CBV is less than the magnitude of change in CBF (Fig. 17-7). In addition, CBV and CBF independently vary under some circumstances. During cerebral ischemia, for example, CBV increases, whereas CBF is significantly reduced.[45] Autoregulation normally serves to prevent MAP-related increases in CBV. In fact, as the cerebral circulation constricts to maintain a constant CBF in the face of an increasing MAP, CBV actually decreases.[46] When autoregulation is impaired or its upper limit (≈150 mm Hg) is exceeded, CBF and CBV then increase in parallel as arterial blood pressure increases (see Fig. 17-6). A declining MAP results in a progressive increase in CBV as the cerebral circulation dilates to maintain constant flow, and exaggerated increases in CBV occur as the MAP decreases to less than the LLA.[46] In normal subjects, the initial increases in CBV do not increase ICP because there

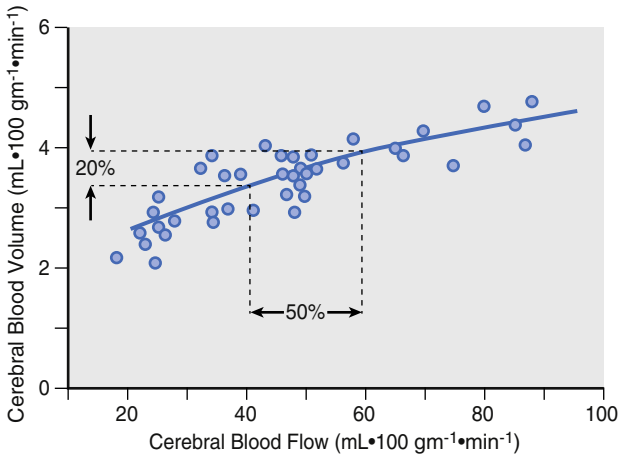

Figure 17-7. Relationship between cerebral blood flow (CBF) and cerebral blood volume (CBV). Although a linear relationship exists between CBF and CBV, the magnitude of the change in CBV for a given change in CBF is considerably less. An increase in CBF of 50% results in a change in CBV of only 20%.

is latitude for compensatory adjustments by other intracranial compartments (e.g., translocation of venous blood and CSF to extracerebral vessels and the spinal CSF space, respectively). When intracranial compliance* is reduced, an increase in CBV can cause herniation or sufficiently reduce CPP to cause ischemia.

INTRAVENOUS ANESTHETIC DRUGS

The action of most intravenous anesthetics leads to parallel reductions in CMR and CBF. Ketamine, which causes an increase in the CMR and CBF, is the exception. The effects of selected intravenous anesthetic drugs on human CBF are compared in Figure 17-8[25,47-59] (also see Chapter 30).

Changes in CBF induced by intravenous anesthetics are largely the result of the effects on the CMR with parallel (coupled) changes in CBF. If this were the entire explanation, then the CBF/CMR ratio would be the same for all anesthetics. Unfortunately, it is not. In addition, direct effects on cerebral vascular smooth muscle (e.g., vasoconstriction, vasodilation, alteration of autoregulatory function) contribute to the net effect. For instance, barbiturates are cerebral vasoconstrictors, yet some barbiturates actually cause relaxation of cerebral vascular smooth muscle in isolated vessel preparations.[60] However, a substantial reduction in the CMR occurs in vivo, and the net effect at the point of EEG suppression is vasoconstriction and a substantial decrease in CBF.[61] In general, autoregulation and CO_2 responsiveness are preserved during the administration of intravenous anesthetic drugs.

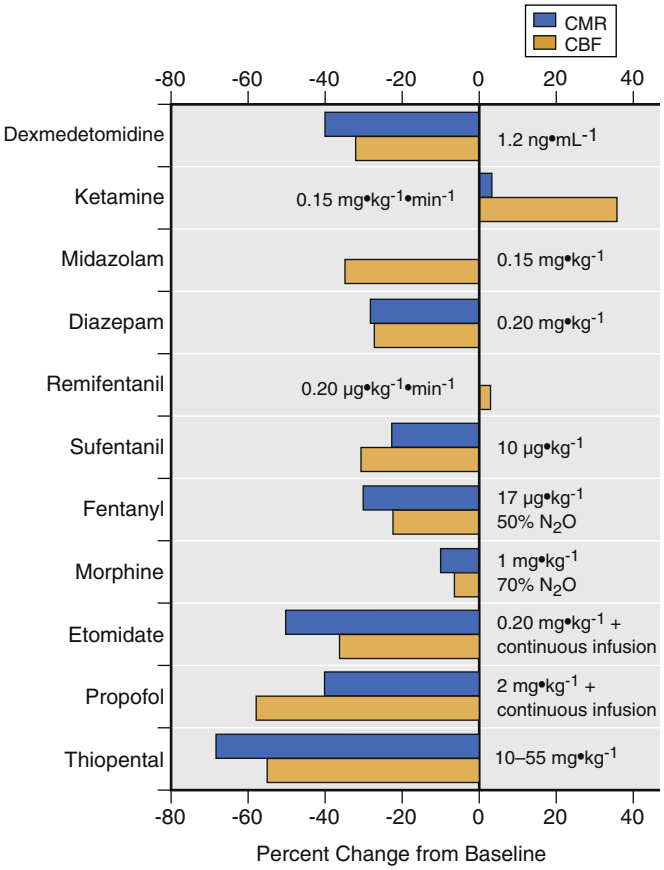

Figure 17-8. Changes in cerebral blood flow (CBF) and the cerebral metabolic rate of oxygen ($CMRO_2$) caused by intravenous anesthetic drugs. The data are derived from human investigations and are presented as percent change from unanesthetized control values. Dexmedetomidine CMR values were determined on a background of 0.5% isoflurane anesthesia (see the text for details). No data for the $CMRO_2$ effects of midazolam in humans are available. *(Data from references 25, 47-59.)*

Barbiturates

A dose-dependent reduction in CBF and CMR occurs with barbiturates. With the onset of anesthesia, both CBF and $CMRO_2$ are reduced by approximately 30%.[62] When large doses of thiopental cause complete EEG suppression, CBF and CMR are reduced by approximately 50%.[61,63] Further increases in the barbiturate dose have no additional effect on the CMR.[61] These observations suggest that the major effect of nontoxic doses of depressant anesthetics is a reduction in the component of cerebral metabolism that is linked to electrical brain function (e.g., neurophysiologic activity) with only minimal effects on the second component, which is related to cellular homeostasis (see Fig. 17-3).

Tolerance to the CBF and CMR effects of barbiturates may quickly develop.[64] In patients with severe head injury in whom *barbiturate coma* was maintained for 72 hours, the blood concentration of thiamylal required to maintain EEG burst suppression was observed to be increased by the end of the first 24 hours and continued to increase over the next 48 hours.[65] During deep pentobarbital anesthesia, autoregulation is maintained at mean arterial pressures as low as 60 mm Hg. CO_2 responsiveness also persists.

*Note a well-entrenched misuse of terminology.[206] The "compliance" curve that is commonly drawn to describe the ICP-volume relationship (see Fig. 70-3) actually depicts the relationship $\Delta P/\Delta V$ (elastance) and not $\Delta V/\Delta P$ (compliance). The reference to "reduced compliance" in this text is more correctly described as "increased elastance." However, because the existing literature most commonly uses the "compliance" terminology, the authors have left the misuse uncorrected herein.

Propofol

The effects of propofol (2,6-diisopropylphenol) on CBF and CMR are similar to those of barbiturates. Both CBF and CMR decrease after the administration of propofol in humans.[66] In healthy volunteers, surgical levels of propofol reduced regional CBF by 53% to 79% in co-mparison with the awake state.[67,68] Alkire and co-workers[69] assessed cerebral glucose metabolism in volunteers by positron-emission tomography (PET) before and during infusion of propofol to the point of unresponsiveness. The whole-brain metabolic rate decreased by 48% to 58%, with limited regional heterogeneity observed. When compared with isoflurane-fentanyl or sevoflurane-fentanyl anesthesia, a combination of propofol and fentanyl decreased subdural pressure in patients with intracranial tumors and decreased the arteriovenous oxygen content difference ($AVDO_2$).[70] Collectively, these investigations in human subjects indicate that propofol effects reductions in the CMR and secondarily decreases CBF, CBV, and ICP.

Both CO_2 responsiveness and autoregulation are preserved in humans during the administration of propofol,[71,72] even when administered in doses that produce burst suppression of the EEG.[73] The magnitude of the reduction in CBF during hypocapnia is decreased during propofol administration. This effect is probably due to the cerebral vasoconstriction induced by suppression of CMR, which further limits hypocapnia-mediated vasoconstriction.

Etomidate

The effects of etomidate on CBF and CMR are also similar to those of barbiturates. Roughly parallel reductions in CBF and CMR occur in humans,[47,74] and, in general, they are accompanied by progressive suppression of the EEG. Induction of anesthesia with either thiopental or etomidate resulted in a similar reduction in MCA flow velocity of approximately 27%.[75] The changes in CBF and CMR are substantial. Renou and colleagues[47] administered approximately 0.2 mg/kg of etomidate to adults and observed mean reductions in CBF and CMR of 34% and 45%, respectively. As is the case with barbiturates, no further reduction in the CMR occurs when additional drug is administered beyond a dose sufficient to produce EEG suppression. This latter phenomenon has not been demonstrated in humans. However, Bingham and associates[76] observed that etomidate lowered ICP when administered to patients with severe head injuries in whom EEG activity was well preserved but was ineffective when substantial antecedent EEG suppression existed. The global CMR suppression attainable with etomidate is slightly less profound than that achieved with isoflurane and barbiturates. This finding is consistent with the observation that unlike barbiturates, which cause CMR suppression throughout the brain, the CMR suppression caused by etomidate is regionally variable and predominantly occurs in forebrain structures.

Etomidate is effective in reducing ICP without causing a reduction in CPP in patients with intracranial tumors[77] and patients with head injuries.[78] However, the administration of etomidate resulted in an exacerbation of brain tissue hypoxia and acidosis in patients in whom the MCA was temporarily occluded during surgery.[79] Additional concerns regarding the occurrence of adrenocortical suppression caused by enzyme inhibition and renal injury caused by the propylene glycol vehicle[80] will probably preclude more than episodic use.

Reactivity to CO_2 is preserved in humans during the administration of etomidate.[47,74] Autoregulation has not been evaluated. Myoclonus and epileptogenesis are discussed in the section, "Epileptogenesis."

Narcotics

Inconsistencies can be found in the available information, but narcotics likely have relatively little effect on CBF and CMR in the normal, unstimulated nervous system. When changes do occur, the general pattern is one of modest reductions in both CBF and CMR. The inconsistencies in the literature probably largely arise because the *control* states entailed paralysis and nominal sedation in many studies, often with N_2O alone. In these studies, in which substantial reductions in CBF and CMR were frequently observed, the effect of the narcotic was probably a combination of the inherent effect of the drug plus a substantial component attributable to reduction of arousal. Comparable effects related to reduction of arousal may occur and can be clinically important. However, they should be viewed as nonspecific effects of sedation or pain control, or both, rather than specific properties of narcotics. The following discussion emphasizes investigations in which control measurements were unlikely to have been significantly influenced by arousal phenomena.

Morphine. When morphine (~1 mg/kg) was administered as the sole drug to humans, Moyer and associates[81] observed no effect on global CBF and a 41% decrease in the $CMRO_2$. The latter is a substantial reduction, and the absence of a simultaneous adjustment in CBF is surprising. No other investigations of morphine have been conducted in humans alone. Jobes and co-workers[48] gave morphine (1 and 3 mg/kg) with 70% N_2O to patients and observed no significant change in CBF or CMR. The N_2O that was used might be expected to have caused a tendency toward increases in CBF and CMR. The relative absence of *net* changes in these variables from awake control measurements suggests a small-to-moderate depressive effect of morphine on CBF and CMR at this large dose. However, morphine can cause a substantial release of histamine in individual patients. Histamine is a cerebral vasodilator that will cause an increase in CBV and a CBF effect that will vary, depending on the systemic blood pressure response.

Autoregulation was observed to be intact between MAP values of 60 and 120 mm Hg in human volunteers anesthetized with morphine, 2 mg/kg, and 70% N_2O.[82]

Fentanyl. Limited human data are available. Vernhiet and colleagues[49] measured CBF and $CMRO_2$ before and during anesthesia with 12 to 30 (mean, 16) μg/kg of fentanyl and 50% N_2O in patients about to undergo cerebral angiography. Atropine and pancuronium were the only other agents administered. Neither CBF nor $CMRO_2$ significantly changed from awake control values in their group of six subjects. However, one of the patients (with epilepsy and with normal results on computed tomography

[CT]) had dramatic and unexplained increases in both CBF and $CMRO_2$. For the remaining five patients, CBF and $CMRO_2$ decreased by 21% and 26%, respectively ($P < .05$). The data for fentanyl-N_2O presented in Figure 17-8 are derived from these patients, who received an average of 17 μg/kg of fentanyl. Murkin and associates[83] measured CBF before and after induction of anesthesia with high-dose fentanyl, 100 μg/kg, and diazepam, 0.4 mg/kg. CBF fell by 25%, although part of this effect may well have been a result of benzodiazepine (see later discussion in the section, "Benzodiazepine") rather than fentanyl. Firestone and co-workers,[84] using PET, observed a heterogeneous CBF response to 1.5 μg/kg of fentanyl in healthy volunteers. Increases occurred in the frontal, temporal, and cerebellar areas simultaneous with decreases in discrete areas associated with pain-related processing. CO_2 responsiveness and autoregulation are unaffected, and the hyperemic CBF response to hypoxia remains intact.

In conclusion, fentanyl will cause a moderate global reduction in CBF and CMR in the normal quiescent brain and will, similar to morphine, cause larger reductions when administered during arousal.

Alfentanil. McPherson and associates[85] administered alfentanil, 320 μg/kg, to pentobarbital-anesthetized dogs. They observed no changes in CBF, CMR, CO_2 responsiveness, autoregulation, or CBF response to hypoxia. No studies of the effects of alfentanil on the CMR in humans have been conducted. Schregel and colleagues[86] administered 25 to 50 μg/kg of alfentanil to patients receiving 60% N_2O after induction of anesthesia with thiopental. CBFV transiently decreased. A Doppler measure of MCA diameter was simultaneously unchanged, thus suggesting that the reduction in CBFV was indicative of a decrease in CBF. Mayberg and co-workers[87] also observed no change in CBFV in response to 25 to 50 μg/kg of alfentanil given to patients during maintenance of anesthesia with isoflurane-N_2O.

Although data are few, the general pattern is similar and the conclusions should be the same as for sufentanil (see the next paragraph).[88-92] Alfentanil was included with fentanyl and sufentanil in two of the investigations of conditions in the surgical field mentioned in connection with sufentanil.[93,94] No adverse effects were noted.

Sufentanil. Studies in animals[95,96] and humans indicate that sufentanil causes, depending on the dose, either no change or a reduction in CBF and CMR. Stephan and colleagues[50] measured CBF and $CMRO_2$ in patients before and after induction of anesthesia with 10 μg/kg of sufentanil. They observed a 29% reduction in CBF and a 22% reduction in $CMRO_2$. Murkin and co-workers,[97] in a study involving the same dose of sufentanil and a similar design, made essentially identical observations. Mayer and associates[98] gave 0.5 μg/kg of sufentanil to volunteers and observed no change in CBF. Weinstabl and co-workers[99] observed reductions in CBFV when 1.0 and 2.0 μg/kg of sufentanil were given to patients with increased ICP who were in the intensive care unit (ICU).[99] Neither Weinstabl and colleagues[99] nor Mayer and associates,[98] who administered sufentanil to healthy volunteers, observed changes in CBFV after 0.5 μg/kg of sufentanil.

A logical conclusion is that no change and no reduction in ICP occurs as a result of the administration of either sufentanil or alfentanil.[99-104] However, in some investigations in humans, sufentanil was associated with modest increases in ICP. The increases in ICP associated with sufentanil are likely the consequence, in part, of a normal autoregulatory response to the sudden reduction in the MAP that can occur as a consequence of sufentanil administration.[105] Therefore sufentanil and fentanyl[102] should be administered in a manner that does not produce a sudden reduction of MAP. Such a decrease will reduce CPP and may increase ICP, each of which, in sufficient extreme, may be deleterious. However, ICP increases attributed to sufentanil are small. Furthermore, four investigations[93,94,106,107] that compared conditions in the surgical field, including pressure under brain retractors,[93] identified no adverse influences attributable to sufentanil. Accordingly, sufentanil need not be viewed as contraindicated in any way, although its effect on the MAP should be closely followed.

Remifentanil. Investigations of moderate doses of remifentanil in patients have revealed similar effects to that of other synthetic narcotics (with the exception of its substantially shorter duration of action). In patients undergoing craniotomy for supratentorial space-occupying lesions, 1 μg/kg of remifentanil caused no change in ICP.[108] In a second investigation in patients undergoing craniotomies, approximately 0.35 μg/kg/min of remifentanil resulted in CBF values comparable to those observed with moderately deep anesthesia with either isoflurane-N_2O or fentanyl-N_2O,[109] and CO_2 responsiveness was preserved. Greater doses of remifentanil may have more substantial effects. CBFV in the MCA decreased 30% in response to 5 μg/kg, followed by 3 μg/kg/min of remifentanil at a constant MAP in patients being anesthetized for bypass surgery.[51] A lower dose of 2 μg/kg, followed by an infusion of 3 μg/kg/min, however, did not affect CBFV. Quantitatively similar observations were made after a large dose of sufentanil in patients undergoing cardiac anesthesia (see earlier discussion in the section, "Sufentanil").[50]

Remifentanil was administered with other drugs that might influence cerebral hemodynamics. More recent studies in human volunteers have demonstrated that the infusion of *small* (*sedative*) doses of remifentanil can increase CBF. A PET study in human subjects to whom remifentanil, 0.05 and 0.15 μg/kg/min, was administered revealed increases in CBF in the prefrontal, inferior parietal, and supplementary motor cortices; reductions in CBF were observed in the cerebellum, superior temporal lobe, and midbrain gray matter.[108] The relative increase in CBF was greater with the administration of the larger dose of remifentanil. Similar data were obtained by Lorenz and colleagues,[110] who used magnetic resonance imaging (MRI) to determine CBF.[110] In a PET investigation in human volunteers, Kofke and co-workers[111] observed remifentanil-induced increases in regional CBF within the limbic system. Although the underlying mechanisms of the increases in CBF are not clear, disinhibition produced by the small-dose remifentanil infusion, or perhaps the sensation of side effects (e.g., warmth, comfort, pruritus),[110] may have contributed. When combined with

N_2O, CBF and CO_2 reactivity is similar in patients given remifentanil or fentanyl.[109] In conclusion, sedative doses of remifentanil alone can cause minor increases in CBF. With larger doses or with the concomitant administration of anesthetic adjuvants, CBF is either unaltered or modestly reduced.

Benzodiazepines

Benzodiazepines cause parallel reductions in CBF and CMR in humans. CBF and $CMRO_2$ decreased by 25% when 15 mg of diazepam was given to patients with head injuries.[52] The effects of midazolam on CBF (but not on CMR) have also been studied in humans. Forster and associates[53,112] observed a 30% to 34% reduction in CBF after the administration of 0.15 mg/kg of midazolam to awake healthy human volunteers. Veselis and coworkers,[113] using PET, observed a global 12% reduction in CBF after a similar dose and noted that the decreases preferentially occurred in the brain regions associated with arousal, attention, and memory. CO_2 responsiveness was preserved.[114]

In conclusion, benzodiazepines cause a moderate reduction in CBF in humans, which may be metabolically coupled. The extent of the maximal reductions of CBF and CMR produced by benzodiazepines is probably intermediate between the decreases caused by narcotics (modest) and barbiturates (substantial). It appears that benzodiazepines should be safe to administer to patients with intracranial hypertension, provided that respiratory depression and an associated increase in $Paco_2$ do not occur.

Flumazenil

Flumazenil is a highly specific, competitive benzodiazepine receptor antagonist. It had no effect on CBF when administered to unanesthetized human volunteers.[112,115] However, flumazenil reverses the CBF-, CMR-, and ICP-lowering effects of midazolam. Whereas Knudsen and colleagues[116] observed no change in either CBF or CMR when patients were aroused from midazolam anesthesia with flumazenil at the conclusion of craniotomy for brain tumor resection, Chiolero and coauthors[117] reported severe increases in ICP when flumazenil was given to patients with head injuries who were sedated with midazolam and in whom ICP was poorly controlled before the administration of flumazenil. These latter observations are consistent with animal investigations during which flumazenil not only reversed the CBF and CMR effects of midazolam, but it also caused a substantial, although short-lived, overshoot above premidazolam levels in both CBF and ICP by 44% to 56% and 180% to 217%, respectively. The CMR did not rise above control levels, thus indicating that the increase in CBF was not metabolically coupled. The CBF overshoot effect is unexplained, but it may be a neurogenically mediated arousal phenomenon. Flumazenil should be very cautiously used to reverse benzodiazepine sedation in patients with impaired intracranial compliance.

Droperidol

No human investigations of the CBF and CMR effects of droperidol have been conducted in isolation. However, the information available from animal investigations and combination drug administration in humans,[118,119] taken together, suggests that droperidol is not a cerebral vasodilator and probably has little effect on CBF and CMR in humans. The occasional increases in ICP that have been observed[118] probably reflect normal autoregulation-mediated vasodilation in response to an abrupt decrease in the MAP.

Ketamine

Among the intravenous anesthetics, ketamine is unique in its ability to cause increases in both CBF and CMR.[120] Animal studies indicate that the changes in the CMR are regionally variable. In rats, substantial increases occur in limbic system structures with modest changes or small decreases in cortical structures.[121] PET studies in humans have demonstrated that subanesthetic doses of ketamine (0.2 to 0.3 mg/kg) can increase global CMR by approximately 25%.[122] The greatest increase in the CMR occurred in the frontal and anterior cingulate cortex. A relative reduction in the CMR in the cerebellum was also observed. Commercially available formulations of ketamine contain both the (*S*)- and (*R*)-ketamine enantiomers. The (*S*)-ketamine enantiomer substantially increases CMR, whereas the (*R*) enantiomer tends to decrease the CMR, particularly in the temporomedial cortex and in the cerebellum.[123] These changes in the CMR are accompanied by corresponding changes in CBF.[124] Global, as well as regional, increases in CBF in humans that were not accompanied by similar increases in the $CMRO_2$ after the administration of (*S*)-ketamine enantiomer have been observed. Both subanesthetic and anesthetic doses of ketamine increased global CBF by approximately 14% and 36%, respectively, without altering global $CMRO_2$. As expected, the oxygen extraction ratio was reduced, considering the unchanged CMR and increased CBF. CBV increased by approximately 50%.[59] The majority of investigations indicate that autoregulation is maintained during ketamine anesthesia,[125] and CO_2 responsiveness is preserved.

The anticipated ICP correlate of the increase in CBF and CBV has been confirmed to occur in humans. However, anesthetic drugs (e.g., diazepam, midazolam, isoflurane-N_2O, propofol) blunt or eliminate the increases in ICP or CBF associated with ketamine.[120,126,127] In fact, decreases in ICP occur when relatively large doses of ketamine (1.5 to 5 mg/kg) are administered to patients with head injuries who are sedated with propofol.[128] Accordingly, although ketamine is probably best avoided as the sole anesthetic drug in patients with impaired intracranial compliance, it may be cautiously given to patients who are simultaneously receiving the drugs mentioned earlier (e.g., propofol, opioids).

Lidocaine

Lidocaine produces a dose-related reduction in the $CMRO_2$ in experimental animals.[129] In dogs, 3 mg/kg decreased the $CMRO_2$ by 10%, and 15 mg/kg decreased it by 27%. When very large doses (160 mg/kg) were given to dogs maintained on cardiopulmonary bypass, the reduction in the $CMRO_2$ was apparently more than that observed with large-dose barbiturates.[130] In addition, the membrane-stabilizing effect of lidocaine likely reduces

the energy required for the maintenance of membrane integrity. In unanesthetized human volunteers, Lam and colleagues[131] observed reductions in CBF and CMR of 24% and 20%, respectively, after the administration of 5 mg/kg of lidocaine over a 30-minute period, followed by an infusion of 45 μg/kg/min.

Bedford and co-workers[132] compared the effectiveness of bolus doses of thiopental, 3 mg/kg, and lidocaine, 1.5 mg/kg, in controlling the acute increase in ICP that occurred after the application of a pin head holder or skin incision in patients undergoing craniotomies. The two regimens were equally effective in causing a reduction in ICP. However, the decrease in the MAP was greater with thiopental. Accordingly, a bolus dose of lidocaine is a reasonable adjunct to the prevention or treatment of acute increases in ICP and can prevent increases in ICP associated with endotracheal suctioning. Although large doses of lidocaine can produce seizures in humans and in some experimental animals, lidocaine-induced seizures have not been reported in anesthetized humans. Nonetheless, lidocaine doses should be adjusted to those that achieve serum levels less than the seizure threshold (>5 to 10 μg/mL) in awake humans. After a 2-mg/kg bolus, peak serum concentrations of 6.6 to 8.5 μg/mL are below the seizure threshold. Bolus doses of 1.5 to 2.0 mg/kg therefore seem appropriate.

INHALED ANESTHETICS

Volatile Anesthetics

The pattern of volatile anesthetic effects on cerebral physiology is quite different than the pattern from intravenous anesthetics, which generally cause parallel reductions in CMR and CBF. All volatile anesthetics, similar to intravenous sedative-hypnotic drugs, suppress cerebral metabolism in a dose-related manner.[133-136] Volatile anesthetics also possess intrinsic cerebral vasodilatory activity as a result of direct effects on vascular smooth muscle. The net effect of volatile anesthetics on CBF is therefore a balance between a reduction in CBF caused by CMR suppression and an augmentation of CBF caused by the direct cerebral vasodilation. When administered at a dose of 0.5 MAC, CMR suppression–induced reduction in CBF predominates, and net CBF decreases in comparison with the awake state. At 1 MAC, CBF remains unchanged; at this dose, CMR suppression and vasodilatory effects are in balance. Beyond 1 MAC, the vasodilatory activity predominates, and CBF significantly increases, even though the CMR is substantially reduced (Fig. 17-9[137]). Vasodilation with increasing doses of volatile agents leads to an attenuation of cerebral autoregulation. With large doses, autoregulation is abolished and cerebral perfusion becomes pressure passive (Fig. 17-10).

The increase in CBF produced by volatile anesthetics at doses larger than 1 MAC could reflect uncoupling of flow and metabolism. However, coupling (CBF adjustments paralleling changes in the CMR) persists during anesthesia with volatile anesthetics.[138-141] Accordingly, the conclusion should be that the CBF/CMR ratio is altered (increased) by volatile anesthetics. This alteration is dose related, and, under steady-state conditions,

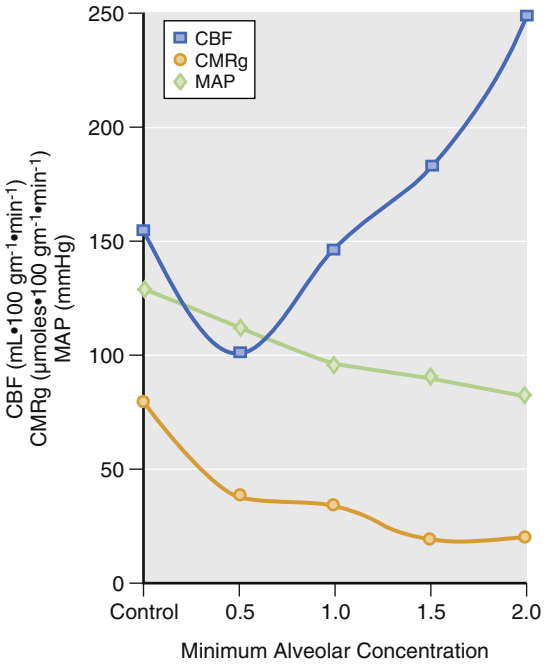

Figure 17-9. Relationship between changes in the cerebral metabolic rate of glucose (CMRg) and cerebral blood flow (CBF) in the motor-sensory cortex in rats during isoflurane anesthesia. The majority of the suppression in the CMR caused by isoflurane has occurred by 1 minimum alveolar concentration (MAC); CBF is not increased in this concentration range. Thereafter, additional isoflurane causes little further reduction in the CMR, and cerebral vasodilation occurs. These data (± standard deviation [SD]) from Maekawa and colleagues[137] suggest the importance of metabolic coupling in determining the effects of isoflurane on CBF. *MAP,* Mean arterial pressure.

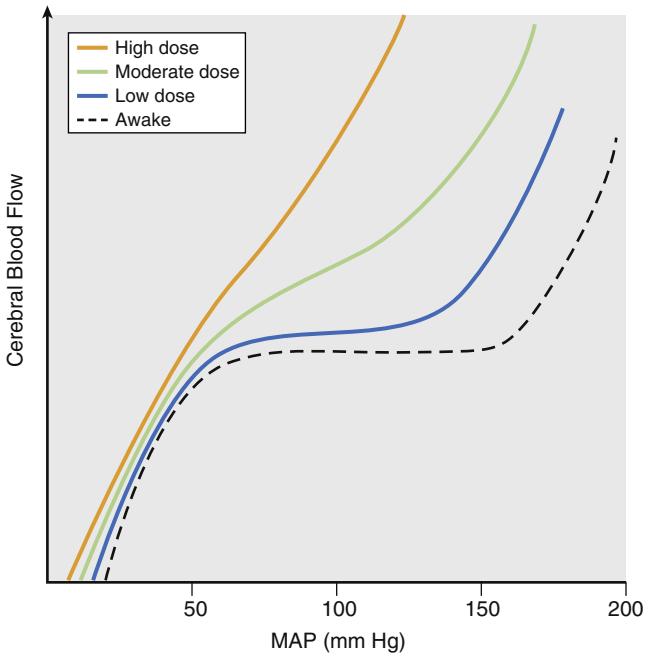

Figure 17-10. Schematic representation of the effect of increasing concentrations of a typical volatile anesthetic drug on autoregulation of cerebral blood flow. Dose-dependent cerebral vasodilation results in attenuation of autoregulatory capacity. Both the upper and lower thresholds are shifted to the left. *MAP,* Mean arterial pressure.

increasing doses of volatile agents lead to greater CBF/$CMRO_2$ ratios[134,142]; that is, higher MAC levels cause more *luxury* perfusion.

The important clinical consequences of the administration of volatile anesthetics are derived from the increases in CBF and CBV—and consequently ICP—that can occur. Of the commonly used volatile anesthetics, the order of vasodilating potency is approximately halothane ≫ enflurane > desflurane ≈ isoflurane > sevoflurane.

Effects on Cerebral Blood Flow. Volatile anesthetics possess intrinsic vasodilatory activity, and they not only modify cerebral autoregulation, but they also produce a dose-dependent decrease in arterial blood pressure. Hence, their effects on CBF and CMR are best evaluated when arterial blood pressure is maintained at the same level. In addition, the cerebrovascular effects of volatile anesthetics are modulated by the simultaneous administration of other CNS-active drugs. The control state, awake, sedated, or anesthetized, against which the CBF and CMR effects of volatile anesthetics are compared, is important to recognize. The best information concerning the cerebrovascular effects of volatile anesthetics is obtained in studies during which a nonanesthetized awake control state is used.

Data on the cerebrovascular effects of halothane and enflurane are limited. Initial studies in humans demonstrated that the administration of 1 MAC halothane significantly increases CBF, even when systemic blood pressure is substantially reduced, in comparison with preanesthetic CBF.[143] The same investigators subsequently showed that in humans, when the MAP is maintained at 80 mm Hg, 1.1 MAC levels of halothane increase CBF by as much as 191% and decrease the CMR by approximately 10% (Fig. 17-11).[143,144,146,148] When compared with awake values, 1.2 MAC enflurane also increased CBF and decreased CMR by 45% and 15%, respectively.[145] The dramatic increases in CBF with a simultaneous modest reduction in the CMR attest to the cerebral vasodilatory properties of halothane and enflurane. Isoflurane, by contrast, does not increase CBF as much as halothane or enflurane. At doses of 1.1 MAC, isoflurane increases CBF by approximately 19% when arterial blood pressure is maintained within the normal range. The CMR is reduced by approximately 45%.[141]

Both sevoflurane and desflurane can significantly reduce CBF in humans when compared with CBF in awake, nonanesthetized patients. At 1 MAC concentrations, sevoflurane[147] and desflurane[145] decreased CBF by 38% and 22% and CMR by 39% and 35%, respectively. These results, which suggest that the cerebral vasodilation produced by isoflurane is greater than that produced by sevoflurane and desflurane, were obtained with CBF measured by the inert gas technique. This technique primarily measures CBF within the cortex and therefore may have substantially underestimated global CBF. PET studies in healthy humans have shown that sevoflurane dose-dependently suppresses the $CMRO_2$ and CBF; at 1 MAC levels, the reduction in CBF and $CMRO_2$ is approximately 50% and 50% to 60%, respectively.[67,68] Even with a significant reduction in CBF, the administration of sevoflurane does not cause a decrease in CBV. In addition, other

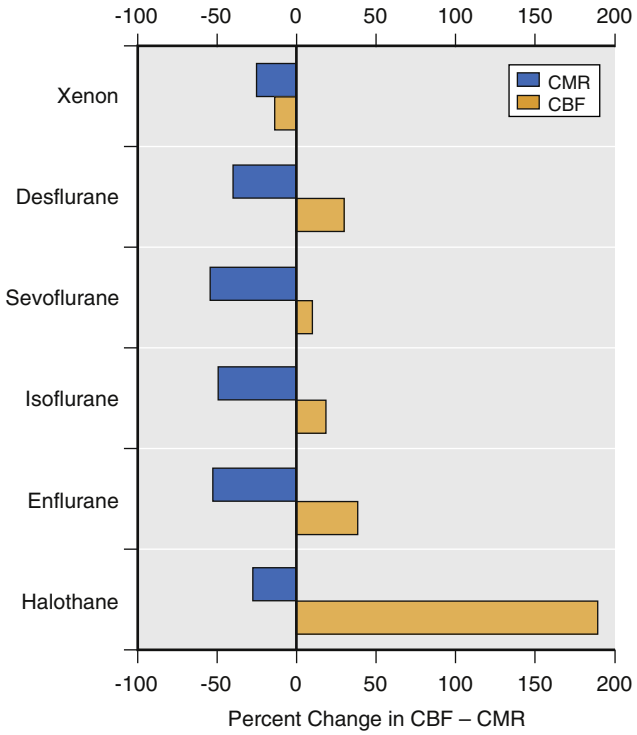

Figure 17-11. Estimated changes in cerebral blood flow (CBF) and the cerebral metabolic rate of oxygen ($CMRO_2$) caused by volatile anesthetics. The CBF data for halothane, enflurane, and isoflurane were obtained during anesthesia (with blood pressure support) at 1.1 minimum alveolar concentration (MAC) in humans[144] and are expressed as percent change from awake control values. The $CMRO_2$ data for halothane, enflurane, and isoflurane were obtained in cats[134,146] and are expressed as percent change from N_2O-sedated control values. The data for sevoflurane were obtained during 1.1 MAC anesthesia in rabbits and are expressed as percent change from a morphine-N_2O–anesthetized control state.[136] CBF values were obtained in patients who received 1 MAC sevoflurane anesthesia.[147] Desflurane data were obtained in patients to whom 1 MAC desflurane was administered.[148]

investigations in humans, most using the measurement of MCA flow velocity by transcranial Doppler, indicate that differences in the effects of isoflurane, desflurane (Fig. 17-12, *A*), and sevoflurane are, at best, modest.[149-151] Unfortunately, a strictly quantitative comparison among these volatile anesthetics is not possible, considering the variations in arterial blood pressure among study group patients. In addition, some discrepancy exists among studies in the literature regarding the magnitude of the effects of volatile anesthetics on CBF. Much of this inconsistency may occur as a result of the interaction of regionally selective CBF methods with the heterogeneity within the cerebrum of the CBF effects of volatile anesthetics. (See the later section, "Distribution of Changes in Cerebral Blood Flow/Cerebral Metabolic Rate.")

The anesthetic properties of xenon were recognized several decades ago, but this anesthetic is only now being evaluated for possible use in patients. The MAC of xenon has been estimated to be 63% to 71%, with female patients having significantly lower MAC values (51%).[152] Xenon primarily exerts its anesthetic effect via noncompetitive antagonism of the *N*-methyl-D-aspartate receptor (NMDAR),[153] although activation of the TREK two-pore

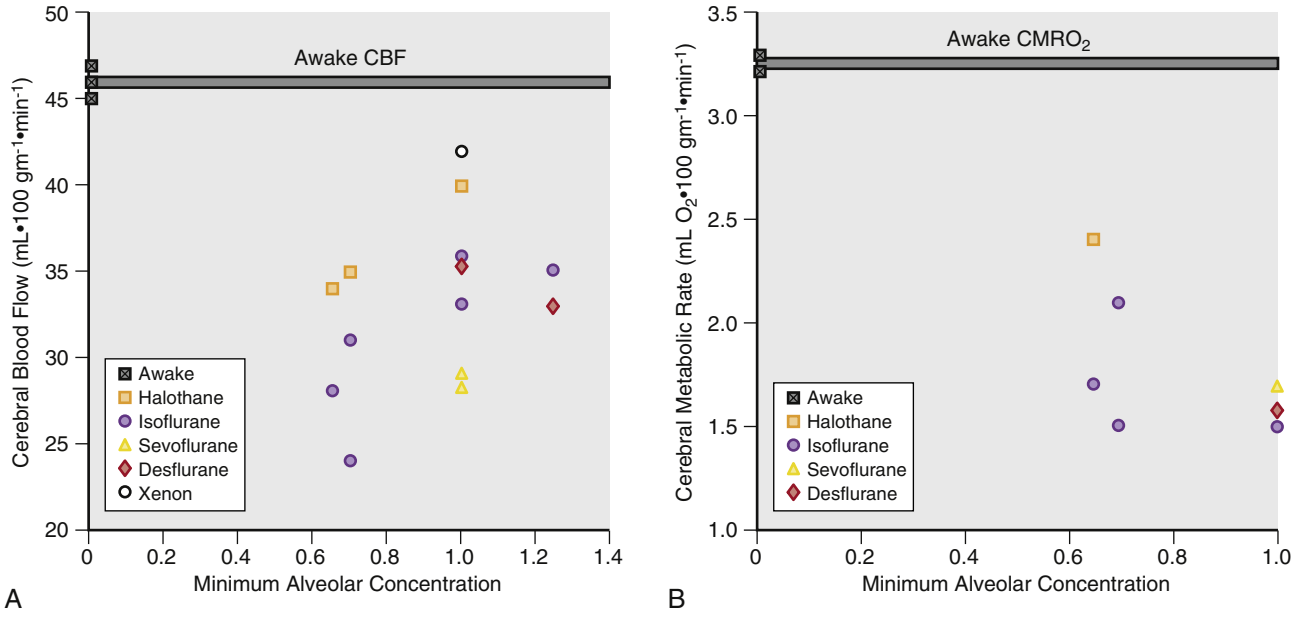

Figure 17-12. Effect of volatile anesthetics on cerebral blood flow (CBF) (**A**) and the cerebral metabolic rate of oxygen ($CMRO_2$) (**B**) in awake humans. The results are a composite of CBF and $CMRO_2$ values obtained from a number of separate investigations.[54,96,134,135,139-151] In these studies, arterial partial pressure of carbon dioxide ($Paco_2$) was maintained in the normocapnic range (~35 to 40 mm Hg), and mean arterial pressure was supported. In most of the investigations, CBF was measured by the inert gas technique. This technique primarily measures cortical CBF and, as such, may underestimate global CBF.

K^+ channel might also play a role.[154] In healthy humans, the administration of 1 MAC xenon resulted in a reduction in CBF by approximately 15% in the cortex and by 35% in the cerebellum; interestingly, CBF in white matter increased by 22%.[155] This reduction in CBF is accompanied by a parallel reduction of the cerebral metabolic rate of glucose (CMRg) by 26%.[156] Cerebral autoregulation and CO_2 reactivity are preserved during xenon anesthesia in animals.[157] Under background pentobarbital anesthesia in an experimental model of increased ICP, the administration of xenon did not increase ICP, and the response to both hypocapnia and hypercapnia was preserved.[158] Diffusion of xenon into air-containing spaces such as the bowel does occur, although the magnitude of air expansion is considerably less than that with N_2O.[159] Accordingly, caution will have to be exercised with the use of xenon in patients with intracranial air. These data indicate that it has a favorable profile for neuroanesthesia.

Effects on Cerebral Metabolic Rate. All of the volatile anesthetics cause reductions in the CMR. The degree of reduction in the $CMRO_2$ that occurs at a given MAC is less with halothane than with the other four anesthetics. Sevoflurane's effect on the $CMRO_2$ is very similar to that of isoflurane. The available information, derived in separate investigations, suggests that desflurane causes slightly less suppression of the $CMRO_2$ than isoflurane, especially at concentrations above 1 MAC.[135] Although a direct comparison of the $CMRO_2$ effects of all of the volatile anesthetics has not been performed in humans, doses of 1 MAC isoflurane, sevoflurane, and desflurane clearly reduce the $CMRO_2$ ($AVDO_2$ in arterial and jugular bulb blood samples) by 25%,[160] 38%,[148] and 22%,[161] respectively. Halothane (0.9 MAC) and isoflurane (0.5 MAC) can decrease the CMRg by 40% and 46%, respectively, in PET studies.[69,162] The decrease in the $CMRO_2$ is dose related. With isoflurane (and almost certainly desflurane and sevoflurane as well), the maximal reduction is simultaneously attained with the occurrence of EEG suppression,[135] which occurs at clinically relevant concentrations, such as 1.5 to 2 MAC in humans. Additional isoflurane up to 6% end-tidal volume results in no further reduction in the CMR and no indication of metabolic toxicity. Halothane presents a contrast to this pattern. Halothane concentrations in excess of 4 MAC are required to achieve EEG suppression in animals, and additional halothane causes a further reduction in the $CMRO_2$ in concert with alterations in energy charge. The latter changes, which are reversible, suggest interference with oxidative phosphorylation. These data indicate that, unlike isoflurane, halothane can produce reversible toxicity when administered in very high concentrations.

Some nonlinearity exists in the CBF and CMR dose-response relationships for volatile anesthetics. The initial appearance of an EEG pattern associated with the onset of anesthesia with halothane, enflurane, and isoflurane is accompanied by a precipitous decline in the $CMRO_2$.[135] Thereafter, the $CMRO_2$ declines in a slower dose-dependent manner. Such an effect has also been demonstrated for sevoflurane. In a dose escalation study in humans, the greatest reduction in entropy (i.e., a measure of anesthetic depth) was observed with 1 MAC sevoflurane anesthesia, with lesser reductions occurring at increasing concentrations.[163] Other studies during anesthetic induction with halothane found significant increases in CBF before any alteration in the CMR. This finding suggests that the direct effect of a volatile agent on smooth muscle may develop more rapidly than influences related to the depression of the CMR.

Distribution of Changes in Cerebral Blood Flow and Cerebral Metabolic Rate. The regional distribution of anesthetic-induced changes in CBF and CMR significantly differs with halothane and isoflurane. Halothane produces relatively homogeneous changes throughout the brain. CBF is globally increased, and CMR is globally depressed. The changes caused by isoflurane are more heterogeneous. Increases in CBF are greater in subcortical areas and hindbrain structures than in the neocortex.[140,164,165] The converse is true for the CMR, with a larger reduction in the neocortex than in the subcortex.[137] In humans, 1 MAC sevoflurane (Fig. 17-13) results in a reduction in CBF within the cortex and the cerebellum. With an increase in sevoflurane dose, CBF within the cortex decreases further. By contrast, flow increases in the cerebellum with doses greater than 1.5 MAC.[67] These effects of sevoflurane are similar to those produced by isoflurane.[67,165] Desflurane has not been evaluated by local CBF studies. However, considering the similarity of its effects on the EEG (suggesting similar cortical CMR and CBF effects), the interim assumption of similar heterogeneity in CBF distribution seems reasonable. These distribution differences may explain certain apparent contradictions in reported CBF effects in the existing literature for isoflurane. Methods that assess global hemodynamic effects reveal greater changes than those that emphasize the cortical compartment. For instance, Eintrei and co-workers[166] found no increase in CBF by surface xenon washout when isoflurane was administered to patients undergoing craniotomy, yet others[167-169] have reported that the administration of isoflurane to normocapnic subjects with intracranial pathologic conditions can result in increases in CSF pressure.

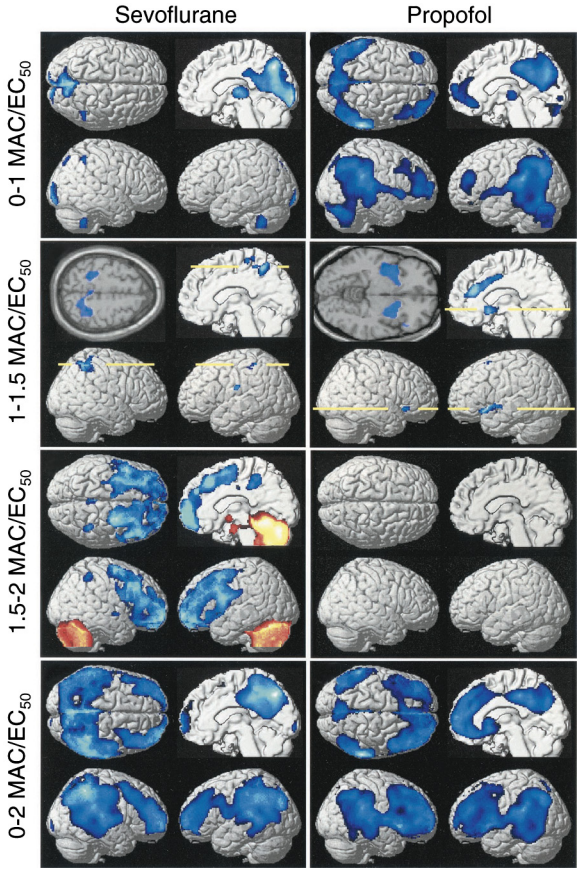

Figure 17-13. Dose-dependent redistribution of cerebral blood flow (CBF) in humans. Positron-emission tomography (PET) scans demonstrate a dose-dependent reduction in CBF in both sevoflurane-anesthetized (*left*) and propofol-anesthetized (*right*) subjects. During sevoflurane anesthesia, an increase in concentration from 1.5 to 2 minimum alveolar concentration (MAC) leads to an increase in CBF within the subcortex, particularly in the cerebellum. A gradual reduction in the mean arterial pressure (MAP) occurred with increasing concentrations of sevoflurane, and the MAP was not supported. The CBF values would be expected to be considerably greater had blood pressure been maintained within the normal range. Therefore the CBF values represented in this figure probably *underestimate* true CBF during sevoflurane anesthesia. In propofol-anesthetized subjects, CBF was uniformly decreased and redistribution of CBF was not observed. EC_{50}, Half-maximal effective concentration. *(From Kaisti K, Metsähonkala L, Teräs M, et al: Effects of surgical levels of propofol and sevoflurane anesthesia on cerebral blood flow in healthy subjects studied with positron emission tomography,* Anesthesiology *96:1358-1370, 2002.)*

Time Dependence of Cerebral Blood Flow Effects. The effects of volatile anesthetics on CBF are time dependent in animal investigations. After an initial increase, CBF substantially decreases and reaches a steady state near pre–volatile agent levels between 2.5 and 5 hours after exposure.[164,170,171] The mechanism of this effect is not understood, and the phenomenon was not evident in humans studied during a 3- or 6-hour exposure to halothane, isoflurane, desflurane, or sevoflurane.[151,172]

Cerebral Blood Volume. The extensive investigation of the influence of volatile anesthetics on CBF has been primarily based on the concern that the cerebral vasodilation produced by volatile anesthetics might increase ICP. However, it is CBV and not CBF, per se, that influences ICP. Most of the intracranial blood is within the cerebral venous circulation; although a reasonable correlation exists between vasodilation-induced increases in CBF and CBV, the magnitude of changes in CBF is considerably greater than that in CBV (see Fig. 17-7). Hence, changes in CBF do not reliably predict changes in CBV and, by extension, in ICP. Nonetheless, CBV is considerably greater during isoflurane anesthesia than during propofol or pentobarbital anesthesia.[43] In human volunteers, 1 MAC sevoflurane reduced regional CBF but not regional CBV; by contrast, propofol reduced both regional CBF and regional CBV (Fig. 17-14).[68] In addition, CBV responds to changes in $Paco_2$ by a reduction in CBV with hypocapnia and an increase in CBV with hypercapnia. The magnitude of the change in CBV is, however, less than the change in CBF. In aggregate, although the effect of anesthetics and interventions on CBF may parallel the effect on CBV, substantial qualitative and quantitative differences may well be observed.

Carbon Dioxide Responsiveness and Autoregulation. CO_2 responsiveness is well maintained during anesthesia with all volatile anesthetics.[173-175] As with all vasodilators, CBF is preserved up to lower MAP values during the administration of volatile anesthetics with no evidence of differences among the various anesthetics. Direct comparisons of CBF with isoflurane, desflurane, and sevoflurane anesthesia

during hypotension are not available. By contrast, autoregulation of CBF in response to increasing arterial blood pressure is impaired, which is most apparent with the anesthetics that cause the most cerebral vasodilation and are dose related. Sevoflurane may cause less impairment of autoregulation than other volatile anesthetics. Recent studies surprisingly report no change in CBFV in response to phenylephrine-induced increases in the MAP during anesthesia with 1.2 to 1.5 MAC sevoflurane[176,177] or in CBF during hemorrhagic hypotension.[178] The autoregulatory response to increasing blood pressure may be pertinent during acute episodes of hypertension, such as during laryngoscopy or mismatch of surgical stimulation to anesthetic depth. Some relevance to hyperemic states after carotid endarterectomy (CEA) or resection of arteriovenous malformations might exist (also see Chapter 70).

Cerebral Vasodilation by Anesthetics—Clinical Implications. Isoflurane, desflurane, and sevoflurane may have a modest cerebral vasodilating effect in the human cortex when administered at doses of 1 MAC or less. In fact, the administration of volatile anesthetics can effect net decreases in CBF (see Fig. 17-12, *A*). These data, however, should be interpreted with considerable caution because the critical variable that is of interest in the clinical setting is CBV. Although a direct correlation exists between CBF and CBV, as noted earlier, the relationship is not strictly 1:1. The magnitude of the changes in CBV is significantly less than the magnitude of the changes in CBF, and modest reductions in CBF may not necessarily be accompanied by reductions in CBV. This finding is exemplified by clinical investigations in which a significant increase in ICP (and by extension, CBV) was observed in patients to whom isoflurane was administered at doses that should reduce CBF.[167,169] Although induction of hypocapnia mitigated the increase in ICP, hyperventilation may not be effective in blunting isoflurane-induced increases in ICP in patients with intracranial tumors.[168] In experimental investigations of cerebral injury, volatile anesthetics significantly increased ICP, which was not ameliorated by hypocapnia.[179] Collectively, these data suggest that volatile anesthetics have minimal effects on cerebral hemodynamics in patients with normal intracranial compliance. However, in patients with abnormal intracranial compliance, the potential for volatile anesthetic–induced increases in CBV and ICP exist. Accordingly, volatile anesthetics should be used with caution in the setting of large or rapidly expanding mass lesions, unstable ICP, or other significant cerebral physiologic derangements in which CO_2 responsiveness and flow-metabolism coupling may be impaired. When they occur (e.g., a somnolent, vomiting patient with papilledema; a large mass; compressed basal cisterns), the clinician may well be advised to use a predominantly intravenous technique until such time when the cranium and dura are open and the effect of the anesthetic technique can be directly assessed. Such circumstances will be relatively rare in elective neurosurgery.

Situations in which the CMR has been decreased by drug administration or disease processes should also justify caution in the use of volatile anesthetics. If a volatile anesthetic has a substantial direct vasodilating effect on the cerebral vasculature that is normally offset by an opposing metabolically mediated vasoconstricting influence, then a near-maximal reduction of the CMR may have occurred; a volatile anesthetic will have a predominantly vasodilating effect.[73,139] These data suggest that isoflurane is a significant cerebral vasodilator when administered in situations during which the component of the CMR that is associated with electrophysiologic function is already suppressed by other drugs[73,139] or pathologic processes, such as traumatic brain injury.

The net vasodilating effects of equi-MAC concentrations of isoflurane, desflurane, and sevoflurane are less in

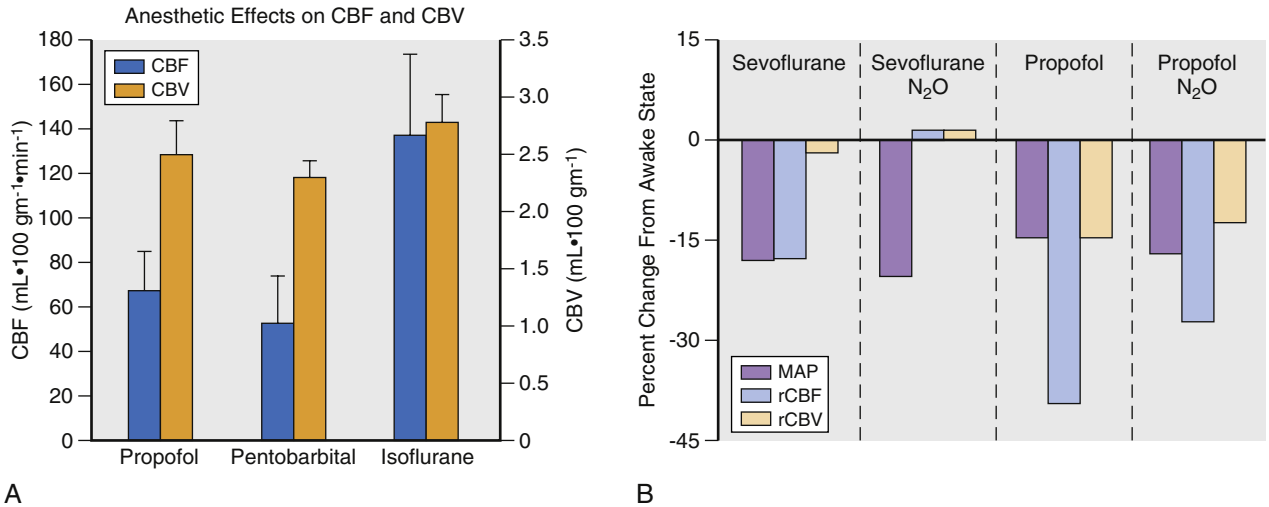

Figure 17-14. Effect of anesthetic drugs on cerebral blood flow (CBF) and cerebral blood volume (CBV). **A,** When compared with isoflurane, propofol and pentobarbital effected substantial reductions in CBF. However, reductions in CBV were more modest.[156] **B,** Although sevoflurane effected a significant reduction in regional CBF (rCBF), regional CBV (rCBV) was unchanged; had blood pressure been supported to normal levels, rCBV may have been greater than the awake state. By contrast, propofol effected a significant reduction in both rCBF and rCBV. These data indicate that the magnitude of the effect of anesthetics on rCBF is substantially greater than on rCBV. Hence, decreases in rCBF may not lead to equivalent reductions in rCBV. *MAP,* Mean arterial pressure; *N_2O,* nitrous oxide.

humans than that of halothane, and the former are probably therefore preferable if a volatile anesthetic is to be used in the setting of impaired intracranial compliance. When hypocapnia is established before the introduction of halothane, the increases in ICP that might otherwise occur in a normocapnic patient with poor intracranial compliance can be prevented or greatly attenuated. Nonetheless, isoflurane, desflurane, or sevoflurane are preferred because the margin for error is probably wider than with halothane.

Nitrous Oxide

N_2O can cause increases in CBF, CMR, and ICP. At least a portion of the increases in CBF and CMR may be the result of a sympathoadrenal-stimulating effect of N_2O. The magnitude of the effect considerably varies according to the presence or absence of other anesthetic drugs (Fig. 17-15[180-182]). When N_2O is administered alone, very substantial increases in CBF and ICP can occur. In sharp contrast, when N_2O is administered in combination with intravenous drugs, including barbiturates, benzodiazepines, narcotics, and propofol, its cerebral-vasodilating effect is attenuated or even completely inhibited. The addition of N_2O to anesthesia established with a volatile anesthetic will result in moderate increases in CBF.

Nitrous Oxide Administered Alone. The most dramatic reported increases in ICP or CBF in humans[183] and experimental animals[184] have occurred when N_2O was administered alone or with minimal background anesthesia. For instance, Henriksen and Jorgensen[183] recorded ICP before and during spontaneous breathing of 66% N_2O by patients with intracranial tumors. Mean ICP increased from 13 to 40 mm Hg. The increases in CBF observed in humans are more modest than those observed in animals but are still substantial.[180] Whether these substantial increases represent the effects of N_2O, per se, or whether they reflect the nonspecific effects of a *second-stage* arousal phenomenon is not known.

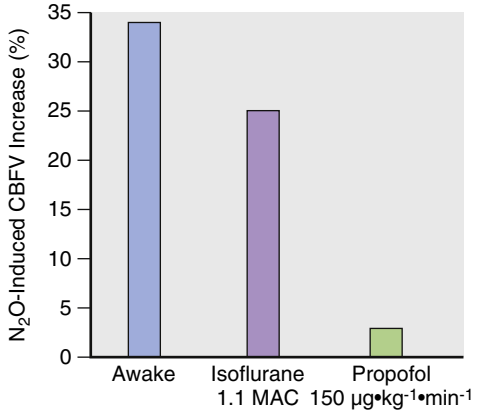

Figure 17-15. Mean percent increases in cerebral blood flow velocity (CBFV) in the middle cerebral artery of normocapnic subjects exposed to 60% nitrous oxide (N_2O) after control recording in three conditions: awake[180]; 1.1 minimum alveolar concentration (MAC) of isoflurane[181]; and propofol, 150 μg•kg^{-1}•min^{-1}.[182]

Nitrous Oxide Administered With Intravenous Anesthetics. When N_2O is administered in conjunction with certain intravenous anesthetics, its CBF effect may be considerably attenuated. Phirman and Shapiro[185] observed that a reproducible increase in ICP that occurred in response to the administration of 70% N_2O to a comatose patient was prevented by the previous administration of a combination of thiopental and diazepam, despite no change in baseline ICP. In an investigation of patients with intracranial tumors and poor intracranial compliance (mean preinduction ICP, 27 mm Hg),[186] 50% N_2O introduced during barbiturate anesthesia and after the induction of hypocapnia had a negligible effect on ICP. Jung and associates[187] compared lumbar CSF pressure in patients with brain tumors during the administration of 0.7% isoflurane or 70% N_2O after the induction of anesthesia with a barbiturate. Lumbar CSF pressure was modestly but significantly greater with N_2O. The fact that the increase was less dramatic than those cited earlier for N_2O alone may reflect the presence of residual barbiturate. Benzodiazepines administered alone have been shown to blunt the CBF response to N_2O in both animals and humans.[110] Narcotics appear to have a similar effect. Jobes and coauthors[48] reported that anesthesia with 1 mg/kg morphine plus 70% N_2O resulted in no change in CBF from awake control values. Because of the very minor effect of morphine on CBF, these data suggest that N_2O did not cause substantial cerebral vasodilation. Although the addition of N_2O to propofol anesthesia in children increased MCA flow velocity,[188] such increases have not been demonstrated by other investigators[182] (also see Chapter 93).

Nitrous Oxide Administered With Volatile Anesthetics. In most investigations, including several in humans, during which N_2O has been added to an anesthetic of 1 MAC or greater, substantial increases in CBF have been recorded.[181,189-192] Algotsson and associates[193] examined the effect of an approximately equi-MAC substitution of N_2O for isoflurane. They compared CBF in patients anesthetized with 1.5 MAC isoflurane and 0.75 MAC isoflurane with 65% N_2O. They observed 43% greater CBF with the latter, again consistent with a substantial vasodilating effect of N_2O in the presence of a volatile agent. Similar observations were made by Lam and coauthors[181] and Strebel and colleagues.[192] Several investigations have confirmed that CBF will be less with 1 MAC isoflurane than with a 1 MAC combination achieved with 50% to 65% N_2O and isoflurane.[181,193,194]

This vasodilating effect of N_2O may be positively correlated with the concentration of inhaled drug[192] and suggests that, in general, the increase in CBF caused by N_2O is exaggerated at higher concentrations of both halothane and isoflurane. Of importance, however, is the observation of Reinstrup and co-workers,[195] who demonstrated that the administration of 50% N_2O to healthy volunteers did not significantly alter CBV. In support of this observation, Kaisti and colleagues[68] did not observe any effect of N_2O on CBV when added to a background of 1 MAC sevoflurane anesthesia. Although N_2O can increase CBF, these data indicate that its effect on CBV is modest at best.

Effects of Nitrous Oxide on Cerebral Metabolic Rate. No uniform agreement has been reached concerning the effect of N_2O on the CMR. Parallel changes in CBF and CMR,[184] increases in CBF without alteration of the CMR,[196] and CMR alteration occurring without changes in CBF[143] have all been reported. These findings are, doubtless, the product of differences in species, methods, depth of background anesthesia, and interactions with simultaneously administered anesthetics. In a recent investigation in humans, the administration of 70% N_2O on a background of either sevoflurane or propofol anesthesia resulted in modest increases in the $CMRO_2$, thus indicating that N_2O does indeed increase cerebral metabolism.[68]

The CBF response to CO_2 is preserved during the administration of N_2O.[197]

Clinical Implications. Despite the inconsistencies that are evident, the vasodilatory action of N_2O can be clinically significant in neurosurgical patients with reduced intracranial compliance. However, N_2O-induced cerebral vasodilation can be considerably blunted by the simultaneous administration of intravenous anesthetics. By contrast, the addition of N_2O to a volatile drug–based anesthetic can modestly increase cerebral metabolism and blood flow. N_2O has been widely used in neurosurgery, and banishing it is inconsistent with the accumulated experience. Nonetheless, in circumstances wherein ICP is persistently elevated or the surgical field is persistently *tight*, N_2O should be viewed as a potential contributing factor. Because N_2O rapidly enters a closed gas space, it should be avoided or omitted when a closed intracranial gas space may exist or intravascular air is a concern.

MUSCLE RELAXANTS

Nondepolarizing Relaxants

The only recognized effect of nondepolarizing muscle relaxants on the cerebral vasculature occurs via the release of histamine (also see Chapters 34 and 53). Histamine can result in a reduction in CPP because of the simultaneous increase in ICP (caused by cerebral vasodilation) and a decrease in the MAP.[198] When the BBB is intact, it is not entirely clear whether histamine directly causes cerebral vasodilation or whether it is a secondary (autoregulatory) response to a reduction in the MAP. *d*-Tubocurarine is the most potent histamine releaser among available muscle relaxants. Metocurine, atracurium, and mivacurium also release histamine in lesser quantities. This effect is likely to be clinically inconsequential unless these muscle relaxants are administered in the large doses necessary to achieve endotracheal intubating conditions rapidly. Of this group of drugs, cisatracurium has the least histamine-releasing effect. No evidence of histamine release was observed after the administration of 0.15 mg/kg (three times the 95% effective dose [ED_{95}] for twitch depression) of cisatracurium to neurosurgical patients in the ICU.[199] Yet, cisatracurium's slow onset of action makes it not useful for a rapid-sequence induction of anesthesia.

Vecuronium, in relatively large doses of 0.1 to 0.14 mg/kg, had no significant effect on cerebral physiology in patients with brain tumors.[200] The other aminosteroids, pipecuronium and rocuronium, should be similarly without direct effect, and no adverse events have been reported.

The indirect actions of relaxants may also have effects on cerebral physiology. Pancuronium given as a large bolus dose can cause an abrupt increase in arterial pressure, which might increase ICP in patients with impaired intracranial compliance and defective autoregulation; however, no significant clinical event has ever been reported. Muscle relaxation may reduce ICP because coughing and straining are prevented, which decreases central venous pressure with a concomitant reduction in cerebral venous outflow impedance.

A metabolite of atracurium, laudanosine, may be epileptogenic. However, although large doses of atracurium caused an EEG arousal pattern in dogs, CBF, CMR, and ICP were unaltered.[201] In rabbits, the administration of laudanosine did not increase the severity of the epileptoid activity caused by the direct application of a cephalosporin to the cortical surface.[202] It appears highly unlikely that epileptogenesis will occur in humans with atracurium.[203]

In summary, vecuronium, pipecuronium, rocuronium, atracurium, mivacurium, cisatracurium, metocurine, and pancuronium (if acute MAP increases are prevented with the latter) are all reasonable muscle relaxants for use in patients with or at risk for intracranial hypertension. Doses of metocurine, atracurium, and mivacurium should be limited to ranges not associated with hypotension.

Rocuronium will probably be increasingly used for the induction of anesthesia, as well as for intraoperative relaxation. It has the most rapid onset time of any nondepolarizing muscle relaxant. With sugammadex, even a profound neuromuscular blockade can be rapidly reversed (see Chapters 34 and 35).

Succinylcholine

Succinylcholine can produce modest increases (~5 mm Hg) in ICP in lightly anesthetized humans. This effect appears to be the result of cerebral activation (as evidenced by EEG changes and increases in CBF) caused by afferent activity from the muscle spindle apparatus.[204] However, a poor correlation between the occurrence of visible muscle fasciculations and an increase in ICP have been noted. As might be expected with what appears to be an arousal phenomenon, deep anesthesia has been observed to prevent succinylcholine-induced increases in ICP in the dog. In humans, the increase in ICP is also blocked by paralysis with vecuronium and by *defasciculation* with metocurine, 0.03 mg/kg.[200] The efficacy of other defasciculating anesthetics has not been examined in humans.

Although succinylcholine *can* produce increases in ICP, it can still be used for a rapid-sequence induction of anesthesia. Kovarik and coauthors[205] observed no change in ICP after the administration of succinylcholine, 1 mg/kg, to 10 nonparalyzed, ventilated neurosurgical patients in the ICU, 6 of whom had sustained a head injury. Their observations are very relevant because it is in precisely this population of patients that the issue of the use of succinylcholine arises most frequently. Considering that the ICP effects of succinylcholine may be an arousal

phenomenon caused by increased afferent traffic from muscle spindles,[204] it is not unreasonable to assume that disease processes that substantially blunt the level of consciousness might similarly blunt this response. As with many anesthetics, the concern should not be whether it is used but how it is used. If administered with proper attention to the control of CO_2 tension, arterial blood pressure, and depth of anesthesia and after defasciculation, then little hazard should attend its use.

OTHER EFFECTS OF ANESTHETICS ON CEREBRAL PHYSIOLOGY

CEREBROSPINAL FLUID DYNAMICS

Approximately 150 mL of CSF is in the adult human, one-half within the cranium and one-half in the spinal CSF space. CSF, which is formed in the choroid plexuses and, to a lesser extent, in the brain's interstitium with transependymal diffusion into the ventricular system, is replaced approximately three to four times per day. It functions both as a cushion for the CNS and as an excretory pathway. Anesthetics have been shown to influence both the rate of formation and the rate of reabsorption of CSF. Table 17-3 provides nonquantitative information about the direction of the influences of common anesthetic drugs. All the information has been derived from animals,[207-213] and these processes have not been examined in humans. Of the volatile anesthetics, halothane decreases secretion of CSF, isoflurane has no effect, and enflurane and desflurane increase secretion. Absorption of CSF is reduced by halothane and enflurane, unchanged by desflurane, and increased by isoflurane. Although probably of minimal relevance to clinical practice, a theoretic concern might be in the setting of a prolonged closed-cranium procedure in a patient with poor intracranial compliance. The most deleterious potential combination of effects in a patient with poor intracranial compliance is increased CSF production and decreased reabsorption. This pattern occurs with enflurane in the dog, which is perhaps another reason (in addition to the potential for epileptogenesis in the presence of cerebral injury and hypocapnia) for omission of enflurane in this circumstance.

BLOOD-BRAIN BARRIER

In the majority of the body's capillary beds, fenestrations between endothelial cells are approximately 65 Å in diameter. In the brain, with the exception of the choroid plexus, in the pituitary, and in the area postrema, tight junctions reduce this pore size to approximately 8 Å. As a result, large molecules and most ions are prevented from entering the brain's interstitium (BBB). A limited number of studies of anesthetic effects on the BBB have been conducted. In experimental animals, 1% isoflurane leads to extravasation of albumin into the thalamus, indicating some compromise of the BBB integrity. At higher doses, isoflurane (3%) significantly increases protein extravasation, not only in the thalamus but also in the cortex.[214] This disruption of the BBB is quantitatively similar to what is achieved by mannitol. In experimental models of brain injury, isoflurane has been reported to both exacerbate[215] and ameliorate[216] edema formation in the injured brain. Whether these effects are the result of isoflurane action at the BBB, per se, or to hemodynamic perturbations attendant with anesthesia is not known. The clinical relevance of the potential BBB modulation by anesthetics is not clear. To the authors' knowledge, no peer-reviewed investigation has attempted a comparison of anesthetic effects on BBB function during anesthesia in normotensive humans.

EPILEPTOGENESIS

An extensive review of the convulsant and anticonvulsant effects of anesthetics and adjuvants is available.[217,218] Several commonly used anesthetics have some epileptogenic potential, particularly in predisposed individuals. A concern is that seizure activity may go unrecognized in an anesthetized and paralyzed patient and may result in neuronal injury if substrate demand (CMR) exceeds supply for a prolonged period.[219] A second concern is that the epileptogenic effect will persist in the postanesthesia period when seizures may occur in less well-controlled circumstances than those that exist in the surgical unit. In practice, it appears that spontaneous seizures during or after anesthesia have been extremely rare events. Nonetheless, in patients with processes that might predispose them to seizures, the use of potentially epileptogenic drugs should be avoided in situations during which reasonable alternatives are available.

Volatile Anesthetics

Enflurane is potentially epileptogenic in the clinical setting. Of particular relevance to neuroanesthesia is the observation that hypocapnia potentiates seizure-type discharges during enflurane anesthesia.[220] A 50% decrease in the $CMRO_2$ was noted in human volunteers anesthetized with 3% enflurane; however, with the onset of seizure activity, the $CMRO_2$ returned to normal,[221] thus indicating preservation of flow-metabolism coupling. No evidence suggests that this type of EEG activity is deleterious when oxygen delivery is maintained during the event. However, because seizure activity can elevate brain metabolism by as much as 400%, the use of enflurane,

TABLE 17-3 EFFECTS OF ANESTHETIC AGENTS ON THE RATE OF CSF SECRETION AND ABSORPTION

	Halothane	Enflurane	Isoflurane	Desflurane	Fentanyl	Etomidate
Secretion	↓	↑	---	↑	---	↓
Absorption	↓	↓	↑	---	↑	↑

Upward arrows indicate an increase in the rate of cerebrospinal fluid (CSF) absorption or secretion, and downward arrows indicate a decrease. The information is presented nonquantitatively, and effects may vary with dose.

especially at high doses and with hypocapnia, should probably be avoided in patients predisposed to seizures or those with occlusive cerebrovascular disease.

The EEG-activating property of enflurane has been intraoperatively used to activate and identify seizure foci that are to be surgically resected; and, in this situation, spike activity not preoperatively present has been observed to persist after surgery.[222] In addition, two reports of seizures in the immediate postoperative period after enflurane anesthesia in both predisposed[223] and nonpredisposed[224] individuals have been recounted. No permanent sequelae appeared to occur as a result of these events, and, in fact, this association is not a rigorously proven one. At worst, such occurrences are extremely uncommon.

Isoflurane can cause EEG spiking and myoclonus, but it has not been associated in the experimental setting with the frank epileptoid activity induced by enflurane. The clinical experience with isoflurane is extremely large, and unexplained seizurelike activity has been reported in only two patients. One occurrence was intraoperative,[225] and the other incidence was immediately postoperative.[226] Therefore epileptogenesis does not appear to be a clinical concern with isoflurane. In fact, isoflurane has been successfully used to control EEG seizure activity in refractory status epilepticus.[227]

Seizures occur during the induction of anesthesia with high concentrations of sevoflurane in children, including those without a recognized seizure diathesis.[228] In two healthy humans, EEG burst suppression with 2 MAC sevoflurane was accompanied by epileptiform discharges that were observed during EEG monitoring.[229] These discharges were associated with a significant increase in CBF, thus demonstrating that flow-metabolism coupling was preserved. In patients with temporal lobe epilepsy, the administration of 1.5 MAC sevoflurane elicited widespread paroxysmal EEG activity. Of note was the observation that paroxysmal activity was not restricted to the ictal focus and that the administration of sevoflurane did not provide any assistance in localizing the epileptogenic region of the brain.[230] The development of tonic-clonic movements indicative of seizure activity has also been reported in otherwise healthy patients on emergence from sevoflurane anesthesia.[231,232] In all of the reported cases of seizure activity attributable to sevoflurane anesthesia, untoward sequelae have not been documented. These reports highlight sevoflurane's ability, albeit small, to evoke epileptiform activity; accordingly, the use of sevoflurane in patients with epilepsy should be undertaken with appropriate caution.

Methohexital

Myoclonic activity is sometimes observed with methohexital. Accordingly, this anesthetic has been used to activate seizure foci during cortical mapping.[229,233] In neurosurgical patients to whom larger doses of methohexital were administered to produce burst suppression of the EEG, refractory seizures have occurred.[234] Accordingly, it appears that patients with seizures of temporal lobe origin, typically of the psychomotor variety or those to whom large doses are administered, are at risk for seizure activation by methohexital. However, prolonged seizure activity after single-dose methohexital administration has not been reported in patients who undergo ECT.

Ketamine

Ketamine can elicit seizures in patients with an epileptic diathesis.[235] Depth electrode recordings in epileptic patients have revealed the occurrence of isolated subcortical seizure activity originating in the limbic and thalamic areas during ketamine anesthesia and demonstrated that this subcortical activation may not be reflected in surface EEG recordings.[236] Seizures have also been reported to occur after ketamine anesthesia in subjects who are neurologically normal on only two occasions[237,238]; seizure thresholds may have been lowered by aminophylline in one of these instances.

Etomidate

Etomidate frequently produces myoclonus that is not associated with epileptiform activity on the EEG.[239] A single instance of severe, sustained myoclonus immediately after anesthesia with etomidate by infusion has been reported.[240] Etomidate has also been shown to precipitate generalized epileptic EEG activity in epileptic patients,[241] and its use in this population should probably be avoided. However, it has been electively used in low doses to activate seizure foci for the purposes of intraoperative EEG localization.[242] In the experience of the authors (unpublished), selective activation of a quiescent focus can be achieved with 0.1 mg/kg etomidate. Larger doses are more likely to lead to generalized activation.

Etomidate is also associated with longer seizures in response to ECT than seizures that occur after the administration of methohexital or propofol. Remarkably, etomidate, in the dose range of 0.15 to 0.3 mg/kg, does not cause dose-related seizure inhibition during ECT as is readily demonstrated with methohexital or propofol.

The preceding information notwithstanding, no convincing reports indicate epileptogenesis in subjects who are neurologically normal, and the use of etomidate need not be restricted on this basis. In fact, etomidate has been used to control refractory status epilepticus.

Propofol

Seizures and opisthotonos can occur after propofol anesthesia. However, systematic studies in both humans[243] and animals,[244] although identifying the occurrence of occasional dystonic and choreiform movements, have failed to confirm propofol as a proconvulsant. In fact, propofol appears to be anticonvulsant in mice.[244] Furthermore, ECT seizures were shorter after induction with propofol than after induction with methohexital,[245] which is more consistent with an *anticonvulsant* effect. In addition, propofol sedation has been widely used during *awake* resection of seizure foci and other intracranial lesions. Although pronounced high-amplitude beta-frequency activity in the EEG has been observed,[246] unexpected incidences of seizures have not been reported.

Narcotics

Seizures or limbic system hypermetabolism (or both) can be readily elicited in some animal species with narcotics. Although an increase in CBF in deep brain

structures associated with pain processing has been observed in human volunteers,[84] humans do not have a clinically apparent correlate of the hypermetabolism effect observed in animals. Several anecdotal accounts, unaccompanied by EEG recordings, have reported the occurrence of grand mal convulsions in patients who received both high and low doses of fentanyl. However, systematic investigations of EEG changes during the administration of relatively large doses of fentanyl, sufentanil, and alfentanil in humans have *not* documented neuroexcitatory activity,[247-249] and the seizures may have been an exaggerated rigidity phenomenon. There are exceptions. Tempelhoff and coauthors[250] reported partial complex seizures on the induction of anesthesia with fentanyl in patients undergoing anterior temporal lobectomy. Eight of the nine patients displayed electrical seizure activity at a range of clinically relevant fentanyl doses (mean, 26 μg/kg).[250] Another study found that alfentanil, 50 μg/kg, augmented temporal lobe spike activity in patients with temporal lobe epilepsy.[251] Untreated rigidity may, itself, also have important CNS consequences. ICP elevation can occur during narcotic-induced rigidity, probably as a consequence of cerebral venous congestion.

NEONATAL ANESTHETIC NEUROTOXICITY

This subject is discussed in detail in Chapter 93.

CEREBRAL PHYSIOLOGY IN PATHOLOGIC STATES

CEREBRAL ISCHEMIA—PATHOPHYSIOLOGIC CONSIDERATIONS

Critical Cerebral Blood Flow Thresholds

The brain has a high rate of energy utilization and very limited energy storage capacity. The brain is therefore extremely vulnerable in the event of interruption of substrate (e.g., oxygen, glucose) supply. Under normal circumstances, global CBF is maintained at approximately 50 mL/100 g/min. In the face of a declining CBF and therefore oxygen supply, neuronal function deteriorates in a progressive manner rather than in an all-or-none fashion (Fig. 17-16[256,257]). There is substantial reserve below normal CBF levels, and not until EEG evidence of ischemia begins to appear is CBF decreased to approximately 20 mL/100 g/min. At a CBF level of approximately 15 mL/100 g/min, the cortical EEG is isoelectric. However, only when CBF is reduced to approximately 6 to 10 mL/100 g/min are indications of potentially irreversible membrane failure, such as increased extracellular potassium[252] and a loss of the direct cortical response, rapidly evident. As CBF decreases in the flow range between 15 and 10 mL/100 g/min, a progressive deterioration in energy supply occurs and eventually leads to membrane failure and neuronal death at a time course that may last hours rather than minutes. The brain regions falling within this CBF range (6 to 15 mL/100 g/min) encompass brain tissue in which neuronal dysfunction is temporarily reversible but within which neuronal death will occur if flow is not restored; such regions are referred to as the *ischemic penumbra*.[252,253] Studies defining progression to cerebral infarction within the penumbra have been principally performed in the cerebral cortex of primates, and the actual CBF levels at which the various decrements in function occur may vary with both anesthetic[254] and species. However, in humans anesthetized with halothane and N_2O, the CBF threshold for the initial EEG change[255] is similar to that observed in the animal investigations.

Models of Cerebral Ischemia

How different is complete cerebral ischemia, as occurs during cardiac arrest, and incomplete cerebral ischemia, as may occur during occlusion of a major cerebral vessel or severe hypotension? From the clinician's vantage, the important difference is that the residual (i.e., collateral) blood flow during incomplete ischemia may result in enough delivery of oxygen to allow some generation of ATP and thereby stave off the catastrophic irreversible membrane failure that occurs within minutes during normothermic complete cerebral ischemia. This difference in the rate of failure of the energy supply[258,259] (Fig. 17-17) can result in significantly more apparent tolerance for focal or incomplete ischemia than for complete global ischemia (e.g., cardiac arrest).

Energy Failure and Excitotoxicity

Energy failure is the central event that occurs during cerebral ischemia.[260] ATP is required for the maintenance of the normal membrane ionic gradient, and energy failure is rapidly attended by membrane depolarization and influx of sodium (Na^+) and calcium (Ca^{2+}) into the neuron. Voltage-dependent Ca^{2+} channels are then activated, and Ca^{2+} gains entry into the cytosol. Depolarization of presynaptic terminals also results in the release of massive quantities of excitatory neurotransmitters, particularly

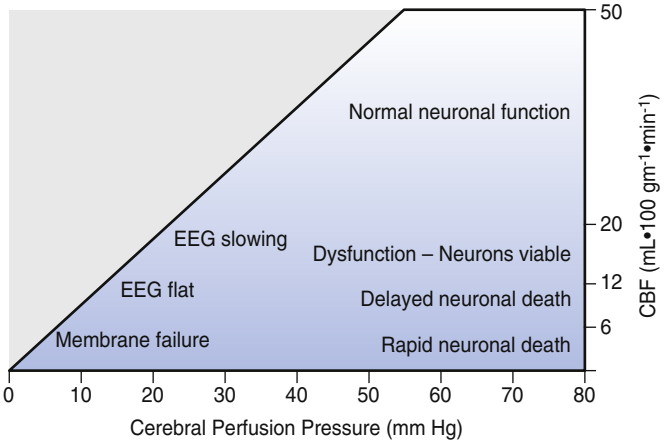

Figure 17-16. Relationships between cerebral perfusion, cerebral blood flow (CBF), the electroencephalogram (EEG), and the functional status and viability of neurons. Note that in the approximate CBF range of 6 to 12 mL/100 g/min, the energy supply is insufficient to support electrophysiologic activity (i.e., flat EEG) but can prevent complete membrane failure and neuronal death for extended periods. These areas are referred to as the *ischemic penumbra*.[252] The data are derived from studies on the cerebral cortex of barbiturate-anesthetized baboons[252,256] and unanesthetized monkeys.[257] The CBF and mean arterial pressure thresholds may vary with anesthetic and species.[254]

glutamate, into the synaptic cleft. Activation of glutamatergic receptors, the NMDAR and the α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid receptors (AMPAR), adds to the influx of Na^+ and Ca^{2+} (Fig. 17-18). Initiation of cellular signaling by the activation of mGluR leads to the release of stored Ca^{2+} from the endoplasmic reticulum (ER) via inositol 1,4,5-triphosphate (IP_3) receptors. Ionic influx is accompanied by an influx of water, and neuronal swelling rapidly occurs after membrane depolarization. The injury that is initiated by excessive mGluR activity is referred to as *excitotoxicity*.

Ca^{2+} is a ubiquitous second messenger in cells and is a cofactor required for the activation of a number of enzyme systems. The rapid, uncontrolled increase in cytosolic Ca^{2+} levels initiates the activation of a number of cellular processes that contribute to injury. Cytoskeletal proteins such as actin are cleaved by activated proteases. These enzymes also degrade a number of the protein constituents of the neuron. Lipases attack cellular lipids and produce membrane damage. An important lipase, phospholipase A_2, releases fatty acids such as AA from membranes. Metabolism of AA to prostaglandins and leukotrienes by cyclooxygenase and lipoxygenase is accompanied by the generation of superoxide free radicals. The latter, in combination with other free radicals generated in response to mitochondrial injury, can lead to lipid peroxidation and membrane injury. Prostaglandins and leukotrienes also evoke an inflammatory response and are powerful chemotactic drugs. Activation of platelets within cerebral microvessels, as well as an influx of white blood cells into damaged areas, aggravates the ischemic injury by occluding the vasculature.

DNA damage is also an important event during ischemic neuronal injury. Generation of free radicals from AA metabolism, from injured mitochondria, and from the production of peroxynitrite from NO leads to oxidative injury to DNA. Activation of endonucleases also produces DNA strand breaks. Under normal circumstances, DNA injury results in the activation of poly–adenosine diphosphate [ADP]–ribose polymerase (PARP), an enzyme that participates in DNA repair. With excessive DNA injury,

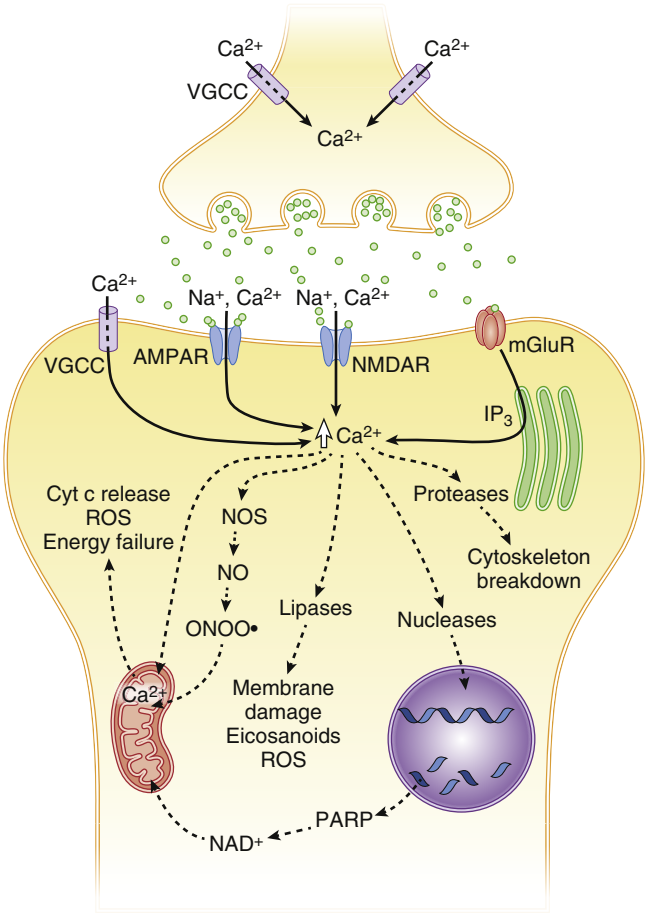

Figure 17-18. During ischemia, depletion of adenosine triphosphate (ATP) leads to neuronal depolarization and the subsequent release of supranormal quantities of neurotransmitters, especially glutamate. Excessive stimulation of ligand-gated channels and the simultaneous opening of voltage-dependent calcium (Ca^{2+}) channels permit rapid entry of Ca^{2+} into neurons. Stimulation of metabotropic glutamate receptors (mGluR) generates inositol 1,4,5-triphosphate (IP_3), which causes the release of Ca^{2+} from the endoplasmic reticulum (ER) and mitochondria. Activation of the α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid receptors (AMPAR)–gated subset of glutamate receptors also permits excessive entry of sodium (Na^+). Excessive free Ca^{2+} results in the activation of numerous enzymes: protease activation causes the breakdown of the cytoskeleton of the neuron; lipases damage plasma membrane lipids and release arachidonic acid (AA), which is metabolized by cyclooxygenases and lipoxygenases to yield free radicals and other mediators of cell injury; activation of nitric oxide synthase (NOS) leads to the release of nitric oxide (NO) and, in turn, the generation of peroxynitrite (ONOO), a highly reactive free radical; and activated endonucleases damage DNA, thereby rendering the neuron susceptible to apoptosis. Injury to the mitochondria leads to energy failure, generation of free radicals, and the release of cytochrome *c* (cyt c) from the mitochondria; the latter is one of the means by which neuronal apoptosis is initiated. *mGluR,* Metabotropic glutamate receptor; *NAD^+,* oxidized form of nicotinamide adenine dinucleotide; *NMDAR, N*-methyl-D-aspartate receptor; *PARP,* poly-ADP-ribose polymerase; *ROS,* reactive oxygen species; *VGCC,* voltage-gated calcium channel.

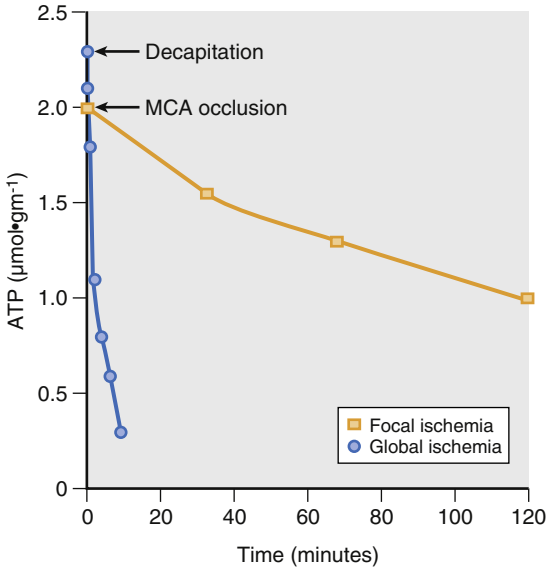

Figure 17-17. Comparison of rates of failure of energy supply (adenosine triphosphate [ATP]) in complete global ischemia in dogs (produced by decapitation[259]) and in incomplete focal ischemia in monkeys (middle cerebral artery [MCA] occlusion[258]). In the presence of residual CBF, energy supply failure is substantially delayed.

PARP activity dramatically increases, which can lead to the depletion of nicotinamide adenine dinucleotide (NAD^+), a substrate of PARP. NAD^+ is also an important coenzyme in energy metabolism, and its depletion further exacerbates energy failure.

Lactate formation is an additional element of the pathophysiologic process. Lactic acid is formed as a result of the anaerobic glycolysis that takes place after failure of the supply of oxygen. The associated decline in pH contributes to the deterioration of the intracellular environment. An increased preischemic serum glucose level may accelerate this process by providing additional substrate for anaerobic glycolysis.

NO, which has emerged as a probable mediator of CBF changes in many normal physiologic states (see the preceding section, "Cerebral Metabolic Rate"), is also of relevance to pathophysiologic ischemia. NO is, in fact, a weak free radical that in turn leads to the generation of a more reactive species (peroxynitrite), and it is the *killer substance* used by macrophages. In cerebral ischemia, NO is probably both friend and foe. During a period of focal ischemia, the vasodilating effect of NO (probably constitutively elaborated NO of endothelial origin) likely serves to augment collateral CBF. However, in the postischemic phase, NO (probably derived from neurons or macrophages) contributes to neuronal injury.

Collectively, the simultaneous and unregulated activation of a number of cellular pathways overwhelms the reparative and restorative processes within the neuron and ultimately leads to neuronal death.

Nature of Neuronal Death

Neuronal death that occurs in response to these processes has been categorized as necrotic or apoptotic in nature. Necrotic death of neurons, mediated by excitotoxic injury, is characterized by rapid cellular swelling, condensation and pyknosis of the nucleus, and swelling of the mitochondria and ER. A characteristic of these necrotic neurons is the presence of acidophilic cytoplasm.[261] Necrotic neuronal death results in local infiltration of the brain by inflammatory cells. A consequence of this inflammation is a considerable amount of collateral damage.

Neuronal apoptosis, a form of *cellular suicide*, has also been demonstrated in a variety of models of cerebral ischemia. Apoptosis is characterized by chromatin condensation, involution of the cell membrane, swelling of mitochondria, and cellular shrinkage. In the later stages of apoptosis, neurons fragment into several apoptotic bodies, which are then cleared from the brain.[261] The lack of a substantial inflammatory response to apoptotic death limits injury to surrounding neurons that have survived the initial ischemic insult.

A number of biochemical pathways that lead to apoptosis have been described. Initiation of apoptosis by the release of cytochrome *c* from injured mitochondria has been studied the most (Fig. 17-19). Cytochrome *c* is restricted from the cytoplasm by the outer mitochondrial membrane.[262] When mitochondria are injured, pores within the outer membrane allow cytochrome *c* to be released into the cytoplasm, where it interacts with procaspase-9 and apoptosis-activating factor (APAF) to produce an apoptosome. Procaspase-9 undergoes activation

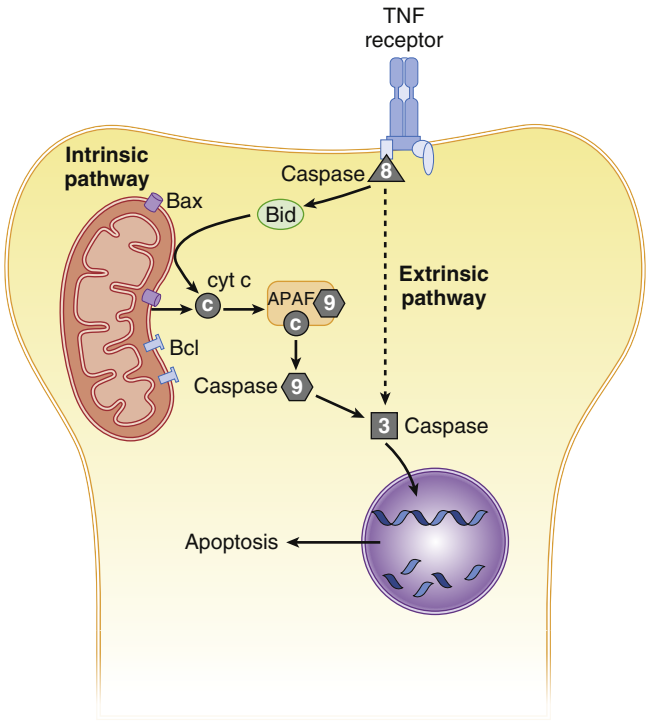

Figure 17-19. Cellular processes that lead to neuronal apoptosis. Cytochrome *c* (cyt c), which is normally restricted to the space between the inner and outer mitochondrial membranes, is released in response to mitochondrial injury. Cyt c, in combination with apoptosis-activating factor (APAF), activates caspase-9 by proteolytic cleavage. Activated caspase-9 then leads to the activation of caspase-3. This enzyme cleaves a number of substrates, including those necessary for DNA repair. Within the mitochondria, Bax augments and Bcl prevents the release of cyt c. The release of cyt c can also be initiated by Bid, a substance that is activated by caspase-8 via tumor necrosis factor (TNF) signaling. In addition, caspase-8 can directly activate caspase-3. Excessive activation of poly-ADP-ribose polymerase (PARP), an enzyme integral to DNA repair, depletes cellular stores of oxidized nicotinamide adenine dinucleotide (NAD^+). Depletion of NAD^+ further exacerbates the energy failure because of its critical role in energy metabolism.

by proteolytic cleavage. Activated caspase-9 then activates caspase-3. The latter serves as an executor of apoptosis by cleaving a number of protein substrates that are essential in DNA repair (such as PARP). Activation of caspase-3 can also occur by inflammatory signaling via tumor necrosis factor alpha (TNF-α) and the activation of caspase-8.[263] It should be noted that the neuronal injury that occurs in response to ischemia cannot be easily divided into necrosis or apoptosis. The nature of neuronal death probably encompasses a spectrum in which some neurons undergo necrosis or apoptosis whereas others undergo cell death that has features of both necrosis and apoptosis.

Timing of Neuronal Death

The traditional concept of ischemic injury was that neuronal death was restricted to the time of ischemia and during the early reperfusion period. However, more recent data indicate that postischemic neuronal injury is a dynamic process during which neurons continue to die for a long period after the initiating ischemic insult (Fig. 17-20).[264] This delayed neuronal death, which was

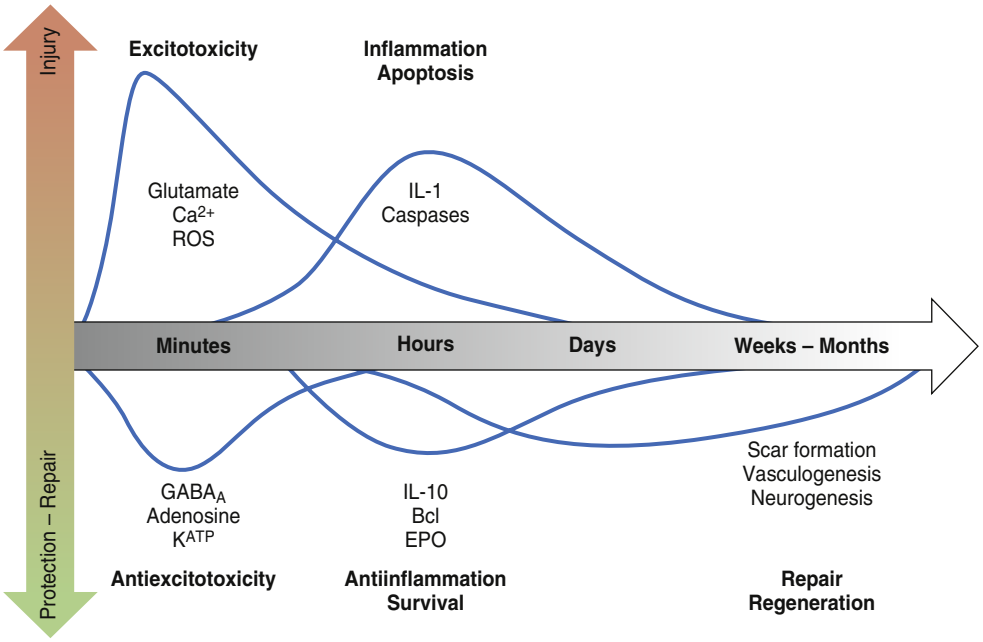

Figure 17-20. Time course of neuronal death. Excitotoxic (glutamate-mediated) injury results in neuronal death within the first few hours after the onset of ischemia. Brain tissue injury elicits an inflammatory response—an important process in the removal of injured tissue and in healing—that leads to a substantial amount of collateral damage. Inflammation-mediated neuronal death can continue for several days. Neuronal apoptosis can occur in injured neurons that survived the initial insult. Apoptotic neuronal death has been demonstrated to occur for many days after the initiating ischemic insult. It is now apparent that ischemic neuronal death is a dynamic process during which neurons continue to die for a long period. *Ca^{2+},* Calcium; *EPO,* erythropoietin; *$GABA_A$,* gamma-aminobutyric acid A; *K^{ATP},* adenosine triphosphate–regulated potassium; *IL-1,* interleukin 1; *IL-10,* interleukin 10; *ROS,* reactive oxygen species. *(Adapted from Dirnagl U, Iadecola C, Moskowitz M: Pathobiology of ischaemic stroke: an integrated view,* Trends Neurosci *22:391-397, 1999.)*

first demonstrated in models of global cerebral ischemia, has been demonstrated during focal ischemia as well. The extent of delayed neuronal death depends on the severity of the ischemic insult. With severe ischemia, most neurons undergo rapid death. With more moderate insults, neurons that survive the initial insult undergo delayed death. This ongoing neuronal loss contributes to the gradual expansion of cerebral infarction after focal ischemia. In experimental studies, evidence of cerebral inflammation, which can theoretically contribute to further injury, has been demonstrated even 6 to 8 months after the primary ischemia.

The occurrence of delayed neuronal death has important implications for the evaluation of studies in which neuroprotective strategies are being investigated. A wide variety of interventions have shown neuroprotective efficacy in studies in which the extent of injury is evaluated within 3 to 4 days after ischemia. However, this neuroprotective efficacy may not be sustained. Recent data indicate that cerebral infarction undergoes gradual expansion and that a reduction in injury attributed to a particular therapeutic intervention is no longer apparent when the injury is evaluated after a long postischemic recovery period.[264] Long-term (>1 month) evaluation of the efficacy of a particular intervention is therefore important.

Much of the literature on the pathophysiologic process of cerebral ischemia has primarily been focused on neuronal injury. However, recent work has highlighted the importance of the contribution of astrocytes, microglia, vascular cells (e.g., endothelium, smooth muscle cells, pericytes), basement membranes, and extracellular matrix to stroke. These individual components in aggregate form the neurovascular unit. A detailed understanding of the contribution of each component of the neurovascular unit is a prerequisite, not only for the protection of the brain against ischemic and traumatic injury, but also for therapeutic approaches for the regeneration of the CNS.

BRAIN PROTECTION

The literature on cerebral ischemia and brain protection is vast, and a detailed discourse on this topic is beyond the scope of the present discussion. A number of excellent recent reviews on the subject are available.[265-273]

Considerations Relevant to Complete Global Ischemia (Cardiac Arrest)

Maintaining adequate perfusion pressure after cardiac arrest is of considerable importance. Hypotension developing after resuscitation from cardiac arrest may aggravate the microcirculatory and vasospastic processes occurring at this time and may increase brain damage. A late phase of intracranial hypertension may occur and is due to the development of extensive cerebral edema (probably both vasogenic and cytotoxic edema) associated with brain necrosis. Attempts to control this type of intracranial hypertension with osmotherapy usually fail. ICP monitoring is not generally used because the patients in whom these delayed increases in ICP develop have sustained massive tissue damage.

Both barbiturates and calcium channel blockers have been administered after cardiac arrest. The former are

ineffective.[274] In a small cohort (51 patients) of patients after cardiac arrest, nimodipine was shown to improve CBF but not neurologic outcome.[275] In a second trial with approximately 150 patients after cardiac arrest, no overall benefit in neurologic outcome was observed.[276] However, a subset of patients in whom the initiation of advanced life support was delayed for longer than 10 minutes demonstrated improved survival. This single study cannot serve as justification for the administration of nimodipine after cardiac arrest, especially in the face of the unequivocally negative results of the multicenter lidoflazine cardiac arrest study.[277] Once again, the important therapeutic objectives are the maintenance of normocapnia and normotension, normalization of systemic pH, avoidance of hyperthermia, and prevention and treatment of seizures.

Induced mild hypothermia is effective in reducing mortality and morbidity in patients who sustain a cardiac arrest that is followed by altered mental status with a Glasgow coma scale of 7 or less.[278] Induction of mild hypothermia in the range of 32° C to 34° C for a period of approximately 24 hours improved neurologic outcome and survival 6 months after cardiac arrest in comparison with a normothermic group. Mild hypothermia was induced without difficulty. Passive rewarming of patients was slowly accomplished over a period of 8 hours. The incidence of complications was similar to that in the control normothermic group. This important study is one of the first to demonstrate the feasibility and efficacy of induced hypothermia as a treatment to prevent injury from global ischemia. In neonates who sustained hypoxic-ischemic encephalopathy, induction of whole body hypothermia (33.5° C) for 72 hours resulted in a reduced incidence of mortality.[279] Long-term follow-up of patients enrolled in the study confirmed the potentially beneficial effects of mild hypothermia.[280] In many institutions, induced hypothermia has been added to the armamentarium for the treatment of cerebral complications of cardiac arrest or global neonatal hypoxic-ischemic encephalopathy.

Considerations Relevant to Focal (Incomplete) Ischemia

Before discussing individual anesthetics, it should be noted that anesthesia, per se, is protective. For undefined reasons, reducing the level of systemic stress associated with a standardized experimental insult results in an improved outcome.[281,282] In reviewing the protection-by-anesthetics literature, readers should be conscious of the possibility that the protective benefit ascribed to an intervention with an anesthetic drug may, in fact, be the product of exaggeration of the injury in a high-stress control state, such as N_2O sedation.

Barbiturates. Numerous demonstrations have revealed the protective efficacy of barbiturates in focal cerebral ischemia in animals,[283-285] and a single demonstration confirmed the effectiveness in a human.[286] The effect has been principally attributed to suppression of the CMR. However, the effects of CBF redistribution and free radical scavenging[287] have been suggested to contribute, and evidence indicates that CMR suppression is not the sole mechanism.[288] Suppression of the CMR might logically be expected to be of benefit to brain regions in which oxygen delivery is inadequate to meet normal demands but is sufficient to allow energy consumption by some ongoing electrophysiologic activity (i.e., in which the EEG was abnormal but not flat). Such regions are likely to be limited in size in the setting of focal ischemia, yet several of the animal investigations suggest a very substantial protective effect.[283,284] Review of these experiments reveals that the methods used to monitor and maintain temperature, although accepted at the time, were below the standards that have evolved from a more recent understanding of the effects of both deliberate[289,290] and inadvertent hypothermia. Unrecognized cerebral hypothermia may well have been a factor in some of the cited investigations, and it is therefore possible that the protective efficacy of barbiturates may have been overestimated. Although more recent publications involving suitable temperature control methods do, in fact, indicate a protective effect of barbiturates,[288,291,292] the magnitude of that effect was modest when compared with the results of earlier studies. Barbiturate-induced EEG suppression in an already anesthetized patient may still be logical therapy when it can be applied before or early in the course of a period of temporary focal ischemia (e.g., temporary occlusion during aneurysm surgery). However, the decision to institute such therapy should be made only after considering the risk of the occlusive event, the patient's cardiovascular status, and the physician's willingness to accept the possibility of delayed emergence, together with an objective view of the probable magnitude of the protective effect.

Numerous investigations in animals and humans have failed to demonstrate any protective effect of barbiturates in the setting of global cerebral ischemia (e.g., cardiac arrest).[274]

Because CMR suppression has been the presumed mechanism of effect, barbiturates have traditionally been administered to produce maximal reduction of the CMR (which is nearly complete when EEG burst suppression has been achieved). However, data presented by Warner and colleagues[288] demonstrated that the same protective benefit (expressed as a reduction of infarct volume) could be achieved with a third of the burst-suppression dose, which raises a clinically important issue. The various barbiturates (e.g., thiopental, thiamylal, methohexital, pentobarbital) have similar effects on the CMR and have generally been assumed to have equal protective efficacy. However, if the mechanism of protection is a pharmacologic effect other than a reduction in the CMR, then is it reasonable to assume equivalence among the barbiturates? Recent data suggest that the neuroprotective efficacy of barbiturates is not similar. In a direct comparison of three clinically used barbiturates, methohexital and thiopental, but not pentobarbital, reduced injury in an animal model of focal ischemia.[293] These data suggest that mechanisms other than or at least in addition to metabolic suppression may contribute to the protective effect of barbiturates.

Volatile Anesthetics. Isoflurane is also a potent suppressant of the CMR in the cerebral cortex, and EEG evidence suggestive of a protective effect in humans has been reported.[254] In comparison with the awake

or N_2O-fentanyl–anesthetized state, isoflurane is neuroprotective in models of hemispheric,[294] focal,[295] and nearly complete ischemia.[296,297] Of interest is the recent observation that isoflurane's neuroprotective efficacy is not sustained.[298] When injury is evaluated 2 days after ischemia, a robust reduction in injury is observed with isoflurane anesthesia. However, by 14 days this reduction in injury was not apparent. These data indicate that neuronal injury continues well into the postischemic recovery period and that the neuroprotective benefit that is evident shortly after ischemia may not persist for the long term. More recent data have shown that isoflurane treatment can improve neuronal survival when the severity of ischemia is limited and the restoration of blood flow after ischemia is complete.[299] The neuroprotective effect of isoflurane is not substantially different from that of other volatile anesthetics. Sevoflurane reduces ischemic injury in animal models of focal[300] and hemispheric ischemia[301]; its efficacy is not different from that of halothane. Desflurane also reduces neuronal injury to the same extent that isoflurane does.[302] The available data therefore suggest that adequate anesthesia, per se, may have a protective effect[281,282] versus the awake state, but there does not appear to be any difference in neuroprotective efficacy among the volatile anesthetics.

Xenon. The inert gas xenon exerts its anesthetic action by noncompetitive blockade of NMDAR. As such, it is logical to suspect that it might provide neuroprotection against excitotoxic injury. The neuroprotective efficacy of xenon has been demonstrated against oxygen-glucose deprivation in vitro,[303] focal ischemia in vivo in mice,[304] and cardiopulmonary bypass–induced cognitive dysfunction in rats.[305] Of interest are observations that simultaneous administration of *subanesthetic* doses of xenon in combination with either hypothermia or isoflurane[306] significantly reduces neuronal injury and improves neurologic function in a neonatal rodent model of hypoxia-ischemia; this protective effect was apparent as late as 30 days after injury. Moreover, the administration of xenon has been shown to have a preconditioning effect on the brain[307]; previous exposure reduces the vulnerability of the brain to ischemic injury. Anesthetic drugs that have activity at NMDAR (ketamine) and γ-aminobutyric acid A ($GABA_A$) receptors (e.g., volatile anesthetics, barbiturates, benzodiazepines, propofol) have been shown to cause neuronal injury in rodent neonatal pups during the critical period of synaptogenesis.[308] Although xenon has antagonist activity at NMDAR, the evidence to date suggests that it does not lead to apoptosis in the developing brain.[309] Note should be made, however, that long-term neuroprotection with xenon has not yet been demonstrated in experimental adult subjects. The specific use of xenon for the purpose of neuroprotection awaits results from outcome studies in humans.

Propofol. EEG suppression can also be achieved with clinically feasible doses of propofol. Anecdotal information suggests that it is being used to provide *protection* during both aneurysm surgery[310] and CEA. In experimental models of cerebral ischemia, the extent of neurologic injury in propofol-anesthetized animals was similar to that in halothane-anesthetized animals.[311] Given the previous demonstration that halothane can reduce injury, these data provide indirect evidence of propofol's neuroprotective efficacy. In a more recent investigation, cerebral infarction was significantly reduced in propofol-anesthetized animals in comparison with awake animals.[312] Direct comparison of propofol to pentobarbital has also demonstrated that cerebral injury after focal ischemia is similar in animals anesthetized with the two drugs.[313] Similar to the situation with volatile anesthetics, initial investigations revealed that propofol protection is not sustained.[314] Durable protection with propofol is achievable if the severity of the ischemic insult is mild.[302] Collectively, these data are consistent with the premise that propofol can reduce ischemic cerebral injury.

Etomidate. Etomidate was proposed as a potential protective anesthetic in the setting of aneurysm surgery.[315] It, too, produces CMR suppression to an extent equivalent to barbiturates, and, similar to the barbiturates, etomidate is an agonist at the (inhibitory) $GABA_A$ receptor. To the contrary, in an experimental model of focal ischemia, the volume of injury was not reduced by etomidate relative to a 1.2 MAC halothane-anesthetized control group. In fact, the volume of injury with etomidate was significantly larger than that in the control group. In patients subjected to temporary intracranial vessel occlusion, the administration of etomidate results in greater tissue hypoxia and acidosis than does equivalent desflurane anesthesia. The aggravation of injury produced by etomidate (an imidazole) may be related to direct binding of NO as a consequence of etomidate-induced hemolysis[316] combined with direct inhibition of the NO synthase enzyme by etomidate. Therefore no scientific studies support the current use of etomidate for cerebral protection.

Calcium Channel Antagonists. Orally administering nimodipine (the intravenous preparation is not approved for clinical use in North America) for 21 days beginning as soon as possible after subarachnoid hemorrhage (SAH) is now established clinical practice.[317] Other calcium channel blockers have reduced vasospasm after SAH but have not improved patient outcome, suggesting that nimodipine's benefit is a cellular rather than a vascular effect. However, routinely administering nimodipine or any other calcium channel blocker after neurologic stroke that has occurred in the surgical unit or in any other environment has not yet become standard practice. Despite favorable results in small trials, not all investigations of those who sustain stroke have confirmed the benefits of nimodipine.[318]

Other Anesthetics. A remarkable number of anesthetics have shown neuroprotective efficacy in animal studies. However, to date, large-scale randomized trials of a variety of anesthetics in patients with stroke have not demonstrated neuroprotection for any drug. With the exception of tissue plasminogen activator (tPA) for thrombolysis and the calcium channel blockers nimodipine and nicardipine for the management of SAH, pharmacologic neuroprotective anesthetics are not available for the treatment

of patients with cerebral ischemia. Details about drugs that have undergone clinical trials and those that are currently being investigated in humans can be found at the Stroke Trials Registry (www.strokecenter.org/trials/TrialDetail.aspx?tid=338) of Washington University in St. Louis.

Cerebral Ischemia: Influence of Physiologic Variables

Cerebral Perfusion Pressure. Measures designed to augment CBF (an important determinant of energy supply) are also important. In the *ischemic penumbra* (described in the section, "Critical Cerebral Blood Flow Thresholds"), small improvements in CBF have the potential to prolong neuronal survival substantially. Maintenance of high-normal CPP can augment collateral perfusion pressure and maintain CBF[319] and has been shown to result in improvement in various neurophysiologic parameters, including neurologic function.[320,321] By contrast, hypotension can reduce CBF and exacerbate injury. In trials of nimodipine in patients with acute stroke, a reduction in blood pressure of 10% to 20% increased the probability of an adverse outcome (either death or dependency) fourfold,[322] thus emphasizing the adverse impact of blood pressure reduction on an injured brain. Therefore in patients with cerebral ischemia, hypotension should be promptly treated and normotension restored. Although the target MAP should obviously be based on knowledge of a patient's preexisting blood pressure, data to provide specific guidelines are insufficient in humans. In the majority of patients, maintenance of the MAP in the 70 to 80 mm Hg range should be adequate. The available data provide support for reducing blood pressure to less than 180/105 mm Hg in patients with stroke who have been treated with tPA in the hope of reducing the incidence of hemorrhage into the ischemic brain.[323,324] In addition, blood pressure augmentation to a systolic pressure of 180 to 220 mm Hg in patients with SAH-induced vasospasm and to a CPP greater than 60 mm Hg in patients with traumatic brain injury is reasonable.[323] Note, however, that augmentation of CPP in the high-normal range carries the inadequately explored risks of increased edema and hemorrhagic infarction if used as support during more than brief periods of ischemia, particularly when several hours has elapsed since the onset of ischemia.

Carbon Dioxide Tension. Hypercapnia has the potential to cause intracerebral steal and may worsen intracellular pH. Despite some support for the occurrence of a favorable so-called Robin Hood or inverse steal,[325] hypocapnia has not generally proved effective in either laboratory or clinical settings.[326-328] Pending further information and in the absence of a means of verifying the perfusion response to the manipulation of $Paco_2$, normocapnia remains standard practice.

Temperature. Hypothermia is *the* principal cerebral protective technique for circulatory arrest procedures (also see Chapter 54). It unequivocally enhances cerebral tolerance for episodes of ischemia. For deep hypothermia, this effect is largely a function of the reduction in the CMR. Although barbiturates reduce only the component of the CMR associated with electrophysiologic *work* (approximately 60% of the $CMRO_2$ in the awake state), hypothermia causes a reduction in both electrophysiologic energy consumption and energy utilization related to the maintenance of cellular integrity; mild hypothermia may preferentially suppress the latter.[329,330] A substantial number of laboratory studies have demonstrated that mild degrees of hypothermia (2° C to 4° C) during an episode of ischemia can confer substantial protection as histologically measured.[289,290] In addition, evidence from animal studies suggests that hypothermia initiated in the immediate postischemic period confers a protective benefit.[331,332]

In light of this dramatic protective effect of mild hypothermia in the laboratory, its use in the surgical setting may be advocated. Proponents of its use argue that hypothermia is readily achieved and not accompanied by significant myocardial depression or arrhythmias. In addition, the patient can be easily rewarmed in the surgical unit after the risk of ischemia has subsided. Results of a pilot study clearly demonstrated a trend toward improved neurologic outcome in hypothermic patients undergoing intracranial aneurysm clipping.[333] Unfortunately, the subsequent definitive trial did not demonstrate any improvement in outcome that could be attributable to hypothermia.[334] However, it should be noted that the majority of the patients in that study had SAH of grades I, II, and III. In addition, the number of patients who had temporary clips applied in excess of 20 minutes was quite small (five to six patients). Consequently, an argument has been made that mild hypothermia may well be of benefit in patients with high-grade aneurysms or in those in whom the complexity of the aneurysm clipping is such that prolonged temporary clipping may be required. Considering that temperature reduction takes time, the decision to induce hypothermia must be made in advance. Therefore the therapeutic use of hypothermia may be considered in such high-risk patients.

The application of mild hypothermia after head injury reduced ICP[335] and improved neurologic outcome[336] in pilot trials. Of note is the finding that complications attributable to hypothermia were not observed. A subsequent multicenter trial of hypothermia in patients with head injuries, however, failed to confirm the findings of the pilot studies.[337] Induction of mild hypothermia did not improve long-term neurologic outcome. Note should be made, however, of the post hoc finding that the outcomes in patients younger than 45 years of age who were initially hypothermic were worse if these patients were rewarmed; these data suggest that such patients should be rewarmed over a prolonged period.

A number of clinical trials of induced hypothermia in a limited number of patients with stroke have been conducted. To date, these trials have demonstrated the feasibility of inducing hypothermia in the range of 33° C to 35° C, even in patients who are not subjected to endotracheal intubation and mechanical ventilation.[338] Hypothermia was associated with improved ICP and CPP. However, complications, particularly thrombocytopenia, bradycardia, ventricular ectopy, hypotension, and infection, are frequent. In addition, an intractable increase in ICP can occur during rewarming, even if the elevation in temperature is gradual and accomplished over a period of

several hours. These side effects attest to the need to conduct randomized trials to evaluate properly the efficacy of mild hypothermia in patients with stroke. Such trials are currently under way.

Data regarding the application of mild hypothermia in survivors of cardiac arrest are more positive. Two recent trials have demonstrated that the induction of hypothermia (32° C to 34° C) after successful resuscitation from cardiac arrest resulted in a significantly better neurologic outcome 6 months after the arrest.[278,339] These studies demonstrate the clinical efficacy of hypothermia for the purposes of reducing ischemic cerebral injury and to provide support for the use of intraoperative hypothermia in patients who are considered to be at high risk.

By contrast, increases in brain temperature during and after ischemia aggravate injury.[340] An increase of as little as 1° C can dramatically increase injury. Ischemia that normally results in scattered neuronal necrosis produces cerebral infarction when body temperature is elevated. Therefore avoiding hyperthermia in patients who have suffered an ischemic insult or in those who are at risk for cerebral ischemia seems prudent. In the surgical setting, hyperthermia is seldom a problem (witness the authors' efforts to prevent hypothermia). One situation in which body temperature is often allowed to increase is during rewarming after hypothermic cardiopulmonary bypass. In this situation, hyperthermia (core body temperature in excess of 38° C) is not uncommon. The suggestion that increases in temperature in excess of 37° C to 38° C are detrimental has some merit, considering the recent information regarding the deleterious effect of hyperthermia.

Glucose. Withholding glucose-containing solutions in situations during which cerebral ischemia may occur is now an established practice. The practice is based on numerous demonstrations in animal models of brain and spinal cord ischemia that elevation of plasma glucose before episodes of either complete or incomplete ischemia results in aggravation of neurologic injury. However, it should be noted that the majority of investigations involved adult animals and that certainty concerning the adverse effects of hyperglycemia in immature subjects, such as neonates, is less.[341] Furthermore, it should be noted that only some[342,343] and not all[344] of the investigations in humans have provided confirmation of an independent effect of serum glucose on neurologic outcome. Nonetheless, in long-term outcome studies, diabetic and nondiabetic hyperglycemia has been shown to be an independent predictor of poor outcome.[343] In the National Institutes of Health–sponsored recombinant tPA stroke trial, hyperglycemia was associated with significantly lower odds for desirable clinical outcomes and a higher incidence of intracranial hemorrhage.[345] These data prompted a randomized clinical trial of the efficacy of insulin administration to patients with acute stroke. Although the trial was underpowered, the results showed that the administration of insulin to control blood glucose levels in patients with stroke did not improve outcome 3 months after stroke.[346] A recurrent theme in the discussion of these studies is that glucose elevation may be the *result* of the stress associated with a severe insult, either ischemic or traumatic, rather than its *cause*. In addition, the inevitable questions of whether and how quickly immediate prerisk treatment of an elevated plasma glucose level with insulin reduces risk to normoglycemic levels have not been thoroughly examined. It is the opinion of the authors that, at this juncture, acute insulin administration (with its attendant risk of hypoglycemia) in patients with modest glucose elevation (~150 mg/dL) in the surgical setting is not yet justified.

By contrast, hypoglycemia is also associated with cerebral injury. With a gradual reduction in blood glucose values to approximately 40 mg/dL, a shift in EEG frequencies occurs from alpha and beta toward delta and theta.[347] Below a blood glucose level of 20 mg/dL, suppression of the EEG (flat) is observed. Persistence of this level of hypoglycemia results in seizure activity and neuronal injury, particularly to the hippocampus.

Seizures. Normalization of systemic pH, prevention and treatment of seizures, which dramatically increase the CMR, and control of the ICP and CPP are all important elements of brain protection and resuscitation, although mundane and lacking in appeal of the pharmacologic silver bullet.

Intravascular Volume and Hematocrit Manipulation. Although hemodilution has not proved effective in studies of human stroke, both laboratory and human data support the practice; hemodilution is an established part of the management of ischemia associated with vasospasm. However, the data do not currently justify routine hemodilution (a hematocrit of 30% to 35% is the theoretic optimum) in patients in whom focal ischemia *might* occur in the surgical unit.[348] On the other hand, the potentially deleterious effects of hemoconcentration should help further suppress the out-of-date notion that neurosurgical patients should be run dry. An increased hematocrit, because of viscosity effects, reduces CBF.[10] In anticipation of a procedure wherein incomplete ischemia might occur, such as CEA, a hematocrit in excess of 55% should be considered for decrease by preoperative phlebotomy.

Summary of Anesthetics and Neuroprotection

In comparison to the awake or lightly sedated state, the vulnerability of the brain to ischemic injury is reduced under anesthesia. Volatile anesthetics, barbiturates, propofol, xenon, and ketamine reduce injury in experimental models and may reduce injury in comparison with a pure N_2O-narcotic anesthetic. However, direct comparison has not demonstrated the superiority of any one anesthetic (or combination of anesthetics) over another. Therefore, based on the available data, the use of a specific anesthetic or anesthetic regimen for the purpose of brain protection in the clinical setting cannot be recommended.

There is a paucity of information about anesthetic neuroprotection in humans and the lack of clinical trials is understandable, considering the low frequency of stroke and ischemic injury in the perioperative setting. There are, however, a few clinical investigations from which inferences about anesthetic neuroprotection can be made. In the Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST), a subset of patients received

supplemental doses of thiopental, etomidate, or propofol for the purposes of neuroprotection. The neurologic outcome in these patients was no different than those who did not receive these anesthetics.[349] In the general anesthesia versus local anesthesia trial,[350] patients undergoing CEA were randomized to receive either general anesthesia or local anesthesia (also see Chapter 70); in the latter group, patients were lightly sedated but were arousable during surgery. The outcome between the two groups was not different, indicating that the general anesthetic state did not provide any protective benefit.[350] Finally, in a recent retrospective trial of thrombolysis for acute stroke, patients who were anesthetized had a worse outcome than those who were only mildly sedated. Although the worse outcome with general anesthesia was attributed to a lower CPP in that group,[351] the results do not provide evidence of anesthetic neuroprotection. In aggregate, these data suggest that supplemental drugs that produce burst suppression of the EEG do not provide protection in anesthetized patients and that the state of general anesthesia does not improve neurologic outcome.

The neuroprotective efficacy of anesthetic drugs in experimental studies is achieved only by strict attention to the maintenance of physiologic homeostasis; in fact, the potential for exacerbation of cerebral injury, either traumatic or ischemic, with physiologic mismanagement is significantly more likely than the modest protection afforded by pharmacologic drugs—these are important observations. Accordingly, with respect to brain protection, efforts should be focused on the maintenance of physiologic parameters (e.g., perfusion pressure, oxygenation, normocapnia, temperature management, control of hyperglycemia, seizure prophylaxis) within the appropriate ranges and less on pharmacologic or anesthetic drugs to reduce cerebral injury.

Deferring Elective Procedures After Stroke

The risk of extension of cerebral infarction in the event of subsequent anesthesia and surgery has not been systematically studied. In patients who have suffered a stroke, CBF undergoes significant changes. Areas of both high and low CBF occur, and stabilization of regional CBF and CMR is apparent after approximately 2 weeks.[352] Loss of normal vasomotor responses (e.g., CO_2 responsiveness, autoregulation) in the early postinsult period is very common,[353-355] and these changes persist beyond 2 weeks in a small percentage of patients with stroke.[354,355] BBB abnormalities, as reflected by the accumulation of CT contrast material or brain scan isotopes, are still present 4 weeks after the insult,[356] and the histologic resolution of large infarcts is not complete for several months. Early CEA after stroke in patients with large strokes and neurologic disability was accompanied by an increased risk of intracerebral hemorrhage.[357] Based on early CEA experience, deferring CEA for 4 to 6 weeks after stroke is recommended.[357] A 6-week delay should give some assurance of the probable recovery of autoregulation, CO_2 responsiveness, and BBB integrity.

A delay in CEA after stroke, however, poses risks. In patients who have sustained a stroke, the incidence of a second stroke is approximately 12%.[358] The risk of a complete carotid occlusion is considerable with delayed surgery. In addition, early CEA can restore cerebral perfusion to the ischemic penumbra, possibly improving long-term functional recovery. [359] However, the size and location of the infarction should be weighed. A small infarction in silent cortex may offer wider latitudes than a large lesion that has resulted in a paresis that is still resolving. A small prospective study suggests that in patients with nondisabling stroke, early CEA can be safely performed within 2 weeks of the stroke.[360] Candidates for early CEA after stroke may include patients with relatively small cerebral infarctions, resolution (either complete or near complete) of neurologic symptoms, and ipsilateral carotid artery stenosis.[361] Delaying CEA in patients who have had large strokes with significant neurologic disability, reduced level of consciousness, and displaying a midline shift on the CT scan is generally preferable.

Outcome data to inform the decision about surgery for the patient after stroke, other than CEA, is lacking. With the extrapolation of the information from the CEA studies, pending other information, deferring elective surgery for at least 4 weeks after a cerebral vascular accident and preferably for 6 weeks from the point at which a stable postinsult neurologic state has been achieved seems reasonable.

CHRONIC ARTERIAL HYPERTENSION

A recurrent concern is that of acceptable levels of arterial blood pressure reduction in patients who are chronically hypertensive. Firm guidelines have not been established. However, from the vantage of cerebral well-being, limiting elective MAP reduction to 30% to 35% of resting mean levels seems appropriate for both hypertensive and normotensive patients. The same guidelines might apply in both populations because in chronic hypertension, both the lower and upper limits of autoregulation are shifted to the right with apparently little distortion.[362]

The rationale for a limit of 30% to 35% is as follows. MAP reductions of 50% in nonanesthetized patients, both normotensive and hypertensive, will commonly produce reversible symptoms of cerebral hypoperfusion.[362-364] Although even greater reductions will probably be tolerated provided that exposures are brief, the hematocrit is reasonable, and the cerebral vasculature is patent, the authors counsel against it. A reduction in the MAP of this magnitude will significantly increase the probability of CPP being close to or below the LLA, thereby reducing cerebrovascular reserve. It has been demonstrated that a 25% reduction in the MAP will bring both normotensive and hypertensive patients to the LLA.[362] As the reduction in the MAP exceeds 25% of baseline, CBF values will be below normal, albeit in patients free of occlusive vascular disease, above the threshold for neurophysiologic dysfunction or injury (see Fig. 17-6). However, physiologic reserve is being encroached upon, thereby leaving little margin for error or for other causes of impaired cerebral oxygen delivery such as low hematocrit or unrecognized cerebrovascular disease.

In animals, treatment of chronic hypertension can restore the LLA to normal.[365,366] A similar phenomenon has been observed in humans by Strandgaard, although restoration was incomplete and had failed to occur after

as long as 12 months of treatment in some patients.[362] It is an unexplored possibility that the extent of restoration of the LLA with antihypertensive therapy is agent dependent. Some may restore the LLA more effectively than others. In particular, ACE inhibitors have been shown to decrease the LLA acutely in both normotensive and hypertensive subjects.[367,368]

Intracranial Hypertension

Control of intracranial hypertension is discussed in detail in Chapter 70.

BRAIN TUMORS

There are few data regarding the physiologic function of intracranial tumors. Arbit and colleagues[369] measured CBF in cerebral tumors with laser Doppler technology. In general, they found that tumors had lower CBF than the normal brain. Autoregulation was occasionally apparent. Vascular responsiveness to changes in Pa_{O_2}[370] and Pa_{CO_2}[371] are generally preserved in patients with gliomas. However, in some circumstances, hyperventilation can at times be associated with paradoxical increases in MCA flow velocity ipsilateral to the tumor.[372] Measurement of regional CBF in the area of the tumor might also be a useful predictor of the grade of intracranial gliomas; both regional CBF and regional CBV are greater with high-grade gliomas.[373] Considerable edema is often associated with intracranial tumors, and the radiologic extent of the edema, which presumably represents the extent of abnormal vessel leakiness, correlates with the severity of the elevation in ICP that occurs in association with intubation-related hypertension.[374] Edema formation in the peritumoral region can be characterized as vasogenic with leakage of plasma proteins from the vascular space, hydrocephalic secondary to obstruction of CSF flow, or static as a result of venous obstruction by tumor.[375] Although the precise mechanisms by which edema formation occurs are not clear, the loss of integrity of the tight junctions of components of the BBB, an increased permeability induced by vascular endothelial growth factor expressed by tumors, and an increased expression of leukotriene C4 in peritumoral fluid probably play a role.[376] Osmotherapy with mannitol will affect a reduction in edema; however, with a permeable BBB, mannitol can diffuse into the peritumoral space and lead to rebound edema formation.[375] For acute reduction of ICP in the surgical unit, this concern is not significant. Dexamethasone remains the mainstay of treatment of tumor edema; it causes a reduction in edema formation with little effect on edema reabsorption, a reduction in permeability of the BBB that can be recognized as rapidly as 1 hour after administration,[377] and a modest reduction in tumor size. See Chapter 70 for a complete discussion.

COMA AND EPILEPSY

Regardless of its cause, coma reduces brain metabolism. In the case of lesions occurring in the reticular activating system, the reduction in the CMR probably represents a normal physiologic adjustment to reduced functional activity. During generalized seizure activity, CMR and CBF may dramatically increase.[202] The intensive motor and brain activity associated with generalized seizures leads to the development of systemic and cerebral acidosis, often accompanied by a reduction in arterial oxygenation, an increase in Pa_{CO_2}, and peripheral lactic acidosis. If generalized seizure activity continues unabated, then arterial hypotension ensues. With muscular relaxation and measures ensuring adequate oxygenation and ventilation, the systemic acidosis and hypotension can be avoided and the severity of the cerebral acidosis diminished. During relatively brief episodes of continuous seizures, the brain seems able to meet the high metabolic demands.[219] However, even with effective ventilation and maintenance of perfusion pressure, when seizures continue for a prolonged period, they can lead to the development of irreversible neuronal damage.[378] Therapy aimed at interrupting the seizure and restoring a normal balance between cerebral metabolic demand and blood flow is indicated. Barbiturates, benzodiazepines, or other potent anticonvulsants are appropriate. Adequate ventilation, oxygenation, and maintenance of arterial blood pressure are important adjunctive measures. Muscle relaxants must be viewed as purely symptomatic therapy because they do not alter the abnormal cerebral electrical activity.

The potentially injurious nature of seizures justifies attention to prevention. Practices vary. However, patients who have sustained a severe head injury or SAH and any patient on whom a substantial cortical incision is planned are at risk, and prophylactic anticonvulsants should be considered.

Chapter 18

Neuromuscular Physiology and Pharmacology

J.A. JEEVENDRA MARTYN

Key Points

- The neuromuscular junction contains the distal nerve terminal, synaptic cleft, and muscle end plate and provides an array of receptors and substrates for drug action. Neuromuscular transmission is predominately dependent on acetylcholine as the natural transmitter. Acetylcholine, when released from the prejunctional nerve terminal, binds to typical acetylcholine receptors (AChRs) that are present either prejunctionally or postjunctionally within the neuromuscular junction and, depending on their structural composition, are classified into the usual muscle subtype AChRs or a variety of neuronal subtype AChRs.
- Muscle relaxants have multiple sites of action. Although the major actions occur by mechanisms and at sites described as agonistic and antagonistic actions at postjunctional receptors for depolarizing and nondepolarizing muscle relaxants (NDMRs), this description of neuromuscular drug action is a simplistic one. Neuromuscular transmission is impeded by NDMRs because they prevent access of acetylcholine to its preferred recognition site on the postjunctional nicotinic AChR.
- If the concentration of NDMR is increased, another, noncompetitive action—block of the ion channel—is superimposed. The postjunctional paralytic effects of muscle relaxants can be enhanced by the actions of the relaxant on prejunctional AChRs, which modulate the release of acetylcholine. The latter can be documented as *fade* that occurs with increased frequency of stimulation. Fade can also be seen when the postjunctional AChRs alone are functionally blocked (e.g., by bungarotoxin) or when the number of AChRs (e.g., myasthenia gravis) is decreased. Hence, the neuromuscular junction is a complex and dynamic system in which the phenomena produced by drugs are composites of actions that vary with the drug, dose, activity at the nerve terminal and muscle, time after administration, presence of anesthetics or other drugs, and age and condition of the patient.
- Inhibition of muscle acetylcholinesterase enzyme by anticholinesterases (e.g. neostigmine) increases the concentration of acetylcholine, which can compete with and displace the NDMRS and thus reverse the paralysis. These anticholinesterase drugs (e.g., neostigmine) also have other effects, including those on nerve terminals and on the receptor, by an allosteric mechanism. Acute bolus or prolonged administration of anticholinesterases can have deleterious effects on neuromuscular function in otherwise healthy patients. A modified cyclodextrin such as sugammadex is a novel and innovative class of compound that reverses paralysis of only steroidal muscle relaxants by encapsulation of this series of compounds.
- Depolarizing compounds (e.g., succinylcholine) initially react with the acetylcholine recognition site and, like the transmitter, open AChR ion channels during depolarization of the end-plate membrane. Unlike the transmitter, they are not subject to hydrolysis by acetylcholinesterase and therefore remain in the junction. Soon after the administration of succinylcholine, some receptors are desensitized, and, although occupied by the agonist, they do not open to allow current to flow to depolarize the muscle membrane area.
- If the depolarizing relaxant is applied in higher-than-usual concentrations or is allowed to remain at the junction for a long time, then other neuromuscular effects occur. Depolarizing relaxants have effects on prejunctional structures, and

KEY POINTS—cont'd

the combination of prejunctional and postjunctional effects plus secondary ones on muscle and nerve homeostasis results in the complicated phenomenon known as *phase II blockade.*

- Intense research in the area of neuromuscular transmission continues at a rapid pace. Newer observations on muscle and neuronal types of AChRs, ion channels, membranes, and prejunctional function reveal a much broader range of sites and mechanisms of action for agonists and antagonists.
- Some of the other drugs used clinically (e.g., Botox) have effects on the nerve and therefore indirectly on muscle. Systemic infection with clostridial toxins (*Clostridium botulinum*, gas gangrene) can lead to systemic paralysis as a result of decreased release of acetylcholine from the nerve terminal. NDMRs administered even for 12 hours or for prolonged periods can have effects on the postsynaptic receptor and simulate denervation (chemical denervation). Magnesium given to preeclamptic mothers decreases the release of acetylcholine with a potential for muscle weakness in the mother or newborn. In recognizing these sites and mechanisms, we begin to bring our theoretical knowledge closer to explaining the phenomena observed when these drugs are exposed to living humans.
- Contemporary research work has focused on the control of AChR expression on the postjunctional membrane in normal and diseased states. The presence or absence of mature and immature isoforms seems to complicate matters further. In certain pathologic states (e.g., denervation, stroke, sepsis, burns, immobilization, chronic use of NMDRs), AChRs are upregulated, with increased expression of the immature isoform. More recently, another isoform of the nicotinic AChR, previously described in neuronal tissues only, the $\alpha 7$ neuronal AChR, has been identified in muscle. These receptors have different functional and pharmacologic properties than conventional muscle postsynaptic receptors. The altered functional and pharmacologic characteristics of the immature (γ-subunit) and neuronal ($\alpha 7$-subunit) receptors result in increased sensitivity to succinylcholine with hyperkalemia and resistance to NDMRs.
- An area of increasing attention is control of the expression of mature versus the other two receptor isoforms (immature γ- and $\alpha 7$-subunits). Re-expression of the immature γ- and $\alpha 7$-subunit receptors is probably related to aberrant growth factor signaling. Genetic mutations in the AChR that result in prolonged or fast open-channel time, can lead to a myasthenia-like state, even in the presence of normal receptor numbers. The weakness is usually related to ineffective depolarization or to the altered open-channel time, or to both.

Despite the fact that cholinergic neurotransmission in the neuromuscular junction is the most widely studied synapse within the nervous system, complete knowledge of its workings has not yet been achieved. This is an area of continuing interest for many researchers worldwide.

The physiology of neuromuscular transmission could be analyzed and understood at the most simple level by using the classic model of nerve signaling to muscle through the acetylcholine receptor (AChR). The mammalian neuromuscular junction is the prototypical and most extensively studied synapse. Research has provided more detailed information on processes that, within the classic scheme, can modify neurotransmission and response to drugs. One example is the role of qualitative or quantitative changes in AChRs that modify neurotransmission and the response to drugs.[1-3] In myasthenia gravis, for example, the decrease in AChRs results in decreased efficiency of neurotransmission (and therefore muscle weakness)[4] and altered sensitivity to neuromuscular relaxants.[3] Another example is the importance of nerve-related (prejunctional) changes that alter neurotransmission and the response to anesthetic drugs.[5-7] Yet, muscle relaxants act in ways that are not encompassed by the classic scheme of a unitary site of action. The observation that muscle relaxants can have prejunctional effects[5] or that some nondepolarizing muscle relaxants (NDMRs) can also have agonist-like stimulatory actions on the receptor,[8] whereas others have effects not explainable by purely postsynaptic actions on muscle,[9-11] has provided new insight into some previously unexplained observations. Although muscle relaxants are known to have effects on the presynaptic and postsynaptic receptors of the neuromuscular junction, recent evidence indicates that they can react with nicotinic and muscarinic AChRs other than those in muscle, including receptors on the carotid sinus, on the vagus to the heart, and on bronchial smooth muscle.[9-13] Although this multifaceted action-response scheme makes the physiologic and

pharmacologic neurotransmission more complex, these added insights also bring experimentally derived knowledge much closer to clinical observations.

Crucial to the seminal concepts that have developed, relative to the neurotransmitter acetylcholine and its receptor systems, is the introduction of powerful and contemporary techniques in molecular biology, immunology, electrophysiology, and genetic manipulation, as well as more elegant techniques for the observation of the neuromuscular junction in vivo.[14] These techniques have augmented the more traditional pharmacologic, protein chemical, morphologic, and cytologic approaches.[15-17] Research has elucidated the manner in which the nerve ending regulates the synthesis and release of transmitter and trophic factors, both of which control muscle function, as well as explained how exogenous and endogenous substances influence these processes.[15-17] Research continues to reveal how receptors are synthesized and anchored at the end plate, the role of the nerve terminal in the maturation processes, and the synthesis and control of acetylcholinesterase, the enzyme that breaks down acetylcholine. Several reviews that provide detailed insight into these areas are available.[16-19]

NEUROMUSCULAR TRANSMISSION

Neuromuscular transmission occurs by a fairly simple and straightforward mechanism. The nerve synthesizes acetylcholine and stores it in small, uniformly sized packages called *vesicles*. Stimulation of the nerve causes these vesicles to migrate to the surface of the nerve, rupture, and discharge acetylcholine into the cleft separating the nerve from muscle. AChRs in the end plate of the muscle respond by opening their channels for influx of sodium ions into the muscle to depolarize the muscle. The endplate potential created is continued along the muscle membrane by the opening of sodium channels present throughout the muscle membrane to initiate a contraction.[16,17] The acetylcholine immediately detaches from the receptor and is destroyed by the enzyme, acetylcholinesterase, which is also present in the cleft. Drugs, notably depolarizing muscle relaxants or nicotine and carbachol (a synthetic analog of acetylcholine not destroyed by acetylcholinesterase), can also act on these receptors to mimic the effect of acetylcholine and cause depolarization of the end plate. These drugs are therefore called *agonists* of the receptor because they turn the receptor into an active state, at least initially. NDMRs also act on the receptors, but they prevent acetylcholine from binding to the receptor and thus prevent depolarization by agonists. Because these NDMRs prevent the action of agonists (e.g., acetylcholine, carbachol, succinylcholine), they belong to the class of compounds known as *antagonists* at the muscle AChRs. Other compounds, frequently called *reversal drugs* or antagonists of neuromuscular paralysis (e.g., neostigmine, prostigmine), inhibit acetylcholinesterase and therefore impair the hydrolysis of acetylcholine. The increased accumulation of undegraded acetylcholine can effectively compete with NDMRs and thereby displace the latter from the receptor (i.e., law of mass action) and antagonize the effects of NDMRs.

MORPHOLOGY

The neuromuscular junction is specialized on both the nerve side and on the muscle side to transmit and receive chemical messages.[15-19] Each motor neuron runs without interruption from the ventral horn of the spinal cord or medulla to the neuromuscular junction as a large, myelinated axon (Fig. 18-1, *A*). As the motor neuron approaches the muscle, the neuron repeatedly branches to contact many muscle cells and gather them into a functional group known as a *motor unit* (see Fig. 18-1, *B*). The architecture of the nerve terminal is quite different from that of the rest of the axon. As the terminal reaches the muscle fiber, it loses its myelin, forms a spray of terminal branches against the muscle surface, and is covered by Schwann cells. This arrangement conforms to the architecture on the synaptic area of the muscle membrane (see Fig. 18-1, *C*). The nerve is separated from the surface of the muscle by a gap of approximately 20 nm, called the *junctional cleft* or *synaptic cleft*. The nerve and muscle are held in tight alignment by protein filaments called *basal lamina* that span the cleft between the nerve and end plate. The muscle surface is heavily corrugated, with deep invaginations of the junctional cleft—the primary and secondary clefts—between the folds in the muscle membrane; thus the end plate's total surface area is very large. The depths of the folds also vary between muscle types and species. Human neuromuscular junctions, relative to muscle size, are smaller than those of the mouse, although the junctions are located on muscle fibers that are much larger. Human junctions have longer junctional foldings and deeper gutters.[14,17] The sodium channels, which propagate the wave of depolarization, are located in the depths of the folds (see Fig. 18-1, *D*). The shoulders of the folds are densely populated with AChRs, approximately 5 million of them in each junction. AChRs are sparse in the depths between the folds.

The trophic function of the nerve is vital for the development and maintenance of adequate neuromuscular function. Before birth, each muscle cell commonly has contacts with several nerves and has several neuromuscular junctions.[14,19] At birth, all but one of the nerves retract, and a single end plate remains (see "Neuromuscular Junction at Extremes of Age" later in this chapter). Once formed, the nerve-muscle contact, especially the end plate, is durable. Even if the original nerve dies, the one replacing it innervates exactly the same region of the muscle. The nerve endings on fast muscles are larger and more complicated than those on slow muscles. The reason for this is unclear. These differences in the nerve endings on muscle surfaces may play a role in the difference in response of fast- and slow-twitch muscle fibers to muscle relaxants.

Because all the muscle cells in a unit are excited by a single neuron, stimulation of the nerve electrically or by an action potential originating from the ventral horn or by any agonist, including depolarizing relaxants (e.g., succinylcholine), causes all muscle cells in the motor unit to contract synchronously. Synchronous contraction of the cells in a motor unit is called *fasciculation* and is often vigorous enough to be observed through the skin. Although most adult human muscles have only one neuromuscular junction per cell, an important exception is some of

the cells in extraocular muscles. The extraocular muscles are *tonic* muscles, and, unlike other mammalian striated muscles, they are multiply innervated with several neuromuscular junctions strung along the surface of each muscle fiber.[20-23] Quite in contrast to other muscles, even the adult ocular muscle contains mature and immature fetal receptors (see "Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors" later in this chapter) segregated into distinct synapses on different fibers.[20,22] The ocular muscles slowly contract and relax rather than quickly as do other striated muscles; they can maintain a steady contraction, or contracture, the strength of which is proportional to the stimulus received. Physiologically, this specialization apparently holds the eye steadily in position. Ocular muscles are important to an anesthesiologist because depolarizing muscle relaxants (e.g., succinylcholine) affect them differently than they do most skeletal muscles. Instead of causing a brief contraction, followed by paralysis, the drug causes a long-lasting contracture response that pulls the eye against the orbit and could contribute to an increase in intraocular fluid pressure.[22,23] The clinical significance of the succinylcholine-induced increase in intraocular pressure has been questioned. Although many textbooks invoke the reported extrusion of intraocular content with succinylcholine, the basis for this effect seems to be anecdotal.[24] Clinical studies,

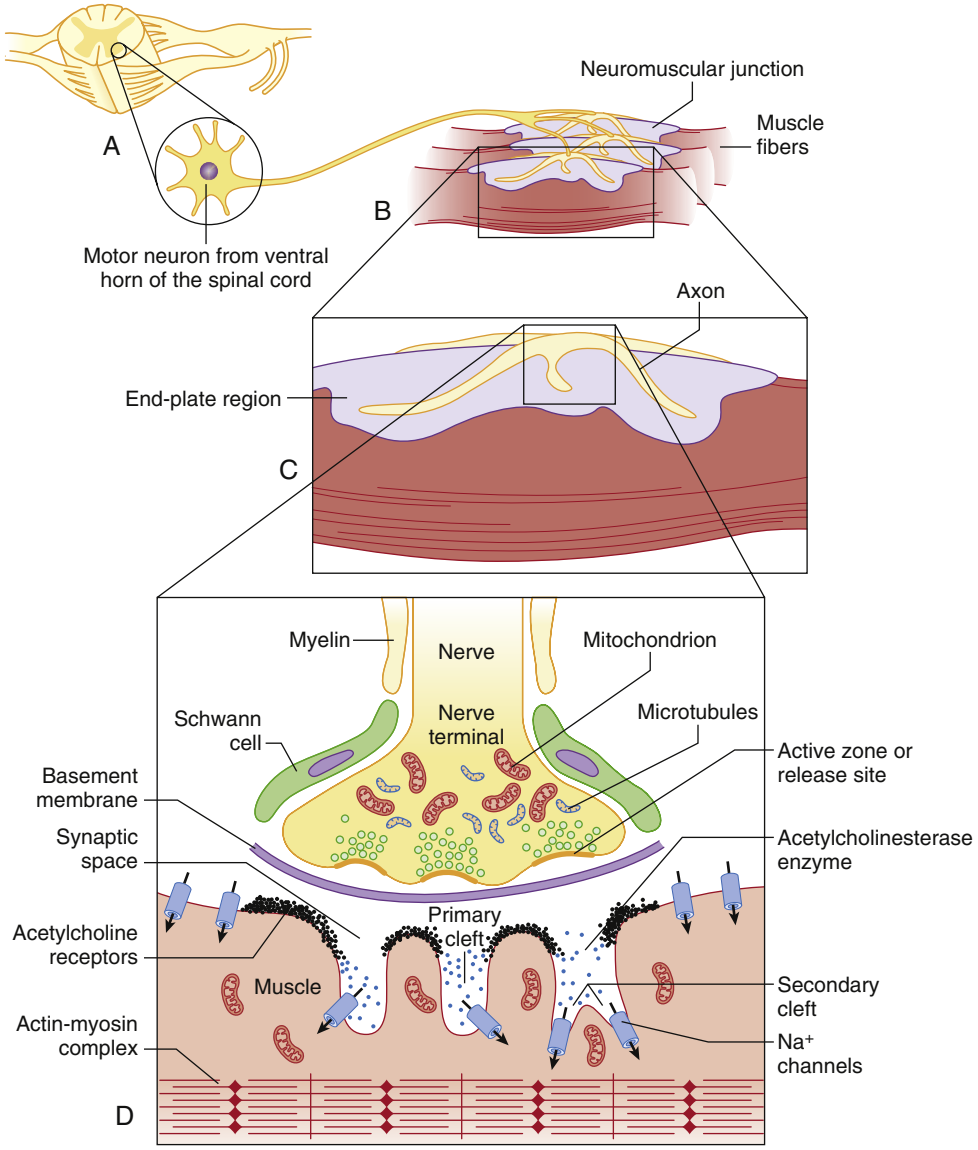

Figure 18-1. Structure of the adult neuromuscular junction shows the three cells that constitute the synapse: the motor neuron (i.e., nerve terminal), muscle fiber, and Schwann cell. **A,** The motor nerve originates in the ventral horn of the spinal cord or brainstem. **B,** As the nerve approaches its muscle fibers and before attaching itself to the surface of the muscle fiber, the nerve divides into branches that innervate many individual muscle fibers. **C,** Each muscle receives only one synapse. The motor nerve loses its myelin and further subdivides into many presynaptic boutons to terminate on the surface of the muscle fiber. **D,** The nerve terminal, covered by Schwann cells, has vesicles clustered about the membrane thickenings, which are the active zones, toward its synaptic side and mitochondria and microtubules toward its other side. A synaptic gutter or cleft made up of a primary and many secondary clefts separates the nerve from the muscle. The muscle surface is corrugated, and dense areas on the shoulders of each fold contain acetylcholine receptors. Sodium (Na^+) channels are present at the bottom of the clefts and throughout the muscle membrane. The acetylcholinesterase and proteins and proteoglycans that stabilize the neuromuscular junction are present in the synaptic clefts.

however, have indicated that succinylcholine-induced contractions of the extraocular muscles can last as long as 1 to 2 minutes and isometric tensions larger than 12 g can develop for each extraocular muscle.[23] Thus succinylcholine probably should not be given to patients with open eye injuries (also see Chapters 34 and 84).

The perijunctional zone is the area of muscle immediately beyond the junctional area and is critical to the function of the neuromuscular junction. The perijunctional zone contains a mixture of receptors, including a smaller density of AChRs and a high density of sodium channels (see Fig. 18-1, *D*). The admixture enhances the capacity of the perijunctional zone to respond to the depolarization (i.e., end-plate potential) produced by the AChRs and to transduce it into the wave of depolarization that travels along the muscle to initiate muscle contraction. The density of sodium channels in the perijunctional area is richer than in more distal parts of the muscle membrane.[25,26] The perijunctional zone is close enough to the nerve ending to be influenced by transmitter released from it. Moreover, special variants (i.e., isoforms) of receptors and sodium channels can appear in this area at different stages of life and in response to abnormal decreases in nerve activity (see "Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors" later in this chapter). Congenital abnormalities in the AChRs or in the sodium and calcium channels (i.e., mutations) are also known.[25-27] These variabilities seem to contribute to the differences in response to relaxants that are observed in patients with different pathologic conditions and ages.[17,27]

QUANTAL THEORY

The contents of a nerve ending are not homogeneous. As illustrated in Figures 18-1 and 18-2, vesicles are congregated in the portion toward the junctional surface, whereas microtubules, mitochondria, and other support structures are located toward the opposite side. The vesicles containing transmitter are ordered in repeating clusters alongside small, thickened, electron-dense patches of membrane referred to as *active zones* or *release sites*. This thickened area is a cross section of a band running across the width of the synaptic surface of the nerve ending that is believed to be the structure to which vesicles attach (active zones) before they rupture into the junctional cleft (see "Process of Exocytosis" later in this chapter). High-resolution

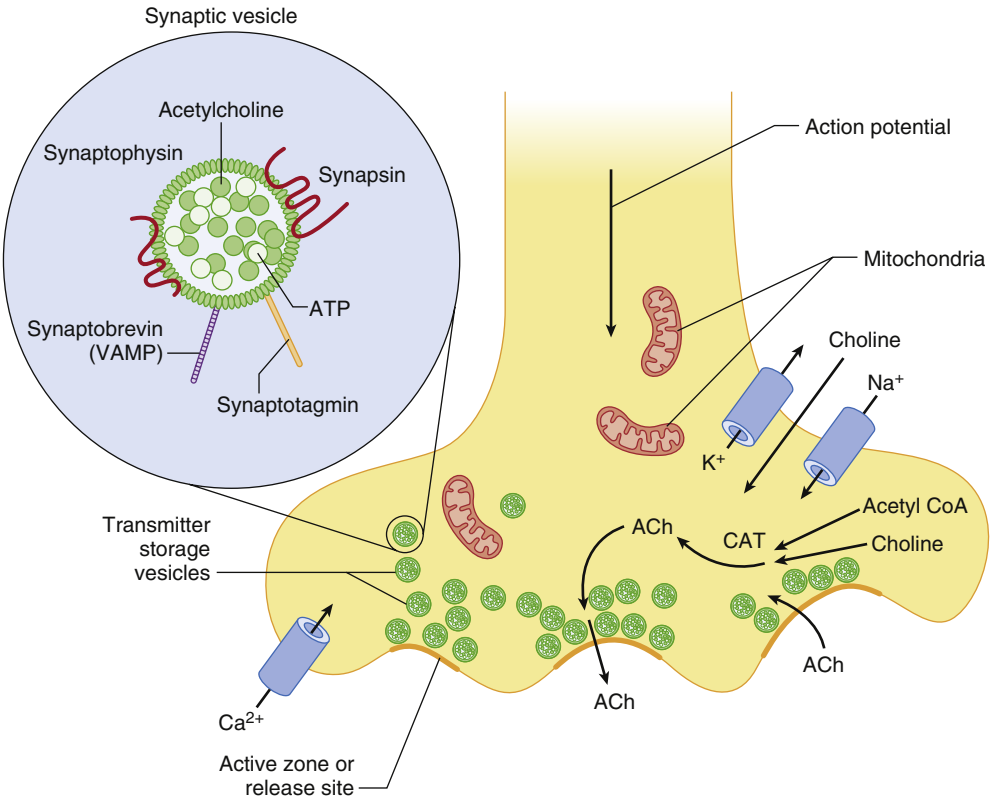

Figure 18-2. The working of a chemical synapse, the motor nerve ending, including some of the apparatus for synthesis of transmitter, is illustrated. The large intracellular structures are mitochondria. Acetylcholine (ACh), synthesized from choline and acetate by acetyl coenzyme A (CoA), is transported into coated vesicles, which are moved to release sites. A presynaptic action potential that triggers the influx of calcium (Ca^{2+}) through specialized proteins (i.e, Ca^{2+} channels) causes the vesicles to fuse with the membrane and discharge transmitter. Membrane from the vesicle is retracted from the nerve membrane and recycled. Each vesicle can undergo various degrees of release of contents—from incomplete to complete. The transmitter is inactivated by diffusion, catabolism, or reuptake. The inset provides a magnified view of a synaptic vesicle. Quanta of ACh, together with adenosine triphosphate (ATP), are stored in the vesicle and covered by vesicle membrane proteins. Synaptophysin is a glycoprotein component of the vesicle membrane. Synaptotagmin is the vesicle's calcium sensor. Phosphorylation of another membrane protein, synapsin, facilitates vesicular trafficking to the release site. Synaptobrevin (vesicle-associated membrane protein [VAMP]) is a SNARE protein involved in attaching the vesicle to the release-site proteins at the nerve terminal (see also Fig. 18-3). *CAT,* Choline acetyltransferase; *K^+*, potassium; *Na^+*, sodium.

scanning electron micrographs reveal small protein particles arranged alongside the active zone between vesicles. These particles are believed to be special channels—voltage-gated calcium channels—that allow calcium to enter the nerve and cause the release of vesicles.[28,29] The rapidity with which the neurotransmitter is released (200 μsec) suggests that voltage-gated calcium channels are close to the release sites. Proteomic studies suggest that at least 26 genes encode presynaptic proteins, and mutations in 12 of them cause defects in presynaptic structure that can lead to decreased acetylcholine release and muscle weakness.[30] These defects can be related to exocytosis, endocytosis, formation of active and periactive zones, vesicle transport, and neuropeptide modulation.[30]

When observing the electrophysiologic activity of a skeletal muscle, small, spontaneous depolarizing potentials at neuromuscular junctions can be seen. These potentials have only one hundredth the amplitude of the evoked end-plate potential produced when the motor nerve is stimulated. Except for amplitude, these potentials resemble the end-plate potential in the time course and manner in which they are affected by drugs. These small-amplitude potentials are called *miniature end-plate potentials* (MEPPs). Statistical analysis led to the conclusion that they are unitary responses; that is, there is a minimum size for the MEPP, and the sizes of all MEPPs are equal to or multiples of this minimum size. Because MEPPs are too large to be produced by a single molecule of acetylcholine, it was deduced that they are produced by uniformly sized packages, or quanta, of transmitter released from the nerve (in the absence of stimulation). The stimulus-evoked end-plate potential is the additive depolarization produced by the synchronous discharge of quanta from several hundred vesicles. The action potential that is propagated to the nerve ending allows the entry of calcium into the nerve through voltage-gated calcium channels, which causes vesicles to migrate to the active zone, fuse with the neural membrane, and discharge their acetylcholine into the junctional cleft.[28,29] Because the release sites are located immediately opposite the receptors on the postjunctional surface, little transmitter is wasted, and the response of the muscle is coupled directly with the signal from the nerve.[17,28]

Alignment of the presynaptic receptor site is achieved by adhesion molecules or specific cell-surface proteins located on both sides of the synapse that grip each other across the synaptic cleft and hold together the prejunctional and postjunctional synaptic apparatuses.[14,19,31] One such protein implicated in synapse adhesion is neurexin, which binds to neuroligins on the postsynaptic membrane. The amount of acetylcholine released by each nerve impulse is large, at least 200 quanta of approximately 5000 molecules each, and the number of AChRs activated by transmitter released by a nerve impulse is also large, approximately 500,000 molecules. The ions (mostly sodium and some calcium) that flow through the channels of activated (open) AChRs cause maximum depolarization of the end plate, which results in an end-plate potential that is greater than the threshold for stimulation of the muscle. This system is extremely vigorous. The signal is carried by more molecules of transmitter than are needed, and they evoke a response that is larger than needed. At the same time, only a small fraction of the available vesicles and receptors or channels are used to send each signal. Consequently, transmission has a substantial margin of safety, and, at the same time, the system has substantial capacity in reserve.[16-18,32]

NEUROMUSCULAR JUNCTION

FORMATION OF NEUROTRANSMITTER AT MOTOR NERVE ENDINGS

The axon of the motor nerve carries electrical signals from the spinal cord to muscles and has all of the biochemical apparatus needed to transform the electrical signal into a chemical one. All the ion channels, enzymes, other proteins, macromolecules, and membrane components needed by the nerve ending to synthesize, store, and release acetylcholine and other trophic factors are made in the cell body and transmitted to the nerve ending by axonal transport (see Fig. 18-2).[15,28,29] The simple molecules, choline and acetate, are obtained from the environment of the nerve ending, where choline is transported by a special system from extracellular fluid to the cytoplasm and acetate in the form of acetyl coenzyme A from mitochondria. The enzyme choline acetyltransferase brings about the reaction of choline and acetate to form acetylcholine. After synthesis, acetylcholine is stored in cytoplasm until it is transported and incorporated into vesicles, which are better positioned for release when an action potential reaches the nerve terminal.

NERVE ACTION POTENTIAL

During a nerve action potential, sodium from outside flows across the membrane, and the resulting depolarizing voltage opens the calcium channels, which allows entry of calcium ions into the nerve and causes acetylcholine to be released. A nerve action potential is the normal activator that releases the transmitter acetylcholine. The number of quanta released by a stimulated nerve is greatly influenced by the concentration of ionized calcium in extracellular fluid. If calcium is not present, then depolarization of the nerve, even by electrical stimulation, will not produce the release of transmitter. Doubling the extracellular calcium results in a 16-fold increase in the quantal content of an end-plate potential.[33] The calcium current persists until the membrane potential is returned to normal by outward fluxes of potassium from inside the nerve cell. Along with calcium channels on the nerve terminal are potassium channels, including the voltage-gated and calcium-activated potassium channels, whose function is to limit entry of calcium into the nerve and therefore depolarization.[26,32] The calcium current can be prolonged by potassium channel blockers (e.g., 4-aminopyridine, tetraethylammonium), which slow or prevent the efflux of potassium out of the nerve. The increase in quantal content produced in this way can reach astounding proportions.[17,34] An effect of increasing calcium in the nerve ending is also clinically observed as the so-called *posttetanic potentiation*, which occurs after a nerve of a patient paralyzed with an NDMR is stimulated at high, tetanic frequencies. Calcium enters

the nerve with every stimulus, but it accumulates during the tetanic period because it cannot be excreted as quickly as the nerve is stimulated. Because the nerve ending contains more than the normal amount of calcium for some time after the tetanus, a stimulus applied to the nerve during this time causes the release of more than the normal amount of acetylcholine. The abnormally large amount of acetylcholine antagonizes the relaxant and causes the characteristic increase in the size of the twitch.

Calcium enters the nerve through specialized proteins called *calcium channels*.[15,35] Of the several types of calcium channels, two seem to be important for the release of transmitter: P channels and the slower L channels. P channels, probably the type responsible for the normal release of transmitter, are found only in nerve terminals.[13,35] In motor nerve endings, they are located immediately adjacent to the active zones (see Fig. 18-2). They are voltage dependent and are opened and closed by changes in membrane voltage caused by the nerve action potential. In addition to calcium channels, several forms of potassium channels are present in the nerve terminal, including voltage-gated and calcium-activated potassium channels. Potassium channels limit the duration of nerve terminal depolarization and hence the entry of calcium and the release of transmitter.[26] Alterations in entry of calcium into the nerve ending can also alter the release of transmitter. The Eaton-Lambert myasthenic syndrome, which should not be confused with myasthenia gravis, is an acquired autoimmune disease in which antibodies are directed against voltage-gated calcium channels at nerve endings.[36] In this syndrome, decreased function of the calcium channel causes decreased release of transmitter, which results in inadequate depolarization and muscle weakness. Patients with the Eaton-Lambert syndrome exhibit increased sensitivity to depolarizing and nondepolarizing relaxants.[37]

Higher-than-normal concentrations of bivalent inorganic cations (e.g., magnesium, cadmium, manganese) can also block the entry of calcium through P channels and profoundly impair neuromuscular transmission. This mechanism is behind the typical muscle weakness and potentiation of the effect of muscle relaxants in a mother and fetus when magnesium sulfate is administered to treat preeclampsia. P channels, however, are not affected by calcium entry–blocking drugs such as verapamil, diltiazem, and nifedipine. These drugs have profound effects on the slower L channels present in the cardiovascular system. As a result, the L-type calcium channel blockers have no significant effect at therapeutic doses on the normal release of acetylcholine or on the strength of normal neuromuscular transmission. However, calcium entry–blocking drugs may increase the block in neuromuscular transmission induced by NDMRs. The effect is small, and not all investigators have been able to observe it. The explanation may lie in the fact that nerve endings also contain L-type calcium channels.

SYNAPTIC VESICLES AND RECYCLING

Two pools of vesicles seem to release acetylcholine, a readily releasable pool and a reserve pool, sometimes called VP2 and VP1, respectively.[38,39] Vesicles in the former are a bit smaller and limited to an area very close to the nerve membrane, where they are bound to the active zones. These vesicles are the ones that ordinarily release transmitter. Electron microscopic studies have demonstrated that the majority of synaptic vesicles (VP1) are sequestered in the reserve pool and tethered to the cytoskeleton in a filamentous network made up of primarily actin, synapsin (an actin-binding protein), synaptotagmin, and spectrin.[38,39]

Release occurs when calcium ions enter the nerve through the P channels lined up on the sides of the active zones by soluble *N*-ethylmaleimide–sensitive attachment protein receptor (SNARE) proteins.[38,39] The SNARE proteins are involved in fusion, docking, and release of acetylcholine at the active zone. Calcium needs to move only a very short distance (i.e., a few atomic radii) to encounter a vesicle and activate the proteins in the vesicle wall involved in a process known as *docking* (see "Process of Exocytosis" later in this chapter).[39] The reactivated proteins seem to react with the nerve membrane to form a pore through which the vesicle discharges its acetylcholine into the junctional cleft. Studies using fluorescent proteins have visualized how synaptic vesicles fuse with release sites and release their contents, which are then retrieved. Some vesicles stay open briefly before retrieval and do not completely collapse into the surface membrane ("kiss and run"). Others stay open longer and probably do not completely collapse ("compensatory"). Still others completely collapse and are not retrieved until another stimulus is delivered ("stranded").[38,39]

The larger reserve (VP1) vesicles, from their position deep from the nerve ending and firmly tethered to the cytoskeleton by many proteins, including actin, synapsin (an actin-binding protein), synaptotagmin, and spectrin,[37,38] may be moved to the readily releasable store to replace worn-out vesicles or to participate in transmission when the nerve is called on to work especially hard (e.g., when it is stimulated at very high frequencies or for a very long time). Under such strenuous circumstances, calcium may penetrate more deeply than normal into the nerve or may enter through L channels to activate calcium-dependent enzymes that break the synapsin links holding the vesicles to the cytoskeleton, thereby allowing the vesicles to be moved to the release sites. Repeated stimulation requires the nerve ending to replenish its store of vesicles filled with transmitter, a process known as *mobilization*. The term is commonly applied to the aggregate of all steps involved in maintaining the nerve ending's capacity to release transmitter—everything from the acquisition of choline and the synthesis of acetate to the movement of filled vesicles to release sites. Uptake of choline and the activity of choline acetyltransferase, the enzyme that synthesizes acetylcholine, are probably the rate-limiting steps.[15,29]

PROCESS OF EXOCYTOSIS

The readily releasable pool of synaptic vesicles constitutes the vesicles directly available for release. During an action potential and calcium influx, neurotransmitter is released. Studies have shed some light on the inner workings by which the vesicle releases its contents. The whole process is called *exocytosis*. The SNARE proteins include the synaptic-vesicle protein, synaptobrevin; the plasmalemma-associated

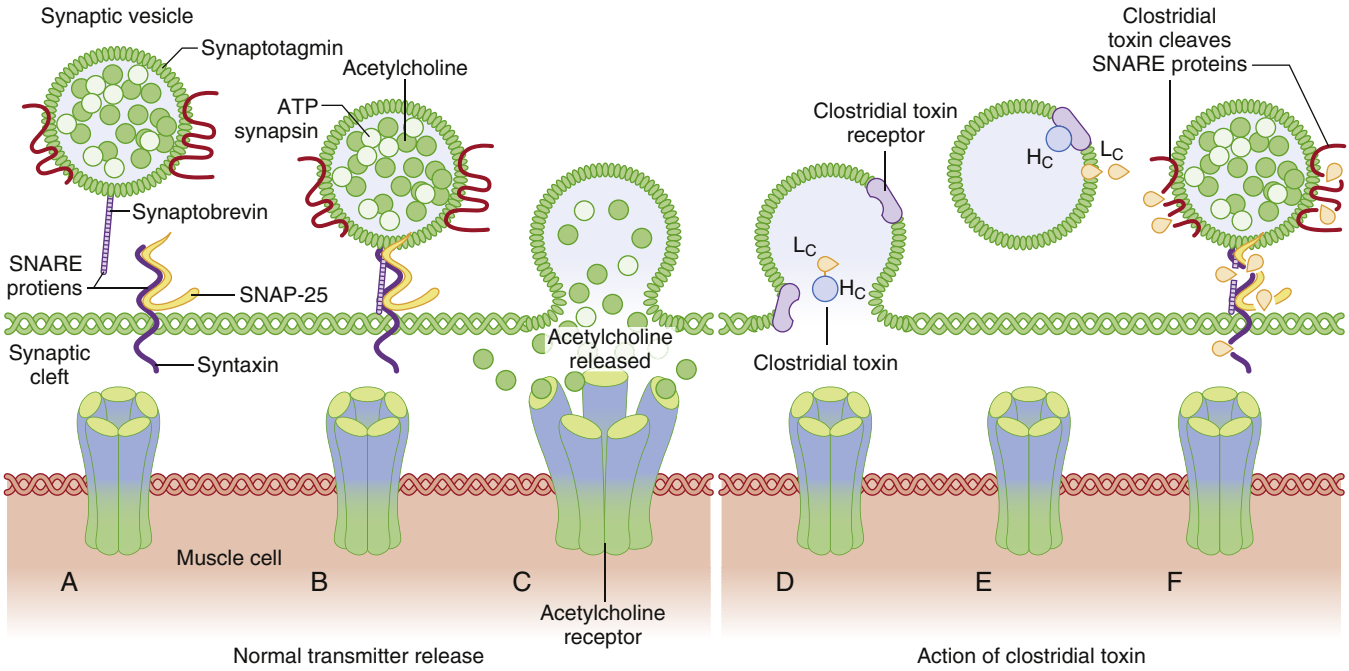

Figure 18-3. Model of protein-mediated membrane fusion and exocytosis. **A,** Release of acetylcholine from vesicles is mediated by a series of proteins collectively called SNARE proteins. Synaptotagmin is the neuronal calcium receptor that detects entry of calcium. Synaptobrevin (i.e., vesicle-associated membrane protein [VAMP]) is a filament-like protein on the vesicle. **B,** During depolarization and entry of calcium, synapsin is also present on the vesicle membrane. Synaptobrevin on the vesicle unfolds and forms a ternary complex with syntaxin/SNAP-25 on the nerve terminal membrane. **C,** Assembly of the ternary complex forces the vesicle in close apposition to the nerve membrane at the active zone with release of its contents, acetylcholine. The fusion is disassembled, and the vesicle is recycled. **D,** Clostridial toxin, botulinum, inhibits the release of acetylcholine and causes paralysis of muscles. The toxin consists of a light chain (L_c) and a heavy chain (H_c). The first stage in intoxication is the interaction of the toxin with a thus far unidentified receptor. **E,** This interaction is followed by internalization of the toxin within the vesicle and the release of the L_c of toxin from the vesicle. **F,** The liberated L_c cleaves a variety of SNARE proteins, depending on the type of toxin released, thereby preventing assembly of the fusion complex and thus blocking the release of acetylcholine. *ATP*, Adenosine triphosphate; *SNAP-25*, synaptosome-associated protein of 25-kd.

protein, syntaxin; and the synaptosome-associated protein of 25-kd (SNAP-25).[38,39] The current model of protein-mediated membrane fusion in exocytosis is as follows. When there is an action potential and calcium ions enter, synapsin becomes phosphorylated, which frees the vesicle from its attachment to the cytoskeleton. Syntaxin and SNAP-25 are complexes attached to the plasma membrane. After the initial contact, the synaptobrevin on the vesicle forms a ternary complex with syntaxin and SNAP-25. Synaptotagmin is the protein on the vesicular membrane that acts as a calcium sensor, localizes the synaptic vesicles to synaptic zones rich in calcium channels, and stabilizes the vesicles in the docked state.[38] Assembly of the ternary complex forces the vesicle to move close to the underlying nerve terminal membrane (i.e., the active zone), and the vesicle is then ready for release (see Fig. 18-3). The close proximity of release sites, calcium channels, and synaptic vesicles and the use of the calcium sensor lead to a burst of release of new transmitter synchronous with the stimulus.[37-40] The vesicle can release part or all of its contents, some of which can be recycled to form new vesicles as previously described ("kiss and run," "compensatory," "stranded").[37-40]

Botulinum neurotoxin selectively digests one or all of these SNARE proteins and blocks exocytosis of the vesicles,[41-42] which ultimately results in muscle weakness or more profound muscle paralysis. This toxin may produce a partial or complete chemical denervation. Botulinum toxin is therapeutically used to treat spasticity or spasm in several neurologic and surgical diseases, to prevent hyperhidrosis in patients with excessive sweating, and cosmetically to correct wrinkles.[43,44] Botulinum toxin consists of two protein segments known as heavy and light chains. The heavy chain interacts with lipid molecules called *polysialogangliosides* in the cell membrane and synaptotagmin on the vesicle to enter the vesicle. Once in the vesicle, the light chain inactivates neuromuscular transmission by breakdown and thereby inhibits the function of SNARE proteins (Fig. 18-4). Some reports indicate an increased incidence of clostridial infections in both Canada and the United States, with *Clostridium botulinum* infection being particularly common after traumatic injuries, in drug abusers, and after musculoskeletal allografts.[6,7] Thus systemic paralysis can occur after clostridial infection. Local injection for therapeutic purposes will usually result in localized paresis, although systemic effects have been reported.[7,45]

ACETYLCHOLINESTERASE

The acetylcholine released from the nerve diffuses across the junctional cleft and reacts with specialized receptor proteins in the end plate to initiate muscle contraction. Transmitter molecules that do not immediately react with a receptor or those released after binding to the

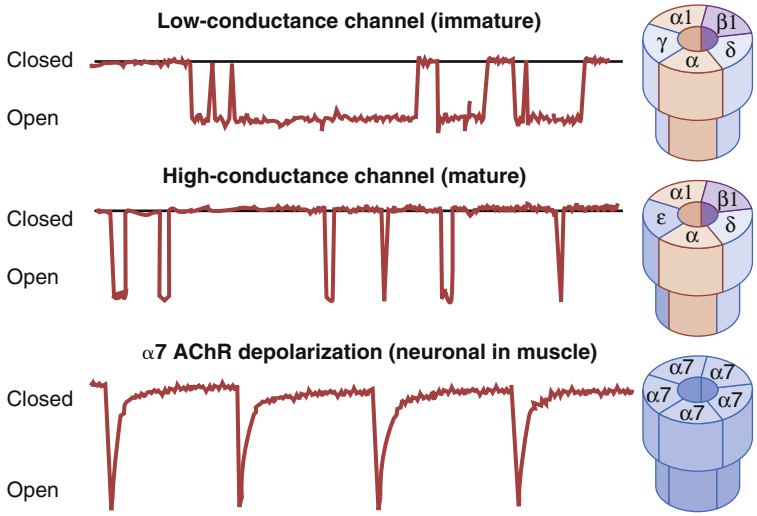

Figure 18-4. Schematic illustration depicts acetylcholine receptor (AChR) channels *(right)* and tracings of cell-patch records of receptor channel openings *(left)*. The mature or junctional receptor consists of two α1-subunits and one each of β1-, δ-, and ε-subunits. The immature, extrajunctional, or fetal form consists of two α1-subunits and one each of β1-, δ-, and γ-subunits. The latter is thus called the γ-subunit receptor. Recently, a neuronal receptor consisting of five α7-subunits has been described in muscle. All of the subunits are arranged around the central cation channel. The immature isoform containing the γ-subunit has long open times and low-amplitude channel currents. The mature isoform containing the ε-subunit has shorter open times and high-amplitude channel currents during depolarization. Substitution of the ε-subunit for the γ-subunit gives rise to the fast-gated, high-conductance channel type. As expected, application of acetylcholine to the α7 AChR also results in a fast, rapidly decaying inward current. All of these depolarizing events are insensitive to treatment with atropine but sensitive to treatment with α-bungarotoxin or muscle relaxants, which block the flow of current. The affinity of the muscle relaxants to each of the three isoforms may be different, α7 AChR being the least sensitive to block.

receptor are almost instantly destroyed by acetylcholinesterase in the junctional cleft. Acetylcholinesterase at the junction is the asymmetric or A12-form protein made in the muscle under the end plate. Acetylcholinesterase (enzyme classification 3.1.1.7) is a type B carboxylesterase enzyme. A smaller concentration of the enzyme is found in the extrajunctional area. The enzyme is secreted from the muscle but remains attached to it by thin stalks of collagen fastened to the basement membrane.[15,37] Most of the molecules of acetylcholine released from the nerve initially pass between the enzymes to reach the postjunctional receptors; however, as they are released from the receptors, they invariably encounter acetylcholinesterase and are destroyed. Under normal circumstances, a molecule of acetylcholine reacts with only one receptor before it is hydrolyzed. Acetylcholine is a potent messenger, but its actions are very short lived because it is destroyed in less than 1 millisecond after it is released.

Some congenital and acquired diseases are caused by altered activity of acetylcholinesterase. The congenital absence of the secreted enzyme (in knock-out mice) leads to impaired maintenance of the motor neuronal system and organization of nerve terminal branches.[46] Many syndromes caused by congenital abnormalities in cholinesterase function have been described and result in neuromuscular disorders whose symptoms and signs usually resemble those of myasthenia gravis or myasthenic syndromes.[27,47] Denervation decreases acetylcholinesterase at the junctional and extrajunctional areas.[37] Other acquired diseases involving cholinesterases are related to chronic inhibition of acetylcholinesterase by organophosphate pesticides or nerve gas (e.g., sarin) or to chronic pyridostigmine therapy given as prophylaxis against nerve gas poisoning.[48,49] Symptoms ranging from chronic fatigue to muscle weakness have been attributed to chronic cholinesterase inhibition, thus underscoring the importance of acetylcholinesterase in normal and abnormal neuromuscular function. A recent rodent study confirms that the muscle weakness associated with chronic pyridostigmine therapy is related to both AChRs downregulation and to receptor-independent factors.[50]

POSTJUNCTIONAL ACETYLCHOLINE RECEPTORS

The similarity of AChRs among many species and the abundance of AChRs from *Torpedo electric fish* have greatly facilitated research in this area. The availability of messenger RNA from humans and other species and DNA has allowed the study of the receptor in artificial systems such as oocytes from frogs and in mammalian cells that do not express the receptor, such as COS or fibroblast cells. Receptors can also be mutated by molecular techniques to simulate pathologic states; the study receptor function in these artificial systems can then be studied. By using these and related techniques, much has been learned about the synthesis, composition, and biologic function and mechanisms that underlie the physiologic and pharmacologic responses in AChRs.[51-53] Three isoforms of postjunctional nicotinic AChRs exist: a junctional or mature receptor, an extrajunctional or immature (fetal) receptor, and the more recently described neuronal α7 receptor[2,16,18] (see "Biology of Prejunctional and Postjunctional Nicotinic Receptors" later in this chapter). The differences between receptor subtypes, however, can be neglected in a general discussion of the role of receptors in neuromuscular transmission.

AChRs are synthesized in muscle cells and are anchored to the end-plate membrane by a special 43-kd protein known as *rapsyn*. This cytoplasmic protein is associated with the AChR in a 1:1 ratio.[16-19] The receptors, formed of five subunit proteins, are arranged like the staves of a barrel into a cylindrical receptor with a central pore for ion channeling (the key features are illustrated in Fig. 18-4). The receptor protein has a molecular mass of approximately 250,000 daltons. Each receptor has five subunits. The mature receptor consists of α1-, β1-, δ-, and ε-subunits, and the fetal (immature, extrajunctional) receptor consists of α1-, β1-, δ-, and γ-subunits; there are two subunits of α and one each of the others. The neuronal α7 AChR consists of five α7-subunits.[16,18] Each of all receptor subunits consists of approximately 400 to 500 amino acids. The receptor-protein complex passes entirely through the membrane and protrudes beyond the extracellular surface of the membrane and into the cytoplasm. The binding site for acetylcholine is on each of the α1-subunits, which is located on the extracellular component and α1-subunit, and these are the sites of competition between receptor agonists and antagonists. Agonists and antagonists are attracted to the binding site, and either may occupy the site, which is located near cysteine residues (unique to the α-chain) at amino acid positions 192-193 of the α-subunit.[16-18] Radiolabeled α-bungarotoxin from the cobra, used to quantitate or fluorescent stain the receptor, binds to heptapeptide region 185-199 of the α-subunit.[54] Motor neuron–derived neuregulin-1β (NRβ-1), originally described as AChR-inducing activity (ARIA), induces AChR gene transcription in subsynaptic myonuclei by activating ErbB receptors.[16-19]

SYNTHESIS AND STABILIZATION OF POSTJUNCTIONAL RECEPTORS

Muscle tissue is formed from the mesoderm and initially appears as myoblasts. Myoblasts fuse to produce myotubes, which therefore have multiple nuclei. As the myotubes mature, the sarcomere, which is the contractile element of the muscle consisting of actin and myosin, develops.[55] The protein β-integrin seems to be essential for myoblast fusion and sarcomere assembly.[55] Shortly afterward, motor nerve axons grow into the developing muscle, and these axons bring in nerve-derived signals (i.e., growth factors), including agrin and neuregulins (NRβ-1 and NRβ-2), which are key to the maturation of myotubes to muscle.[19] Agrin is a protein from the nerve that stimulates postsynaptic differentiation by activating muscle-specific tyrosine kinase (MuSK), a tyrosine kinase expressed selectively in muscle. With signaling from agrin, the AChRs, which have been scattered throughout the muscle membrane, cluster at the area immediately beneath the nerve. Agrin, together with neuregulins and other growth factors, induce the clustering of other critical muscle-derived proteins, including MuSK, rapsyn, and ErbB proteins, all of which are necessary for maturation and stabilization of AChRs at the junction. In addition to the effects on postsynaptic differentiation, agrin and MuSK display effects on presynaptic differentiation as well. Agrin and MuSK induce retrograde signals that instruct axons to undergo neuron outgrowth and terminal differentiation.[19] Current understanding of presynaptic development of the neuromuscular junction, however, is significantly less advanced than the understanding of postsynaptic development. Just before and shortly after birth, the immature, γ-subunit–containing AChRs are replaced by the mature, ε-subunit–containing receptors. Although the mechanism of this change is unclear, a neuregulin, NRβ-1, also called *ARIA*, that binds to one of the ErbB receptors seems to play a role.[19,56]

BASIC ELECTROPHYSIOLOGY OF NEUROTRANSMISSION

Progress in electrophysiologic techniques has moved at a pace equal with the advances in molecular approaches for studying prejunctional and postjunctional receptors. Patch-clamping is a technique during which a glass micropipette is used to probe the membrane surface until a single functional receptor is encompassed. The tip of the pipette is pressed into the lipid of the membrane, and the electronic apparatus is arranged to keep the membrane potential clamped (i.e., fixed), and the current that flows through the channel of the receptor is measured. The solution in the pipette can contain acetylcholine, muscle relaxant, another drug, or a mixture of drugs. By applying these drugs to the receptor through the micropipette, electrical changes can be monitored.

Figure 18-5 illustrates the results of the classic depolarizing action of acetylcholine on end-plate receptors. Normally, the pore of the channel is closed by approximation of the cylinders (i.e., subunits). When an agonist occupies both α-subunit sites, the protein molecule undergoes a conformational change with a twisting movement along the central axis of the receptor that results in the opening of the central channel through which ions can flow along a concentration gradient. When the central channel is open, sodium and calcium flow from the outside of the cell to the inside and potassium flows from the inside to the outside. The channel in the tube is large enough to accommodate many cations and electrically neutral molecules, but it excludes anions (e.g., chloride). The current transported by the ions depolarizes the adjacent membrane. The net current is depolarizing and creates the end-plate potential that stimulates the muscle to contract. In this instance, downward-going (i.e., depolarizing) current can be recorded by the patch-clamp electrophysiologic technique previously described (see Fig. 18-4).

The pulse stops when the channel closes by a reversed mechanical conformation (see earlier discussion), which is typically initiated when one or both agonist molecules detach from the receptor. In the activated, open state, the current that passes through each open channel is minuscule, only a few picoamperes (approximately 10^4 ions/msec). However, each burst of acetylcholine from the nerve normally opens approximately 500,000 channels simultaneously, and the total current is more than adequate to produce depolarization of the end plate and contraction of muscle. Opening of a channel causes conversion of chemical signals from a nerve to the flow of current on the muscle disease to

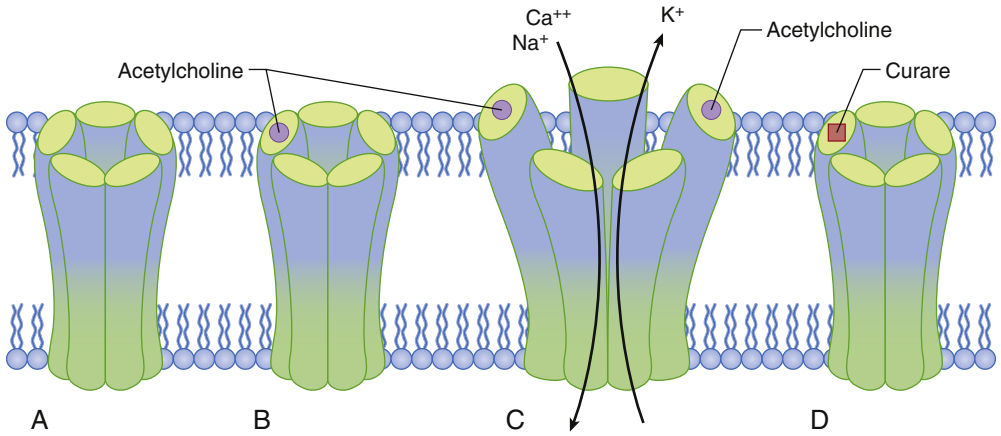

Figure 18-5. Actions of acetylcholine or curare on end-plate receptors. **A,** The ion channel is inactive and does not open in the absence of acetylcholine. **B,** Although one acetylcholine molecule *(filled circle)* is binding to one of two binding sites, the central channel does not open. **C,** When acetylcholine simultaneously binds to the recognition sites of both α-subunits *(filled circles)*, a conformation change is triggered that opens the channel and allows the cations to flow across the membrane. **D,** Action of antagonists such as curare *(filled square)*. Acetylcholine is in competition with tubocurarine for the receptor's recognition site but may also react with acetylcholinesterase. Tubocurarine is a prototypical nondepolarizing muscle relaxant. Inhibiting the acetylcholinesterase enzyme increases the lifetime of acetylcholine and the probability that it will react with a receptor. When one of the two binding (recognition) sites is occupied by curare, the receptor will not open, even if the other binding site is occupied by acetylcholine. Ca^{2++}, Calcium ion; K^{+}, potassium ion; Na^{+}, sodium ion.

cause end-plate potentials, thereby leading to muscle contraction. The end-plate potential has been viewed as a graded event that may be reduced in magnitude or extended in time by drugs, but, in reality, the end-plate potential is the summation of many all-or-nothing events simultaneously occurring at myriad ion channels. It is these tiny events that are affected by drugs.

Receptors that do not have two molecules of agonist (e.g., acetylcholine) bound remain closed. Both α-subunits must be simultaneously occupied by agonist; if only one of them is occupied, then the channel remains closed (see Fig. 18-5). This is the basis for preventing depolarization by antagonists. NDMRs act by binding to either or both α-subunits and thus preventing acetylcholine from binding and opening the channel. This interaction between agonists and antagonists is competitive, and the outcome—transmission or block—depends on the relative concentrations and binding characteristics of the drugs involved (see "Drug Effects on Postjunctional Receptors").

Individual channels are also capable of a wide variety of conformational states.[17,57] They may stay open or remain closed and thereby affect total current flow across the membrane, but they can do more. They may open for a longer or shorter time than normal, open or close more gradually than usual, open briefly and repeatedly (i.e., chatter), or pass fewer or more ions per opening than they usually do. Their function is also influenced by drugs, changes in fluidity of the membrane, temperature, electrolyte balance in the milieu, and other physical and chemical factors.[38,39] Receptor channels are dynamic structures that are capable of a wide variety of interactions with drugs and of entering a wide variety of current-passing states. All these influences on channel activity are ultimately reflected in the strength or weakness of neuromuscular transmission and the contraction of a muscle.

DRUG EFFECTS ON POSTJUNCTIONAL RECEPTORS

CLASSIC ACTIONS OF NONDEPOLARIZING MUSCLE RELAXANTS

Neurotransmission occurs when acetylcholine released by the nerve action potential binds to nicotinic AChRs. All NDMRs impair or block neurotransmission by competitively preventing the binding of acetylcholine to the muscle AChR. The final outcome—block or transmission—depends on the relative concentrations of the chemicals and their comparative affinities for the receptor. Figure 18-5 shows a system exposed to acetylcholine and the nondepolarizing neuromuscular blocking compound, tubocurarine. All other muscle relaxants (e.g., pancuronium, vecuronium) (also see Chapter 34) have similar actions as that of tubocurarine. One receptor has attracted two acetylcholine molecules and has opened its channel, where current will flow to depolarize that segment of membrane. Another has attracted one tubocurarine molecule; its channel will not open, and no current will flow, even if one acetylcholine molecule binds to the other site. The third receptor has acetylcholine on one α-subunit and nothing on the other. What will happen depends on which of the molecules binds. If acetylcholine binds, then the channel will open and the membrane will be depolarized; if tubocurarine binds, then the channel will remain closed and the membrane will not be depolarized. At other times, one or two tubocurarine molecules may attach to the receptor, in which case the receptor is not available to agonists; no current flow is recorded. In the presence of moderate concentrations of tubocurarine, the amount of current flowing through the entire end plate at any instant is reduced from normal, which results in a smaller end-plate potential and, if carried far enough, a block in neurotransmission or the production of neuromuscular paralysis.

Normally, acetylcholinesterase destroys acetylcholine and removes it from competition for a receptor; therefore tubocurarine has a better chance of inhibiting transmission. If, however, an inhibitor of acetylcholinesterase such as neostigmine is added, then the cholinesterase cannot destroy acetylcholine. The concentration of agonist in the cleft remains high, and this high concentration shifts the competition between acetylcholine and tubocurarine in favor of the former, thereby improving the chance of two acetylcholine molecules binding to a receptor even though tubocurarine is still in the environment. This mechanism causes the cholinesterase inhibitors to overcome the neuromuscular paralysis produced by NDMRs. The channel opens only when acetylcholine attaches to both recognition sites. A single molecule of antagonist, however, is adequate to prevent depolarization of that receptor. This modifies the competition by strongly biasing it in favor of the antagonist (relaxant). Mathematically, if the concentration of tubocurarine is doubled, then the concentration of acetylcholine must be increased fourfold if acetylcholine is to remain competitive. Paralysis produced by high concentrations of muscle relaxants (antagonist) is more difficult to reverse with cholinesterase inhibitors than that produced by low concentrations. After large doses of NDMRs, cholinesterase inhibitors may be ineffective until the concentration of relaxant in the perijunctional area decreases to a lower level by the redistribution or elimination of the drug. In contrast to reversal with a cholinesterase inhibitor, cyclodextrin encapsulation takes place at any concentration of a steroid-based compound, such as vecuronium or rocuronium, and reversal by this novel mechanism can therefore be achieved at any level of neuromuscular block provided the amount of cyclodextrin (sugammadex) is large enough (for further details, see also Chapter 35).

CLASSIC ACTIONS OF DEPOLARIZING MUSCLE RELAXANTS

Depolarizing relaxants (e.g., succinylcholine, decamethonium) initially simulate the effect of acetylcholine and can therefore be considered agonists, despite the fact that they block neurotransmission after the initial stimulation. Structurally, succinylcholine is very similar to the natural ligand acetylcholine and consists of two molecules of acetylcholine bound together through their backbones. It is thus not surprising that succinylcholine can mimic the effects of acetylcholine.

Succinylcholine or decamethonium can bind to the receptor, open the channel, pass current, and depolarize the end plate. These agonists, similar to acetylcholine, attach only briefly; each opening of a channel is very short in duration—1 millisecond or less. The response to acetylcholine, however, is over in milliseconds because of its rapid degradation by acetylcholinesterase, and the end plate resets to its resting state long before another nerve impulse arrives. In contrast, the depolarizing relaxants characteristically have a biphasic action on muscle—an initial contraction, followed by relaxation lasting from minutes to hours. Because they are not susceptible to hydrolysis by acetylcholinesterase, the depolarizing relaxants are not eliminated from the junctional cleft until after they are eliminated from plasma. The time required to clear the drug from the body is the principal determinant of how long the drug effect lasts. Whole-body clearance of the relaxant is very slow in comparison to acetylcholine, particularly when plasma (pseudo) cholinesterase is abnormal. Because the relaxant molecules are not quickly cleared from the cleft, compared with acetylcholine, they repeatedly react with receptors even with normal levels of plasma cholinesterase, almost immediately attaching to a receptor after separating from another, thereby repeatedly depolarizing the end plate and opening channels. For details on the effect of succinylcholine in patients with cholinesterase deficiency, also see Chapter 34.

The quick shift from excitation of muscle contraction to block of transmission by depolarizing relaxants occurs because the end plate is continuously depolarized. This comes about as a result of the juxtaposition of the edge of the end plate with a different kind of ion channel, the sodium channel that does not respond to chemicals but opens when exposed to a transmembrane voltage change. The sodium channel is also a cylindrical transmembrane protein through which sodium ions can flow. Two parts of its structure act as gates that allow or stop the flow of sodium ions.[58] Both gates must be open if sodium is to flow through the channel; closing of either cuts off the flow. Because these two gates act sequentially, a sodium channel has three functional conformational states and can progressively move from one state to another (Fig. 18-6).

When the sodium channel is in its resting state, the lower gate (i.e., the time-dependent or inactivation gate) is open, but the upper gate (i.e., the voltage-dependent gate) is closed, and sodium ions cannot pass. When the molecule is subjected to a sudden change in voltage by the depolarization of the adjacent membrane, the top gate opens; because the bottom (time-dependent) gate is still open, sodium flows through the channel. The voltage-dependent gate stays open as long as the molecule is experiencing a depolarizing influence from the membrane around it; it will not close until the depolarization disappears. However, shortly after the voltage-dependent gate opens, the bottom gate closes and again cuts off the flow of ions. It cannot open again until the

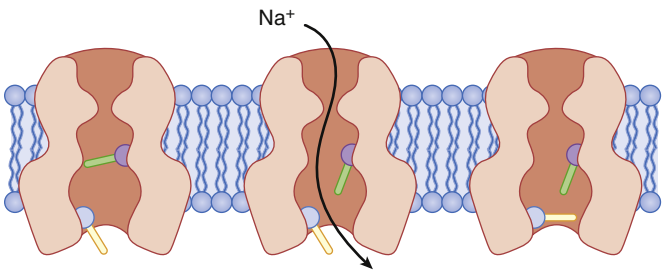

Figure 18-6. Illustration of a sodium (Na^+) channel. The bars represent parts of the molecule that act as gates. The upper bar is voltage dependent; the lower bar is time dependent. The left side of the drawing represents the resting state. Once activated by a change in voltage, the molecule and its gates progress as illustrated *(left to right)*. See text for details.

voltage-dependent gate closes. When depolarization of the end plate stops, the voltage-dependent gate closes, the time-dependent gate opens, and the sodium channel returns to its resting state. This whole process is short lived when depolarization occurs with acetylcholine.[58] The initial response of a depolarizing muscle relaxant resembles that of acetylcholine, but because the muscle relaxant is not rapidly hydrolyzed, depolarization of the end plate is not brief.

Depolarization of the end plate by the depolarizing relaxant initially causes the voltage gate in adjacent sodium channels to open, thereby producing a wave of depolarization that sweeps along the muscle and generates a muscle contraction. Shortly after the voltage-dependent gate opens, the time-dependent inactivation gate closes. Because the relaxant is not removed from the cleft, the end plate continues to be depolarized. Because the sodium channels immediately adjacent to the end plate are influenced by depolarization of the end plate, their voltage-dependent gates stay open and their inactivation gates stay closed. Since sodium cannot flow through a channel that has a closed inactivation gate, the perijunctional muscle membrane does not depolarize. When the flow of ions through sodium channels in the perijunctional zone stops because of a closure of the inactivation gates, the channels downstream (beyond the perijunctional zone) are freed of depolarizing influence. In effect, the perijunctional zone becomes a buffer that shields the rest of the muscle from events at the end plate. Consequently, the muscle membrane is separated into three zones: (1) the end plate, which is depolarized by succinylcholine; (2) the perijunctional muscle membrane, in which the sodium channels are frozen in an inactivated state; and (3) the rest of the muscle membrane, in which the sodium channels are in the resting state. Because a burst of acetylcholine from the nerve cannot overcome the inactivated sodium channels in the perijunctional zone, neuromuscular transmission is blocked. This phenomenon is also called *accommodation*. During accommodation, when the synapse is inexcitable through the nerve (transmitter), direct electrical stimulation of muscle causes muscle contraction because the sodium channels beyond the junctional area are in the resting excitable state.

The extraocular muscles are tonic muscles, which are multiply innervated and chemically excitable along most of its surface.[20-23] Despite its innervated state, the ocular muscles express both mature and immature receptors.[20,22] Accommodation does not occur, and these muscles can undergo a sustained contracture in the presence of succinylcholine. The tension thus developed forces the eye against the orbit and accounts for part of the increase in intraocular pressure produced by depolarizing relaxants (also see Chapter 34). The extraocular muscles contain a special type of receptor that does not become desensitized (see later discussion) during the continued presence of acetylcholine or other agonists.[21,23] A single dose of succinylcholine can cause contracture lasting several minutes.[23] Whether it is the immature γ-subunit AChR or the α7 AChR subunit that plays a role in this resistance to desensitization in the ocular muscles is unknown.

NONCLASSIC AND NONCOMPETITIVE ACTIONS OF NEUROMUSCULAR DRUGS

Several drugs can interfere with the receptor, directly or through its lipid environment, and can change transmission. These drugs react with the neuromuscular receptor to change its function and impair transmission, but they do not act through the acetylcholine binding site. These reactions cause drug-induced changes in the dynamics of the receptor; instead of sharply opening and closing, the modified channels are sluggish. They open more slowly and stay open longer, or they close slowly and in several steps, or both. These effects on channels cause corresponding changes in the flow of ions and distortions of the end-plate potential. The clinical effect depends on the molecular events. For example, procaine, ketamine, inhaled anesthetics, or other drugs that dissolve in the membrane lipid may change the opening or closing characteristics of the channel.[57,59] If the channel is prevented from opening, then transmission is weakened. If, however, the channel is prevented from or slowed in closing, then transmission may be enhanced. These drugs do not fit the classic model, and the impaired neuromuscular function is not antagonized by increasing perijunctional acetylcholine concentrations with cholinesterase inhibitors. Such drugs can be involved in two clinically important reactions: receptor desensitization and channel blockade. The former occurs in the receptor molecule, whereas the latter occurs in the ion channel.

DESENSITIZATION BLOCK

The AChR, as a result of its flexibility and the fluidity of the lipid around it, is capable of existing in a number of conformational states.[57-61] Because the resting receptor is free of agonist, its channel is closed. The second state exists when two molecules of agonist are bound to the α-subunit of the receptor and the receptor has undergone the conformational change that opens the channel and allows ions to flow. These reactions are the bases of normal neuromuscular transmission. Some receptors that bind to agonists, however, do not undergo the conformational change to open the channel. Receptors in these states are called desensitized (i.e., they are not sensitive to the channel-opening actions of agonists). They bind agonists with exceptional avidity, but the binding does not result in the opening of the channel. The mechanisms by which desensitization occurs are not known. The receptor macromolecule, 1000 times larger by weight than most drugs or gases, provides many places at which the smaller molecules may act. The interface between lipid and receptor protein provides additional potential sites of reaction. Several different conformations of the protein are known, and because acetylcholine cannot cause the ion channel to open in any of them, they all are included in the functional term *desensitization*. Desensitization is accompanied by phosphorylation of a tyrosine unit in the receptor protein.[61,62]

Although agonists (e.g., succinylcholine) induce desensitization, the receptors are in a constant state of transition between resting and desensitized states, regardless of whether agonists are present. Agonists do

promote transition to a desensitized state or, because they bind very tightly to desensitized receptors, trap a receptor in a desensitized state. Antagonists also tightly bind to desensitized receptors and can trap molecules in these states. This action of antagonists is not competitive with that of acetylcholine; it may be augmented by acetylcholine if the latter promotes the change to a desensitized state. Desensitization can lead to significant misinterpretation of data. Superficially, the preparation seems to be normal, but its responsiveness to agonists or antagonists is altered. One variety occurs very rapidly, within a few milliseconds after application of an agonist, which may explain the increased sensitivity to nondepolarizing relaxant after the prior administration of succinylcholine. Desensitization may also be a part of the phenomenon known as *phase II block* (see "Phase II Block," later in this chapter), which is caused by a prolonged administration of depolarizing relaxants. Phase II block is frequently referred to as a desensitization block, but it should not be because desensitization of receptors is only one of many phenomena that contribute to the process.

Many other drugs used by anesthetists also promote the shift of receptors from a normal state to a desensitized state.[58-60] These drugs, some of which are listed in Box 18-1, can weaken neuromuscular transmission by reducing the margin of safety that normally exists at the neuromuscular junction, or they can cause an apparent increase in the capacity of nondepolarizing agents to block transmission. These actions are independent of the classic effects, based on competitive inhibition of acetylcholine. The presence of desensitized receptors means that fewer receptor channels than usual are available to carry transmembrane current. The production of desensitized receptors decreases the efficacy of neuromuscular transmission. If many receptors are desensitized, then insufficient normal ones are left to depolarize the motor end plate, and neuromuscular transmission will not occur. Even if only some receptors are desensitized, neuromuscular transmission will be impaired, and the system will be more susceptible to block by conventional antagonists such as atracurium or rocuronium.

BOX 18-1 ***Drugs That Can Cause or Promote Desensitization of Nicotinic Cholinergic Receptors***

- Volatile anesthetics
  - Halothane
  - Sevoflurane
  - Isoflurane
- Antibiotics
  - Polymyxin B
- Cocaine
- Alcohols
  - Ethanol
  - Butanol
  - Propanol
  - Octanol
- Barbiturates
  - Thiopental
  - Pentobarbital
- Agonists
  - Acetylcholine
  - Decamethonium
  - Carbachol
  - Succinylcholine
- Acetylcholinesterase inhibitors
  - Neostigmine
  - Pyridostigmine
  - Difluorophosphate
  - Edrophonium
- Local anesthetics
  - Dibucaine
  - Lidocaine
  - Prilocaine
  - Etidocaine
- Phenothiazines
  - Chlorpromazine
  - Trifluoperazine
  - Prochlorperazine
- Phencyclidine
- Calcium channel blockers
  - Verapamil

CHANNEL BLOCK

Local anesthetics and calcium entry blockers prevent the flow of sodium or calcium through their respective channels, thus explaining the term *channel-blocking drugs*. Similarly, block of the flow of ions can occur at the AChR with concentrations of drugs used clinically and may contribute to some of the phenomena and drug interactions observed at the receptor. Two major types, closed-channel and open-channel block, can occur.[60,63,64] In a closed-channel block, certain drugs can occupy the mouth of the channel and prevent ions from passing through the channel to depolarize the end plate. The process can take place even when the channel is not open. In an open-channel block, a drug molecule enters a channel that has been opened by reaction with acetylcholine but does not necessarily penetrate all the way through. Open-channel blockade is a use-dependent block, which means that molecules can enter the channel only when it is open. In open- and closed-channel blocks, the normal flow of ions through the receptor is impaired, thereby resulting in the prevention of depolarization of the end plate and a weakened or blocked neuromuscular transmission. However, because the action is not at the acetylcholine recognition site, it is not a competitive antagonism of acetylcholine and is not relieved by anticholinesterases that increase concentrations of acetylcholine. Increasing the concentration of acetylcholine may cause the channels to open more often and, consequently, become more susceptible to blockade by use-dependent compounds. Evidence suggests that neostigmine and related cholinesterase inhibitors can act as channel-blocking drugs.[17,63]

Channel block may account for the antibiotic-, cocaine, quinidine-, piperocaine-, tricyclic antidepressant–, naltrexone-, naloxone-, and histrionicotoxin-induced alterations in neuromuscular function. Muscle relaxants, in contrast, can bind to the acetylcholine recognition site of the receptor and occupy the channel. Pancuronium

preferentially binds to the recognition site. Gallamine seems to act equally at the two sites (channel-blocking and acetylcholine-blocking sites). Tubocurarine is in between; at small doses that clinically produce minimal blockage of transmission, the drug is essentially a pure antagonist at the recognition site; at larger doses, it also enters and blocks channels. Decamethonium and succinylcholine, as agonists, can open channels and, as slender molecules, also enter and block them. Decamethonium and some other long, thin molecules can penetrate all the way through the open channel and enter the cytoplasm of muscle cells. Whether prolonged administration of NDMRs, as used in an intensive care unit, can result in the NDMR occupation of the channel, and even entry of drug into the cytosol is unknown.

PHASE II BLOCK

A phase II block is a complex phenomenon associated with a typical fade in muscle during continuous exposure to depolarizing drugs. This fade phenomenon is likely due to the interaction of depolarizing action of succinylcholine on distinct neuronal (prejunctional) AChRs; these prejunctional receptors are blocked by higher than usual concentrations of succinylcholine. This fade after succinylcholine is at least partly dependent on a presynaptic interaction with cholinergic transmission of importance for neurotransmitter mobilization and release. However, fade in muscle during repetitive nerve stimulation can also be attributable to postjunctional AChR block.[65]

Other factors may also be involved. The repeated opening of channels allows a continuous efflux of potassium and influx of sodium, and the resulting abnormal electrolyte balance distorts the function of the junctional membrane. Calcium entering the muscle through the opened channels can cause disruption of receptors and the sub–end-plate elements themselves. The activity of the sodium-potassium adenosine triphosphatase pump in the membrane increases with increasing intracellular sodium and, by pumping sodium out of the cell and potassium into it, works to restore the ionic balance and membrane potential toward normal. As long as the depolarizing drug is present, the receptor channels remain open and ion flux through them remains frequent.[66]

Factors influencing the development of a phase II block include the duration of exposure to the drug, the particular drug used and its concentration, and even the type of muscle (i.e., fast or slow twitch). Interactions with anesthetics and other agents also affect the process. All of these drugs may also have prejunctional effects on the rate and amount of transmitter released and mobilized. With so many variables involved in the interference with neuromuscular transmission, a phase II block is a complex and ever-changing phenomenon. The reversal response of a phase II block produced by a depolarizing muscle relaxant to the administration of cholinesterase inhibitors is difficult to predict. It is therefore best that reversal by cholinesterase inhibitors not be attempted, although the response to tetanus or train-of-four stimulation resembles that produced by NDMRs.

BIOLOGY OF PREJUNCTIONAL AND POSTJUNCTIONAL NICOTINIC ACETYLCHOLINE RECEPTORS

POSTJUNCTIONAL CONVENTIONAL ACETYLCHOLINE RECEPTORS IN MUSCLE VERSUS NEURONAL ACETYLCHOLINE RECEPTORS IN MUSCLE

Currently, three variants of postjunctional AChRs have been identified. The AChR isoform present in the innervated, adult neuromuscular junction is referred to as the adult, mature, or junctional receptor. Another AChR isoform, also described more than 4 decades ago, is expressed when activity in muscle is decreased, as observed in the fetus before innervation or after chemically or physically induced immobilization; after lower or upper motor neuron injury, burns, or sepsis; or after other events that cause increased muscle protein catabolism, including sepsis or generalized inflammation.[1-3] In contrast with the mature or junctional receptors, the other isoform is referred to as the immature, extrajunctional, or fetal form of AChR. Some evidence suggests that the immature isoform is not observed in the muscle protein catabolism and wasting that occur with malnutrition.[67] Qualitative differences in the mature isoform can occur as a result of gene mutations, which therefore alters the subunit protein structure. These qualitative changes in AChR can also cause abnormalities in neurotransmission (e.g., slow- or fast-channel syndrome)[27,47] and therefore the response to muscle relaxants.

At the molecular level, the mature and immature receptors consists of five subunits (see Fig. 18-4).[1-3] The mature junctional receptor is a pentamer of two α1-subunits and one each of the β1-, δ7-, and ε-subunits. The immature receptor consists of two α-subunits and one each of the β7-, δ7-, and γ-subunits; that is, in the immature receptor, the γ-subunit is present instead of the ε-subunit. The γ- and ε-subunits differ very little from each other in amino acid homology, but the differences are great enough to affect the physiologic function and pharmacologic characteristics of the receptor and its ion channel. Junctional receptors are always confined to the end-plate region of the muscle membrane. The immature, or extrajunctional, receptor may be expressed anywhere on the muscle membrane, although their junctional expression seems minimal.[16] During development and in certain pathologic states, junctional and extrajunctional receptors can coexist in the perijunctional area of the muscle membrane (Fig. 18-7).

Quite in contrast to the conventional muscle AChRs consisting of α1-, β1-, δ-, and ε/γ-subunits described earlier, receptors formed of α7 AChR subunits have recently been found in skeletal muscle during immobilization, sepsis, and denervation.[68,69] Two recent studies have evidenced the increased expression of α7 AChR subunits in muscle by Western blotting, ligand binding or genetic techniques after sepsis, and burn injury or immobilization, during which no overt denervation occurs.[16,70] These α7 AChR subunits are homomeric (i.e., formed of the same subunits) channels arranged as pentameres (see Fig. 18-4). Ligand (drug)–binding pockets are thought to be formed

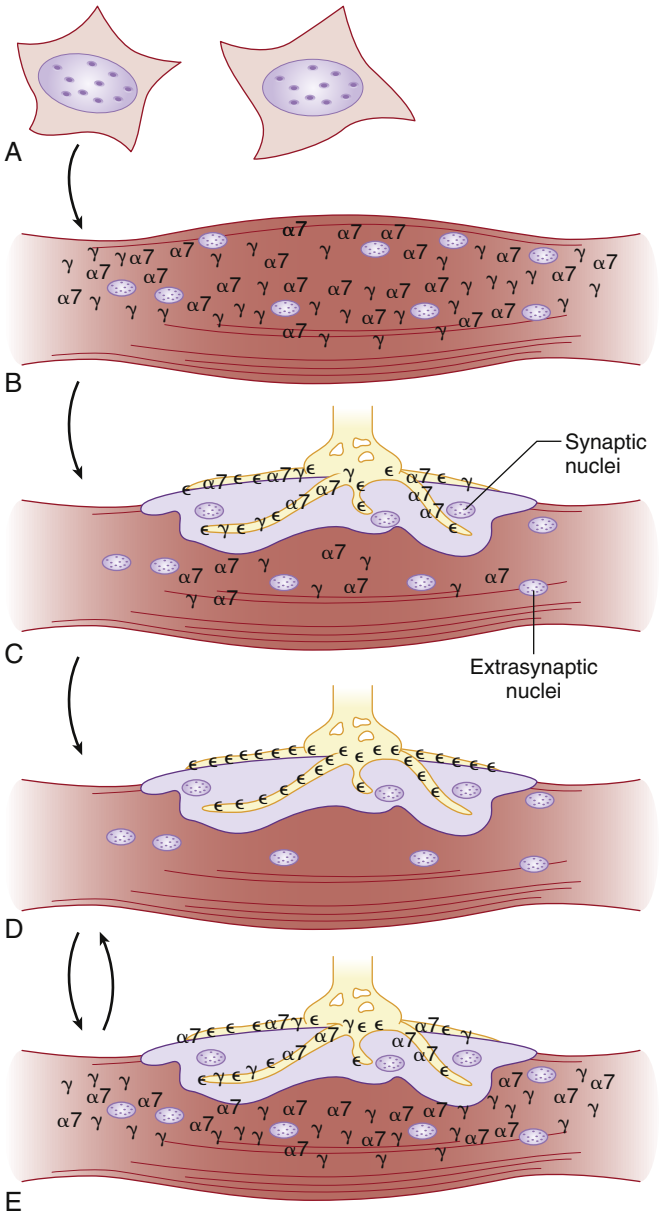

Figure 18-7. Distribution of acetylcholine receptors in developing adult, mature, denervated muscle or in immobilized or inflammation-induced catabolic muscle. **A** and **B**, In the early fetal stage, mononucleated myoblasts, derived from the mesoderm, fuse with each other to form multinucleated myotubes. The γ-subunit–containing immature acetylcholine receptors (AChRs) and the neuronal α7-subunit AChRs are scattered throughout the muscle membrane before innervation. **C,** As the nerve makes contact with muscle, clustering of the receptors occurs at the synapse and is associated with some loss of extrasynaptic receptors. **D,** Maturation of the junction is said to occur when ε-subunit–containing receptors replace γ-subunit– and α7-subunit–containing AChRs at the neuromuscular junction. Even mature muscle is multinucleated, but it is devoid of extrasynaptic AChRs. **E,** Denervation and some other pathologic states, even without anatomic denervation (e.g., burns, immobilization, chronic muscle relaxant therapy, stroke, sepsis), lead to the re-expression of the γ-subunit–containing AChRs mostly at the extrajunctional areas. The α7-subunit AChRs are expressed in the junctional areas and are also most likely in the extrajunctional areas. These receptor changes are potentially reversible if muscle immobilization, catabolism, and inflammation are restored to normal.

at negative and positive faces of the α7-subunit assembly interphases. As expected, the endogenous agonist, acetylcholine, binds to α7 AChR subunits, and each of the five subunits has the potential to bind acetylcholine or succinylcholine molecules.[18,69] Other agonists, including nicotine and choline, and antagonists, including muscle relaxants, cobra toxin, and α-bungarotoxin, also bind to the α7 AChR.[18,69-72]

The α7 AChRs in muscle display unusual functional and pharmacologic characteristics when compared with conventional muscle (α1, β1, δ, ε/γ) AChRs or neuronal α7 AChRs in the brain. Choline, a precursor and metabolite of acetylcholine (and succinylcholine), is a weak agonist of conventional muscle AChRs but is a full agonist of muscle α7 AChRs; that is, concentrations of choline that do not open conventional AChR channels will open α7 AChR channels.[69] Furthermore, no desensitization of the α7 AChRs occurs even during the continued presence of choline,[69] thus allowing a greater chance for potassium to efflux (approximately 145 mEq/L) from within the cell to the extracellular space, including plasma (approximately 4.5 mEq/L), down its concentration gradient. The chemical α-conotoxin GI from the snail specifically inhibits the conventional (mature and immature) AChRs in muscle but does not inhibit α7 AChRs. The important role of α7 AChRs in resistance to NDMRs is evidenced by the presence of immobilization-induced resistance in wild-type mice and the absence of resistance in α7 AChRs knockout mice.[73] The α7 AChRs expressed in neuronal tissue are also readily desensitized with choline, a feature that contrasts with muscle α7 AChRs, which do not desensitize with choline.[69] The α7 AChRs in muscle also have lower affinity for its antagonists, including pancuronium, rocuronium, atracurium, or α-bungarotoxin; higher concentrations of these drugs are therefore required to block agonist-induced depolarization in α7 AChRs *in vitro* or cause neuromuscular paralysis *in vivo* or *ex vivo* when α7 AChRs are upregulated.[69-72] In the conventional muscle AChRs, binding of even one of the α1-subunits by an antagonist results in inactivation of that receptor because acetylcholine needs both α1-subunits of the AChR for its activation. In α7 AChRs, however, even when three subunits are bound by an antagonist (e.g., muscle relaxant), two other subunits are still available for binding by agonist and cause depolarization. This feature may account for some of the resistance to muscle relaxants when α7 AChRs are expressed in muscle and other tissues in pathologic states.[69-73]

The clinical pharmacologic characteristics of the muscle α7 AChR have not yet been completely studied, but its basic composition also provides some insight into succinylcholine-related hyperkalemia. Chemical or physical denervation of muscle results in not only upregulation and qualitative (ε-subunit → γ-subunit) changes in AChRs, but it also results in upregulation of α7 AChRs in muscle. Succinylcholine, a synthetic analog of acetylcholine that consists of two molecules of acetylcholine joined together, is capable of depolarizing not only conventional AChRs but also α7 AChRs in muscle.[72] In addition, the metabolite of succinylcholine, choline, can depolarize α7 AChRs with little desensitization. The depolarizing effects of succinylcholine and choline on upregulated α7 AChRs can

result in continued leakage of intracellular potassium and flooding of extracellular fluid, including plasma, thereby leading to hyperkalemia. Thus differences in the subunit composition and number of the three isoforms junctionally and extrajunctionally expressed may account for aberrant responses to muscle relaxants clinically observed as resistant only to NDMRs and hyperkalemic response to succinylcholine.[2,72,73]

MAINTENANCE OF MATURE NEUROMUSCULAR JUNCTIONS

Quite unlike other cells, muscle cells are unusual in that they have many, usually hundreds, of nuclei per cell. Each nucleus has the genes to make all three isoform receptors. Multiple factors, including electrical activity, growth factor signaling (e.g., insulin, agrin, neuregulins), and the presence or absence of innervation, control the expression of the three types of receptor isoforms.[19,37] This control is most clearly observed in the developing embryo as the neuromuscular junction is formed. Before they are innervated, the muscle cells of a fetus synthesize only immature and α7 AChRs—hence the term *fetal isoform* for the former receptor. Synthesis is directed by nearly all of the nuclei in the cell, and the receptors are expressed throughout the membrane of the muscle cell (Fig. 18-8). As the fetus develops and the muscles become innervated, muscle cells begin to synthesize the mature isoform of receptors, which are exclusively inserted into the developing (future) end-plate area.[14-19] The nerve releases several growth factors that influence the synthetic apparatus of the nearby nuclei. First, nerve-supplied factors induce the subsynaptic nuclei to increase synthesis of AChRs. Next, the nerve-induced electrical activity results in the repression of receptors in the extrajunctional area. Nerve-derived growth factors, including agrin and ARIA/neuregulin, cause the receptors to cluster in the subsynaptic area and prompt the expression of the mature isoform (see Fig. 18-8).[19,37] Several lines of evidence indicate that clustering, expression, and stabilization of mature receptors are triggered by at least two growth factors: agrin, neuregulin/ARIA, and possibly calcitonin gene–related peptide.[56,74,75] Neuregulin and agrin are also released from muscle, but muscle-derived agrin is not as important in clustering and maturation of the receptor. ARIA is made in the nerve and plays a role in the maturation of vesicular arrangement and conversion of the γ-to-ε switch.[75] All of these growth factors interact with distinct membrane and cytosolic receptor proteins to cause phosphorylation and activation of nuclear (gene) transcriptional systems. Agrin signals through MuSK and neuregulins through ErbB receptors (see Fig. 18-8). These receptors control qualitative and quantitative changes at the junction. Once begun, the process is very stable, and nuclei in the junctional area continue to express mature receptors. In certain pathologic state–induced insulin resistance, a concomitant proliferation of AChRs seems to occur beyond the junctional area. Conditions in which this form of insulin resistance (i.e., decreased growth factor signaling) has been observed include immobilization, burns, and denervation[75-78]; in these conditions, not only does upregulation of total AChRs occur, but *de novo*

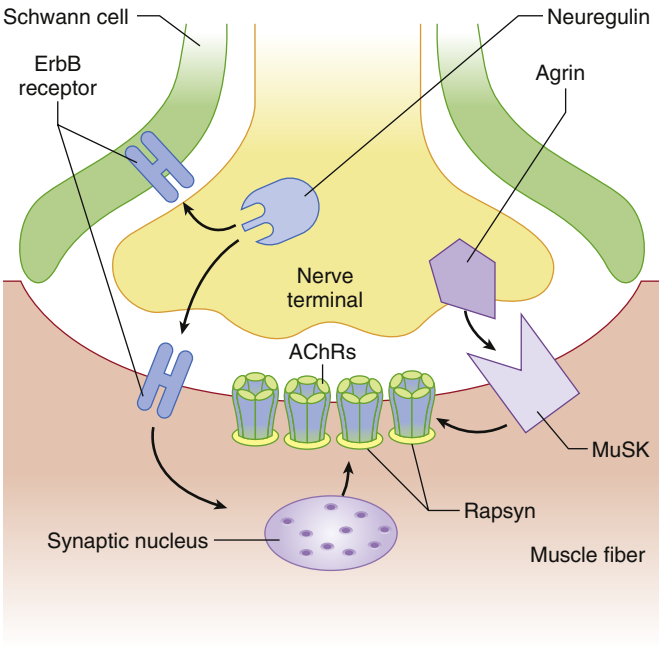

Figure 18-8. Diagram of agrin- and acetylcholine receptor–inducing activity (ARIA)/neuregulin-dependent events during maturation of the neuromuscular junction. After the establishment of a nerve on the muscle, growth factors, including agrin and neuregulins, are released. Neuregulin signaling is essential for Schwann cell survival, and Schwann cells are essential for axonal maintenance. Agrin interacting with its receptor muscle-specific tyrosine kinase (MuSK) enhances the clustering of synaptic proteins, including acetylcholine receptors (AChRs), rapsyn, and ErbB receptors. ARIA/neuregulin is the best candidate for the involvement in the conversion of γ-subunit–containing immature receptor to ε-subunit–containing mature (innervated) receptor, which is synapse specific and therefore not inserted in the extrajunctional area.

upregulation of the immature and α7 AChR isoforms are also observed.[1-3] This upregulation may be related to the fact that agrin and possibly neuregulin signal via some of the same downstream signaling proteins as insulin (e.g., phosphoinositide 3-kinase [PI3K]).[56,76-79] Therefore agrin and neuregulin signaling may be important for the suppression of α7 AChRs and immature AChRs in the normal neuromuscular junction.

Before innervation, as in the fetus, AChRs are present throughout the muscle membrane. After innervation, AChRs become more and more concentrated at the postsynaptic membrane and are virtually absent in the extrasynaptic area at birth. The innervation process progresses somewhat slowly during fetal life and matures during infancy and early childhood.[14-19] With time, the immature receptors diminish in concentration and disappear from the peripheral part of the muscle. In the active, adult, and normal innervated muscle, just the nuclei under and very near the end plate direct the synthesis of the receptor; only the genes for expressing mature receptors are active. Nuclei beyond the junctional area are not active, and therefore no receptors are expressed anywhere in the muscle cells beyond the perijunctional area. Conversion of all of the γ-subunit– to ε-subunit–containing AChRs in the perijunctional area continues to take place after birth. In the rodent, conversion takes approximately

2 weeks.[14-19] In humans, this process takes longer. The timeframe for the disappearance of α7 AChRs in the fetus or newborn is also unknown. Proteins implicated in the linking of mature receptors to the cytoskeleton include integrin, syntrophin, utrophin, α- and β-dystroglycan, and rapsyn, just to name a few.[14-19]

RE-EXPRESSION OF IMMATURE (FETAL) γ-SUBUNIT AND α7-SUBUNIT AChRs IN ADULT LIFE

The extrajunctional immature receptors can reappear soon after upper and lower motor denervation and in certain pathologic states (e.g., burns, sepsis, immobilization, chronic muscle relaxant therapy or botulism, loss of muscle electrical activity). Stimulation of a denervated muscle with an external electrical stimulus can prevent the appearance of immature receptors. It has been suggested that the calcium that enters the muscle during activity is important in the suppression process.[16,17] In the pathologic states previously enumerated, if the process is severe and prolonged, then extrajunctional receptors are inserted all over the surface of the muscle, including the perijunctional area (see Fig. 18-7). The junctional nuclei also continue to make mature receptors. The synthesis of immature receptors is initiated within hours of inactivity, but it takes several days for the whole muscle membrane to be fully covered with receptors. This upregulation of receptors has implications for the use of depolarizing and possibly NDMRs. The changes in α7 AChRs parallel the expression of immature receptors, although this has not been well studied.

The changes in subunit composition (γ versus ε) in the receptor confer certain changes in electrophysiologic (functional), pharmacologic, and metabolic characteristics.[16-18] Mature receptors are metabolically stable, with a half-life approximating 2 weeks, whereas immature receptors have a metabolic half-life of less than 24 hours. Immature receptors have a smaller single-channel conductance and a twofold to tenfold longer mean channel open time than do mature receptors (see Fig. 18-4). The changes in subunit composition may also alter the sensitivity or affinity, or both, of the receptor for specific ligands. Depolarizing or agonist drugs such as succinylcholine and acetylcholine more easily depolarize immature receptors, thereby resulting in cation fluxes; doses one tenth to one hundredth of those needed for mature receptors can effect depolarization.[2] The potency of nondepolarizers is also reduced, as demonstrated by the resistance to nondepolarizers documented in patients with burns, denervation, and immobilization.[1,3] In light of recent research, however, it seems that the resistance to nondepolarizers is more likely due to the junctional area expression of the α7 AChRs, which has a decreased affinity NDMRs.[16,69-73] Some NDMRs may also cause a partial agonist response in immature receptors, thus explaining the decreased potency in conditions in which upregulation of AChRs occurs.[8] The upregulation of immature AChRs in the perijunctional and extrajunctional areas may have a buffering effect for diffusion of relaxants, contributing to resistance to NDMRs.[80]

The altered sensitivity to muscle relaxants may occur in only certain parts of the body or certain muscles if only some muscles are affected by the diminution in nerve activity (e.g., after a stroke). Sensitivity to relaxants can begin to change between 48 and 72 hours after an injury or hospitalization. The most serious side effect with the use of succinylcholine in the presence of upregulated AChRs in one or more muscles is hyperkalemia.[1-3] In these subjects, the receptors can be scattered over a large surface of the muscle. The AChR channels opened by the agonist (succinylcholine) allow potassium to escape from the muscle and enter the blood (Fig. 18-9).[2,3] If a large part of the muscle surface consists of upregulated (immature) receptor channels, each of which stays open for a longer time, then the amount of potassium that moves from muscle to blood can be considerable. The resulting hyperkalemia can cause dangerous disturbances in cardiac rhythm, including ventricular fibrillation. Moreover, hyperkalemia probably cannot be prevented by prior administration of NDMRs because large doses required to block the AChRs, in and of itself, will cause paralysis, obviating the need for succinylcholine.[3] Larger-than-normal doses of NDMRs may attenuate the increase in blood potassium concentrations but cannot completely prevent it. However, hyperkalemia and cardiac arrest can occur after the administration of succinylcholine, even in the absence of denervation states. These effects are observed in certain congenital muscle dystrophies in which the muscle membrane is prone to damage by the depolarization produced by succinylcholine, resulting in potassium release via the membrane damage.[81]

PREJUNCTIONAL ACETYLCHOLINE RECEPTORS

Nicotinic AChRs exist in a variety of forms apart from that observed in muscle.[16,18] The classic muscle-type nicotinic AChR is postsynaptically present, whereas neuronal subtype receptors may be presynaptically and postsynaptically present. The neuronal subtype nicotinic AChRs expressed prejunctionally are usually heteromeric and built up by *only* α- and β-subunits. This family of nicotinic AChRs is widely expressed in the peripheral and central nervous systems, on autonomous nerves and ganglia on oxygen-sensing cells within the carotid bodies. There are also α7 AChRs in immune-competent cells, such as macrophages, lymphocytes and granulocytes, and fibroblasts and chondrocytes.[16,18] Diverse genes encode the heterogeneous AChRs, and the ion channel is formed of multiple subunits (multimers). Seventeen AChR genes have been cloned from vertebrates. They include various combinations of α-subunits (α1 through α10) and β-subunits (β1 through β4) and one each of γ-, δ-, and ε-subunits. The γ-, δ-, and ε-subunits are found only in muscle.[16-18]

Prejunctional- or nerve terminal–associated cholinergic receptors have been demonstrated by morphologic pharmacologic and by molecular biologic techniques, but their form and functions are not as completely understood as those in the postjunctional area. Many drugs with an abundance of potential targets for drug action can affect the capacity of the nerve terminal to carry out

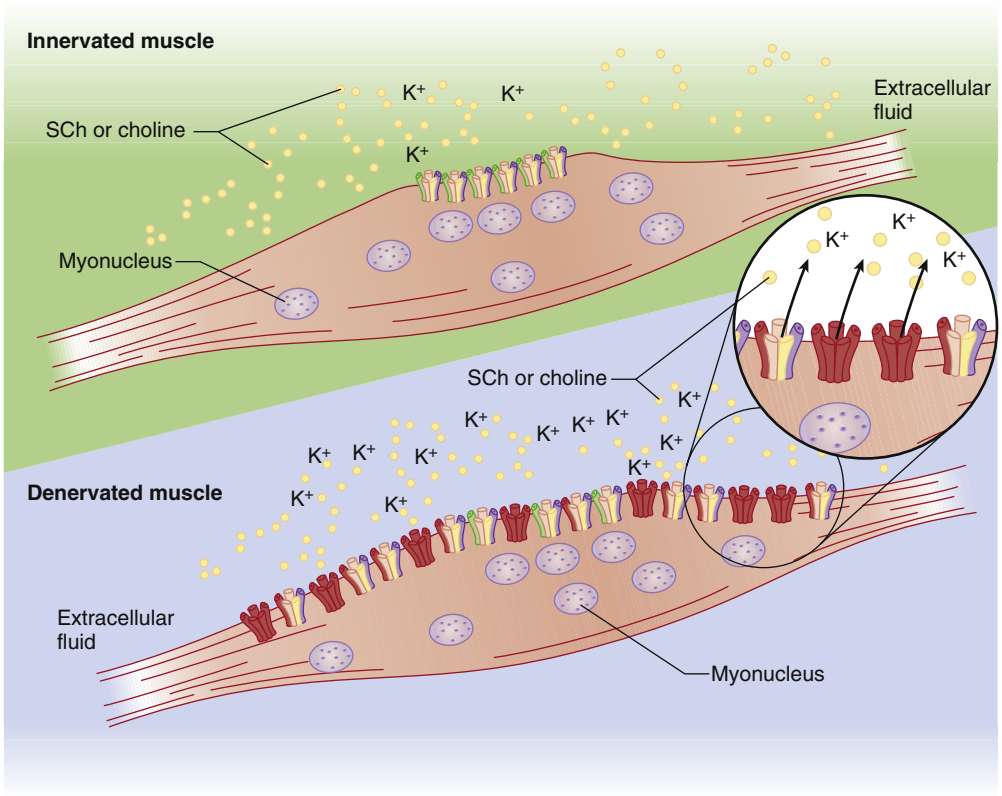

Figure 18-9. Schematic of the succinylcholine (SCh)–induced potassium (K^+) release in an innervated *(top)* and denervated muscle *(bottom)*. In the innervated muscle, the systemically administered SCh reaches all of the muscle membrane but depolarizes only the junctional (α1, β1, δ/ε) receptors because acetylcholine receptors (AChRs) are located only in this area. With denervation, the muscle nuclei express not only extrajunctional (α1, β1, δ/γ) AChRs but also α7-nicotinic AChRs throughout the muscle membrane. Systemic SCh, in contrast to acetylcholine released locally, can depolarize all of the up-regulated AChRs, which leads to massive efflux of intracellular K^+ into the circulation, resulting in hyperkalemia. The metabolite of SCh, choline, and possibly succinylmonocholine can maintain this depolarization via α7-nicotinic AChRs, enhancing the K^+ release and maintaining the hyperkalemia. *(From Martyn JAJ, Richtsfeld M: Succinylcholine-induced hyperkalemia in acquired pathologic states: etiologic factors and molecular mechanisms,* Anesthesiology *104: 158-169, 2006.)*

its functions. The trophic function to maintain nerve-muscle contact involves the release and replenishment of acetylcholine together with other trophic factors that require signaling through many receptors, of which the prejunctional nicotinic AChR is just one. Succinylcholine produces fasciculations that can be prevented by NDMRs. Because a fasciculation is, by definition, the simultaneous contraction of the multitude of muscle cells in a single motor unit and because only the nerve can synchronize all the muscles in its motor unit, it became apparent that succinylcholine must also act on nerve endings. Because NDMRs prevent fasciculation, it was concluded that they acted on the same prejunctional receptor. Very small doses of cholinergic agonists (e.g., succinylcholine) and antagonists (e.g., NDMRs) affect nicotinic receptors on the nerve ending, the former by depolarizing the ending and sometimes inducing repetitive firing of the nerve and the latter by preventing the action of agonists.[5]

By the use of specific monoclonal antibodies, the presence of nicotinic α3-subunits has been demonstrated in the nerve terminal.[82] Another clue to the differences between prejunctional and postjunctional AChRs was the finding that some drugs (e.g., dihydro-β-erythroidine) bind only to prejunctional AChRs, whereas other drugs (e.g., α-bungarotoxin) bind only to postjunctional receptors.[65] Additional clues were found in the many demonstrations of quantitative differences in the reaction of prejunctional and postjunctional nicotinic receptors to other cholinergic agonists and antagonists.[65,82-84] For instance, it was known that tubocurarine binds with lower affinity to the recognition sites of ganglionic nicotinic cholinoceptors and is not a competitive antagonist of acetylcholine at this site. Decamethonium (i.e., a depolarizing muscle relaxant no longer clinically used) is a selective inhibitor of the muscle receptor, and hexamethonium is a selective inhibitor of nicotinic receptors in the autonomic ganglia.[80-85] Instead, D-tubocurarine and hexamethonium can block the opened channels of these receptors and owe their ability to block ganglionic transmission to this property. The functional characteristics of prejunctional receptor channels may also be different. For example, the depolarization of motor nerve endings initiated by the administration of acetylcholine can be prevented by tetrodotoxin, a specific blocker of sodium flux with no effect on the end plate.

Specific information on the molecular organization of neuronal nicotinic receptors on the motor neuron terminal is still lacking. Some of the subunit composition is similar, but other subunits do not resemble those of the postjunctional receptor. Of the 16 different nicotinic AChR gene

products identified, only 12 (α2 to α10 and β2 to β4) are thought to contribute nicotinic receptors expressed on neurons. Most strikingly, nervous tissue does not express γ-, δ-, or ε-receptor subunits; it contains genes only for the α- and β-subunits. The α- and β-subunit genes in nerve and muscle are not exactly the same; they are variants. To emphasize the distinction between neural and muscle nicotinic receptors, the former are sometimes designated *Nn* and the latter *Nm*. With so many different subunits available, possible combinations are many, and it is not known which combinations are found in motor nerves. Their physiologic roles have also not been completely characterized. Expression of neuronal nicotinic AChRs in *in vitro* systems has confirmed that muscle relaxants and their metabolites can bind to some of these neuronal AChRs.[53,83-85]

The nicotinic receptor on the junctional surface of the nerve (nerve terminal) senses transmitter in the cleft and, by means of a positive-feedback system, causes the release of more transmitter. In other parts of the nervous system, this positive feedback is complemented by a negative-feedback system that senses when the concentration of transmitter in the synaptic cleft has appropriately increased and shuts down the release system. It is believed that tetanic fade and train-of-four fade during neuromuscular blockade with NDMRs arise from presynaptic cholinergic autoreceptors at the motor nerved ending.[5,52]

The neuronal AChR subtype that is critically involved in acetylcholine release and subsequent fade phenomenon (as observed in tetanic or train-of-four stimulus patterns) has been identified as the α3β2-subtype nicotinic AChR.[10,84] When this prejunctional receptor is specifically blocked by a nondepolarizing relaxant such as tubocurarine, a reduction in neurotransmitter release occurs upon repeated stimulation with subsequent fade phenomenon. It should be noted, however, block of the prejunctional AChRs alone is not necessary and sufficient to induce fade; concomitant reduction in the safety of neurotransmission prejunctionally or postjunctionally must be present for it to be noticeable.[65] Although all clinically used nondepolarizing neuromuscular blocking drugs inhibit this prejunctional nicotinic AChR, as well as several other neuronal nicotinic AChRs, in the clinically relevant concentration range, succinylcholine neither activates nor inhibits the presynaptic α3β2 autoreceptor at clinically relevant concentrations.[53,85] This observation may be the reason for the typical lack of fade during succinylcholine-induced neuromuscular block. Succinylcholine, however, does not interact with α3β4 AChR found in autonomic ganglia.[53] It has also been shown that NDMRs reduce the hypoxic ventilatory response in partially paralyzed humans,[86] and the mechanism behind the depression might be related to inhibition of nicotine receptors on the carotid body.[11] Nicotinic α3, 7, and β2 AChRs have recently been documented in the human carotid body.[87] Whether the inhibition of these receptors plays a role in attenuated response to hypoxia drive needs further investigation. The motor nerve terminal is also known to bear several other receptors, such as opioid, adrenergic, dopamine, purine, and adenosine receptors, as well as receptors for endogenous hormones, neuropeptides, and a variety of proteins.[88,89] The physiologic roles of these receptors and the effects of anesthetics on them are unknown.

NEUROMUSCULAR JUNCTION AT EXTREMES OF AGE

NEWBORN

Just before birth, the AChRs are all clustered around the nerve in the junctional area, and minimal extrajunctional AChRs are present. The newborn postsynaptic membrane, itself, is not specialized, having almost no synaptic folds, a widened synaptic space, and a reduced number of AChRs.[14,19] The early postnatal AChR cluster appears as an oval plaque (Fig. 18-10). Within a few days,

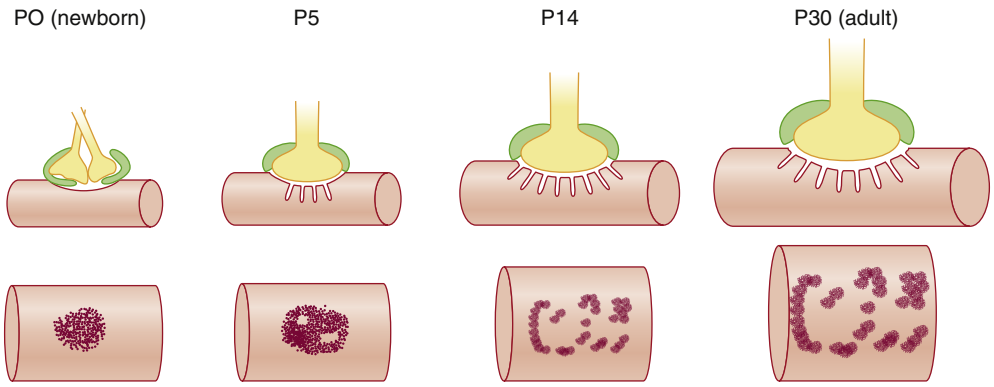

Figure 18-10. Maturation of the postsynaptic apparatus. *Postnatal day 0 (PO)*: At the time of birth, the aggregates of AChRs have consolidated to form an oval-like plaque with irregular borders. At this point, each junction may have more than one nerve terminal innervating it. *Postnatal day 5 (P5)*: Approximately 5 days after birth, the postsynaptic membrane invaginates to form a gutter and small perforations develop on the plaque. *Postnatal day 14 (P14)*: At approximately 14 days after birth, the immature γ-subunit–containing acetylcholine receptors (AChRs) are completely replaced by mature AChRs containing α-subunit. The invaginations or clefts increase in numbers, resulting in more perforations in the pretzel-shaped junction. The perforations correspond to the synaptic clefts or folds. *Postnatal day 30 (P30)*: The neuromuscular junction is completely developed at 30 days after birth. The AChRs have maximal density. A distinct set of postsynaptic proteins and signaling molecules are selectively transcribed in the subsynaptic area, providing integrity to the neuromuscular junction and efficient neurotransmission. *(Modified from Shi L, Fu AK, Ip NY: Molecular mechanisms underlying maturation and maintenance of the vertebrate neuromuscular junction,* Trends Neurosci *35:441-453, 2012; and Sanes JR, Lichtman JW: Induction, assembly, maturation and maintenance of a postsynaptic apparatus,* Nat Rev Neurosci *2:791-805, 2001.)*

simplified folds appear. With continued maturation, the plaque is transformed to a multiperforated pretzel-like structure. The polyinnervated end plate is converted to a singly innervated junction because of a retraction of all but one terminal. In the adult, the terminals perfectly align with the AChR clusters. Morphologically, the postsynaptic membrane of the newborn and that from the patient with myasthenia gravis is not too different; the AChR number is decreased, and the postsynaptic folds are decreased. It is not surprising therefore that neurotransmission is not as efficient in the newborn and in patients with myasthenia gravis. For this reason, neonates and infants behave similar to patients with myasthenia gravis when NDMRs are administered to them.[90] In humans, maturation of the neuromuscular junction probably occurs at approximately 2 years of age[90] (see also Chapter 93).

OLD AGE

Old age–associated functional denervation, muscle wasting, and weakness is now well established.[91,92] Anatomic changes involve increased preterminal and axonal branching within the individual neuromuscular junction, either with or without an increase in the junctional size. The points of contacts between the prejunctional and postjunctional membrane decrease, resulting in a decline in trophic interactions between nerve and muscle and stimulus transmission. Muscle weakness associated with aging is not entirely peripheral in origin.[93] The ability to communicate neural activity from brain to skeletal muscle is impaired with age. Despite these structural and functional changes associated with aging, the overall margin of safety is better in the older individual than in the neonate.[94] (Also see Chapter 80.)

Chapter 19

Respiratory Physiology and Pathophysiology

BRIAN P. KAVANAGH • GÖRAN HEDENSTIERNA

KEY POINTS

- Removal of CO_2 is determined by alveolar ventilation, not by total (minute) ventilation.
- Dead space ventilation can be dramatically increased in patients with chronic obstructive pulmonary disease and pulmonary embolism to more than 80% of minute ventilation.
- Breathing at small lung volumes increases airway resistance and promotes closure of airways.
- Hypoxemia can be caused by alveolar hypoventilation, diffusion impairment, ventilation-perfusion mismatch, and right-to-left shunt.
- Almost all anesthetics reduce skeletal muscle tone, which decreases functional residual capacity (FRC) to levels close to the awake residual volume (RV).
- Atelectasis during anesthesia is caused by decreased FRC and the use of high inspired oxygen concentrations (Fio_2), including breathing oxygen before induction of anesthesia.
- General anesthesia causes ventilation-perfusion mismatch (airway closure) and shunts (atelectasis).
- Venous admixture is due to $\dot{V}_A/\dot{Q}$ mismatch (response to increased Fio_2) and shunts (unresponsive to increased Fio_2).
- Hypoxic pulmonary vasoconstriction is blunted by most anesthetics, and this results in increased ventilation-perfusion mismatching.
- Respiratory work is increased during anesthesia as a consequence of reduced respiratory compliance and increased airway resistance.

RESPIRATORY PHYSIOLOGY IS CENTRAL TO THE PRACTICE OF ANESTHESIA

Respiratory function is inextricably linked to the practice of anesthesia. Adverse respiratory effects can occur during anesthesia,[1] and the most serious cases of adverse events involve hypoxemia. These events range from intractable hypoxemia caused by loss of airway patency to postoperative respiratory depression from opioids or regional anesthesia (see Chapter 96).[2,3] In the absence of adverse outcomes, general anesthesia has significant effects on respiratory function and lung physiology by observations made in the operating room. Improved appreciation of anesthesia-induced physiologic alterations (e.g., mechanisms of bronchospasm,[4] impact of mechanical ventilation),[5] as well as pioneering developments in monitoring (e.g., pulse oximetry and capnography; see Chapter 44),[6] together are associated with the specialty of anesthesiology's emergence as a leader in patient safety (see Chapter 6).[7] Finally, integrative measures of respiratory function, ranging from exercise capacity,[8] spirometry to tissue oxygenation,[9] or global O_2 consumption,[8] are likely predictors of outcome following anesthesia and surgery.

PULMONARY PHYSIOLOGY IN HEALTH

The mechanisms by which anesthesia-associated respiratory dysfunction are caused can be determined with an examination of the normal functions and mechanisms of respiration in health. We briefly review cellular respiration whereby O_2 is consumed and CO_2 is produced, the transport of O_2 and CO_2 in the blood, and the principles by which the lung oxygenates blood and eliminates CO_2.

RESPIRATION IN THE CELL

The partial pressure of oxygen (PaO_2) in normal arterial blood is approximately 100 mm Hg, and decreases to 4 to 22 mm Hg in the mitochondrion where it is consumed. Glucose ($C_6H_{12}O_6$) is converted into pyruvate (CH_3COCOO^-) and H^+ by glycolysis in the cytoplasm, and the pyruvate diffuses into the mitochondria and forms the initial substrate for Krebs cycle, which in turn produces nicotinamide adenine dinucleotide (NADH), as well as adenosine triphosphate (ATP), CO_2, and H_2O. The NADH is a key electron (and H^+) donor in the process of oxidative phosphorylation, wherein O_2 and adenosine diphosphate (ADP) are consumed and ATP and H_2O are produced. Thus, the net effect is oxidation of glucose to produce energy (ultimately as ATP), H_2O, and CO_2.[10]

TRANSPORT OF O_2 IN THE BLOOD

O_2 reaches the cells following transport by arterial blood, and the overall delivery of O_2 ($\dot{D}O_2$) is the product of the arterial blood O_2 content (CaO_2) and blood flow (cardiac output, $\dot{Q}$) as:

$$\dot{D}O_2 = CaO_2 \times \dot{Q}$$

The carriage in the blood is in two forms: O_2 bound to hemoglobin (the vast bulk), and O_2 dissolved in the plasma, and is expressed as the sum of these components as follows:

$$CaO_2 = \left[\begin{array}{l} (SaO_2 \times Hb \times O_2 \textit{ combining capacity of Hb}) \\ + (O_2 \textit{ solubility} \times Pao_2) \end{array} \right]$$

where CaO_2 (O_2 content) is the milliliters of O_2 per 100 mL of blood, SaO_2 is the fraction of hemoglobin (Hb) that is saturated with O_2, O_2-combining capacity of Hb is 1.34 mL of O_2 per gram of Hb, *Hb* is grams of Hb per 100 mL of blood, Pao_2 is the O_2 tension (i.e., dissolved O_2), and solubility of O_2 in plasma is 0.003 mL of O_2 per 100 mL plasma for each mm Hg Pao_2

The binding of O_2 to hemoglobin is a complex, allosteric mechanism. Important insights can be gained by understanding how characteristic abnormalities of blood O_2 carriage (e.g., carbon monoxide [CO] poisoning, methemoglobinemia) affect on O_2 tension, content, and delivery.

Methemoglobin (MetHb), formed by the oxidation to Fe^{3+} (ferric) instead of the usual Fe_2^+ (ferrous), is less able to bind O_2, resulting in diminished O_2 content and less O_2 delivery. Here, the Pao_2 (in the absence of lung disease) will be normal: if the O_2 content is calculated from the Pao_2, it will appear normal, but if measured it will be low. In contrast, MetHb level will be elevated. In severe cases, lactic acidosis develops because of impaired O_2 delivery. In addition, because MetHb has a blue-brown color, the patient will appear blue, even if the fraction of MetHb is modest and specialized oximetry can separately measure MetHb levels.[11,12] The apparent cyanosis is not responsive to supplemental O_2, and therapy involves converting (i.e., reducing) the MetHb to Hb (e.g., by using methylene blue). Important medical causes of MetHb include benzocaine; dapsone; or in susceptible patients, inhaled nitric oxide (NO).

In CO poisoning, the CO binds to Hb, with far greater (over ×200-fold) avidity than molecular O_2, tightly forming CO-Hb and resulting in two main effects.[13] First, formation of CO-Hb results in fewer sites available for O_2 binding, and this reduces the blood O_2 content. Second, the formation of CO-Hb causes conformational changes in the Hb molecule such that the tendency to release bound O_2 is reduced. This effect corresponds to a leftward shift of the Hb-O_2 dissociation curve, and although this aspect of CO binding does not reduce the O_2 content or "global" delivery of O_2, it does reduce the release of O_2 and its delivery to the cells. Because the color of CO-Hb closely resembles that of O_2-Hb, the color of the blood (and the patient) is bright red; however, as with Met-Hb, the PaO_2 will be normal (assuming no pulmonary disease) as will the calculated CaO_2; however, the measured CaO_2 will be low and if severe, a lactic acidosis will be present. Modern can distinguish between Hb-O_2 and CO-Hb.[13]

Finally, the *Bohr effect* refers to a shift of the Hb-O_2 dissociation curve caused by changes in CO_2 or pH.[14] In the systemic capillaries, the Pco_2 is higher than in the arterial blood (and the pH correspondingly lower) because of local CO_2 production. These circumstances shift the Hb-O_2 dissociation curve to the right, which increases the offloading of O_2 to the tissues. The opposite occurs in the pulmonary capillaries; the $Paco_2$ is lower (and the pH correspondingly higher) because of CO_2 elimination, and the dissociation curve is shifted to the left to facilitate O_2 binding to Hb.

TRANSPORT OF CO_2 IN THE BLOOD

CO_2 is produced by metabolism in the mitochondria, where the CO_2 levels are highest. The transport path (involving progressively decreasing pressure gradients) is from mitochondria through cytoplasm, into venules and finally, in mixed venous blood from where it is eliminated through the alveoli. In the blood, CO_2 is transported in three main forms: dissolved (reflected as $Paco_2$, partial pressure; accounts for approximately 5% of transported CO_2), bicarbonate ion (HCO_3^-; almost 90%), and carbamino CO_2 (CO_2 bound to terminal amino groups in Hb molecules; approximately 5%).[10] The usual quantities of CO_2 in the arterial and (mixed) venous blood are approximately 21.5 and 23.3 mmol of CO_2 per liter of blood, respectively.

Breathing O_2 can sometimes induce hypercapnia, as occurs in patients with severe chronic lung disease who are breathing supplemental O_2. Although traditionally thought to occur because increased Pao_2 reduces ventilatory drive, this is now known not to be the case[15]; it results from the Haldane effect, as well as from impairment of hypoxic pulmonary vasoconstriction (HPV). The Haldane effect[16] is the difference in the amount of CO_2 carried in oxygenated versus deoxygenated blood, and two mechanisms explain this. First, increased Pao_2 decreases the ability to form carbamino compounds—reducing the amount of CO_2 bound to Hb—thereby raising the amount of dissolved CO_2 (i.e., elevated Pco_2). Second, the amino acid histidine, which has an imidazole group that is an effective H^+ buffer at physiologic pH, is an important linking molecule between heme groups

and the Hb chains. Increasing the partial pressure of oxygen (PO_2) increases the amount of O_2 bound to Hb; this changes the conformation of the Hb molecule, which in turn alters the heme-linked histidine and reduces its H^+ buffering capacity. Therefore, more H^+ is free (not buffered) and binds to HCO_3^-, releasing stored CO_2. Impairment of HPV by elevated O_2 allows increased perfusion to poorly ventilated regions; this has the effect of decreasing perfusion (and delivery of CO_2) to better ventilated regions, diminishing the efficiency of CO_2 elimination. Patients with impaired ability to increase alveolar ventilation ($\dot{V}_A$) cannot compensate for the increased CO_2 availability, and therefore, in these patients, adding supplemental O_2 can result in elevated Pa_{CO_2}.

OXYGENATION IN THE LUNG

Systemic venous blood (central venous blood) enters the right ventricle via the right atrium. The O_2 saturation (SO_2) differs among the major veins: higher venous SO_2 reflects greater blood flow, less tissue oxygen uptake, or both.[17] SO_2 is usually higher in the inferior vena cava (IVC) than in the superior vena cava (SVC), possibly because of the high renal and hepatic flow relative to O_2 consumption. In the right ventricle, the central venous blood ($S_{cv}O_2$) from the SVC and IVC, is joined by additional venous blood from the coronary circulation (via the coronary sinuses). In the right ventricle, an additional small amount of venous drainage from the myocardium enters through the Thebesian veins, and as all this venous blood enters the pulmonary artery it is well mixed and is termed *mixed-venous blood* ($S_{\bar{v}}O_2$); thus, $S_{\bar{v}}O_2 < S_{cv}O_2$, although the trends of each usually run in parallel.[18]

VENTILATION

Ventilation refers to the movement of inspired gas into and exhaled gas out of the lungs.

ALVEOLAR VENTILATION

Fresh gas enters the lung by cyclic breathing at a rate and depth (tidal volume, V_T) determined by metabolic demand, usually 7 to 8 L/min.[19] While most inspired gas reaches the alveoli, some (100 to 150 mL) of each V_T remains in the airways and cannot participate in gas exchange. Such dead space (V_D) constitutes approximately one third of each V_T.[20] Anatomic V_D is the fraction of the V_T that remains in the "conducting" airways, and physiologic V_D is any part of a V_T that does not participate in gas exchange (Fig. 19-1).

For a single tidal volume (V_T, mL), the following is true:

$$V_T = V_A + V_D$$

The product of V_T (mL) times the respiratory rate (per minute) is the minute ventilation ($\dot{V}_E$). Aggregated over time, minute ventilation ($\dot{V}_E$, mL/min) is:

$$\dot{V}_E = \dot{V}_A + f \times V_D$$

The portion of the $\dot{V}_E$ that reaches the alveoli and respiratory bronchioles each minute and participates in gas exchange is called the *alveolar ventilation* ($\dot{V}_A$), and it is approximately 5 L/min. Because this is similar to the blood flow through the lungs (i.e., the cardiac output, also 5 L/min), the overall alveolar ventilation-perfusion ratio is approximately 1.

DEAD SPACE VENTILATION

Maintenance of Pa_{CO_2} is a balance between CO_2 production ($\dot{V}CO_2$, reflecting metabolic activity) and alveolar ventilation ($\dot{V}_A$. If $\dot{V}_E$ is constant but V_D is increased, $\dot{V}_A$ will naturally be reduced, and the Pa_{CO_2} will therefore rise. Therefore, if V_D is increased, $\dot{V}_E$ must also increase to prevent a rise in Pa_{CO_2}. Such elevations in V_D occur when a mouthpiece or facemask is used, and in such cases, the additional V_D is termed "apparatus deadspace" (which can be up to 300 mL; anatomic V_D of the airways is 100 to 150 mL).[21]

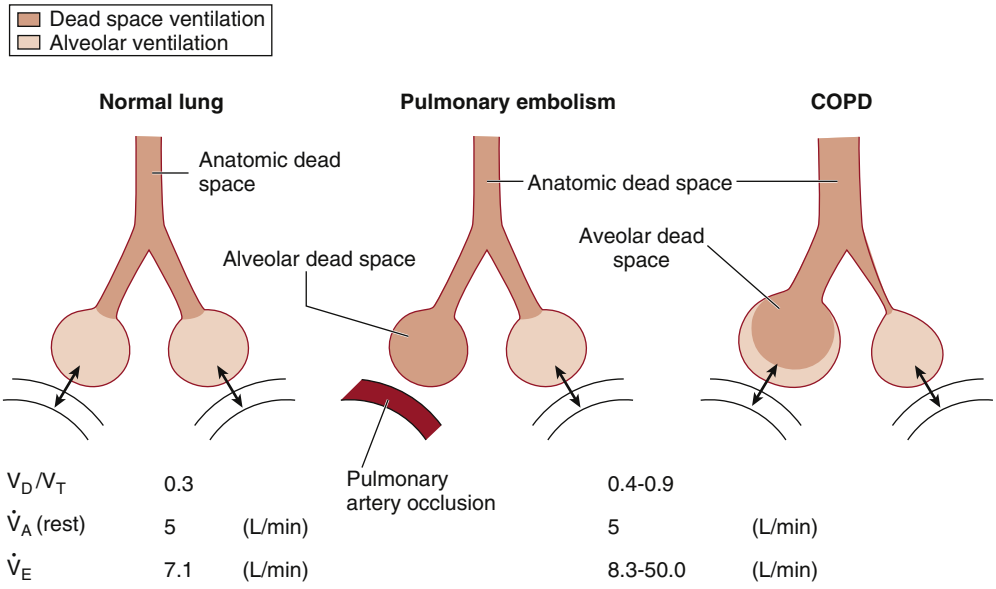

Figure 19-1. Dead space and alveolar ventilation in normal and diseased lungs. Either cessation of blood flow or excessive alveolar ventilation relative to perfusion will cause an increase in dead space. If V_D is increased, a large compensatory increase in minute ventilation is required to preserve $\dot{V}_A$. V_D/V_T, dead space to tidal volume ratio; $\dot{V}_A$, alveolar ventilation; $\dot{V}_E$, minute ventilation. $\dot{V}_E = \dot{V}_A + f \times V_D$. *Double arrows* indicate normal CO_2 exchange. *COPD*, Chronic obstructive pulmonary disease. *(From Hedenstierna G: Respiratory measurement. London, 1998, BMJ Books, 1998, p. 184; see also book review of* Respiratory Measurement in Thorax *53:1096, 1998.)*

Increases in the volume of the conducting airways (e.g., bronchiectasis) increase the overall V_D only slightly. Far more significant increases in V_D occur when perfusion to a large number of ventilated alveoli is interrupted, as occurs in a pulmonary embolus (see Fig. 19-1). Indeed, with multiple pulmonary emboli, V_D/V_T can exceed 0.8 (2.7-fold normal). In such a case, to maintain a normal $\dot{V}_A$ (5 L/min), the $\dot{V}_E$ would have to increase (also 2.7-fold) to almost 20 L/min. This effort would cause considerable dyspnea, in addition to the dyspnea induced by the lowered PaO_2.

Obstructive lung disease can result in diversion of inspired air into (nonobstructed) ventilated, but poorly perfused, regions of the lung. This results in local excesses of ventilation versus perfusion (high $\dot{V}_A/\dot{Q}$ ratio) in such regions,[22] which is equivalent to an increase in V_D/V_T (see Fig. 19-1). Patients with severe chronic obstructive pulmonary disease (COPD) may have a V_D/V_T ratio of up to 0.9, and would have to hyperventilate massively (30 to 50 L/min) to maintain normal $Paco_2$, which is not possible where ventilator reserve is diminished. Such patients demonstrate reduced $\dot{V}_A$ but often have an elevated $\dot{V}_E$. An important compensatory mechanism is that a lower level of $\dot{V}_A$ will maintain stable CO_2 excretion where the $Paco_2$ is increased (Box 19-1).

STATIC LUNG VOLUMES—FUNCTIONAL RESIDUAL CAPACITY

The amount of air in the lungs after an ordinary expiration is called *functional residual capacity* (Fig. 19-2); it is usually 3 to 4 L and occurs because of the balance of inward (lung) forces and outward (chest wall) forces. The inward force is the "elastic recoil" of the lung and emanates from the elastic lung tissue fibers, contractile airway smooth muscle, and alveolar surface tension. The outward force is developed by passive recoil from the ribs, joints, and muscles of the chest wall. FRC is greater with increased height and age (loss of elastic lung tissue), and smaller in women and in obesity (see Chapter 71).[19,23]

There are two reasons why maintenance of gas in the lung at end-expiration (i.e., FRC) is important. First, inflating an already opened (inflated) lung is easier than when the lung is already deflated. This is because complete collapse results in liquid-only surfaces interfacing in alveoli (high surface tension), whereas alveoli in partially inflated lung have air-liquid interfaces (lower surface tension). Second, although perfusion in the lung is phasic, the frequency is rapid and the oscillations in flow are low, resulting in nearly continuous flow. Ventilation is different: the frequency is far slower and the size of the oscillations far larger. If the lung (or large parts of it) completely deflate between breaths, the blood flowing from closed alveoli (that contain zero O_2) would have very low SO_2 (the same as mixed venous blood); this would mix into the overall blood flow from the lungs and cause a major O_2 desaturation after every exhalation.

RESPIRATORY MECHANICS

The study of respiratory mechanics tells us how inspired air is distributed within the lung and permits quantitation of the severity of lung disease. The components of overall impedance to breathing results from elastance (the reciprocal of compliance), resistance, and inertia.

COMPLIANCE OF THE RESPIRATORY SYSTEM

The lung is like a rubber balloon that can be distended by positive pressure (inside) or negative pressure (outside). Under normal circumstances, inflation of the lung is maintained because although the pressure inside (alveolar pressure) is zero, the outside pressure (i.e., the pleural pressure) is sufficiently negative. The net distending pressure, which is the difference of the (positive) airway pressure (P_{AW}) and the (negative) pleural pressure (P_{PL}) is termed the *transpulmonary pressure* (P_{TP}). Thus:

$$P_{TP} = P_{AW} - P_{PL}$$

Clearly, increasing the P_{AW} increases the P_{TP}. In addition, lowering the P_{PL} (which is usually negative and making it more negative) making it more negative) also increases the P_{TP}.

Compliance—the reciprocal of elastance—is the term that expresses how much distention (volume in liters) occurs for a given level of P_{TP} (pressure, cm H_2O); it is usually 0.2 to 0.3

BOX 19-1 *Alveolar Gas Equations*

Alveolar Oxygen Tension (PAO_2)

$$PAO_2 = PIO_2 - \frac{PACO_2}{R} + \left[PACO_2 \times FiO_2 \times \frac{1-R}{R}\right]$$

where PIO_2 is inspired oxygen tension, $PACO_2$ is alveolar CO_2 tension (assumed to equal arterial Pco_2), R is the respiratory exchange ratio (normally in the range of 0.8 to 1.0), and FiO_2 is the inspired oxygen fraction. The term within brackets compensates for the larger O_2 uptake than CO_2 elimination over the alveolar capillary membranes.

A simplified equation can be written without the compensation term:

$$PAO_2 = PIO_2 - \frac{PACO_2}{R}$$

Alveolar Ventilation

Alveolar ventilation ($\dot{V}A$) can be expressed as

$$\dot{V}A = f \times (VT - VDS)$$

where f is breaths/min, VT is tidal volume, and VDS is physiologic dead space.

Alveolar ventilation can also be derived from:

$$\dot{V}CO_2 = c \times \dot{V}A \times FACO_2$$

where $\dot{V}CO_2$ is CO_2 elimination, c is a conversion constant, and $FACO_2$ is the alveolar CO_2 concentration.

If $\dot{V}A$ is expressed in L/min, $\dot{V}CO_2$ in mL/min, and $FACO_2$ is replaced by $PACO_2$ in mm Hg, $c = 0.863$. By rearranging:

$$\dot{V}A = \frac{\dot{V}CO_2 \times 0.863}{PACO_2}$$

L/cmH_2O.[24] However, although higher values of P_{TP} maintain greater levels of lung opening, the relationship—as with most elastic structures—between applied pressure and resultant volume is curvilinear (Fig. 19-3).[24] Lung compliance depends on the lung volume; it is lowest at an extremely low or high FRC (see Fig. 19-3). In lung diseases characterized by reduced compliance (e.g., ARDS, pulmonary fibrosis or edema), the pressure-volume curve is flatter and shifted to the right (Fig. 19-4).[24] In contrast, although emphysema involves the loss of elastic tissue, the overall loss of lung tissue (as seen on computed tomography [CT] scanning)[25] means that the compliance is increased; the pressure-volume curve is therefore shifted to the left and is steeper (see Fig. 19-4).[24]

The chest wall impedance is not noticed during spontaneous breathing because the respiratory "pump" includes the chest wall. Chest wall mechanics can be measured only if complete relaxation of the respiratory muscles can be achieved[26]; however, during mechanical ventilation the respiratory muscles can be completely relaxed. As the lung is inflated by P_{AW}, the properties of the chest wall will determine the resulting change in P_{PL}. Under these circumstances, the increase in lung volume per unit increase in P_{PL} is the chest wall compliance. Values of chest wall compliance are about the same as that of the lung and are reduced with obesity, chest wall edema, pleural effusions, and diseases of the costovertebral joints.[26]

RESISTANCE OF THE RESPIRATORY SYSTEM

Airways

Resistance impedes airflow into (and out of) the lung. The major component of resistance is the resistance exerted by the airways (large and small), and a minor component is the sliding of lung and the chest wall tissue elements during inspiration (and expiration).[27] Resistance is overcome by (driving) pressure. In spontaneous breathing, driving pressure will be the P_{PL}; in positive pressure ventilation, the

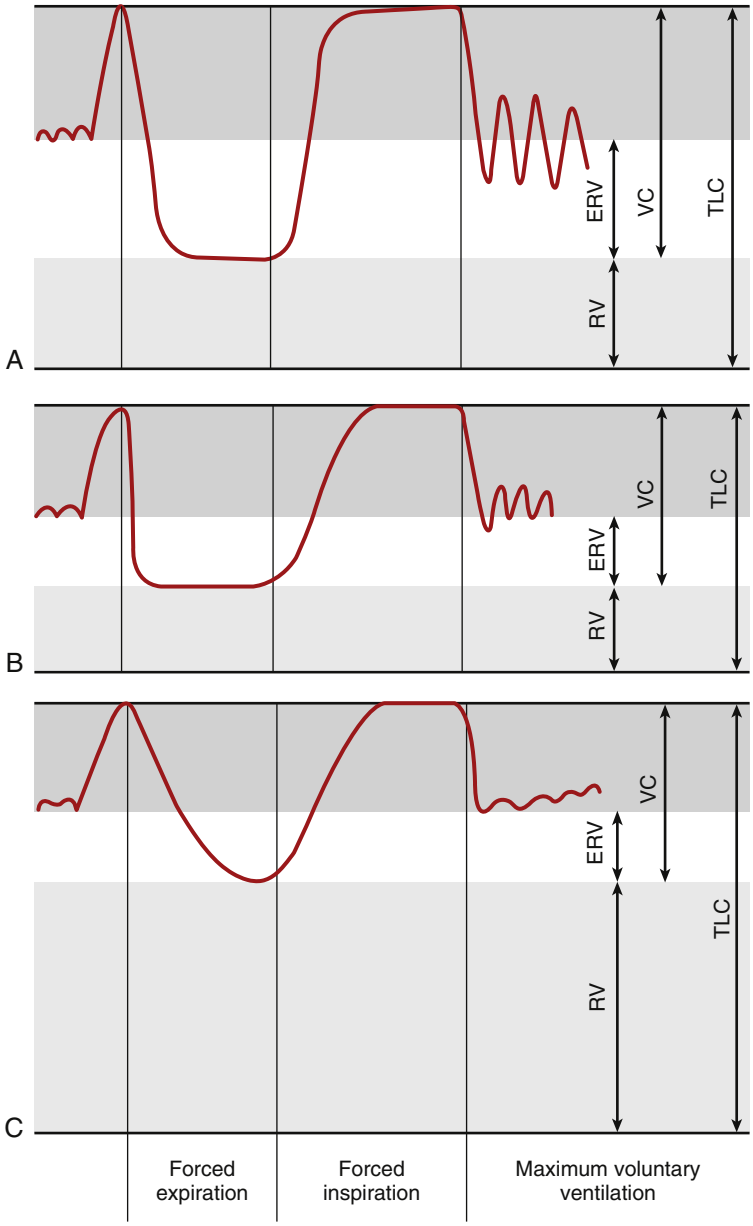

Figure 19-2. A, Ventilation and lung volumes in a healthy subject with normal lungs. **B,** A patient with restrictive lung disease. **C,** A patient with chronic obstructive pulmonary disease (COPD). In restrictive disease, the vital capacity (VC) is decreased and expiratory flow rate is increased (i.e., steeper than the normal slope of the forced expiratory curve). In COPD, the residual volume (RV) is increased, the VC is reduced, and forced expiration is slowed. *ERV,* Expiratory reserve volume; *TLC,* total lung capacity. *(From Hedenstierna G: Respiratory measurement. London, 1998, BMJ Books, 1998, p. 184; see also book review of* Respiratory Measurement in Thorax *53:1096, 1998.)*

driving pressure will be difference between the pressures applied to the endotracheal tube (P_{AW}; "source") and the alveolus (P_{ALV}; "destination"). Resistance (R) is calculated as driving pressure (ΔP) divided by the resultant gas flow (F):

$$R = {}^{\Delta P}/_{F}$$

The value of airway resistance is approximately 1 cm H_2O/L/sec, and is higher in obstructive lung disease (e.g., COPD, asthma); in severe asthma, it is elevated approximately tenfold.[28] The presence of an endotracheal tube adds a resistance of 5 (or 8) cm H_2O/L/min for a tube with internal diameter of size 8 (or 7) cm.[29] For any tube for which the airflow is laminar (smooth, streamlined), the resistance increases in direct proportion to the tube length and increases dramatically (to the fourth power) as the diameter of the tube is reduced.

Two factors explain why most (approximately 80%) of the impedance to gas flow occurs in the large airways.[27] First, as bronchi progressively branch, the resistances are arranged in parallel and the total cross-sectional area at the level of the terminal bronchioles adds up to almost tenfold that at the trachea. Second, in tubes that are large, irregular or branched, the flow is often turbulent, not laminar. When flow is laminar:

$$F_{(lam)} = {}^{\Delta P}/_{R}$$

In contrast, when flow is turbulent:

$$F_{(turb)} = {}^{\Delta P}/_{R^2}$$

Therefore, for a given radius, far more pressure is required to achieve comparable flow where flow is turbulent; thus, the effort required is greater and if prolonged or severe, respiratory failure is more likely.

Several factors can alter airflow resistance. First, resistance lessens as lung volume increases; this is intuitive as increasing volume (positive pressure or spontaneous breathing) stretches the diameter of the airways; because this is the key determinant of resistance, the resistance falls to a small extent. The opposite occurs with exhalation (Fig. 19-5). However, as lung volume approaches RV—as can happen during anesthesia—the airways are narrowed in parallel with the compressing lung tissue and the resistance rises

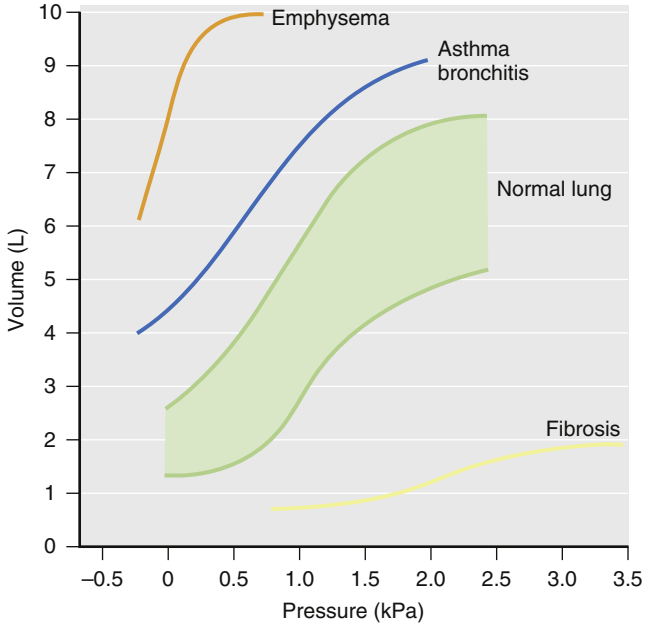

Figure 19-4. Pressure-volume curves of the lung in health and lung disease. In fibrosis, the slope of the curve is flatter, reflecting considerable increases in pressure variation and in respiratory work. In asthma or bronchitis, there is a parallel (upward) shift of the pressure-volume curve, indicating an increase in lung volume but no change in compliance. In emphysema, the slope of the curve is steeper, reflecting tissue loss and possible increased compliance. However, in emphysema, asthma, or bronchitis, the airway resistance is increased; this increases work of breathing and overrides any benefit from increased compliance. *(From Hedenstierna G: Respiratory measurement. London, 1998, BMJ Books, 1998, p. 184; see also book review of* Respiratory Measurement in Thorax *53:1096, 1998.)*

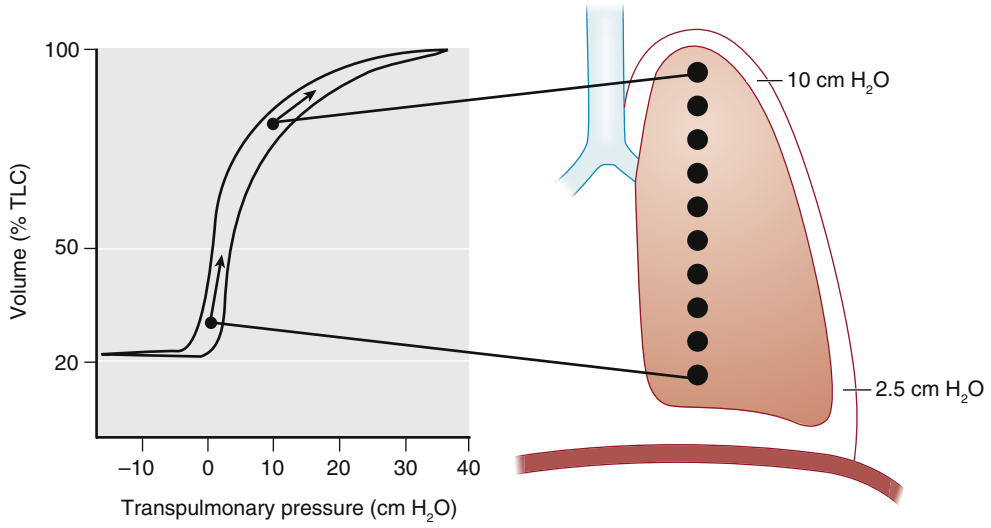

Figure 19-3. The pressure-volume relationships of the lung. The relationship is curvilinear (typical for an elastic structure). The pleural pressure is lower (more subatmospheric) in the upper regions. In the upright subject, the transpulmonary pressure ($P_{TP} = P_{AW} - P_{PL}$) is higher in apical than in basal regions. This results in different positions on the pressure volume curve of the upper (flatter, less compliant) versus lower (steeper, more compliant) lung regions. Thus, lower lung regions expand more (i.e., receive more ventilation) for a given increase in transpulmonary pressure than upper units. *TLC,* Total lung capacity.

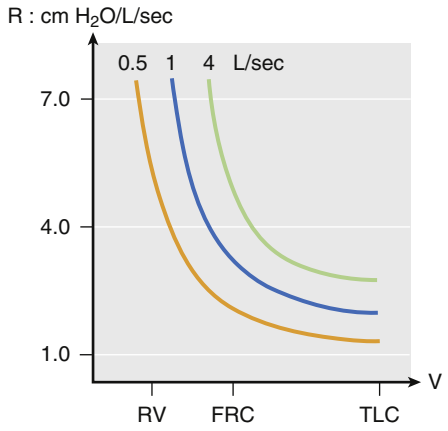

Figure 19-5. Schematic drawing of airflow resistance against lung volume at different flow rates. As lung volume falls, the resistance to flow increases; the steepness of this increase is far greater at lung volumes below functional residual capacity (FRC). In addition, higher airflow rates are associated with greater resistance. At extremely low lung volume, the resistance is comparable to values seen in moderate to severe asthma (6 to 8 cm $H_2O \times l^{-1} \times$ sec). *RV,* residual volume; *TLC,* total lung capacity.

exponentially. These effects are apparent with active or passive ventilation. Second, active ventilation has additional effects. Forced expiration can compress small airways (i.e., that do not contain cartilage).[27] In addition, forced expiration can cause turbulent flow in small airways in patients with COPD, precipitously dropping pressure in the lumen and thereby narrowing the bronchioles[30] and resulting in expiratory flow limitation and, after multiple breaths, eventual "dynamic hyperinflation."[31] Expiring against resistance (or pursed-lips breathing) is sometimes used by those with COPD to make breathing easier. This works by increasing expiratory resistance and slowing expiration. The slowed expiration reduces the pressure gradient driving expiration (i.e., pressure highest in the alveolus, lower toward the mouth). Therefore, the point along the airway tree at which pressure inside the airway has decreased to less than that outside the airway (equal to pleural pressure) is moved from smaller collapsible airways toward the mouth to noncollapsible, cartilaginous airways (Fig. 19-6); this prevents collapse of the smaller airways, which are vital for proper gas exchange.[32]

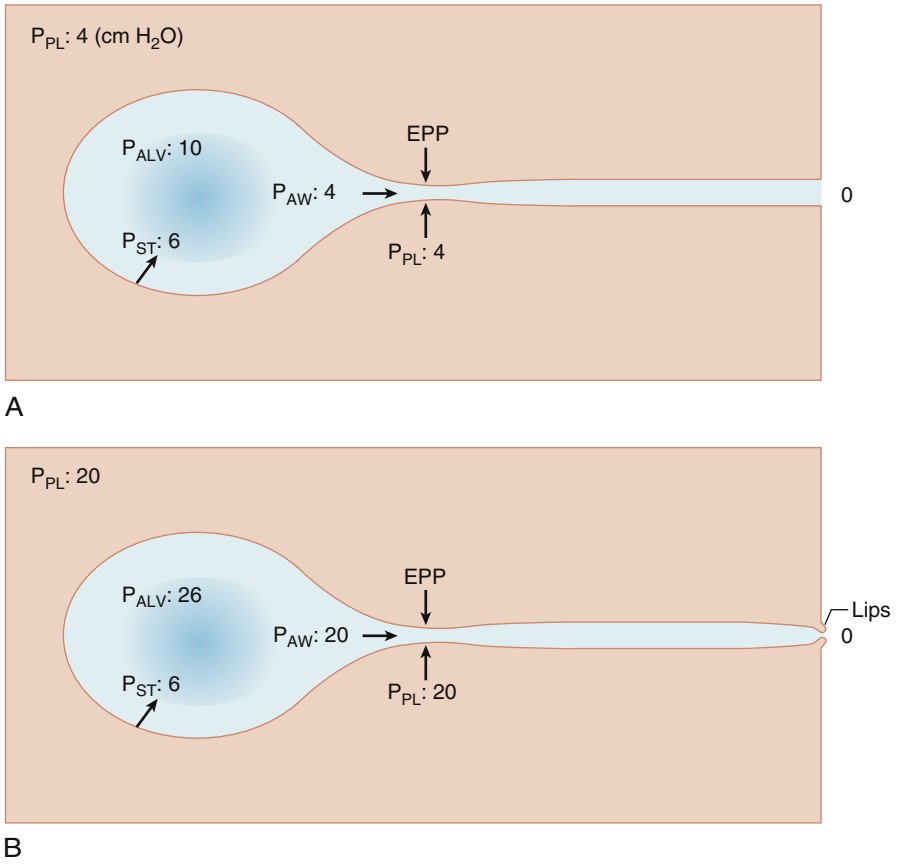

Figure 19-6. Schematic drawings of the equal pressure point (EPP) concept and dynamic compression of airways. **A,** Slightly forced expiration during otherwise normal conditions. With the application of some expiratory muscle effort, pleural pressure (P_pl) is positive, 4 cm H_2O (0.4 kPa). The elastic recoil pressure (Pst) of the alveoli (6 cm H_2O) and the pleural pressure add together to yield intraalveolar pressure (Palv) (10 cm H_2O). This causes expiratory flow. At some point downstream toward the airway opening, airway pressure (Paw) has dropped by 6 cm H_2O, so intraluminal pressure and pleural, extraluminal pressure are the same. This is the EPP. From this point to the mouth, intraluminal airway pressure is lower than the surrounding, extraluminal pressure and the airway may be compressed. **B,** An attempt to stabilize the airway by so-called "pursed-lip" breathing. The increased resistance to expiratory flow requires increased expiratory effort to maintain gas flow. Thus, pleural pressure is increased in comparison to the normal conditions (Ppl = 20 cm H_2O). Alveolar elastic recoil pressure (Pst) is the same as in the earlier condition, provided that lung volume is the same. If expiratory flow is of the same magnitude as during normal breathing, pressure along the airway falls to the same extent as during normal breathing. Thus the EPP will have the same location as during normal breathing, and no stabilization of the airway has been achieved. The two ways of moving the EPP toward the mouth and to less collapsible airways is by raising alveolar recoil pressure (Pst) by an increase in lung volume or by lowering the expiratory flow rate so that the pressure drop along the airway tree is slowed down.

The large airways (i.e., pharynx, larynx, and trachea) are outside the chest wall. During inspiration, the intrathoracic airways are exposed to extraluminal pressure (i.e., P_{PL}) that is less than the lumen pressure; in contrast, the extrathoracic airways are exposed to lumen pressure that is less than the extraluminal (i.e., atmospheric) pressure.[27] This feature, coupled with downward stretch induced by inspiration, narrows the large extrathoracic airways; in the presence of preexisting narrowing (e.g., thyroid enlargement or tumor, paralyzed vocal cord, epiglottitis), it can critically reduce the cross-sectional area.

Tissue

Although not intuitively obvious, resistance of the lung tissue is the applied pressure on tissue divided by the resulting velocity of tissue movement. There are various approaches to determining this in humans, including separately considering the pressure-volume (PV) characteristics using plethysmography (where the area of the PV curve corresponds to work against total pulmonary resistance) and esophageal pressure (where the area of the PV curve corresponds to work against "tissue" resistance).[33] Alternative approaches mathematically model the lung responses to varying respiratory frequencies.[34] Lung tissue resistance amounts to 20% of the total resistance to breathing; it can be increased threefold or fourfold in chronic lung disease[35] and is reduced by panting respirations.[36] Finally, in ARDS the chest wall resistance is increased (see Chapter 103).[37]

INERTIA OR ACCELERATION OF GAS AND TISSUE

A final component of the total impedance to breathing is inertance, or the pressure required to accelerate air and tissue during inspiration and expiration. This component is minor, however, and can hardly be measured under normal breathing, regardless of whether the lungs are healthy. Nonetheless, tissue inertia is large during rapid ventilation,[38] and it could be important during the rapid, shallow breathing characteristic of weaning failure or during high-frequency oscillation.

DISTRIBUTION OF INSPIRED GAS

Inspired gas is not evenly distributed throughout the lung; naturally, more gas enters those lung units that expand most during inspiration. In the resting lung, the basal (dependent) regions are less aerated than the apical (nondependent) regions; therefore, they have the capacity to undergo greater expansion. During inspiration, most gas goes to the basal units (dorsal, when supine; lower right lung when in the right lateral position).[39] This distribution is because of the compliance properties of the lung and the effects of position on the distribution of the distending pleural pressure (i.e., the P_{PL} gradient). These changes are not related to the properties of the inspired gas.

In the upright position, the P_{PL} is less negative at the base of the lung than at the apex. Because the P_A is uniform throughout the lung, the distending P_{TP} is greater at the apex; therefore, before inspiration commences, the apical lung is more open (and is less compliant) than the basal lung (Figs. 19-3 and 19-7). With inspiration, the contracting diaphragm lowers the P_{PL} by a comparable amount in all areas of the pleural surface (because of the fluid-like behavior of normal lung[39]) and distends the basal more than the apical regions (see Figs. 19-3 and 19-7). Because the pleural pressure gradient is oriented according to gravity, the distribution of ventilation changes with body position.

The P_{PL} gradient exists because lung density, gravity, and conformation of the lung to the shape of the thorax[40] result in crowding the basal lung tissue, making the local P_{PL} less negative in the basal regions. Because the density of normal lung is approximately 0.3, P_{PL} will become more positive by 0.3 cm H_2O for each downward vertical centimeter, and more so with injured or edematous lungs. Indeed, experimentally induced weightlessness decreases inhomogeneity in the distribution of ventilation[41], but does not eliminate it; therefore, nongravitational (e.g., tissue, airway) factors also play a role.[42]

Although the vertical height of the lung is the same in the prone and supine positions, the vertical gradient P_{PL} is less when prone,[43] perhaps because the mediastinum compresses the dependent lung when supine but rests on the sternum when prone.[44] A more even distribution of inspired gas—with improved oxygenation—in the prone position was predicted by Bryan in 1974[44]; this has been confirmed experimentally.[45,46]

During low-flow states (e.g., at rest) distribution is determined by differences in compliance and not by airway resistance. Because compliance at the start of inflation is less in the (already more aerated) apex, ventilation is preferentially directed to the base. In contrast, at high airflow, resistance (not compliance) is the key determinant of distribution; because the resistance is lower in upper, more expanded lung regions, increasing flow rate equalizes the distribution of ventilation, as shown by distribution of ^{133}Xe gas in humans[47,48] (Fig. 19-8). This is important during exercise or stress because greater amounts of the alveolar-capillary surface area will be used.

AIRWAY CLOSURE

Expiration causes the airways to narrow, and deep expiration can cause them to close. The volume remaining above RV where expiration below FRC closes some airways is termed *closing volume* (CV), and this volume added to the RV is termed the *closing capacity* (CC; i.e., the total capacity of the lung at which closing can occur).[49] Closure of airways during expiration is normal and is potentiated by increasing P_{PL}, especially with active expiration. When P_{PL} exceeds the P_{AW}, the airway—if collapsible—will tend to close, and this usually commences at the bases because the basal P_{PL} is greatest (see Fig. 19-7).

Three applications of this important principle are of key relevance to anesthesia. First, airway closure depends on age: in youth, the closure does not occur until expiration is at or near RV, whereas with older age, it occurs earlier in expiration (i.e., at higher lung volumes). This occurs because P_{PL} is on average more "positive"

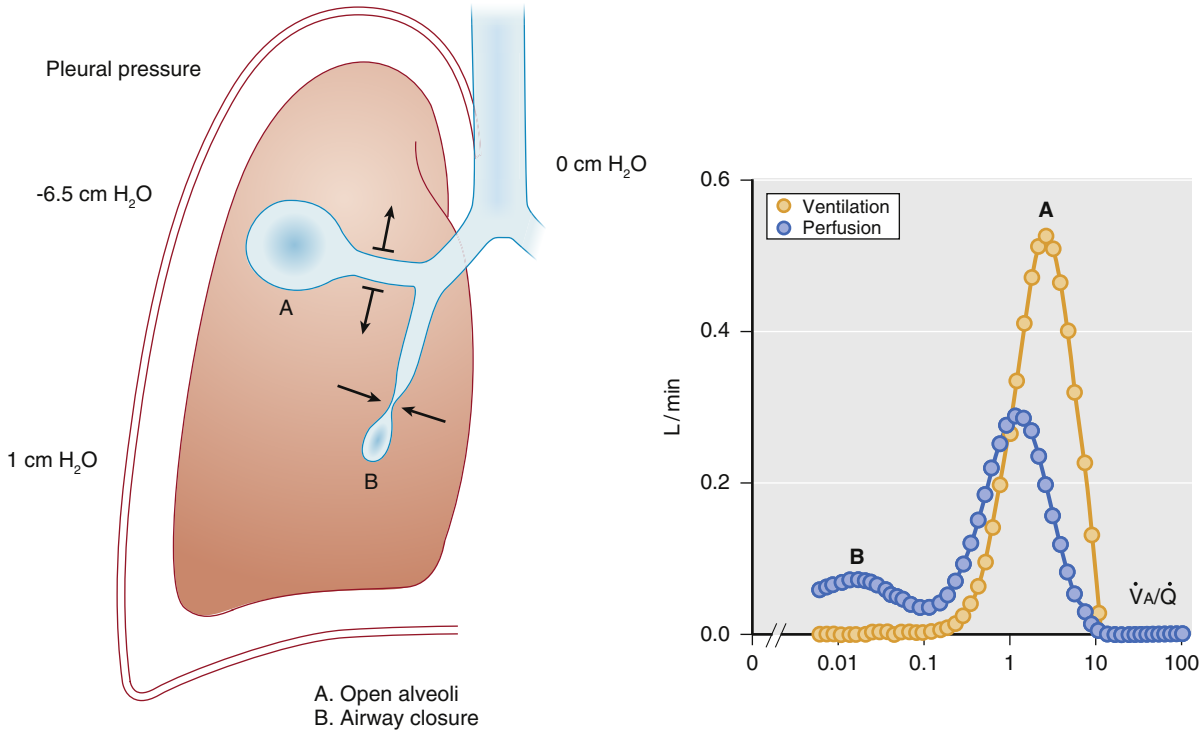

Figure 19-7. Schematic of regional alveolar and airway volume at an upper (*A*) and a lower (*B*) lung level (*left panel*). There is a vertical pleural pressure (P_{PL}) gradient between the uppermost and lowermost regions (–6.5 to 1 = –7.5 cm H_2O). Airway pressure (P_{AW}) is athmospheric, or 0 cm H_2O throughout; thus, in the upper regions, $P_{AW} > P_{PL}$ maintains airways open. In contrast, in the lower regions, $P_L > P_{AW}$ causes airway closure—potentially exacerbated by subsequent alveolar gas absorption behind the occluded airway. The *right panel* shows the distribution of ventilation and perfusion ratios from the multiple inert gas elimination technique. A "normal" mode of ventilation and blood flow (*A*) can be seen corresponding to the open and ventilated alveoli in the upper parts of the lung. In addition there is a range of low $\dot{V}_A/\dot{Q}$ ratios with more perfusion than ventilation (*B*). This pattern is compatible with intermittent airway closure during breathing.

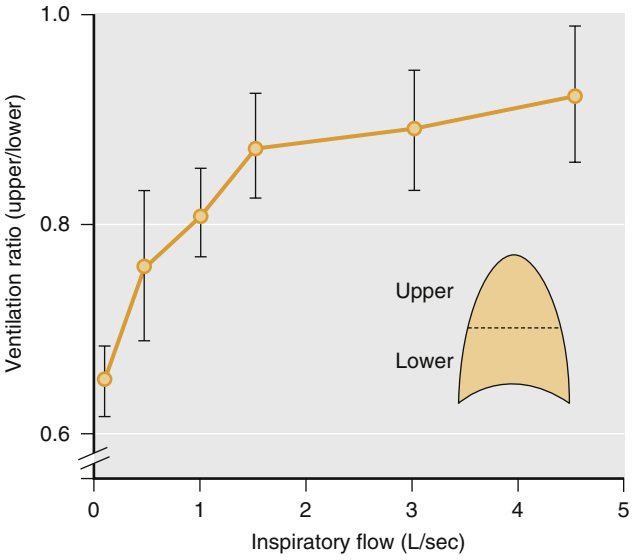

Figure 19-8. Distribution of ventilation to upper versus lower lung regions as inspiratory flow is altered. At low flow, the bulk of the airflow goes to the lower regions. At higher flow rates (e.g., during exercise) the distribution is more even, ensuring more efficient use of all alveolar-capillary membranes for gas transfer (provided that pulmonary blood flow shows a similar distribution pattern).

(i.e., atmospheric, equal to P_{AW}) as age increases. Closing can occur at or above FRC in individuals aged 65 to 70 years[50] such that dependent regions will undergo closure during normal expiration. This may be the major reason why oxygenation decreases with age (see Chapter 80). Second, in the supine position FRC is less than when upright, but CC is unchanged; therefore, exhalation of a usual V_T (from FRC) encroaches on CC in a supine 45 year old, and closure may be continuous in a supine 70 year old (Fig. 19-9). Finally, COPD increases the lung volume at which closure occurs, possibly exacerbated by airway edema and increased bronchial tone.[49]

DIFFUSION OF GAS

Gas moves in the large and medium-sized airways by bulk flow (i.e., convection) meaning that the gas molecules travel together at a given mean velocity according to a driving pressure gradient. Flow is through multiple generations of bronchi, and the net resistance falls with each division. After the fourteenth generation, airways merge with alveoli and participate in gas exchange (respiratory bronchioles). The cross-sectional area expands massively (trachea, 2.5 cm^2; twenty-third generation bronchi, 0.8 m^2; alveolar surface, 140 m^2),[51] resulting in a sharp drop in overall resistance. Because the number of gas molecules is constant, the velocity falls rapidly, which by the time the gas enters the alveoli is miniscule (0.001 mm/sec) and is

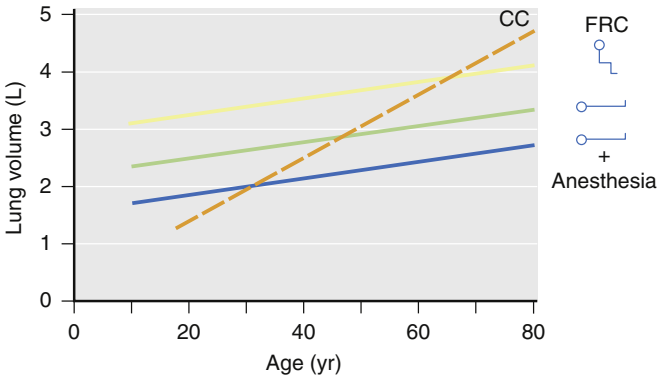

Figure 19-9. Resting functional residual capacity (FRC) and closing capacity (CC). FRC increases with age (because of loss of elastic tissue), and superimposed upon this is a step decrease in FRC with supine position (because of diaphragm elevation by abdominal contents), and a further decrease with anesthesia in the supine position. The CC is also increased with age, but far more steeply, causing airway closure above FRC in upright subjects (>65 yr) and in supine subjects (>45 yr). This relationship between CC and FRC explains decreasing oxygenation with age.

zero when it reaches the alveolar membrane. The velocity of the gas entering the alveolus is slower than the diffusion rates of O_2 and CO_2; therefore, diffusion—not convection—is necessary for transport in the distal airways and alveoli. Indeed, CO_2 is detectable at the mouth after just seconds of breath holding, because of rapid diffusion and because of cardiac oscillations (i.e., mixing).

Gas mixing is complete in the alveoli of a normal lung during normal breathing. However, if the alveolus expands (e.g., emphysema), the diffusion distance may be too great to allow complete mixing, potentially leaving a layer of CO_2-rich gas lining the alveolar membrane and a core of O_2-rich gas in the alveolus. This represents a "micro" version of inhomogeneous distribution of ventilation.[52]

PERFUSION

The pulmonary circulation differs from the systemic circulation: it operates at a five fold to tenfold lower pressure, and the vessels are shorter and wider. There are two important consequences of the particularly low vascular resistance. First, the downstream blood flow in the pulmonary capillaries is pulsatile, in contrast to the more constant systemic capillary flow.[53] Second, the capillary and alveolar walls are protected from exposure to high hydrostatic pressures; therefore, they can be sufficiently thin to optimize diffusion (i.e., exchange) of gas but not permit leakage of plasma or blood into the airspace. Whereas an abrupt increase in the pulmonary arterial (or venous) pressure can cause breaks in the capillaries,[54] slower increases (i.e., months to years) stimulate vascular remodeling.[55] This remodeling might protect against pulmonary edema[56] (and possibly against lung injury[57]), but diffusion will be impaired.

DISTRIBUTION OF LUNG BLOOD FLOW

Pulmonary blood flow depends on driving pressure and vascular resistance; these factors (and flow) are not homogenous

$$\text{Pulmonary vascular resistance (PVR)} = \frac{\bar{P}_{PA} - P_{LA}}{\dot{Q}_T}$$

(true only if lung is in zone III)

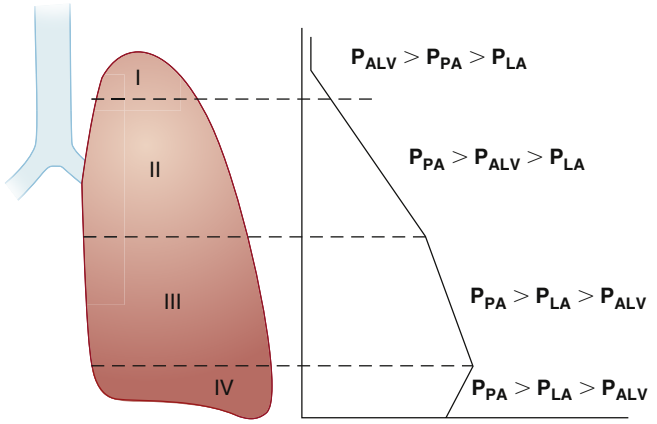

Figure 19-10. Vertical distribution of lung blood flow. The so-called zones I, II, III, and IV are indicated. In zone I there is no perfusion, only ventilation. In zone II, pulmonary artery pressure exceeds alveolar pressure which in turn exceeds venous pressure; the driving pressure is P_{PA}-P_A. In zone III, arterial and venous pressures both exceed alveolar pressure, and here the driving pressure is P_{PA}-P_{LA}. In the lung base, blood flow is decreased possibly because of increased interstitial pressure that compresses extra alveolar vessels. P_A, Alveolus pressure; P_{ALV}, positive intraalveolar pressure; P_{LA}, positive artery pressure; P_{PA}, pulmonary artery pressure; Q_T, cardiac output.

throughout the lung. The traditional thinking about lung perfusion emphasized the importance of gravity[58]; however, factors other than gravity are also important.

DISTRIBUTION OF BLOOD FLOW IN THE LUNG: THE EFFECT OF GRAVITY

Blood has weight and therefore blood pressure is affected by gravity. The height (base to apex) of an adult lung is approximately 25 cm; therefore, when a person is standing, the hydrostatic pressure at the base is 25 cm H_2O (i.e., approximately 18 mm Hg) higher than at the apex. The mean pulmonary arterial pressure is approximately 12 mm Hg at the level of the heart, and the pulmonary artery pressure at the lung apex can therefore approach zero. Thus, less blood flow will occur at the apex (versus the base), and in the setting of positive pressure ventilation, the apical alveoli can compress the surrounding capillaries and prevent any local blood flow.

Based on such gravitational distribution of pulmonary artery pressure, as well as the effect of alveolar expansion, West and colleagues[59] divided the lung into zones I to III (Fig. 19-10). This system is based on the principle that perfusion to an alveolus depends on the pressures in the pulmonary artery (P_{PA}), pulmonary vein (P_{PV}), and alveolus (P_{ALV}). In the apex (zone I), the key issue is that pulmonary arterial pressure is less than alveolar pressure; therefore, no perfusion occurs. Zone I conditions can exist during mechanical ventilation and be exacerbated by low P_{PA}. Whenever zone I conditions exist, the nonperfused alveoli constitute additional dead space (V_D).

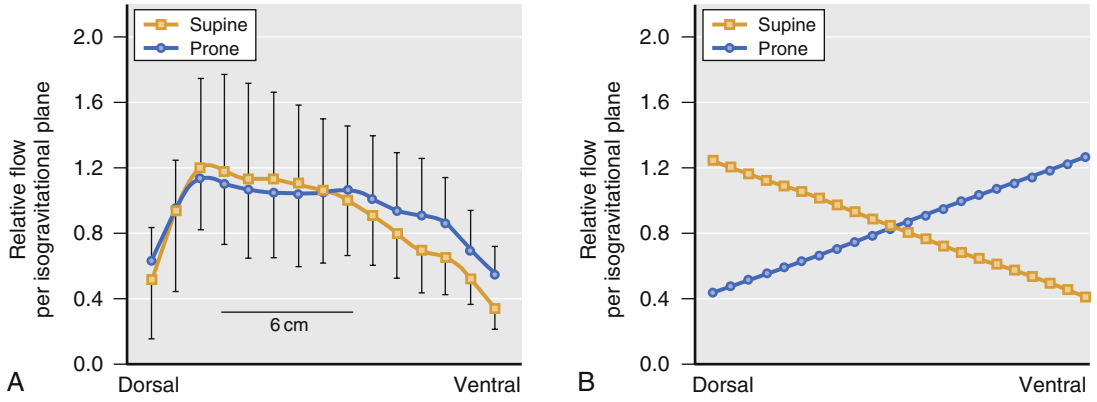

Figure 19-11. Distribution of blood flow (ventral, dorsal) in supine versus prone position. The distributions from ventral to dorsal are similar, irrespective of position, suggesting that that anatomic features (and not simply gravity) determine the distribution of flow. The magnitude of the variability in either the prone (or in the supine) position (i.e., nongravitational inhomogeneity) is far greater than the differences in distribution between the prone and the supine positions (i.e., gravitational inhomogeneity). *(From Glenny RW et al: Gravity is a minor determinant of pulmonary blood flow distribution,* J Appl Physiol *71:620-629, 1991.)*

Below the apex in zone II, P_{PV} is less than alveolar pressure, and the veins are collapsed except during flow, as in a "vascular waterfall." Although P_{ALV} is always greater than P_{PV}, perfusion occurs when P_{PA} exceeds P_{ALV} (i.e., intermittently, during systole). Below this zone is zone III, in which there are two important differences: P_{PA} and P_{PV} both always exceed P_{ALV}. As a result, there is perfusion throughout systole and diastole (and inspiration and expiration). Gravity results in equal increases in both P_{PA} and P_{PV} toward the lung base; therefore, gravity cannot affect flow throughout zone III by increasing the P_{PA} to P_{PV} pressure gradient alone. Nonetheless, it is possible that the greater weight of the blood nearer the base results in vessel dilatation, thereby lowering vascular resistance and increasing flow.[58] It was subsequently recognized that there is also a decrease in perfusion in the lung base, or zone IV, that is thought to occur because of the effects of gravity compressing the lung at the bases—and the blood vessels therein—and thereby increasing vascular resistance.[60]

Finally, additional evidence for the effect of gravity comes from volunteer experiments in which gravity was increased or abolished by altering the flight pattern of a jet aircraft.[61] In these experiments, zero gravity decreased cardiac oscillations of O_2 and CO_2 during a breath hold, indicating development of more homogeneous perfusion. In contrast, more recent experiments of exhaled gas analysis (on the Mir space station) reported that the heterogeneity of lung perfusion was reduced, but not eliminated, in the presence of microgravity, indicating that gravity contributes to the heterogeneity of blood flow distribution but does not explain it entirely.[62] While the precise role of gravity is disputed, it is likely to play a smaller role when supine versus when upright.

DISTRIBUTION OF BLOOD FLOW IN THE LUNG: INFLUENCE OF FACTORS NOT RELATED TO GRAVITY

Key experiments have reconsidered the effects of gravity. Blood flow measured in the same gravitational plane was less per unit of lung tissue at the apex than at the base.[63] In addition, microsphere assessment demonstrated significant variability within iso-gravitational planes, and lung height appeared to account for less than 10% of the distribution of flow in either the prone or supine positions.[64] In addition, inhomogeneity in the horizontal planes can exceed that in the vertical direction (Fig. 19-11).[65] Other studies have reported a preponderance of perfusion to the central lung (versus peripheral) tissue,[66] which can be reversed by the application of positive end-expiratory pressure (PEEP).[67] Although greater length of radial blood vessels was considered to explain this central-peripheral difference, others have suggested that it is not significant.[64] Finally, differences have been reported among lung regions in local vascular resistance.[68]

Fractal distribution of blood flow may be more important than the influence of gravity.[69] A fractal pattern of perfusion means that in any given region, there will be "spatial correlation" (similarity) of the blood flow between neighboring regions.

Although the methods to study lung perfusion are complex—and there is a spectrum of opinion[71,72], the aggregate data suggest that factors other than gravity contribute to the heterogeneity of the distribution of perfusion.

HYPOXIC PULMONARY VASOCONSTRICTION

Hypoxic pulmonary vasoconstriction is a compensatory mechanism that diverts blood flow away from hypoxic lung regions toward better oxygenated regions.[73] The major stimulus for HPV is low alveolar oxygen tension (P_AO_2), whether caused by hypoventilation or by breathing gas with a low PO_2, and is more potent when affecting a smaller lung region. The stimulus of hypoxic mixed venous blood is weaker.[74,75] Whereas in humans older volatile anesthetics were thought to inhibit HPV more than intravenously based anesthesia (in humans), modern volatile anesthetics, including sevoflurane[76] and desflurane,[77] have little effect. During intravenously based anesthesia, exposure of one lung to an Fio_2 of 1.0 and the contralateral to a hypoxic gas mixture (Fio_2, 0.12 to 0.05) reduced perfusion to the hypoxic lung to 30% of

the cardiac output.[78] Pulmonary hypertension, because of vascular remodeling owing to ongoing HPV, can develop in humans at high altitude[79] or in the presence of chronic hypoxemic lung disease.

CLINICAL ASSESSMENT OF LUNG FUNCTION

SPIROMETRY—TOTAL LUNG CAPACITY AND SUBDIVISIONS

The gas volume in the lung after a maximum inspiration is called the *total lung capacity* (TLC; usually 6 to 8 L). TLC can be increased in COPD either by overexpansion of alveoli or by destruction of the alveolar wall, resulting in loss of elastic tissue, as in emphysema (see Fig. 19-4).[80] In extreme cases, TLC can be increased to 10 to 12 L. In restrictive lung disease, TLC is reduced, reflecting the degree of fibrosis, and can be as low as 3 to 4 L (see Fig. 19-4).[80]

Following maximum expiratory effort, some air is left in the lung and constitutes the RV (about 2 L). However, usually no region develops collapse because distal airways (<2 mm) close before alveoli collapse,[81] trapping gas and preventing further alveolar emptying. In addition, there is a limit to how much the chest wall, rib cage, and diaphragm can be compressed. The importance of preventing collapse of lung tissue was presented earlier (see Fig. 19-6).

The maximum volume that can be inhaled and then exhaled is the vital capacity (VC; 4 to 6 L), and this is the difference between TLC and RV. VC is reduced in both restrictive and obstructive lung disease. In restriction, VC reduction reflects the loss of lung volume, such as from the constricting (i.e., shrinking) effects of fibrosis. In obstructive lung disease, long-term trapping of air increases the RV and can occur either by encroaching on (and reducing) the VC or in association with a (proportionally smaller) increase in FVC.[80]

Tidal volume (V_T, usually 0.5 L) is inspired from the resting lung volume reached at end-expiration (FRC, 2.0 L). With increased ventilation, as in exercise, V_T is increased and FRC may be reduced by approximately 0.5 L. However, in airway obstruction, exhalation is impeded such that inspiration commences before the usual resting lung volume is reached; thus end-expiratory volume is increased.[80] Such air trapping reduces the resistance to gas flow in the narrowed airways, but because the lung tissue is hyperinflated and mechanically disadvantaged, the work of breathing overall is increased (also see Chapter 103).

FRC increases with age as elastic lung tissue is lost; this reduces the lung recoil force countering the outward chest wall force, and lung assumes a higher volume (see Chapter 80). The rate of this aging process is accelerated in COPD because of the contributions of chronic air trapping and marked loss of elastic tissue.[19] FRC is reduced in fibrotic lung diseases,[80] sometimes to 1.5 L (see Fig. 19-4). Lung resection also reduces FRC, but the remaining lung will expand to fill the lung tissue void partially; this is called *compensatory emphysema* (see Chapter 66).

DIFFUSING CAPACITY (DL_{CO})—DIFFUSION ACROSS ALVEOLAR-CAPILLARY MEMBRANES

The diffusing capacity test integrates many phenomena that are central to respiratory physiology. The test and the factors affecting its interpretation are described here. In the lungs, O_2 and CO_2 diffuse passively: O_2 from alveolar gas into plasma and red cells, where it binds to hemoglobin, and CO_2 in the opposite direction, from plasma to the alveoli. The amount that can diffuse across a membrane in a given period is the diffusing capacity, and it is determined with the following equation:

$$Diffusing\ capacity = \frac{(SA \times \Delta P \times Sol)}{\left(h \times \sqrt{MW}\right)}$$

where SA is the surface area of the membrane exposed to gas, ΔP is the gradient of partial pressure between administered gas vs. blood tension, Sol is the solubility of the gas in the membrane, h is the thickness of the membrane, and MW is the molecular weight of the gas.

Assessment of diffusing capacity (sometimes called *transfer factor*) uses CO as the test gas; it is inhaled at a small concentration (0.3%) to TLC just after a maximal expiration, filling the lung as much as possible with the dilute CO. The breath is held and then deeply exhaled to RV. The difference between the quantity of CO exhaled versus inhaled will therefore either be taken up by the perfusing blood (i.e., Hb) or remain in the lung (RV). The latter can be determined if the CO is coadministered with an insoluble gas (e.g., He) that remains in the lung.

Surface Area

The surface area is taken as the area that is capable of exchanging gas on the alveolar and the capillary sides; thus, it assumes a ventilated and perfused lung (i.e., not dead space). It will be lower in small lungs, lung fibrosis (restriction), after lung resection, or in cases of lung tissue destruction, such as emphysema.

Membrane Thickness

Thicker membranes reduce the CO transfer because the longer diffusion distance lowers the diffusion capacity, and the solubility of O_2 (and CO_2) is lower in fibrotic tissue than in plasma. Differentiating between effects of the volume of capillary blood and the membrane thickness can be difficult, but because oxygen and CO compete for binding to hemoglobin, distinguishing between these issues may be possible by measuring CO transfer with altered Fio_2 (see review by Hughes and colleagues[82,83]).

Pressure Gradient

The larger the O_2 or CO_2 tension difference (ΔP) between the gas phase (alveolus) and the plasma (capillary), the greater the rate of diffusion. The mixed venous blood entering the pulmonary capillary has a PO_2 of 40 mm Hg (5.3 kPa), and alveolar PO_2 is approximately 100 mm Hg (13.3 kPa); therefore, the driving pressure (ΔP) is 60 mm Hg (8 kPa).

When blood flows through the capillary, it takes up oxygen and delivers CO_2, but because oxygen pressure

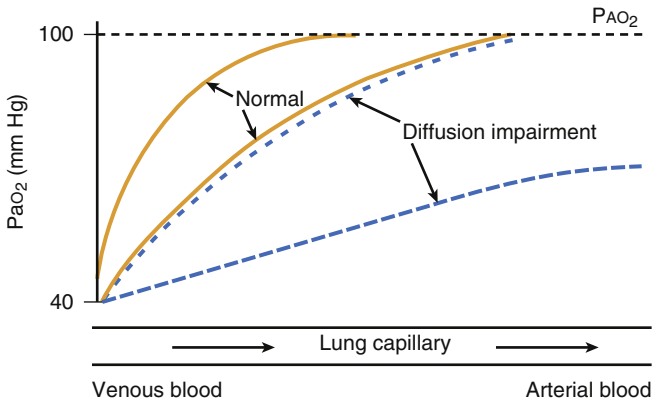

Figure 19-12. Schematic of oxygenation of pulmonary capillary blood. In a healthy subject, there is a rapid equilibration (<30% capillary length) of the oxygen tension in capillary blood with that in alveolar gas; however, during exercise, the flow rate is greater (i.e., transit time shorter) and most of the capillary distance is used before equilibration is reached. This effect can be offset by distention and recruitment of pulmonary capillaries. If diffusion is impaired, equilibration takes longer, and it might not occur with exercise.

builds up in capillary blood, the diffusion rate slows down and becomes zero when pressure is equilibrated across the alveolar-capillary wall. At rest, equilibrium is usually reached within 25% to 30% of the capillary length, and almost no gas transfer occurs in the remaining capillary (Fig. 19-12). However, during exercise or stress (i.e., high cardiac output), blood flow through the capillary is faster, and a longer capillary distance is required before equilibrium is reached. Thickened alveolar-capillary membranes will also prolong the equilibration process and, if severe, can prevent equilibration occurring and increasing the propensity to hypoxemia. If the mixed venous PO_2 ($P_{mv}O_2$) is lower than normal, the driving pressure increases and partially compensates towards achieving equilibrium with alveolar O_2. The driving pressure is expressed:

$$\Delta P = (PaO_2 - P_{mv}O_2)\ mm\ Hg$$

Most of the oxygen that dissolves in plasma diffuses into the red cell and binds to hemoglobin; therefore, 1 L of blood (Hb 150 g/L) with a saturation of 98%—normal in arterial blood—carries 200 mL of Hb-bound O_2, compared with 3 mL that is dissolved (PaO_2 100 mm Hg). The Hb-bound oxygen creates no pressure in plasma, which is important because it allows much more oxygen to diffuse over the membranes before a pressure equilibration is reached. Anemia (or prior CO exposure) reduces—and polycythemia increases—diffusion capacity.

Molecular Weight and Solubility

The rate of diffusion of a gas is inversely related to the square root of its molecular weight (MW); the larger the molecule, the slower the diffusion. O_2 is a light gas (MW 32) and CO_2 is heavier (MW 44). However, diffusion is also directly proportional to solubility in tissue, and CO_2 is almost thirtyfold times more soluble than O_2. The aggregate effect is that CO_2 diffuses about twentyfold faster than O_2[84]; therefore, there is no lung disease compatible with life that measurably impairs CO_2 diffusion.

INTRAOPERATIVE RESPIRATORY EVENTS

RESPIRATORY FUNCTION DURING ANESTHESIA

Anesthesia impairs pulmonary function, whether the patient is breathing spontaneously or is receiving mechanical ventilation. Impaired oxygenation of blood occurs in most subjects who are anesthetized,[85] and this is why supplemental O_2 (Fio_2 usually 0.3 to 0.5) is almost invariably used. Mild to moderate hypoxemia (SaO_2, 85% to 90%) is common and lasts from seconds to minutes; sometimes it is severe, and approximately 20% of patients may suffer from SaO_2 less than 81% for up to 5 minutes.[86] Indeed, greater than 50% of claims in anesthesia-related deaths relate to hypoxemia during anesthesia.[2] Beyond the operating room, the alterations in lung function acquired during anesthesia persist: clinically significant pulmonary complications can be seen in 1% to 2% patients after minor surgery, and in up to 20% of patients after more major upper abdominal or thoracic surgery.[87] Such consequences of anesthesia place prime importance on ascertaining the causes of perioperative respiratory dysfunction and the clinical approaches to treatment.

In this section, w describe the effects of anesthesia and mechanical ventilation on lung function. The arrangement of this section parallels the sequence of events involved in oxygenating the blood and removing CO_2. Thus, the first phenomenon that might be seen with anesthesia is loss of muscle tone with a subsequent change in the balance between outward forces (i.e., respiratory muscles) and inward forces (i.e., elastic tissue in the lung) leading to a fall in FRC. This causes or is paralleled by an increase in the elastic behavior of the lung (reduced compliance) and an increase in respiratory resistance. The decrease in FRC affects the patency of lung tissue with the formation of atelectasis (made worse with the use of high concentrations of inspired oxygen) and airway closure. This alters the distribution of ventilation and matching of ventilation and blood flow and impedes oxygenation of blood and removal of carbon dioxide.

LUNG VOLUME AND RESPIRATORY MECHANICS DURING ANESTHESIA

Lung Volume

Resting lung volume (i.e., FRC), is reduced by almost 1 L by moving from upright to supine position; induction of anesthesia further decreases the FRC by approximately 0.5 L.[88] This reduces the FRC from approximately 3.5 to 2 L, a value close to RV. General anesthesia causes a fall in FRC (approximately 20%), whether breathing is controlled or spontaneous[89,90] and whether the anesthetic is inhalational or intravenous[91]; this is a major contributor to lowered oxygenation (discussed later). Muscle paralysis in the context of general anesthesia does not cause additional reduction in FRC.

The anatomic basis of the FRC reduction is not well understood. A landmark experiment on three volunteers using two-dimensional tomography suggested that a cephalad shift of the diaphragm, induced by anesthesia

and paralysis, was responsible.[92] Recent studies using CT scanning also suggest cephalad diaphragm shift, as well as a decrease in the transverse chest area.[91,93] However, other data suggest little role for the diaphragm, with possible caudal (not cephalad) shift of its anterior aspect.[94] Simple CT suggests a cranial displacement except in severe obstructive lung disease. Although the anatomic components of reduced FRC are debatable, the mechanism appears to be related to loss of respiratory muscle tone. FRC is maintained by a balance of the forces inward (lung recoil) versus forces outward (chest wall recoil, chest wall muscles, diaphragm). For example, maintenance of muscle tone using ketamine as the anesthetic does not reduce FRC.[91] Because patients are usually supine, the FRC will already have been reduced, and in elderly patients, this is particularly the case; in this context, the effects of anesthesia are more marked (see Fig. 19-9). As can be seen in the figure, FRC decreases with age assuming that weight does not change.

Compliance and Resistance of the Respiratory System

Static compliance of the total respiratory system (lungs and chest wall) is reduced on average from 95 to 60 mL/cm H_2O during anesthesia.[95] Most studies of lung compliance during anesthesia indicate a decrease compared with the awake state, and pooled data from several studies suggest that anesthesia is associated with a reduction in mean static compliance from almost 190 to approximately 150 mL/cm H_2O.[95] Data on changes in respiratory resistance are less clear. Although most studies suggest that anesthesia increases respiratory resistance, especially during mechanical ventilation,[95] no studies have corrected for lung volume and flow rates (both affect resistance considerably), and it is possible that changes in resistance occur merely because of volume (i.e., FRC) loss (Fig. 19-13).

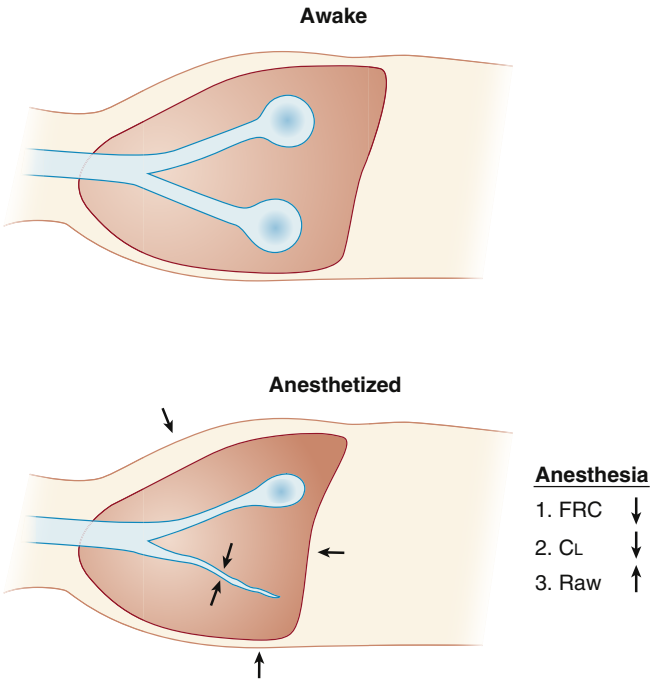

Figure 19-13. Anesthesia induces cranial shift of the diaphragm and a decrease of transverse diameter of the thorax. These effects contribute to a lowered functional residual capacity (FRC). The decreased ventilated volume (atelectasis and airway closure) can contribute to reduced compliance (C_L). Decreased airway dimensions by the lowered FRC can contribute to increased airway resistance (Raw).

ATELECTASIS AND AIRWAY CLOSURE DURING ANESTHESIA

The classic article by Bendixen and colleagues[96] proposed "a concept of atelectasis" as a cause of impaired oxygenation and reduced respiratory compliance during anesthesia.[96] That study described a progressive decrease in compliance that paralleled decreases in oxygenation in both anesthetized humans and experimental animals, which was interpreted as progressive of atelectasis. However, others noticed an abrupt decrease in compliance and PaO_2 during induction of anesthesia, and yet atelectasis could not be shown on conventional chest radiography.

Since then, CT scanning has improved our knowledge of the nature of anesthesia-induced atelectasis, and the technique reveals prompt development of densities in the dependent regions of both lungs during anesthesia (data up to 1990 reviewed by Moller and associates[86,97]). Morphologic studies of these densities in various animals supported the diagnosis of atelectasis. An example of atelectasis as seen on a CT scan is shown in Figure 19-14.

Atelectasis develops in approximately 90% of patients who are anesthetized, but it is unrelated to the choice of

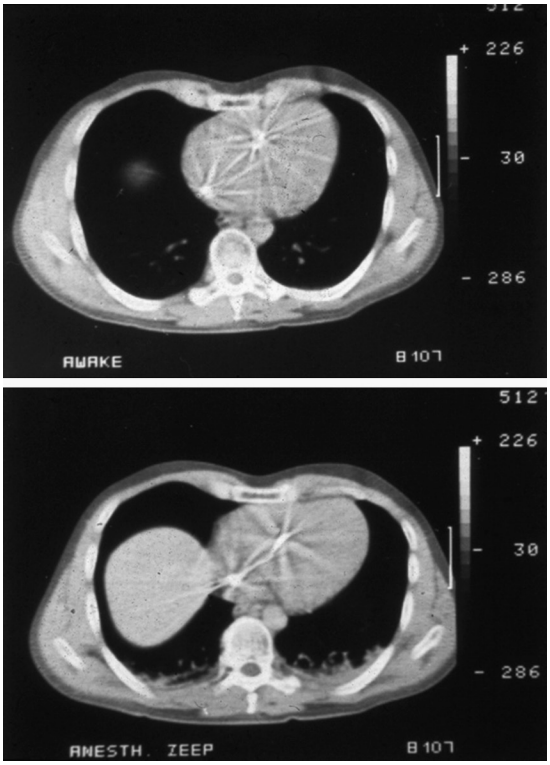

Figure 19-14. Computed tomography with transverse exposures of the chest when the subject is awake (upper panel) and anesthetized (lower panel). In the awake condition, the lung is well aerated (radiations from a pulmonary artery catheter are seen in the heart). During anesthesia, atelectasis has developed in the dependent regions (grey/white irregular areas). The large grey/white area in the middle of the right lung field is caused by a cranial shift of the diaphragm and the underlying liver.

anesthesia.[98] It is seen during spontaneous breathing and after muscle paralysis and when intravenous or inhaled anesthetics are used.[91] The atelectatic area near the diaphragm is 5% to 6% of the total lung area, but can easily exceed 20%. The amount of lung tissue that is collapsed is larger, because the atelectatic area consists mostly of lung tissue, whereas normal aerated lung consists of 20% to 40% tissue (the rest being air). Thus, 15% to 20% of the lung is atelectatic during uneventful anesthesia, before surgery has commenced; it decreases toward the apex, which usually remains aerated (Fig. 19-15). However, this degree of atelectasis is larger (upwards of 50% of lung volume) after thoracic surgery or cardiopulmonary bypass, and can last for several hours.[99] Abdominal surgery adds little to the atelectasis, but after such surgery it can persist for several days.[100]

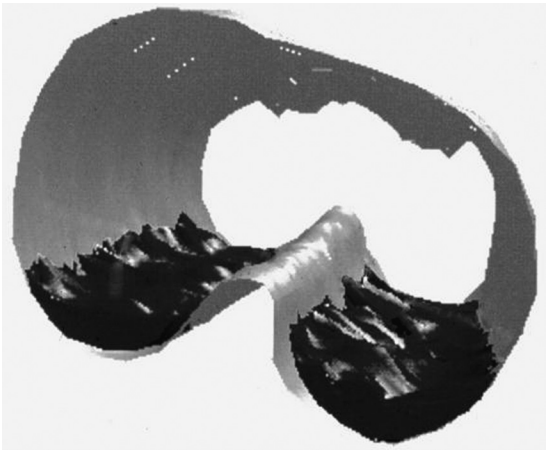

Figure 19-15. A three-dimensional reconstruction of the thorax of an anesthetized patient with atelectasis in the dependent regions of both lungs. There is a slight decrease in the degree of atelectasis toward the apex (distal in this image). *(Data from Reber A, Nylund U, Hedenstierna G: Position and shape of the diaphragm: implications for atelectasis formation.* Anaesthesia *53:1054-1061, 1998.)*

Atelectasis is an important cause of hypoxemia: there is a strong and significant correlation between the degree of atelectasis and the size of the pulmonary shunt ($R = 0.81$), where atelectasis is expressed as the percentage of lung area just above the diaphragm on CT scan and shunt is expressed as the percentage of cardiac output using the multiple inert gas elimination technique (MIGET).[98] The site of the increased shunt has been colocalized to the areas of atelectasis, using a technique that combines CT scanning and single photon emission computed tomography (SPECT; Fig. 19-16).[101] In addition to shunt, atelectasis may form a focus of infection and can certainly contribute to pulmonary complications.[102]

Aside from anesthesia (and the type of surgery), it is difficult to predict the development of atelectasis. Although obesity is associated with greater degrees of atelectasis, there is only poor correlation between the magnitude of the body weight (or body mass index [BMI]) and the extent of atelectasis.[89,91] Moreover, neither age[98] nor the presence of COPD[103] predicts the development or extent of atelectasis. In COPD, it may be that airway closure precedes (and therefore prevents) alveolar closure. Alternatively, the greater loss of lung (elastic recoil) versus chest wall tissue may serve to protect against atelectasis.

PREVENTION OF ATELECTASIS DURING ANESTHESIA

Several interventions can help prevent atelectasis[97] or even reopen collapsed tissue, as discussed in the following paragraphs.

Positive End-Expiratory Pressure

The application of PEEP (10 cm H_2O) has been repeatedly demonstrated to reexpand atelectasis partially

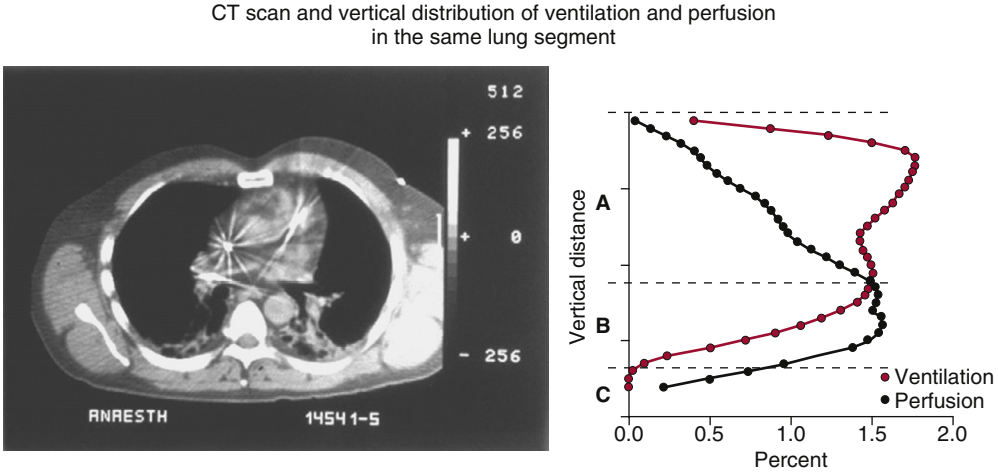

Figure 19-16. Atelectasis and distribution of ventilation and blood flow. The *left panel* is a cross-sectional slice of a computed tomographic image of the chest of an anesthetized patient, illustrating atelectasis in the basal (dorsal) regions. The *right panel* illustrates the distribution of ventilation and perfusion throughout that slice. The bulk of the ventilation is to the upper lung region (zone *A*), in contrast to the awake subject without atelectasis, and it exceeds the level of local perfusion; this results in wasted ventilation (i.e., deadspace) in the upper regions. In the lower region (zone *B*), the ventilation is less (probably because of intermittent airway closure) and is exceeded by the local perfusion, resulting in areas of low $\dot{V}_A/\dot{Q}$, causing hypoxemia. In the next lowest region (zone *C*), there is complete cessation of ventilation because of atelectasis, but some perfusion exists and causes a shunt. The farther from the top of the lung, the higher the perfusion; however, in the lowermost regions perfusion decreases (see text). *(Data from Hedenstierna G: Alveolar collapse and closure of airways: regular effects of anaesthesia,* Clin Physiol Funct Imaging *23:123-129, 2003.)*

(Fig. 19-17). Some atelectasis may persist and might require higher PEEP and inspiratory airway pressure.[91] The application of larger levels of PEEP can have complex effects. Reversal of hypoxemia is not proportionally associated with applied PEEP, and a threshold exists in many cases. In addition, SaO_2 may decrease during the application of increased PEEP for two reasons. First, the increased P_{PL} owing to the PEEP can impair venous return, especially in the presence of hypovolemia, lowering the cardiac output and DO_2 and thereby reducing mixed venous O_2 content ($C_{\bar{v}}O_2$). In the presence of an intrapulmonary shunt, such as with atelectasis, the mixed venous blood is shunted directly into pulmonary venous blood causing arterial desaturation. Second, increased PEEP can cause redistribution of blood flow away from the aerated, expanded regions (distended by PEEP) toward atelectatic areas (not distended by PEEP; Fig. 19-18).[104] In this context, persisting atelectasis in dependent lung receives a larger proportion of the total pulmonary blood flow than without PEEP.[59] Finally, anesthesia-induced atelectasis rapidly reemerges after discontinuation of PEEP.[91] Indeed, Hewlett and coworkers[105] in 1974 cautioned against "indiscriminate use of PEEP in routine anesthesia."

Recruitment Maneuvers

A sigh maneuver, or a large V_T, has been suggested for reversing atelectasis[10]; however, atelectasis is not uniformly reduced by a V_T increase or sigh up to P_{AW} of 20 cm H_2O.[106] Instead, a P_{AW} of 30 cm H_2O is required for initial opening, and 40 cm H_2O for more complete reversal (Fig. 19-19). In the presence of normal lungs, such inflation is equivalent to a VC and can therefore be called a *VC maneuver* (albeit achieved with positive P_{AW}). In addition, a significant hemodynamic effect is likely if the VC maneuver is sustained; in fact, inflation with a P_{AW} of 40 cm H_2O for 7 to 8 seconds appears to successfully open almost all anesthesia-induced atelectasis.[107]

Minimizing Gas Resorption

Although recruitment of anesthesia-induced atelectasis is completely possible with either PEEP or a VC maneuver, continuous application of some level of PEEP is required to prevent rapid recurrence of the atelectasis.[108] However, N_2—an insoluble gas that is not absorbed into the blood—can "splint" the alveolus if the alveolus is already opened. As a result, in anesthetized patients, a VC maneuver followed by ventilation with a gas mixture containing 60%

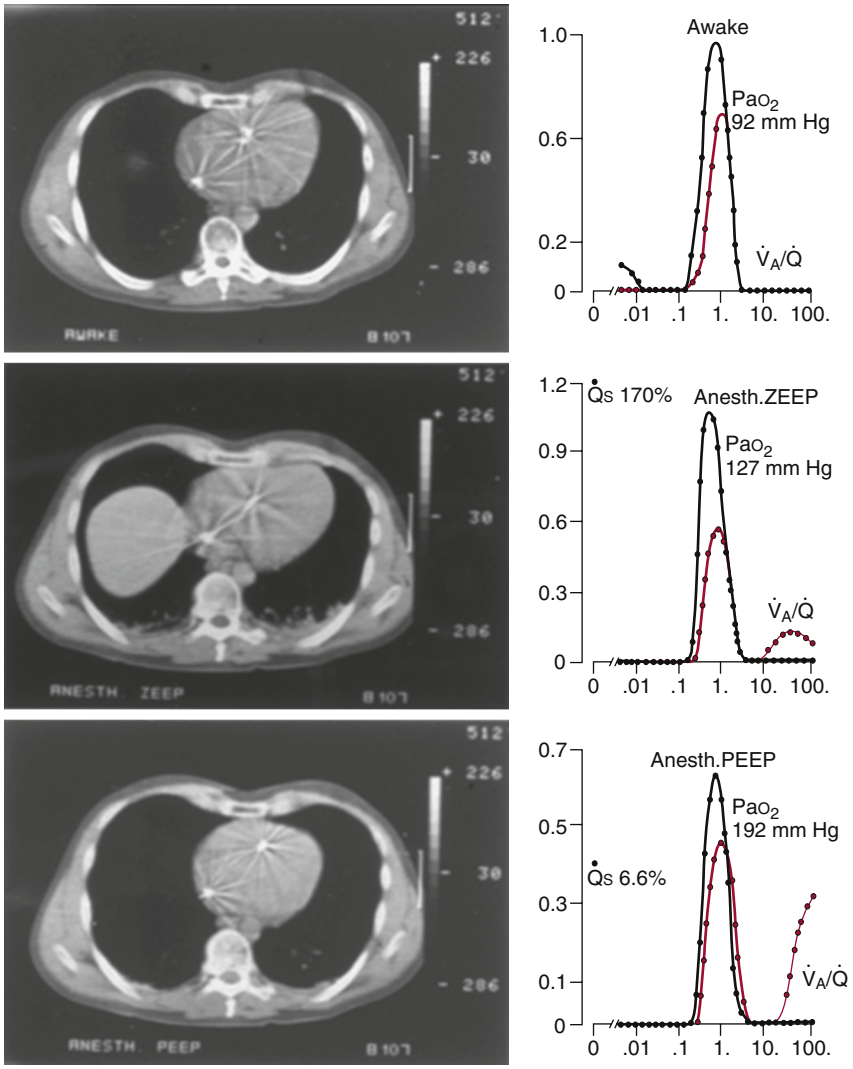

Figure 19-17. Computed tomographic scans and $\dot{V}_A/\dot{Q}$ distributions in the lung of a healthy, awake subject during anesthesia (zero positive end-expiratory pressure [ZEEP]) and during anesthesia (10 cm H_2O positive end-expiratory pressure [PEEP]). In the awake state, there is no atelectasis and the corresponding minor low $\dot{V}_A/\dot{Q}$ distribution (*left side* of plot) may reflect intermittent airway closure. During anesthesia with ZEEP, atelectasis is apparent in the lung bases (and the diaphragm has been pushed cranially). The low $\dot{V}_A/\dot{Q}$ has been replaced by atelectasis and large shunt; in addition, a small "high" $\dot{V}_A/\dot{Q}$ mode (right side of plot) may reflect alveolar dead space in upper lung regions. With the addition of PEEP during anesthesia, the collapsed lung tissue has been recruited and the shunt has been reduced considerably. Moreover, the "high" $\dot{V}_A/\dot{Q}$ mode (*right side* of plot) has significantly increased; this may reflect additional inflation of nonperfused upper lung.

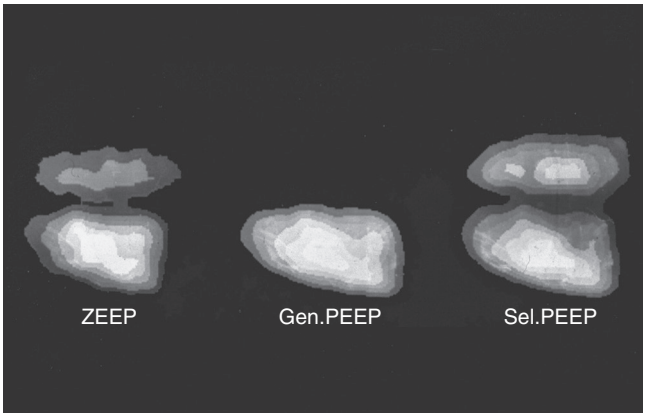

Figure 19-18. Gamma camera images of lung blood flow in an anesthetized subject in the lateral position. During mechanical ventilation with zero end-expiratory pressure (ZEEP), perfusion is predominantly (60% to 70% of cardiac output) to the lower lung. Applying PEEP (10 cm H_2O) to both lungs forces more perfusion to the lower lung, leaving almost no perfusion to the upper lung (i.e., major increase in V_D). In contrast, selective application of PEEP to the lower lung causes redistribution of perfusion to the upper lung. Of course, the image presented is perfused tissue (not total anatomic lung tissue; in the right lateral position the upper-right lung would be larger). *(From Hedenstierna G et al: Ventilation and perfusion of each lung during differential ventilation with selective PEEP,* Anesthesiology *61:369-376, 1984.)*

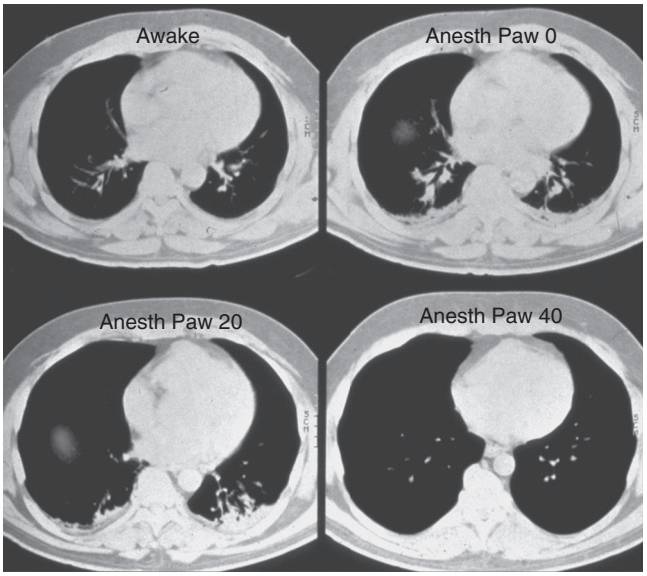

Figure 19-19. Computed tomographic (CT) scans during awake and anesthetized states with altered airway pressure (P_{AW}). The CT scan in the awake subject (*upper left panel*) shows normal vasculature and no atelectasis. During anesthesia (P_{AW}, 0 cm H_2O; *upper right panel*), bilateral basal atelectasis is seen; the PAW is increased in increments (20 cm H_2O shown), but the atelectasis is not reversed until a P_{AW} of 40 cm H_2O is applied (*lower right panel*). Thus, a vital capacity maneuver was required to open the lung. *(From Rothen HU et al: Re-expansion of atelectasis during general anaesthesia: a computed tomography study,* Br J Anaesth *71:788-795, 1993.)*

N_2 (40% O_2) reduced the propensity for reaccumulation of atelectasis with only 20% reappearing 40 minutes after recruitment.[108]

The same principles apply in the practice of preoxygenation of patients during induction of anesthesia.

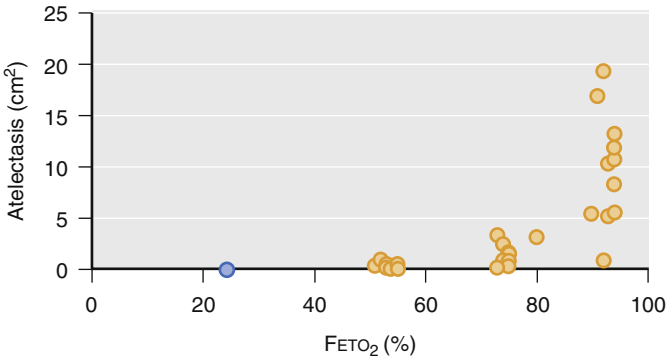

Figure 19-20. Atelectasis formation in anesthetized subjects following preoxygenation with different inspired oxygen concentrations. Increasing the Fio_2 during preoxygenation increases the propensity to subsequent atelectasis (closed symbols), although there is much variability. The open circle at around an expired oxygen concentration (FeO_2) of 25% represents data from anesthesia being induced while breathing 30% O_2. *(From Rothen HU et al: Prevention of atelectasis during general anaesthesia,* Lancet *345:1387-1391, 1995.)*

Here, the aim is to prevent O_2 desaturation (i.e., gain an O_2 safety margin) during induction before the airway has been secured when the anesthesiologist can better manage ventilation and oxygenation. Traditionally, the application of Fio_2 1.0 has been used. Although the SaO_2 is usually well maintained with this approach, atelectasis inevitably forms. The use of 30% versus 100% O_2 during induction was demonstrated in a clinical study to eliminate the formation of atelectasis.[109] Later, a comparison of breathing 100%, 80%, and 60% O_2 during induction demonstrated ubiquitous atelectasis with 100%, less with 80%, and even less with 60% O_2 (Fig. 19-20); however, the trade-off for less atelectasis was a shorter safety margin before occurrence of O_2 desaturation.[110]

An alternative approach may be continuous positive airway pressure (CPAP). Application of CPAP 10 cm H_2O permitted the use of 100% inspired O_2 without formation of significant degrees of atelectasis.[111] This might provide an ideal combination of minimal risk of either O_2 desaturation or atelectasis, but it has not been repeatedly verified.

Maintenance of Muscle Tone

Because loss of muscle tone in the diaphragm or chest wall appears to increase the risk of atelectasis, techniques that preserve muscle tone may have advantages. Intravenous ketamine does not impair muscle tone and is the only individual anesthetic that does not cause atelectasis. If neuromuscular blockade is added, atelectasis occurs as with other anesthetics.[91] Ketamine is an extremely useful agent in special circumstances, but it has significant challenges in routine cases.

An experimental approach is restoration of respiratory muscle tone by diaphragm pacing. This approach is achieved with phrenic nerve stimulation, and it can modestly reduce the degree of atelectasis; however, the effect is minor and the approach complicated.[112]

Atelectasis Following Surgery

Hypoxemia is common after anesthesia and surgery. It is enhanced by breathing oxygen before induction of

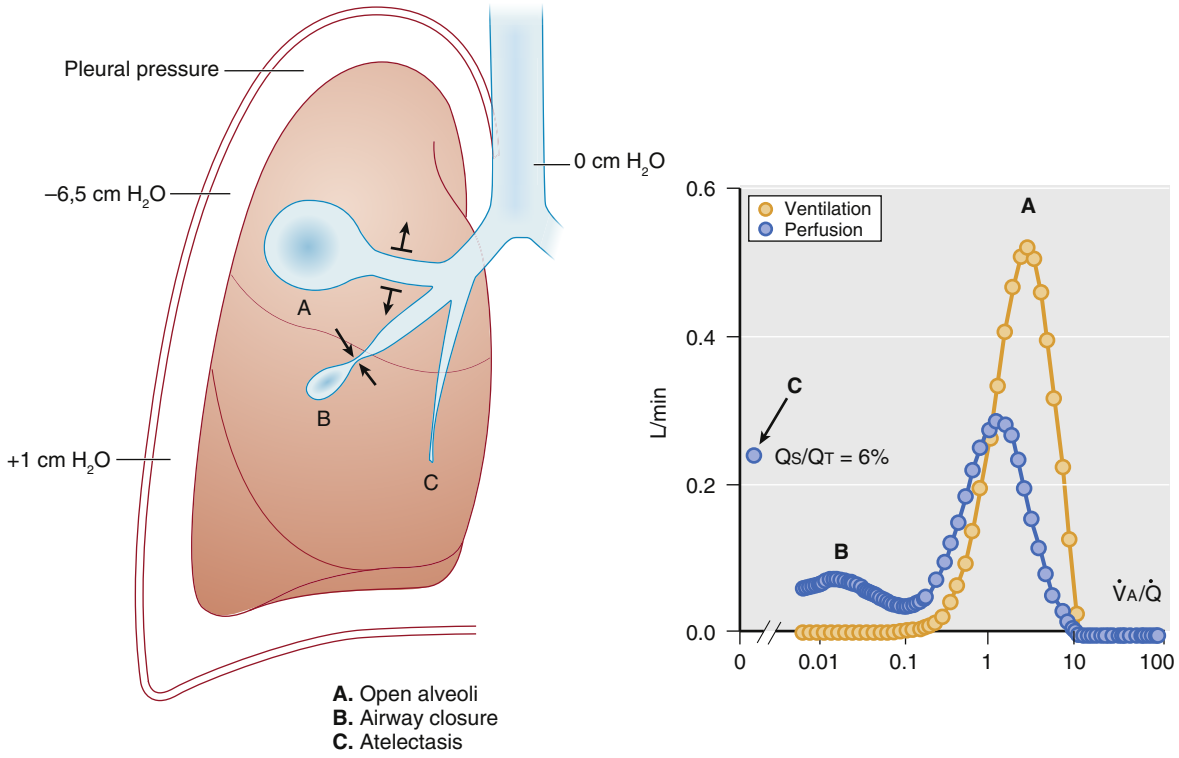

Figure 19-21. A three-compartment model of ventilation and perfusion during anesthesia. In the upper regions, the alveoli and airways are open (*left panel, A*). In the middle region, the airways are intermittently closed (*B*), and atelectasis is present in the lower region (*C*). The corresponding ventilation-perfusion distribution (multiple inert gas elimination technique) is illustrated in the *right panel*. Mode *A* reflects good ventilation and perfusion, whereas mode *B* reflects intermittent airway closure. In addition, there is a shunt in the atelectatic region (mode *C*).

anesthesia and suctioning of the airway (negative pressure) before extubation of the trachea. In addition, splinting and inhibition of coughing associated with pain can cause atelectasis postoperatively. Several approaches have been tried to address such atelectasis-associated hypoxemia following surgery. Administration of 100% O_2 coupled with a VC maneuver is not effective; this is probably because while the VC maneuver recruits lung, alveolar opening is not maintained (in fact closure is encouraged by the N_2-free O_2).[113] However, a VC maneuver followed by a lower O_2 concentration (40% O_2 in N_2) can maintain an open lung until the end of anesthesia.[107] Oxygenation is sustained for a longer period following ventilation with 50% O_2 in air (i.e., N_2) compared with 100%, following cardiopulmonary bypass.[114] Finally, treatment of postoperative hypoxemia, considered to be due to atelectasis, is associated with better outcomes when CPAP is used instead of 100% O_2.[115]

AIRWAY CLOSURE

Intermittent airway closure reduces ventilation of the affected alveoli. Such lung regions can become regions of low $\dot{V}_A/\dot{Q}$ if perfusion is maintained or is not reduced to the same degree as ventilation. The propensity to airway closure increases with age[49] (see Fig. 19-9), as does perfusion to low $\dot{V}_A/\dot{Q}$ regions.[116] Anesthesia reduces FRC by about 0.5 L,[88] which increases airway closure during tidal ventilation.[117,118] In fact, the reduction in ventilation in the nonatelectatic lung (Fig. 19-21) is caused by airway closure. In addition, ventilation in these regions is less than perfusion (i.e., regions of low $\dot{V}_A/\dot{Q}$) and contributes to impaired oxygenation during anesthesia. Taken together, the combination of atelectasis and airway closure explain about 75% of the overall impairment in oxygenation.[89] In addition, where (CV – ERV) indicates the amount of airway closure occurring above FRC (and ERV is expiratory reserve volume), this value increased with induction of anesthesia, and there is good correlation between low $\dot{V}_A/\dot{Q}$ and the extent of airway closure.[89] In summary, a simple three-compartment lung model (normal $\dot{V}_A/\dot{Q}$ matching regions, region of airway closure, and atelectatic lung) describes well the components contributing to impairment of oxygenation during anesthesia (see Fig. 19-21).

DISTRIBUTION OF VENTILATION AND BLOOD FLOW DURING ANESTHESIA

Distribution of Ventilation

Redistribution of inspired gas away from dependent to nondependent lung regions has been demonstrated, using isotope techniques in anesthetized supine humans. Radiolabeled aerosol and SPECT demonstrate that ventilation is distributed mainly to the upper lung regions, with a successive decrease toward the lower lung regions, and an absence of ventilation in the lowermost regions, a finding consistent with the atelectasis demonstrable using CT (see Fig. 19-16).[101]

Recruitment maneuvers increase dependent lung ventilation in anesthetized subjects in the lateral[119] and supine[120] positions, restoring the distribution of ventilation to that in the awake state. Thus, restoration of overall FRC toward the awake level returns gas distribution toward the awake pattern. The explanations are recruitment of atelectatic lung, reopening of closed airways, and further expansion of already expanded (upper) lung regions, decreasing regional compliance and lessening incremental ventilation.

Distribution of Lung Blood Flow

The distribution of lung blood flow has been studied by injection of radioactively labeled macroaggregated albumin and SPECT.[101] During anesthesia, a successive increase in perfusion occurs from upper towards lower regions, with a slight drop in perfusion in the lowermost portion of the lung, which was atelectatic on simultaneous CT (see Fig. 19-16). PEEP will impede venous return to the right heart and reduce cardiac output. It can also affect pulmonary vascular resistance, although this would have little effect on cardiac output. In addition, PEEP redistributes blood flow toward dependent lung regions,[59,120] reducing flow (and increasing deadspace) in the upper lung; the increased dependent flow may increase shunt through atelectatic lung.[104]

HYPOXIC PULMONARY VASOCONSTRICTION

Several inhaled—but not intravenous—anesthetics inhibit HPV in isolated lung preparations.[121] Human studies of HPV are complex with multiple parameters changing simultaneously, thereby confounding the HPV response with changes in cardiac output, myocardial contractility, vascular tone, blood volume distribution, pH, P_{CO_2}, and lung mechanics. However, studies with no obvious changes in cardiac output, isoflurane and halothane depress the HPV response by 50% at a minimum alveolar concentration (MAC) of 2 (Fig. 19-22).[122]

VENTILATION-PERFUSION MATCHING DURING ANESTHESIA

DEAD SPACE, SHUNT, AND VENTILATION-PERFUSION RELATIONSHIPS

CO_2 Elimination

Anesthesia impairs CO_2 elimination and oxygenation of blood. The explanation for reduced CO_2 elimination is reduced minute ventilation ($\dot{V}_E$) because of respiratory depression, or where this is preserved, because of an increase in the V_D/V_T. Single-breath washout recordings demonstrate that "anatomic" dead space is unchanged, indicating that increased V_D/V_T is alveolar and confirmed by MIGET scan (Fig. 19-23).[10] Such high $\dot{V}_A/\dot{Q}$ can be explained by the tiny perfusion of corner vessels in interalveolar septa in the upper lung regions, where alveolar pressure can exceed pulmonary vascular pressure (zone I).[85] The impaired CO_2 elimination is most easily corrected by increasing the ventilation and is seldom a problem in routine anesthesia with mechanical ventilation.

Oxygenation

The impairment in arterial oxygenation during anesthesia is more marked with increased age, obesity, and smoking (see Chapter 80).[123,124] Venous admixture, as calculated by the standard oxygen shunt equation, is also increased during anesthesia to approximately 10% of cardiac output. However, this is an averaged calculation that considers hypoxia caused by pure shunt only, when actually it is due to a combination of "true" shunt (i.e., perfusion of nonventilated lung), poor ventilation of some regions, and regions that are ventilated but are perfused in excess of their ventilation (low $\dot{V}_A/\dot{Q}$ regions). The combination of these effects is called *venous admixture*. The shunt equation (derived in Box 19-2) assumes that all blood flow through the lung goes to either of two compartments: in one (the non–shunt fraction), all the blood is oxygenated; and in the other (the shunt fraction), all blood is shunted.

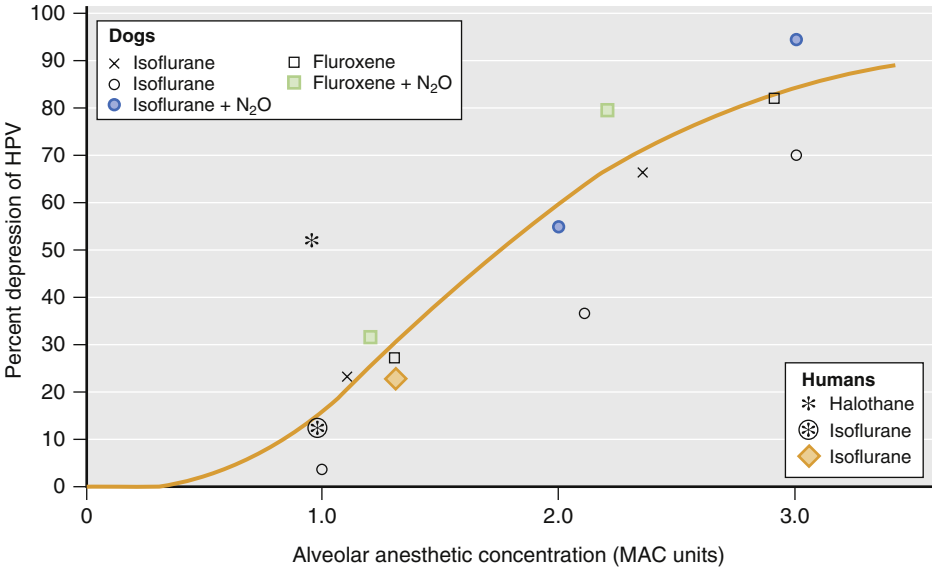

Figure 19-22. Effect of inhaled anesthetics on hypoxic pulmonary vasoconstriction (HPV). A concentration of 1 MAC causes a 20% to 30% depression of HPV, and the HPV depression decreases sharply with higher concentrations. The effect is that the shunt (i.e., perfusion through nonventilated regions) will be less reduced during inhalational anesthesia. *(From Marshall BE: Hypoxic pulmonary vasoconstriction,* Acta Anaesthesiol Scand Suppl *94:37-41, 1990.)*

The shunt equation (or venous admixture) can be written[125]:

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{(C_cO_2 - C_aO_2)}{(C_cO_2 - C_{\bar{v}}O_2)}$$

Because pulmonary end-capillary blood is assumed to be maximally saturated (therefore, $S_cO_2 = 1$), the quantity of dissolved O_2 can be ignored, and it can be the difference between $C_{\bar{v}}O_2$ and $C_{\bar{v}}O_2$ can be assumed to be small ($C_vO_2 = C_{\dot{v}}O_2$):

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{(1 - S_aO_2)}{(1 - S_vO_2)}$$

Thus, the effect of interventions on estimated shunt can be calculated easily from the changes in SaO_2 and SvO_2.

The extent of venous admixture depends on the inspired oxygen fraction (Fio_2). The higher the inspired oxygen fraction, the less there are of the low $\dot{V}_A/\dot{Q}$ regions. However, with high Fio_2, regions with low $\dot{V}_A/\dot{Q}$ may collapse because of gas adsorption and be transformed to shunt regions.[126] A good correlation between venous admixture vs. the sum of "true" shunt and perfusion of low $\dot{V}_A/\dot{Q}$ regions was seen in a study involving 45 anesthetized subjects (Fig. 19-24).[98] Derivation of the "oxygen shunt" or venous admixture is shown in Box 19-2.

In young healthy volunteers during anesthesia with thiopental and methoxyflurane, both ventilation and perfusion were distributed to wider ranges of $\dot{V}_A/\dot{Q}$ ratios,

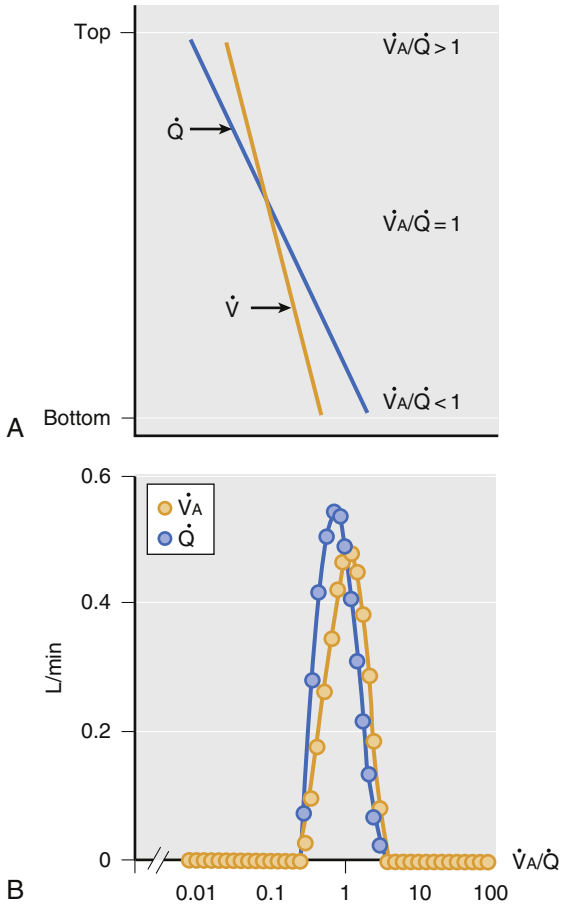

Figure 19-23. A schematic drawing of **(A)** the vertical distributions of ventilation ($\dot{V}_A$) and blood flow through the lung ($\dot{Q}$) and **(B)** the resulting ventilation-perfusion distribution ($\dot{V}_A/\dot{Q}$). The $\dot{V}_A/\dot{Q}$ distribution is centred at a ratio of 1, corresponding to the intersection of the ventilation and perfusion distribution curves. The slightly larger ventilation than perfusion in upper lung regions contribute to the high $\dot{V}_A/\dot{Q}$ ratios greater than 1, whereas the larger perfusion than ventilation in the lower part of the lung is the cause of the lower $\dot{V}_A/\dot{Q}$ ratios, less than 1. Although there is a moderate increase in ventilation down the lung, the increase in perfusion is greater.

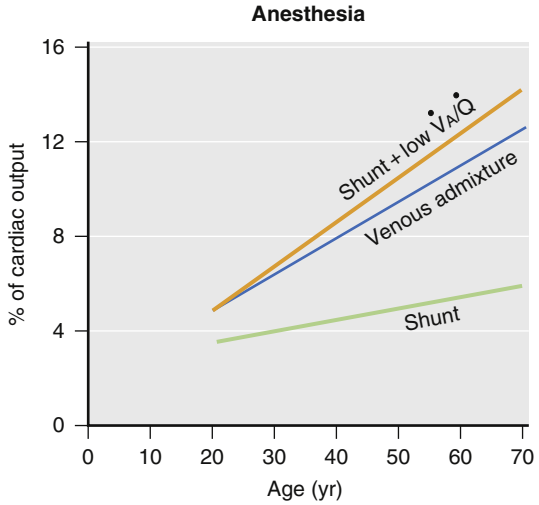

Figure 19-24. The effect of age on oxygenation during anesthesia. The combination of shunt with low $\dot{V}_A/\dot{Q}$ increases sharply with age (as does the degree of venous admixture). The increase in shunt with age, while significant, is less striking. *(From Gunnarsson L et al: Influence of age on atelectasis formation and gas exchange impairment during general anaesthesia,* Br J Anaesth *66:423-432, 1991.)*

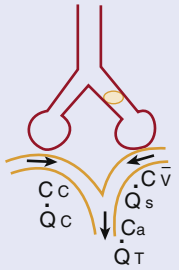
BOX 19-2 *Derivation of the Venous Admixture (Shunt) Equation*



$$Ca \times \dot{Q}_T = \left(Cc' \times \dot{Q}_C\right) + \left(C\bar{v} \times \dot{Q}_S\right) \quad (1)$$

$$\dot{Q}_C = \dot{Q}_T - \dot{Q}_S \quad (2)$$

By inserting Equation 2 (accounts for all blood flow through the lungs) into Equation 1 (accounts for all oxygen carriage through the lungs),

$$Ca \times \dot{Q}_T = \left(Cc \times \left[\dot{Q}_T - \dot{Q}_S\right]\right) + (C\bar{v} \times \dot{Q}_S)$$

Rearranging,

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{Cc' - Ca}{Cc' - C\bar{v}}$$

where Cc', Ca, and Cv are oxygen content in pulmonary end-capillary, arterial, and mixed venous blood, respectively; $\dot{Q}_T$ is cardiac output; $\dot{Q}_C$ is capillary flow; and $\dot{Q}_S$ is shunt.

which can be expressed as an increase in the logarithmic standard deviation of the perfusion distribution (log SD$\dot{Q}$). In a similar group of patients studied during halothane anesthesia and muscle paralysis, log SD$\dot{Q}$ was almost doubled (0.43 awake, 0.80 during anesthesia). In addition, true shunt was increased to a mean of 8%. A similar increase in shunt from 1% awake to a mean of 9% during anesthesia was recorded in a study on middle-aged (37 to 64 years) surgical patients, and there was a widening of the distribution (log SD$\dot{Q}$: 0.47 awake, 1.01 during anesthesia). In older patients with more severe impairment of lung function, halothane anesthesia with muscle paralysis, with or without nitrous oxide, caused considerable widening of the $\dot{V}_A/\dot{Q}$ distribution (log SD$\dot{Q}$ 0.87 awake, 1.73 during anesthesia). In addition, shunt increased to a mean of 15%, with large variation among patients (0% to 30%). Thus, the most consistent findings during anesthesia are an increased $\dot{V}_A/\dot{Q}$ mismatch, expressed as an increased log SDQ, and an increase in shunt. For review, see the article by Hedenstierna.[85]

Spontaneous ventilation is frequently reduced during anesthesia; therefore, inhaled anesthetics[127] or barbiturates[128] reduce sensitivity to CO_2. The response is dose-dependent; ventilation decreases with deepening anesthesia. Anesthesia also reduces the response to hypoxia, possibly because of effects on the carotid body chemoreceptors.[129]

The effects of anesthesia on respiratory muscle function are becoming better understood.[130] The effects are not uniform. Rib cage excursions diminish with deepening anesthesia.[131] The normal ventilatory response to CO_2 is produced by the intercostal muscles,[132,133] but with no clear increase in rib cage motion with CO_2 rebreathing during halothane anesthesia. Thus, the reduced ventilatory response to CO_2 during anesthesia is due to impeded function of the intercostal muscles.

FACTORS THAT INFLUENCE RESPIRATORY FUNCTION DURING ANESTHESIA

SPONTANEOUS BREATHING

Most studies of lung function have been performed on anesthetized, mechanically ventilated subjects or animals. Spontaneous breathing has been studied rarely. FRC decreases to the same extent during anesthesia, regardless of whether a muscle relaxant is used,[90,91] and atelectasis occurs to almost the same extent in anesthetized, spontaneously breathing subjects as during muscle paralysis.[134] Furthermore, the cranial shift of the diaphragm, as reported by Froese and Bryan,[92] was of the same magnitude both during general anesthesia with spontaneous breathing and with muscle paralysis, even though a difference in movement of the diaphragm from the resting position was noted. Thus, during spontaneous breathing, the lower, dependent portion of the diaphragm moved the most, whereas with muscle paralysis, the upper, nondependent part showed the largest displacement.

All these findings have raised the question of whether regional ventilation is different between spontaneous breathing and mechanical ventilation and whether mechanical ventilation worsens $\dot{V}_A/\dot{Q}$ as a consequence of poor ventilation of well-perfused, dependent lung regions. However, there is not much support for worsening of gas exchange by muscle paralysis in the literature. There is also no support from the few studies of $\dot{V}_A/\dot{Q}$ distribution that have been performed. Dueck and colleagues[135] found the same increase in $\dot{V}_A/\dot{Q}$ mismatch in anesthetized sheep during anesthesia, regardless of whether they were spontaneously breathing or ventilated mechanically. The log SDQ, indicating the degree of mismatch, increased (0.66 [awake], 0.83 [inhaled anesthesia with spontaneous breathing], 0.89 [mechanical ventilation]). Shunt is also increased during anesthesia from 1% (awake) to 11% (anesthetized, spontaneous breathing) or 14% (anesthetized, mechanical ventilation). In a study of anesthetized human subjects, shunt and log SDQ increased from 1% and 0.47 while awake to 6% and 1.03 during anesthesia with spontaneous breathing and 8% and to 1.01 during mechanical ventilation.[85] Thus, most of the gas exchange effects of anesthesia occurs during spontaneous breathing, with little or no further derangement added by muscle paralysis and mechanical ventilation.

INCREASED OXYGEN FRACTION

In the studies cited thus far, an inspired oxygen fraction (Fio_2) of approximately 0.4 was used. Anjou-Lindskog and colleagues[136] induced anesthesia in subjects breathing air (Fio_2, 0.21) in middle-aged to older patients during intravenous anesthesia before elective lung surgery and found only small shunts of 1% to 2%, although log SDQ increased from 0.77 to 1.13. When Fio_2 was increased to 0.5, the shunt increased (by 3% to 4%). In another study of older patients during halothane anesthesia,[85] an increase in Fio_2 from 0.53 to 0.85 caused an increase in shunt from 7% to 10% of cardiac output. Thus, increasing Fio_2 increases shunt, possibly because of attenuation of HPV by increasing Fio_2[122] or further development of atelectasis and shunt in lung units with low $\dot{V}_A/\dot{Q}$ ratios.[126]

BODY POSITION

Functional residual capacity is reduced dramatically by the combined effect of the supine position and anesthesia (see Chapter 41). The effects on the FRC of inducing anesthesia in the upright position were tested by Heneghan and associates,[137] and there was no difference in oxygenation in the semirecumbent versus supine position. Decreased cardiac output and enhanced inhomogeneity of blood flow distribution can outweigh any effects of posture. Fractional perfusion of the most dependent lung regions—likely poorly or not ventilated—may actually have been increased in the semirecumbent position. In the lateral position, differences in lung mechanics, resting lung volumes, and atelectasis formation between the dependent and nondependent portions of the lung have been demonstrated[138] and shown to result in further disturbance of the ventilation-perfusion match, with severe impairment in oxygenation. However, there are large and unpredictable inter-individual variations.[139] Using isotope techniques, an increase in $\dot{V}_A/\dot{Q}$ mismatch was also demonstrated in anesthetized, paralyzed patients in the lateral position,[140] and an improvement was noticed in the prone position.[141]

In addition, the vertical inhomogeneity of perfusion distribution is less marked in the prone position,[69] possibly reflecting regional differences in vascular configuration that promote perfusion of dorsal lung regions, regardless of whether they are in a dependent or nondependent position. Finally, distribution of ventilation may be uniform in anesthetized subjects when prone.[142]

AGE

Oxygenation is less efficient in older patients (see Chapter 80).[10] However, the formation of atelectasis does not increase with age in adults, and the few CT studies of infants during anesthesia suggest greater degrees of atelectasis.[98] In addition, shunt is independent of age between 23 and 69 years. However, $\dot{V}_A/\dot{Q}$ mismatch increases with age, with enhanced perfusion of low $\dot{V}_A/\dot{Q}$ regions when awake and when anesthetized. The major cause of impaired gas exchange during anesthesia in those younger than 50 years is shunt, whereas beyond 50 years $\dot{V}_A/\dot{Q}$ mismatch (i.e., increased log SDQ) becomes increasingly important (see Fig. 19-24). Because the correlation between log SDQ and age during anesthesia is almost parallel with that during the awake state, it can be said that anesthesia worsens $\dot{V}_A/\dot{Q}$ matching to the same extent as 20 years of aging.

OBESITY

Obesity worsens oxygenation (see Chapter 71)[143,144] predominantly because of reduced FRC resulting in a greater propensity to airway closure.[145] In addition, the use of high inspired oxygen concentrations promotes rapid atelectasis formation in alveoli distal to closed airways,[89,110] and there are good correlations between BMI and the extent of atelectasis (both during and after anesthesia)[101,146] and between BMI and pulmonary shunt (Fig. 19-25).[145]

Preventing a decrease in FRC by applying CPAP during induction of anesthesia probably reduces atelectasis formation, and thereby maintains oxygenation.[124,147,148] Indeed, the reduced "safety window" (the time taken to develop desaturation following breathing oxygen before induction of anesthesia) is much reduced in obese patients, and this may be prolonged by PEEP or CPAP[149] increasing lung volume and increasing the reservoir of O_2 available for diffusion into the capillary blood.

The use of high levels of inspired oxygen concentration, often almost 100%, to keep an acceptable level of oxygenation during anesthesia and surgery may be the simplest but not necessarily the best approach. It will promote further atelectasis formation,[109] and if the shunt is larger than 30%, which may well be the case in these patients, additional oxygen will add little to arterial oxygenation.[150] The application of PEEP has been advocated, and it may reduce the atelectasis[123,145,147] but will also have adverse effects, such as reduced cardiac output and redistribution of blood flow toward residual collapsed lung regions. Ventilation with inflations close to VC to reopen collapsed tissue, followed by ventilation with added PEEP, is another option. Recruitment of the lung with an inflation to 55 cm H_2O opened essentially all collapsed lung tissue in patients with a BMI of 40 kg/m^2 or more.[151] However, a recruitment alone did not keep the lung open for more than a few minutes. To keep the lung open, a PEEP of 10 cm H_2O after the recruitment was needed. PEEP of 10 was not enough to open up the lung.[151] Body position can have a substantial effect on lung volume and should be considered to the extent that surgery allows.[152]

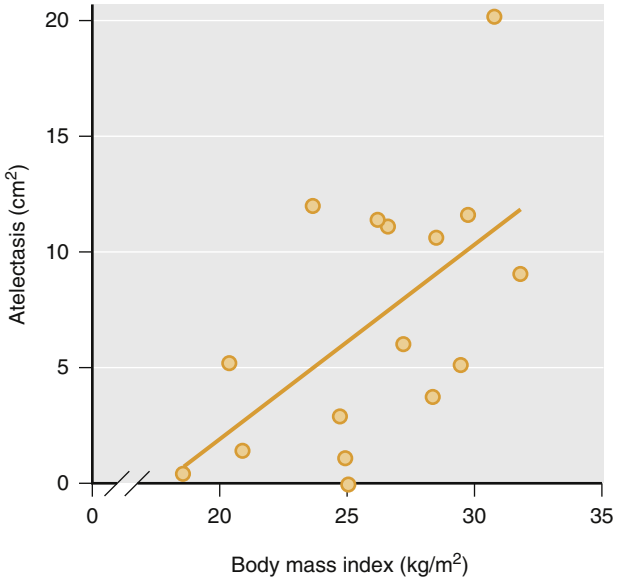


Figure 19-25. Relationship between body mass index (BMI) and extent of atelectasis during general anesthesia. As BMI increases, so does the extent of atelectasis (although there is considerable variability). *(From Rothen HU et al: Re-expansion of atelectasis during general anaesthesia: a computed tomography study,* Br J Anaesth *71:788-795, 1993.)*

PREEXISTING LUNG DISEASE

Smokers and patients with chronic lung disease have impaired gas exchange in the awake state, and anesthesia-associated deterioration in oxygenation is greater than in healthy individuals.[10] Interestingly, smokers with moderate airflow limitation may have less shunt as measured by MIGET than in subjects with healthy lungs. Thus, in patients with mild to moderate bronchitis who were to undergo lung surgery or vascular reconstructive surgery in the leg, only a small shunt was noticed, but log SDQ was increased.[85] In patients with chronic bronchitis studied by MIGET and CT, no or limited atelectasis developed during anesthesia and no or only minor shunt[103]; however, a considerable mismatch was seen with a large perfusion fraction to low $\dot{V}_A/\dot{Q}$ regions. Consequently, arterial oxygenation was more impaired than in lung-healthy subjects, but the cause was different from that in healthy subjects. A possible reason for the absence of atelectasis and shunt in these patients is chronic hyperinflation, which changes the mechanical behavior of the lungs and their interaction with the chest wall such that the tendency to collapse is reduced. It should be kept in mind that a patient with obstructive lung disease may have large regions with low $\dot{V}_A/\dot{Q}$ ratios that can be converted over time to resorption atelectasis. Thus, the protection against atelectasis formation during anesthesia by

TABLE 19-1 CAUSES OF HYPOXEMIA

Disturbance	Pao_2 (Breathing Air) at Rest	Pao_2 (Breathing Oxygen) at Rest	Pao_2 (Breathing air) With Exercise (Versus Rest)	$Paco_2$
Hypoventilation	Reduced	Normal	No change or further decrease	Increased
$\dot{V}_A/\dot{Q}$ mismatch	Reduced	Normal	No change or minor increase or decrease	Normal
Shunt	Reduced	Reduced	No change or further decrease	Normal
Diffusion impairment	Reduced	Normal	Small to large decrease	Normal

the obstructive lung disease might not last long. Regions with low $\dot{V}_A/\dot{Q}$ can be replaced by atelectasis as a result of slow absorption of gas behind occluded airways later during surgery and in the postoperative period.

REGIONAL ANESTHESIA

The ventilatory effects of regional anesthesia depend on the type and extension of motor blockade (see Chapters 56 and 57). With extensive blocks that include all the thoracic and lumbar segments, inspiratory capacity is reduced by 20% and expiratory reserve volume approaches zero.[153,154] Diaphragmatic function, however, is often spared, even in cases of inadvertent extension of subarachnoid or epidural sensory block up to the cervical segments.[153] Skillfully handled regional anesthesia affects pulmonary gas exchange only minimally. Arterial oxygenation and carbon dioxide elimination are well maintained during spinal and epidural anesthesia. This is in line with the findings of an unchanged relationship of CC and FRC[155] and unaltered distributions of ventilation-perfusion ratios assessed by MIGET during epidural anesthesia.[85]

CAUSES OF HYPOXEMIA AND HYPERCAPNIA

In the previous sections, we discussed ventilation, gas distribution, and the respiratory mechanics that govern distribution, diffusion, and pulmonary perfusion. All these components of lung function can affect the oxygenation of blood, and all except diffusion can also measurably affect CO_2 elimination. The different mechanisms behind hypoxemia and CO_2 retention, or hypercapnia or hypercarbia, have been mentioned previously but will be analyzed in more detail here.

Causes of hypoxemia include hypoventilation, $\dot{V}_A/\dot{Q}$ mismatch, impaired diffusion, and right-to-left shunt (Table 19-1). Hypercapnia is usually caused by hypoventilation although it can be caused by, $\dot{V}_A/\dot{Q}$ mismatch and shunt (Table 19-2). Increased $\dot{V}CO_2$ occurs in hypermetabolic conditions (e.g., fever, malignant hyperthermia, thyroid crisis) or with the use of CO_2-generating buffers such as $NaHCO_3$.

HYPOVENTILATION

If ventilation is low in proportion to metabolic demand, elimination of CO_2 will be inadequate, and CO_2 will accumulate in the alveoli, blood, and other body tissues. Hypoventilation is often defined as ventilation that results in a Pa_{CO_2} greater than 45 mm Hg (6 kPa). Thus, hypoventilation could be present even when minute ventilation is high, provided the metabolic demand or dead space ventilation is increased to a greater extent.

TABLE 19-2 MECHANISMS OF HYPOXEMIA IN DIFFERENT LUNG DISORDERS

Disorder	Hypoventilation	Diffusion Impairment	$\dot{V}_A/\dot{Q}$ Mismatch	Shunt
Chronic bronchitis	(+)	–	++	–
Emphysema	+	++	+++	–
Asthma	–	–	++	–
Fibrosis	–	++	+	+
Pneumonia	–	–	+	++
Atelectasis	–	–	–	++
Pulmonary edema	–	+	+	++
Pulmonary emboli	–	–	++	+
Acute respiratory distress syndrome	–	–	+	+++

The increased alveolar P_{CO_2} reduces the alveolar space available for oxygen. Alveolar PO_2 (PAO_2) can be estimated by the alveolar gas equation (see Box 19-1). The simplified equation is expressed:

$$PaO_2 = P_IO_2 - \left(Pa_{CO_2}/R\right)$$

Assuming that the respiratory exchange ratio (R) is 0.8 (more or less true at rest), PAO_2 can be estimated. In the ideal lung, PaO_2 equals PAO_2. For example, if PiO_2 is 149 mm Hg (19.9 kPa) and Pa_{CO_2} is 40 mm Hg (5.3 kPa), then PaO_2 is 99 mm Hg (13.2 kPa). If hypoventilation develops and the Pa_{CO_2} rises to 60 mm Hg (8 kPa) and there is no other gas exchange impairment, the PaO_2 will fall to 74 mm Hg (9.9 kPa). Clearly, a decrease in PaO_2 caused by hypoventilation is easily overcome by increasing PiO_2 (i.e., by increasing Fio_2). If there is a gap between the PAO_2 (estimated from this equation) and the measured (actual) PaO_2, then a cause of hypoxemia in addition to hypoventilation is present. These causes are discussed in the following paragraphs.

VENTILATION-PERFUSION MISMATCH

For optimal gas exchange, ventilation and perfusion must match each other in all lung regions. At rest, both ventilation and perfusion increase downward through the lung. However, perfusion increases more than ventilation, the

TABLE 19-3 **MEAN (SD) VENTILATION-PERFUSION RELATIONSHIPS WITH NO CARDIOPULMONARY DISEASE (NORMAL, *N* = 45), AWAKE AND DURING GENERAL ANESTHESIA AND MUSCLE PARALYSIS**

difference between the uppermost and lowermost 5-cm segments being threefold for ventilation and tenfold for perfusion. This change results in a mean $\dot{V}_A/\dot{Q}$ ratio of approximately 1 somewhere in the middle of the lung and a range of $\dot{V}_A/\dot{Q}$ ratios (0.5 at the bottom, 5.0 in the apex; see Fig. 19-23, upper panel, the perfusion distribution being a simplified drawing of Fig. 19-11).

Another way of showing the matching between ventilation and blood flow is by illustrating a multicompartmental analysis of ventilation and distribution of blood flow against $\dot{V}_A/\dot{Q}$ ratios. This can be achieved with MIGET.[156] In short, MIGET is based on the constant intravenous infusion of a number of inert gases (usually six) with differing solubilities in blood. When passing through the lung capillaries, the different gases are eliminated via the alveoli and expired in indirect proportion to their solubility. A poorly soluble gas will rapidly leave the bloodstream and be more or less completely eliminated and exhaled (e.g., sulfur hexafluoride); a gas with a high solubility in blood will be almost completely retained in the blood and will not be exhaled (e.g., acetone); and a gas of intermediate solubility will be retained (and expired) to an intermediate extent (e.g., halothane).

As a result, the concentration of the different gases in arterial blood will differ, with higher concentrations of gases with high solubility. Retention can be calculated as the ratio between arterial and mixed venous blood concentrations. Similarly, the ratio of the concentrations (i.e., expired:mixed venous) can be calculated and gives the excretion for each gas. With knowledge of the retention, excretion, and solubility of each gas, an essentially continuous distribution of blood flow against $\dot{V}_A/\dot{Q}$ ratios can be constructed. The lower panel in Figure 19-23 shows an example from a healthy subject. Note that ventilation and blood flow are well matched, being distributed to a limited number of compartments centered on a $\dot{V}_A/\dot{Q}$ ratio of 1. MIGET has a high discriminatory capacity of detecting different $\dot{V}_A/\dot{Q}$ disturbances, but does not provide topographic information. Several variables that reflect the degree of mismatch can be calculated and are shown in Table 19-3. In the following paragraphs, examples of $\dot{V}_A/\dot{Q}$ mismatch are discussed.

If ventilation and perfusion are not matched, gas exchange will be affected. The most common cause of impaired oxygenation is $\dot{V}_A/\dot{Q}$ mismatch. Low $\dot{V}_A/\dot{Q}$ will impede oxygenation because ventilation is insufficient to fully oxygenate the blood, and the degree of impairment is dependent on the degree of $\dot{V}_A/\dot{Q}$ mismatch; in fact, even normal lung regions $\dot{V}_A/\dot{Q}$ (0.5 to 1) cannot completely saturate the blood. Thus, PaO_2 cannot equal alveolar PO_2, and a difference ($PAO_2 - PaO_2$) of 3 to 5 mm Hg (0.4 to 0.7 kPa) is normal. With more $\dot{V}_A/\dot{Q}$ mismatch, the PAO_2–PaO_2 difference is further increased. The $\dot{V}_A/\dot{Q}$ mismatch can account for all the hypoxemia seen in a patient with severe obstruction.[116] Shunt ($\dot{Q}$, but no $\dot{V}_A$), which is often claimed to exist in patients with COPD, is mostly absent when analyzed with a more sophisticated technique such as MIGET. Indeed, shunt in a patient with obstruction likely represents a complicating factor in the disease (Fig. 19-26).

In severe asthma, a distinct bimodal pattern of low ratios occurs when using MIGET[157] (see Fig. 19-26). The reason may be that alveoli behind airways obstructed by edema (or a mucous plug or spasm) can still be ventilated by collateral ventilation (i.e., alveolar pores, interbronchial communications); these regions would otherwise be shunt (no $\dot{V}_A$, some $\dot{Q}$), resulting in the additional peak in $\dot{V}_A/\dot{Q}$ explaining the bimodal distribution. Such collateral ventilation might be part of the reason that true shunt is not normally seen in COPD. Of course, if the standard shunt equation is used to explain hypoxemia, there is no capacity to distinguish between the contributions of low $\dot{V}_A/\dot{Q}$ vs. shunt to hypoxemia (the net effect is best called *venous admixture*).

Airway obstruction is distributed unevenly, and a large variation in $\dot{V}_A/\dot{Q}$ ratios results. Indeed, ventilation is redistributed from regions with high airway resistance to other regions that can then become overventilated in proportion to their perfusion; this causes high $\dot{V}_A/\dot{Q}$ ratios. There are normally regions in the apex that have $\dot{V}_A/\dot{Q}$ ratios of up to 5, but ratios of 100 or more exist in patients with obstruction, making the regions practically indistinguishable from true dead space; this is what causes the increase in physiologic dead space in obstructive lung disease. The effect of high $\dot{V}_A/\dot{Q}$ is also the same as for airway dead space—that is, ventilation that seems not to participate in gas exchange ("wasted ventilation"). Consequently, a patient with COPD has low $\dot{V}_A/\dot{Q}$ (impedes oxygenation) and high $\dot{V}_A/\dot{Q}$ (mimics dead space, impedes CO_2 elimination). However, MIGET is a complex, research-orientated tool, and the calculation of dead space for clinical purposes relies instead on expired CO_2. Derivation of the CO_2 dead space is shown in Box 19-3.

$\dot{V}_A/\dot{Q}$ mismatch exists to varying degrees in all patients with COPD, and it fully explains hypoxemia in most of them. Hypoventilation can also contribute, whereas impaired diffusion or shunt rarely contributes to hypoxemia. Diffusion capacity, or transfer test, can be reduced markedly in severe COPD, in particular in emphysema; in this case the decrease is not caused by thickened alveolar-capillary membranes but rather by reduced capillary blood volume and reduced area for diffusion.

Pulmonary vessels can be affected by lung disease and can cause $\dot{V}_A/\dot{Q}$ mismatch by impeding regional blood flow. Systemic diseases with vascular involvement can cause severe pulmonary dysfunction because of $\dot{V}_A/\dot{Q}$

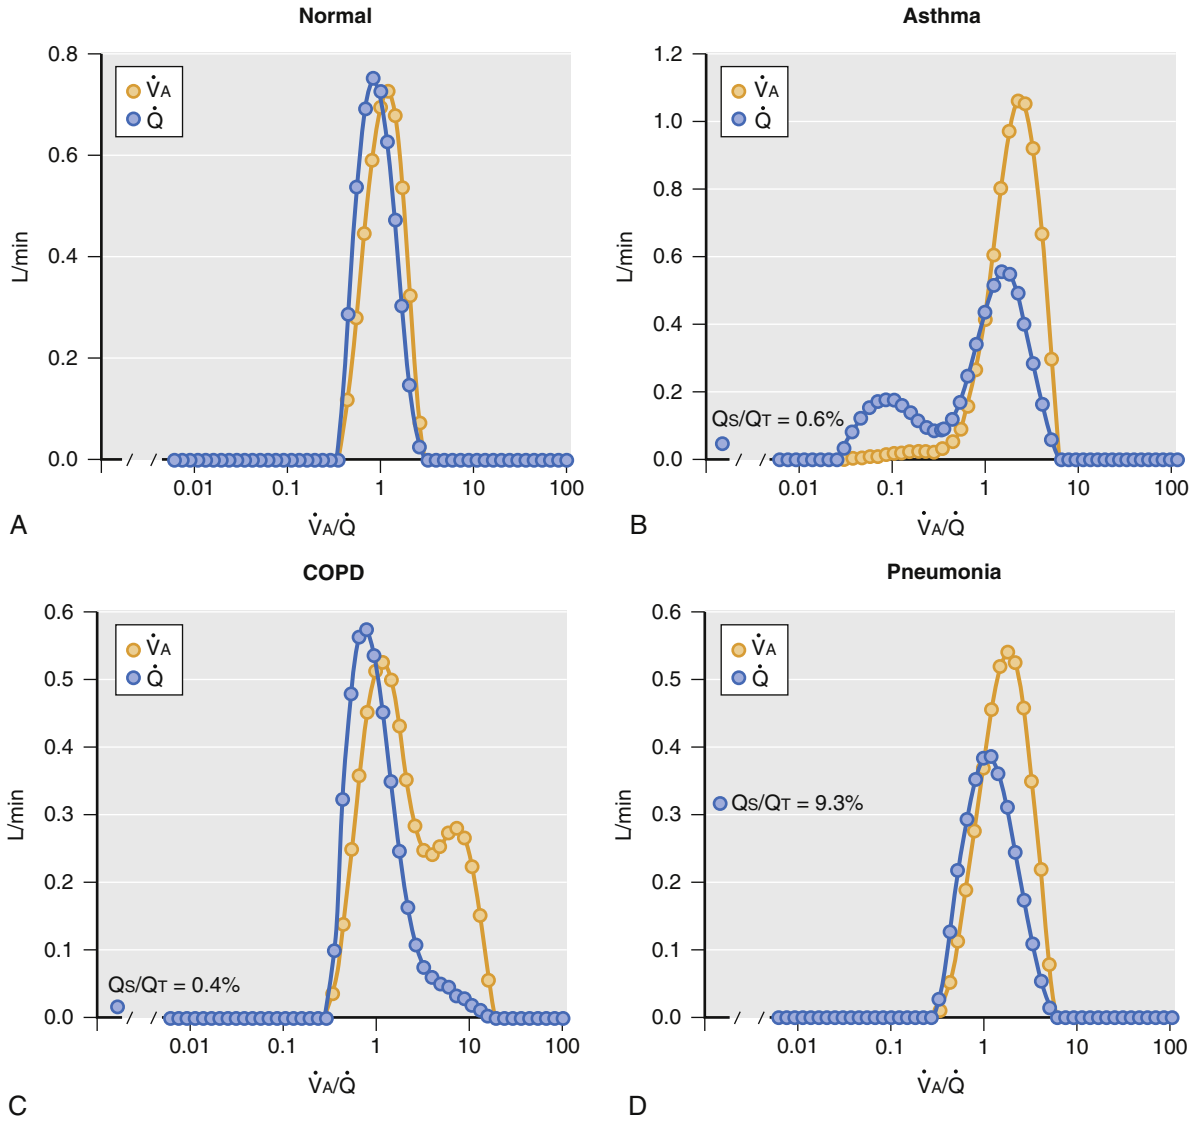

Figure 19-26. Distribution of ventilation and perfusion in normal lungs, asthma, chronic obstructive pulmonary disease (COPD), and pneumonia. **A,** In normal lungs **(A)** there is good matching between ventilation (o) and perfusion (•) with a mode centerd around a $\dot{V}_A/\dot{Q}$ ratio of 1. This results in near optimal oxygenation of blood and CO_2 removal. **B,** In asthma **(B)** there is broader distribution of $\dot{V}_A/\dot{Q}$ with some regions being ventilated well in excess of perfusion ($\dot{V}_A/\dot{Q}$ = 10 and greater), with another mode of low $\dot{V}_A/\dot{Q}$ centred around a ratio of 0.1. This mode can be explained by collateral ventilation maintaining gas exchange in alveoli behind occluded airways. There is no shunt seen in asthma. **C,** In COPD **(C)** the pattern is similar to asthma, but with an additional "high" $\dot{V}_A/\dot{Q}$ mode that adds to dead space such as ventilation. Shunt is not present, and the pattern of $\dot{V}_A/\dot{Q}$ distribution is not associated with significant hypoxemia. **D,** In lobar pneumonia **(D)** the major finding is pure shunt (consolidated, perfused, and poorly ventilated lobe); there is only minor widening of the $\dot{V}_A/\dot{Q}$ distribution.

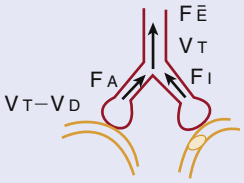
mismatch, impaired diffusion, and shunt. $\dot{V}_A/\dot{Q}$ mismatch causes most of the hypoxemia in pulmonary fibrosis.[158] In addition, hypoxemia can be caused by impaired diffusion (in particular, during exercise, when it can dominate) and a varying degree of shunt (discussed later).

Pulmonary emboli cause $\dot{V}_A/\dot{Q}$ mismatch in three ways. First, vascular beds are occluded, causing extremely high $\dot{V}_A/\dot{Q}$ locally; this is manifest as increased dead space. Second, the occluded vascular bed diverts blood flow to other, already ventilated regions, thus converting these into low $\dot{V}_A/\dot{Q}$ regions. Finally, if P_{PA} (pulmonary artery pressure) is markedly increased, then any propensity to shunt will be increased.[159] In patients with acute pulmonary embolism,[160] hypoxemia appears to be principally caused by increased variability of $\dot{V}_A/\dot{Q}$, and this has been confirmed experimentally.[161]

Pneumonia involving large areas of consolidated, edematous, or atelectatic (i.e., all non-aerated) lung involves significant shunt, and areas of partial aeration contribute to $\dot{V}_A/\dot{Q}$ mismatch (see Fig. 19-26).[150] In bacterial pneumonia, HPV appears to be inhibited, which is an important mechanism that worsens hypoxemia.[162,163]



EFFECT OF $\dot{V}_A/\dot{Q}$ ON CO_2 ELIMINATION

A common perception is that although $\dot{V}_A/\dot{Q}$ impedes oxygenation, it has little effect on CO_2 clearance. Actually, elimination of CO_2 is even more limited by $\dot{V}_A/\dot{Q}$ mismatch than is oxygenation of blood[84]; however this seldom results in hypercapnia because minimal increases in $\dot{V}_A$ rapidly correct Pa_{CO_2}. If alveolar ventilation is

BOX 19-3 ***Derivation of the Physiologic Dead Space Equation***

The quantity of CO_2 expired in an exhaled tidal volume = $F_ECO_2 \times V_T$

This comes from perfused lung and from nonperfused lung.

CO_2 exhaled from perfused lung = $F_ACO_2 \times V_A = F_ACO_2 \times (V_T - V_D)$

CO_2 from nonperfused (dead space) lung is derived from inspired gas = $F_ICO_2 \times V_D$

Thus, $F_ECO_2 \times V_T = F_ACO_2(V_T V_D) + (F_ICO_2 \times V_D)$

By rearranging,

$$\frac{V_{DS}}{V_T} = \frac{F_A - F_E}{F_A - F_I}$$

If $F_I = 0$, F is replaced by P, and P_A is replaced by Pa, for CO_2,

$$\frac{V_{DS}}{V_T} = \frac{Paco_2 - P_Eco_2}{Paco_2}$$

where F_E, F_A, and F_I are mixed expired, alveolar, and inspired gas concentration, respectively, and V_T, V_{DS}, and V_A are tidal volume, dead space, and part of the tidal volume to perfused alveoli, respectively.

already impaired and cannot be increased, the addition of $\dot{V}_A/\dot{Q}$ mismatch will increase $Paco_2$.

IMPAIRED DIFFUSION

Hypoxemia can occur because of impaired diffusion in fibrosis or vascular diseases because of severely thickened of the alveolar-capillary membranes. Diffusion is slowed down and the entire length of capillary may be required before the capillary blood has been fully oxygenated, even in resting conditions. On the other hand, this means that a diffusion barrier is unlikely to cause hypoxemia provided the perfusion time and distance permits O_2 equilibration (see Fig. 19-12); however, when these reserves are spent, PaO_2 begins to fall. This decrease is particularly noticeable in patients with pulmonary fibrosis, who might have normal PaO_2 at rest but show dramatic decreases during exercise.[84,116] Development of, or increase in right-to-left shunting in the heart, such as atrial septal defect, can also cause this exercise-induced hypoxemia because the left-to-right shunt at rest becomes right-to-left (or a small right-to-left shunt increases) because of increased P_{PA}.

RIGHT-TO-LEFT SHUNT

If blood passes through the lung without contacting ventilated alveoli, then the blood will not oxygenate or release CO_2. This condition is called a *shunt*, and it lowers PaO_2 and can increase $Paco_2$. Healthy people have a small shunt (2% to 3% of cardiac output) that is caused by venous drainage of the heart muscle into the left atrium by the Thebesian veins. In pathologic states, the shunt ranges from 2% to 50% of cardiac output.

Shunt is often confused with $\dot{V}_A/\dot{Q}$ mismatch. While a $\dot{V}_A/\dot{Q}$ of zero (some perfusion, no ventilation) constitutes a shunt, there are two clear and important differences between low $\dot{V}_A/\dot{Q}$ and shunt. First, the anatomy of a shunt differs from an area of low $\dot{V}_A/\dot{Q}$. Regions with low $\dot{V}_A/\dot{Q}$ are characterized by narrowing of the airways and vasculature, which reduces ventilation and blood flow in some regions and increases them in others. Examples are obstructive lung disease and vascular disorders. Shunt is caused by the complete cessation of ventilation in a region, usually as a result of collapse (atelectasis) or consolidation (e.g., pneumonia). Asthma or COPD does not involve the formation of a shunt[116]; if a shunt is present, it indicates a complication. Second, supplemental O_2 improves the hypoxemia caused by low $\dot{V}_A/\dot{Q}$, but it has less effect on hypoxemia caused by shunt. Although aeration may be poor in regions of low $\dot{V}_A/\dot{Q}$, aeration does exist in these regions, and the concentration of O_2 in these alveoli can be enriched by increasing Fio_2. In contrast, supplemental O_2 cannot access the alveoli in a true (anatomic) shunt.

Anatomic shunt and low $\dot{V}_A/\dot{Q}$ usually coexist, and the net effect is sometimes referred to as *percent shunt* (per the standard shunt equation). In this situation, the low $\dot{V}_A/\dot{Q}$ component will contribute to the response from increasing Fio_2, and the regions of anatomic (true) shunt will not; therefore, shunt will always lower PaO_2 (at any Fio_2). When the calculated fraction increases to 25%, the response to increased Fio_2 will be small; when it increases to 30% or greater, the response will be negligible.[150] This varying response is the net effect of mixing blood with normal pulmonary end-capillary PO_2 and shunt blood, which has the same PO_2 as mixed venous blood. If shunt is a large enough fraction of total lung blood flow, the additional O_2 that can be physically dissolved by the raised Fio_2 is so small that it is almost immeasurable; such a shunt is said to be refractory.

RESPIRATORY FUNCTION DURING ONE-LUNG VENTILATION

Oxygenation can be a challenge during one-lung surgery. One lung is not ventilated but is still perfused, and in the postoperative period, restoration of lung integrity and ventilation–perfusion matching can take time (see Chapter 66).[164]

The technique of one-lung anesthesia and ventilation means that only one lung is ventilated and that the lung provides oxygenation of—and elimination of carbon dioxide from—the blood. Persisting perfusion through the nonventilated lung causes a shunt and decreases PaO_2 (Fig. 19-27); measures can be taken to reduce this blood flow.[165,166]

During one-lung anesthesia, there are two main contributors to impaired oxygenation: (1) the persisting blood flow through nonventilated lung and (2) development of atelectasis in the dependent lung, resulting in local shunt and low $\dot{V}_A/\dot{Q}$.[139] A recruitment maneuver can dissect the influence of the dependent atelectasis[167]; serial increases in peak airway pressure and PEEP directed to the dependent, ventilated lung increased significantly the PaO_2, indicating that dependent atelectasis was an important cause of hypoxemia. In this situation, diversion of perfusion from the dependent (ventilated) to the

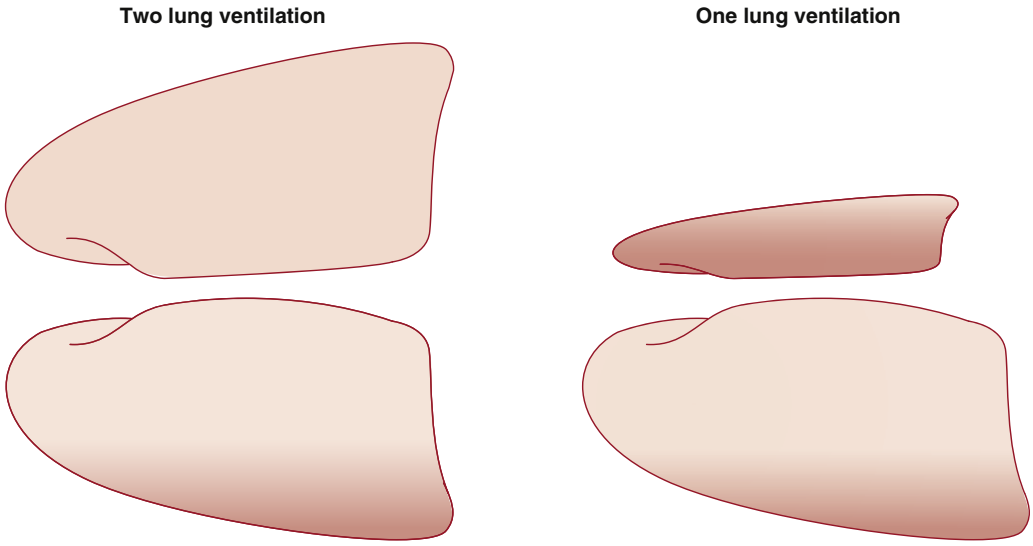


Figure 19-27. Schematic drawing of the distribution of shunt during two-lung ventilation and one-lung ventilation during anesthesia. Shunt region is indicated by dark area in the lower lung during two-lung ventilation and in the lower lung—plus the entire upper lung—during one-lung ventilation.

nondependent (i.e., nonventilated) lung would have worsened oxygenation and not improved it.

Recruitment can also affect V_D. Recruitment during one-lung anesthesia improved oxygenation, but also decreased V_D.[168] The slope of the CO_2 curve during a tidal expiration (phase III) was flatter, indicating a more even distribution of inspired gas throughout the lung and more synchronous alveolar emptying. Thus, a secondary effect of recruiting collapsed lung tissue can be (presumably not when recruitment causes overinflation) more even distribution of ventilation and a decrease in the dead space fraction. This effect should facilitate the use of a smaller V_T. In contrast to an individual recruitment, the application of continuous elevated P_{AW} (PEEP titrated to optimal compliance in the ventilated lung) increased compliance by 10% but slightly worsened oxygenation, probably because of redistribution of blood from the ventilated to the nonventilated (nondependent) lung.[169] The rationale for identifying and using optimal PEEP has also been reviewed.[170]

Maneuvers can also be applied to the nondependent lung. The effects of compressing the nondependent lung on oxygenation were examined using an intra-arterial O_2 sensor, which provides instantaneous and continuous PaO_2.[171] Compression resulted in increased PaO_2, suggesting a shift of blood flow from the nondependent (nonventilated) to the dependent (ventilated) lung; development of complete absorption atelectasis in the nondependent lung may have similar effects.[172]

Inhaled nitric oxide (NO; pulmonary vasodilator) and intravenous almitrine (pulmonary vasoconstrictor) have been studied alone and in combination (see Chapter 104). NO alone has little effect,[173] but oxygenation is improved when NO is combined with almitrine.[174,175] Almitrine alone also improves oxygenation[176] at a dose that does not alter P_{PA} or cardiac output. Although inhaled NO increases perfusion to already ventilated regions (increasing $\dot{V}_A/\dot{Q}$), almitrine potentiates HPV, decreasing perfusion to nonventilated (i.e., shunt) areas (reducing shunt) and potentially diverting blood flow to ventilated regions of the lung. Selective pulmonary vasodilation is reviewed.[177,178]

Careful analysis of the mechanical obstruction caused by kinking of pulmonary vessels and by HPV has shown that HPV is the important determinant of diversion of blood flow away from nonventilated lung (though not complete).[179] Moreover, positioning of the patient can affect the degree of shunting.[180]

PNEUMOPERITONEUM

Laparoscopic operations are usually performed by insufflation of CO_2 into the abdominal cavity The effects are twofold. First, the consequences of hypercapnic acidosis[181,182] include depressed cardiac contractility, sensitization of the myocardium to the arrhythmogenic effects of catecholamines, and systemic vasodilation.[183] There can also be long-lasting postoperative effects on breathing control.[184] In addition, the physical effects of pneumoperitoneum are important. These include decreased FRC and VC,[185] formation of atelectasis,[186] reduced respiratory compliance,[187] and increased peak airway pressure.[188] Nonetheless, shunt is reduced and arterial oxygenation is mostly improved during CO_2 pneumoperitoneum.[189] This paradox—more atelectasis and less shunt—suggests that efficient redistribution of blood flow away from collapsed lung regions is attributable to hypercapnic acidosis CO_2. Indeed, a recent experimental study showed that if the abdomen was inflated with air, a much larger shunt developed than if CO_2 had been used for inflation.[190]

LUNG FUNCTION AFTER CARDIAC SURGERY

Cardiac surgery produces the greatest degree of atelectasis in the postoperative period (see Chapter 67),[191] perhaps because both lungs are often collapsed. Spontaneous resolution of the atelectasis is gradual, leaving a residual shunt of up to 30% by day 1 or 2[99,192]; however, recruitment at the end of the case is possible. In some cases, 30 cm H_2O for 20 seconds is sufficient,[99] facilitated by the chest being open. A recruitment maneuver

(with zero PEEP) causes transient increase in PaO_2 and EELV, and with PEEP alone EELV was increased but PaO_2 unchanged; however, a recruitment maneuver followed by PEEP resulted in a large and sustained increase in both Pa_{O_2} and EELV.[193] The separation of effect whereby PEEP alone increases EELV to a greater extent than it increases oxygenation suggests further opening of already opened lung rather than opening of atelectatic lung.

Head-to-head comparison of intermittent CPAP versus constant noninvasive pressure support ventilation reported intriguing findings. There was less radiographic evidence of atelectasis following pressure support, without differences in oxygenation of bedside pulmonary function testing.[194] Although the authors' conclusion was no clinical benefit with noninvasive pressure support ventilation, differences in Fio_2 could cause differences in propensity to atelectasis. Recruitment maneuvers up to moderately high levels of airway pressure (46 cm H_2O) do not appear to affect the pulmonary vascular resistance or right ventricular afterload,[195] which is an issue of considerable importance following cardiac surgery. Nonetheless, it is prudent to consider RV loading and ejection in such circumstances, especially in the setting of diminished RV reserve or tricuspid regurgitation. Finally, many cardiac surgeries are now being performed "off pump," and the postoperative pulmonary effect is reduced, with less postoperative intrapulmonary shunt and correspondingly shorter hospital stays.[196]

POSTOPERATIVE PHYSIOTHERAPY

Physiotherapy, much debated after surgery (including cardiac surgery; see Chapter 103)[197] is associated with more effective lung recruitment (seen on thoracic CT) when involving deliberate approaches, such as flow bottles following exercise.[198] In effect, large and early inspiration following surgery may be key to preventing postoperative lung complications. Whether the deep inspiration needs to be accomplished with a specific forced breathing device is uncertain.

EFFECT OF SLEEP ON RESPIRATION

Sleep has a major effect on many aspects of respiration, perhaps the most obvious being ventilation.[199] Sleep reduces V_T and inspiratory drive, and $\dot{V}_E$ falls by approximately 10%, depending on the sleep stage, with the most marked fall occurring during rapid-eye-movement (REM) sleep. Lung volume (i.e., FRC) is also reduced[200]; this commences almost immediately after the onset of sleep, and the lowest levels of FRC (down to 10% of resting levels) occur in REM sleep.[201] CT studies in healthy volunteers demonstrate that the sleep-induced decrease in FRD is accompanied by reduced aeration in the dependent lung. Such loss in aeration was demonstrated in anesthetized patients when their Fio_2 was increased from 0.3 to 1.0; atelectasis developed rapidly. It is possible that during normal sleep, breathing with high levels of O_2 would also cause atelectasis.

Chapter 20

Cardiac Physiology

LENA S. SUN • JOHANNA SCHWARZENBERGER • RADHIKA DINAVAHI

KEY POINTS

- The cardiac cycle is the sequence of electrical and mechanical events during the course of a single heartbeat.
- Cardiac output is determined by the heart rate, myocardial contractility, and preload and afterload.
- The majority of cardiomyocytes consist of myofibrils, which are rodlike bundles that form the contractile elements within the cardiomyocyte.
- The basic working unit of contraction is the sarcomere.
- Gap junctions are responsible for the electrical coupling of small molecules between cells.
- Action potentials have four phases in the heart.
- The key player in cardiac excitation-contraction coupling is the ubiquitous second messenger calcium.
- Calcium-induced sparks are spatially and temporally patterned activations of localized calcium release that are important for excitation-contraction coupling and regulation of automaticity and contractility.
- β-Adrenoreceptors stimulate chronotropy, inotropy, lusitropy, and dromotropy.
- Hormones with cardiac action can be synthesized and secreted by cardiomyocytes or produced by other tissues and delivered to the heart.
- Cardiac reflexes are fast-acting reflex loops between the heart and central nervous system that contribute to the regulation of cardiac function and the maintenance of physiologic homeostasis.

In 1628, English physician, William Harvey, first advanced the modern concept of circulation with the heart as the generator for the circulation. Modern cardiac physiology includes not only physiology of the heart as a pump but also concepts of cellular and molecular biology of the cardiomyocyte and regulation of cardiac function by neural and humoral factors. Cardiac physiology is a component of the interrelated and integrated cardiovascular and circulatory physiology. This chapter discusses only the physiology of the heart. It begins with the physiology of the intact heart. The second part of the chapter focuses on cellular cardiac physiology. Finally, the various factors that regulate cardiac function are briefly discussed.

The basic anatomy of the heart consists of two atria and two ventricles that provide two separate circulations in series. The pulmonary circulation, a low-resistance and high-capacitance vascular bed, receives output from the right side of the heart, and its chief function is bidirectional gas exchange. The left side of the heart provides output for the systemic circulation. It functions to deliver oxygen (O_2) and nutrients and to remove carbon dioxide (CO_2) and metabolites from various tissue beds.

PHYSIOLOGY OF THE INTACT HEART

Understanding of mechanical performance of the intact heart begins with the knowledge of the phases of the cardiac cycle and the determinants of ventricular function.

CARDIAC CYCLE

The cardiac cycle is the sequence of electrical and mechanical events during the course of a single heartbeat. Figure 20-1 illustrates (1) the electrical events of a single cardiac cycle represented by the electrocardiogram (ECG) and (2) the mechanical events of a single cardiac cycle represented by left atrial and left ventricular pressure pulses correlated in time with aortic flow and ventricular volume.[1]

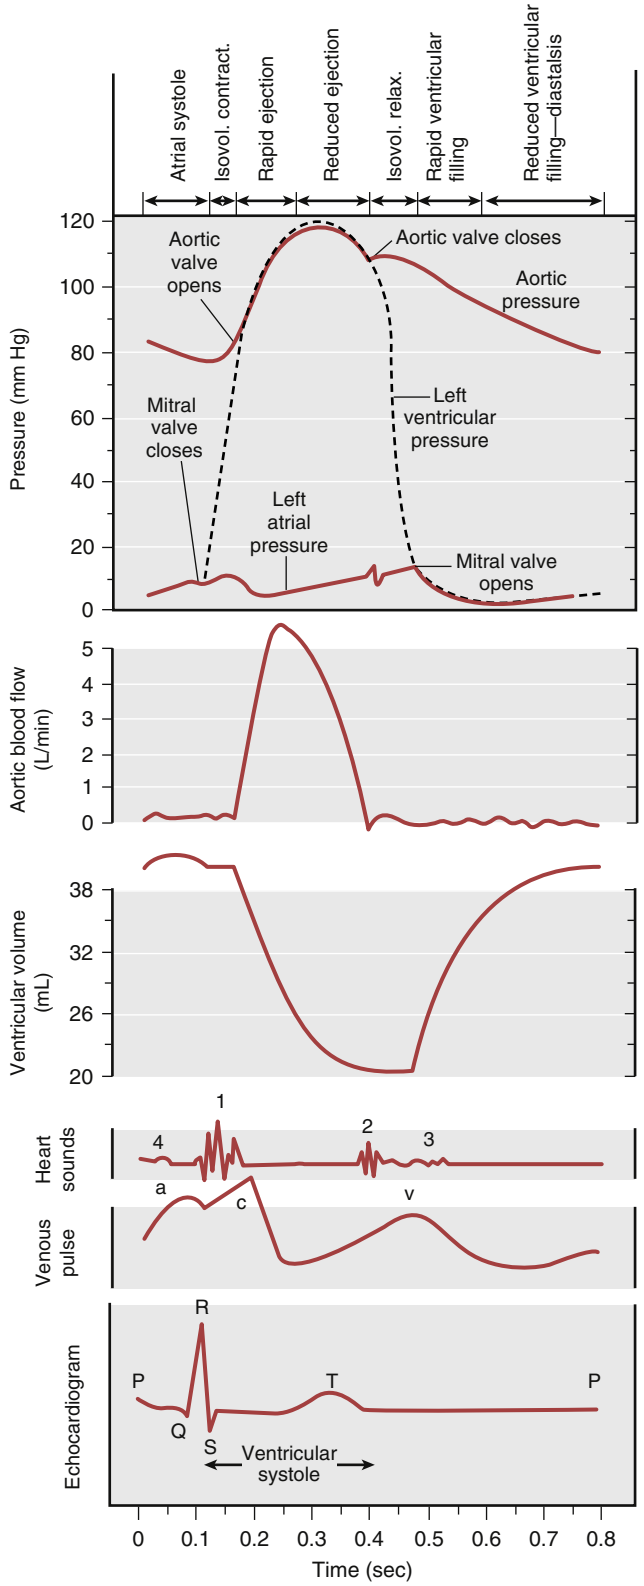

Figure 20-1. Electrical and mechanical events during a single cardiac cycle. The pressure curves of aortic blood flow, ventricular volume, venous pulse, and electrocardiogram are shown. *(From Berne RM, Levy MN: The cardiac pump. In* Cardiovascular physiology, *ed 8. St. Louis, 2001, Mosby, pp 55-82.)*

The cardiac cycle begins with the initiation of the heartbeat. Intrinsic to the specialized cardiac pacemaker tissues is automaticity and rhythmicity. The sinoatrial (SA) node is usually the pacemaker; it can generate impulses at the greatest frequency and is the natural pacemaker.

Electrical Events and the Electrocardiogram

Electrical events of the pacemaker and the specialized conduction system are represented by the ECG at the body surface (also see Chapters 45 and 47). The ECG is the result of differences in electrical potential generated by the heart at sites of the surface recording. The action potential initiated at the SA node is propagated to both atria by specialized conduction tissue that leads to atrial systole (contraction) and the P wave of the ECG. At the junction of the interatrial and interventricular septa, specialized atrial conduction tissue converges at the atrioventricular (AV) node, which is distally connected to the His bundle. The AV node is an area of relatively slow conduction, and a delay between atrial and ventricular contraction normally occurs at this locus. The PR interval represents the delay between atrial and ventricular contraction at the level of the AV node. From the distal His bundle, an electrical impulse is propagated through large left and right bundle branches and finally to the Purkinje system fibers, which are the smallest branches of the specialized conduction system. Finally, electrical signals are transmitted from the Purkinje system to individual ventricular cardiomyocytes. The spread of depolarization to the ventricular myocardium is exhibited as the QRS complex on the ECG. Depolarization is followed by ventricular repolarization and the appearance of the T wave on the ECG.[2]

Mechanical Events

The mechanical events of a cardiac cycle begin with the return of blood to the right and left atria from the systemic and pulmonary circulation, respectively. As blood accumulates in the atria, atrial pressure increases until it exceeds the pressure within the ventricle, and the AV valve opens. Blood passively flows first into the ventricular chambers, and such flow accounts for approximately 75% of the total ventricular filling.[3] The remainder of the blood flow is mediated by active atrial contraction or systole, known as the atrial *kick*. The onset of atrial systole is coincident with depolarization of the sinus node and the P wave. While the ventricles fill, the AV valves are displaced upward and ventricular contraction (systole) begins with closure of the tricuspid and mitral valves, which corresponds to the end of the R wave on the ECG. The first part of ventricular systole is known as *isovolumic* or *isometric contraction*. The electrical impulse traverses the AV region and passes through the right and left bundle branches into the Purkinje fibers, which leads to contraction of the ventricular myocardium and a progressive increase in intraventricular pressure. When intraventricular pressure exceeds pulmonary artery and aortic pressure, the pulmonic and aortic valves open and ventricular ejection occurs, which is the second part of ventricular systole.

Ventricular ejection is divided into the rapid ejection phase and the reduced ejection phase. During the rapid

ejection phase, forward flow is maximal, and pulmonary artery and aortic pressure is maximally developed. In the reduced ejection phase, flow and great artery pressure taper with progression of systole. Pressure in both ventricular chambers decreases as blood is ejected from the heart, and ventricular diastole begins with closure of the pulmonic and aortic valves. The initial period of ventricular diastole consists of the isovolumic (isometric) relaxation phase. This phase is concomitant with repolarization of the ventricular myocardium and corresponds to the end of the T wave on the ECG. The final portion of ventricular diastole involves a rapid decrease in intraventricular pressure until it decreases to less than that of the right and left atria, at which point the AV valve reopens, ventricular filling occurs, and the cycle repeats itself.

VENTRICULAR STRUCTURE AND FUNCTION

Ventricular Structure

The specific architectural order of the cardiac muscles provides the basis for the heart to function as a pump. The ellipsoid shape of the left ventricle (LV) is a result of the laminar layering of spiraling bundles of cardiac muscles (Fig. 20-2). The orientation of the muscle bundle is longitudinal in the subepicardial myocardium and circumferential in the middle segment and again becomes longitudinal in the subendocardial myocardium. Because of the ellipsoid shape of the LV, regional differences in wall thickness result in corresponding variations in the cross-sectional radius of the left ventricular chamber. These regional differences may serve to accommodate the variable loading conditions of the LV.[4] In addition, such anatomy allows the LV to eject blood in a corkscrew-type motion beginning from the base and ending at the apex. The architecturally complex structure of the LV thus allows maximal shortening of myocytes, which results in increased wall thickness and the generation of force during systole. Moreover, release of the twisted LV may provide a suction mechanism for filling of the LV during diastole. The left ventricular free wall and the septum have similar muscle bundle architecture. As a result, the septum moves inward during systole in a normal heart. Regional wall thickness is a commonly used index of myocardial performance that can be clinically assessed, such as by perioperative echocardiography or magnetic resonance imaging.

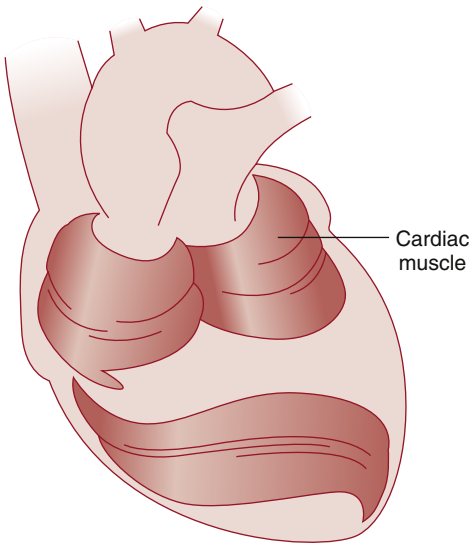

Figure 20-2. Muscle bundles. *(From Marieb EN:* Human anatomy & physiology, *ed 5. San Francisco, 2001, Pearson Benjamin Cummings, p 684.)*

Unlike the LV, which needs to pump against the higher-pressure systemic circulation, the right ventricle (RV) pumps against a much lower pressure circuit in the pulmonary circulation. Consequently, wall thickness is considerably less in the RV. In contrast to the ellipsoidal form of the LV, the RV is crescent shaped; as a result, the mechanics of right ventricular contraction are more complex. Inflow and outflow contraction is not simultaneous, and much of the contractile force seems to be recruited from interventricular forces of the LV-based septum.

An intricate matrix of collagen fibers forms a scaffold of support for the heart and adjacent vessels. This matrix provides enough strength to resist tensile stretch. The collagen fibers are made up of mostly the thick collagen type I fiber, which cross-links with the thin collagen type III fiber, the other major type of collagen.[5] Elastic fibers that contain elastin are in close proximity to the collagen fibers. They account for the elasticity of the myocardium.[6]

Ventricular Function

Systolic Function. The heart provides the driving force for delivering blood throughout the cardiovascular system to supply nutrients and to remove metabolic waste. Because of the anatomic complexity of the RV, the traditional description of systolic function is usually limited to the LV. Systolic performance of the heart is dependent on loading conditions and contractility. Preload and afterload are two interdependent factors extrinsic to the heart that govern cardiac performance.

Diastolic Function. Diastole is ventricular relaxation, and it occurs in four distinct phases: (1) isovolumic relaxation; (2) the rapid filling phase (i.e., the LV chamber filling at variable left ventricular pressure); (3) slow filling, or diastasis; and (4) final filling during atrial systole. The isovolumic relaxation phase is energy dependent. During the auxotonic relaxation (phases 2 through 4), ventricular filling occurs against pressure. It encompasses a period during which the myocardium is unable to generate force, and filling of the ventricular chambers takes place. The isovolumic relaxation phase does not contribute to ventricular filling. The greatest amount of ventricular filling occurs in the second phase, whereas the third phase adds only approximately 5% of total diastolic volume and the final phase provides 15% of ventricular volume from atrial systole.

To assess diastolic function, several indices have been developed. The most widely used index for examining the isovolumic relaxation phase of diastole is to calculate the peak instantaneous rate of decline in left ventricular pressure ($-dP/dt$) or the time constant of isovolumic decline in left ventricular pressure (τ). The aortic closing–mitral opening interval and the isovolumic relaxation time and peak rate of left ventricular wall thinning, as determined by echocardiography, have both been used to estimate

diastolic function during auxotonic relaxation. Ventricular compliance can be evaluated by pressure-volume relationships to determine function during the auxotonic phases of diastole.[7,8]

Many different factors influence diastolic function: magnitude of systolic volume, passive chamber stiffness, elastic recoil of the ventricle, diastolic interaction between the two ventricular chambers, atrial properties, and catecholamines. Whereas systolic dysfunction is a reduced ability of the heart to eject, diastolic dysfunction is a decreased ability of the heart to fill. Abnormal diastolic function is now being recognized as the predominant cause of the pathophysiologic condition of congestive heart failure.[9]

Ventricular interactions during systole and diastole are internal mechanisms that function as internal feedback to modulate stroke volume. Systolic ventricular interaction involves the effect of the interventricular septum on the function of both ventricles. Because the interventricular septum is anatomically linked to both ventricles, it is part of the load against which each ventricle has to work. Therefore, any changes in one ventricle will also be present in the other. In diastolic ventricular interaction, dilatation of either the LV or RV will have an impact on effective filling of the contralateral ventricle and thereby modify function.

Preload and Afterload. *Preload* is defined as the ventricular load at the end of diastole, before contraction has started. First described by Starling, a linear relationship exists between sarcomere length and myocardial force (Fig. 20-3). In clinical practice, surrogate representatives of left ventricular volume such as pulmonary wedge pressure or central venous pressure are used to estimate preload.[3] With the development of transesophageal echocardiography, a more direct measure of ventricular volume is available.

Afterload is defined as systolic load on the LV after contraction has begun. Aortic compliance is an additional determinant of afterload.[1] Aortic compliance is the ability of the aorta to give way to systolic forces from the ventricle. Changes in the aortic wall (dilation or stiffness) can alter aortic compliance and thus afterload. Examples of pathologic conditions that alter afterload are aortic stenosis and chronic hypertension. Both impede ventricular ejection, thereby increasing afterload. Aortic impedance, or aortic pressure divided by aortic flow at that instant, is an accurate means of gauging afterload. However, clinical measurement of aortic impedance is invasive. Echocardiography can noninvasively estimate aortic impedance by determining aortic blood flow at the time of its maximal increase. In clinical practice, the measurement of systolic blood pressure is adequate to approximate afterload, provided that aortic stenosis is not present.

Preload and afterload can be thought of as the wall stress that is present at the end of diastole and during left ventricular ejection, respectively. Wall stress is a useful concept because it includes preload, afterload, and the energy required to generate contraction. Wall stress and heart rate are probably the two most relevant indices that account for changes in myocardial O_2 demand. Laplace's law states that wall stress (σ) is the product of pressure (P) and radius (R) divided by wall thickness (h)[3]:

$$\sigma = P \times R/2h$$

The ellipsoid shape of the LV allows the least amount of wall stress such that as the ventricle changes its shape from ellipsoid to spherical, wall stress is increased. By using the ratio of the long axis to the short axis as a measure of the ellipsoid shape, a decrease in this ratio would signify a transition from ellipsoid to spherical.

Thickness of the left ventricular muscle is an important modifier of wall stress. For example, in aortic stenosis, afterload is increased. The ventricle must generate a much higher pressure to overcome the increased load opposing systolic ejection of blood. To generate such high performance, the ventricle increases its wall thickness (left ventricular hypertrophy). By applying Laplace's law, increased left ventricular wall thickness will decrease wall stress, despite the necessary increase in left ventricular pressure to overcome the aortic stenosis (Fig. 20-4).[10] In a failing heart, the radius of the LV increases, thus increasing wall stress.

Frank-Starling Relationship. The Frank-Starling relationship is an intrinsic property of myocardium by

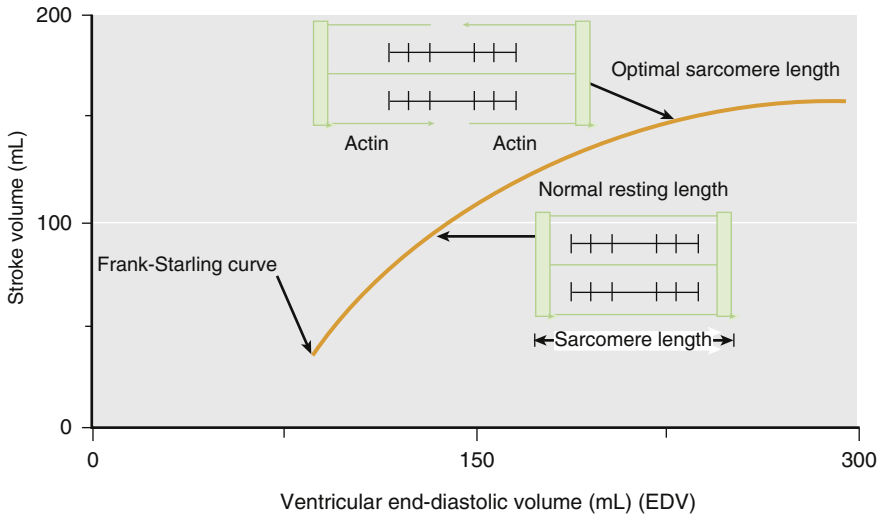

Figure 20-3. Frank-Starling relationship. The relationship between sarcomere length and tension developed in cardiac muscles is shown. In the heart, an increase in end-diastolic volume is the equivalent of an increase in myocardial stretch; therefore, according to the Frank-Starling law, increased stroke volume is generated.

which stretching of the myocardial sarcomere results in enhanced myocardial performance for subsequent contractions (see Fig. 20-3). In 1895, Otto Frank first noted that in skeletal muscle, the change in tension was directly related to its length, and as pressure changed in the heart, a corresponding change in volume occurred.[11] In 1914, E. H. Starling, using an isolated heart-lung preparation as a model, observed that "the mechanical energy set free on passage from the resting to the contracted state is a function of the length of the muscle fiber."[12] If a strip of cardiac muscle is mounted in a muscle chamber under isometric conditions and stimulated at a fixed frequency, then an increase in sarcomere length results in an increase in twitch force. Starling concluded that the increased twitch force was the result of a greater interaction of muscle bundles.

Electron microscopy has demonstrated that sarcomere length (2 to 2.2 μm) is positively related to the amount of actin and myosin cross-bridging and that there is an optimal sarcomere length at which the interaction is maximal. This concept is based on the assumption that the increase in cross-bridging is equivalent to an increase in muscle performance. Although this theory continues to hold true for skeletal muscle, the force-length relationship in cardiac muscle is more complex. When comparing force-strength relationships between skeletal and cardiac muscle, it is noteworthy that the reduction in force is only 10%, even if cardiac muscle is at 80% sarcomere length.[11] The cellular basis of the Frank-Starling mechanism is still being investigated and is briefly discussed later in this chapter. A common clinical application of Starling's law is the relationship of left ventricular end-diastolic volume (LVEDV) and stroke volume. The Frank-Starling mechanism may remain intact even in a failing heart.[13] However, ventricular remodeling after injury or in heart failure may modify the Frank-Starling relationship.

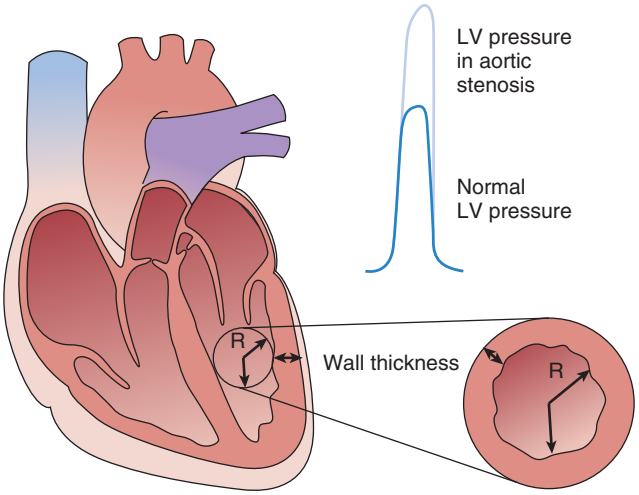

Figure 20-4. In response to aortic stenosis, left ventricular (LV) pressure increases. To maintain wall stress at control levels, compensatory LV hypertrophy develops. According to Laplace's law, wall stress = pressure · radius (R) ÷ (2 × wall thickness). Therefore the increase in wall thickness offsets the increased pressure, and wall stress is maintained at control levels. *(From Opie LH: Ventricular function. In* The heart. Physiology from cell to circulation, *ed 4. Philadelphia, 2004, Lippincott-Raven, pp 355-401.)*

Contractility. Each Frank-Starling curve specifies a level of contractility, or the inotropic state of the heart, which is defined as the work performed by cardiac muscle at any given end-diastolic fiber. Factors that modify contractility will create a family of Frank-Starling curves with different contractility (Fig. 20-5).[10] Factors that modify contractility are exercise, adrenergic stimulation, changes in pH, temperature, and drugs such as digitalis. The ability of the LV to develop, generate, and sustain the necessary pressure for the ejection of blood is the intrinsic inotropic state of the heart.

In isolated muscle, the maximal velocity of contraction (Vmax) is defined as the maximal velocity of ejection at zero load. Vmax is obtained by plotting the velocity of muscle shortening in isolated papillary muscle at varying degrees of force. Although this relationship can be replicated in isolated myocytes, Vmax cannot be measured in an intact heart because complete unloading is impossible. To measure the intrinsic contractile activity of an intact heart, several strategies have been attempted with varying success. Pressure-volume loops, albeit requiring catheterization of the left side of the heart, are currently the best way to determine contractility in an intact heart (Fig. 20-6).[10] The pressure-volume loop represents an indirect measure of the Frank-Starling relationship between force (pressure) and muscle length (volume). Clinically, the most commonly used noninvasive index of ventricular contractile function is the ejection fraction, which is assessed by echocardiography, angiography, or radionuclide ventriculography.

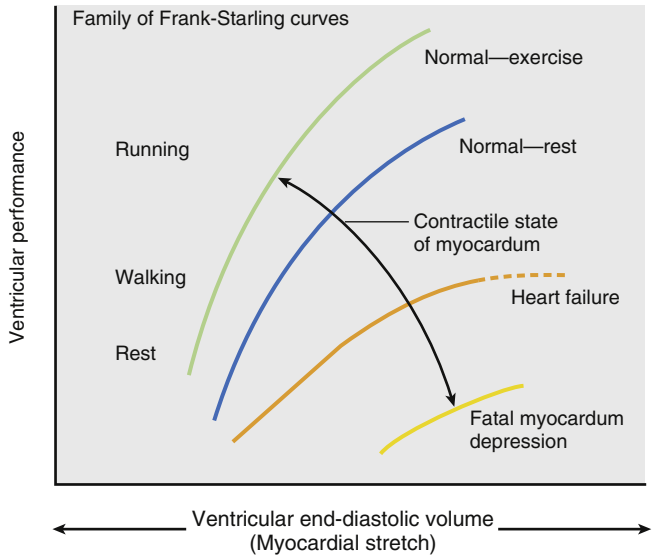

Figure 20-5. A family of Frank-Starling curves is shown. A leftward shift of the curve denotes enhancement of the inotropic state, whereas a rightward shift denotes decreased inotropy. *(From Opie LH: Ventricular function. In* The heart. Physiology from cell to circulation, *ed 4. Philadelphia, 2004, Lippincott-Raven, pp 355-401.)*

$$\text{Ejection fraction} = (\text{LVEDV} - \text{LVESV})/\text{LVEDV}$$

where LVESV is left ventricular end-systolic volume.

Cardiac Work. The work of the heart can be divided into external and internal work. External work is expended to eject blood under pressure, whereas internal work is expended within the ventricle to change the shape of the heart and to prepare it for ejection. Internal work contributes to inefficiency in the performance of the heart. Wall stress is directly proportional to the internal work of the heart.[14]

External work, or stroke work, is a product of the stroke volume (SV) and pressure (P) developed during ejection of the SV.

$$\text{Stroke work} = \text{SV} \times \text{P} \text{ or } (\text{LVEDV} - \text{LVESV}) \times \text{P}$$

The external work and internal work of the ventricle both consume O_2. The clinical significance of internal work is illustrated in the case of a poorly drained LV during cardiopulmonary bypass. Although external work is provided by the roller pump during bypass, myocardial ischemia can still occur because poor drainage of the LV creates tension on the left ventricular wall and increases internal work.

The efficiency of cardiac contraction is estimated by the following formula[8]:

$$\text{Cardiac efficiency} = \text{External work}/\text{Energy equivalent of } O_2 \text{ consumption}$$

The corkscrew motion of the heart for the ejection of blood is the most favorable in terms of work efficiency, based on the architecture in a normal LV (with the cardiac muscle bundles arranged so that a circumferentially oriented middle layer is sandwiched by longitudinally oriented outer layers). In heart failure, ventricular dilation reduces cardiac efficiency because it increases wall stress, which in turn increases O_2 consumption.[11]

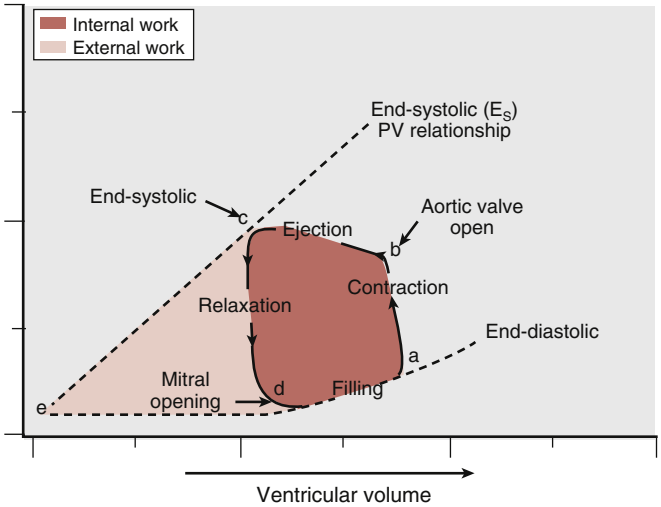

Figure 20-6. Pressure-volume (PV) loop. Point *a* depicts the start of isovolumetric contraction. The aortic valve opens at point *b,* and ejection of blood follows *(points b→c).* The mitral valve opens at point *d,* and ventricular filling ensues. External work is defined by points *a, b, c,* and *d,* and internal work is defined by points *e, d,* and *c.* The PV area is the sum of external and internal work. *(From Opie LH: Ventricular function. In* The heart. Physiology from cell to circulation, *ed 4. Philadelphia, 2004, Lippincott-Raven, pp 355-401.)*

Heart Rate and Force-Frequency Relationship. In isolated cardiac muscle, an increase in the frequency of stimulation induces an increase in the force of contraction. This relationship is termed the *treppe*, which means *staircase* in German, and is the phenomenon or the force-frequency relationship.[8,15] At between 150 and 180 stimuli per minute, maximal contractile force is reached in an isolated heart muscle at a fixed muscle length. Thus an increased frequency incrementally increases inotropy, whereas stimulation at a lower frequency decreases contractile force. However, when the stimulation becomes extremely rapid, the force of contraction decreases. In the clinical context, pacing-induced positive inotropic effects may be effective only up to a certain heart rate, based on the force-frequency relationship. In a failing heart, the force-frequency relationship may be less effective in producing a positive inotropic effect.[8]

CARDIAC OUTPUT

Cardiac output is the amount of blood pumped by the heart per unit of time ($\dot{Q}$) and is determined by four factors: two factors that are intrinsic to the heart—heart rate and myocardial contractility—and two factors that are extrinsic to the heart but functionally couple the heart and the vasculature—preload and afterload.

Heart rate is defined as the number of beats per minute and is mainly influenced by the autonomic nervous system. Increases in heart rate escalate cardiac output as long as ventricular filling is adequate during diastole. *Contractility* can be defined as the intrinsic level of contractile performance that is independent of loading conditions. Contractility is difficult to define in an intact heart because it cannot be separated from loading conditions.[8,15] For example, the *Frank-Starling relationship* is defined as the change in intrinsic contractile performance, based on changes in preload. Cardiac output in a living organism can be measured with the Fick principle (a schematic depiction is illustrated in Fig. 20-7).[1]

The Fick principle is based on the concept of conservation of mass such that the O_2 delivered from pulmonary venous blood (q_3) is equal to the total O_2 delivered to pulmonary capillaries through the pulmonary artery (q_1) and the alveoli (q_2).

The amount of O_2 delivered to the pulmonary capillaries by way of the pulmonary arteries (q_1) equals total pulmonary arterial blood flow ($\dot{Q}$) times the O_2 concentration in pulmonary arterial blood ($CpaO_2$):

$$q_1 = \dot{Q} \times CpaO_2$$

The amount of O_2 carried away from pulmonary venous blood (q_3) is equal to total pulmonary venous blood flow ($\dot{Q}$) times the O_2 concentration in pulmonary venous blood ($Cpvo_2$):

$$q_3 = \dot{Q} \times CpvO_2$$

The pulmonary arterial O_2 concentration is the mixed systemic venous O_2, and the pulmonary venous O_2 concentration is the peripheral arterial O_2. O_2 consumption

is the amount of O_2 delivered to the pulmonary capillaries from the alveoli (q_2). Because $q_1 + q_2 = q_3$,

$$\dot{Q}\,(CpaO_2) + q_2 = \dot{Q}\,(CpvO_2)$$

$$q_2 = \dot{Q}\,(CpvO_2) - \dot{Q}\,(CpaO_2)$$

$$q_2 = \dot{Q}\,(Cpvo_2) - CpaO_2$$

$$\dot{Q} = q_2 / (CpvO_2 - CpaO_2)$$

Thus if the $CpaO_2$, $CpvO_2$, and O_2 consumption (q_2) are known, then the cardiac output can be determined.

The indicator dilution technique is another method for determining cardiac output also based on the law of conservation of mass. The two most commonly used indicator dilution techniques are the dye dilution and the thermodilution methods. Figure 20-8 illustrates the principles of the dye dilution method.[1]

CELLULAR CARDIAC PHYSIOLOGY

CELLULAR ANATOMY

At the cellular level, the heart consists of three major components: (1) cardiac muscle tissue (contracting cardiomyocytes), (2) conduction tissue (conducting cells), and (3) extracellular connective tissue. A group of cardiomyocytes with its connective tissue support network or extracellular matrix make up a myofiber (Fig. 20-9). Adjacent myofibers are connected by strands of collagen. The extracellular matrix is the synthetic product of fibroblasts and is made up of collagen, which is the main determinant of myocardial stiffness, and other major matrix proteins. One of the matrix proteins, elastin, is the chief constituent of elastic fibers. The elastic fibers account for, in part, the elastic properties of the myocardium.[6] Other matrix proteins include the glycoproteins or proteoglycans and matrix metalloproteinases. Proteoglycans are proteins with short sugar chains, and they include heparan sulfate, chondroitin, fibronectin, and laminin. Matrix metalloproteins are enzymes that degrade collagen and other extracellular proteins. The balance between the accumulation of extracellular matrix proteins by synthesis and

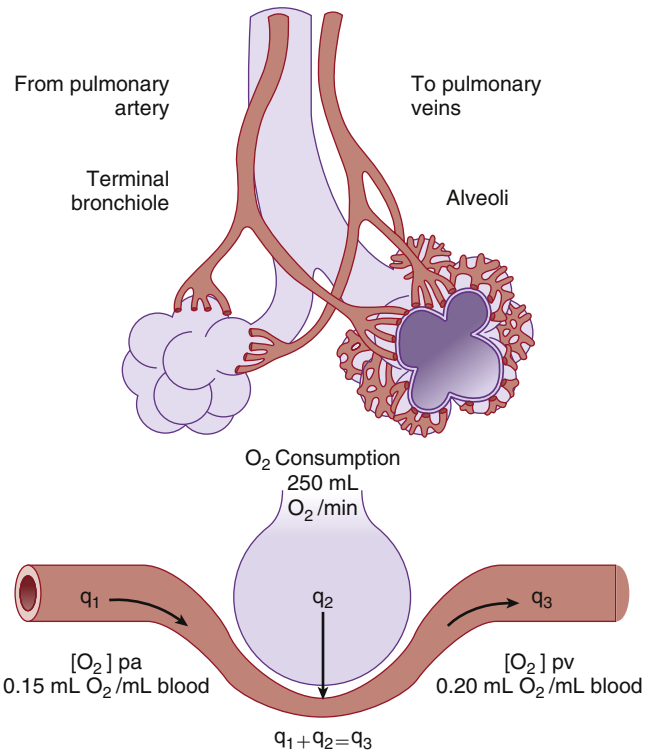

Figure 20-7. Illustration demonstrates the principle of determination of cardiac output according to the Fick formula. If the oxygen (O_2) concentration in pulmonary arterial blood ($CpaO_2$), the O_2 concentration of the pulmonary vein ($CpvO_2$), and the O_2 consumption are known, then cardiac output can be calculated. *pa,* Pulmonary artery; *pv,* pulmonary vein. *(From Berne RM, Levy MN: The cardiac pump. In* Cardiovascular physiology, *ed 8. St. Louis, 2001, Mosby, pp 55-82.)*

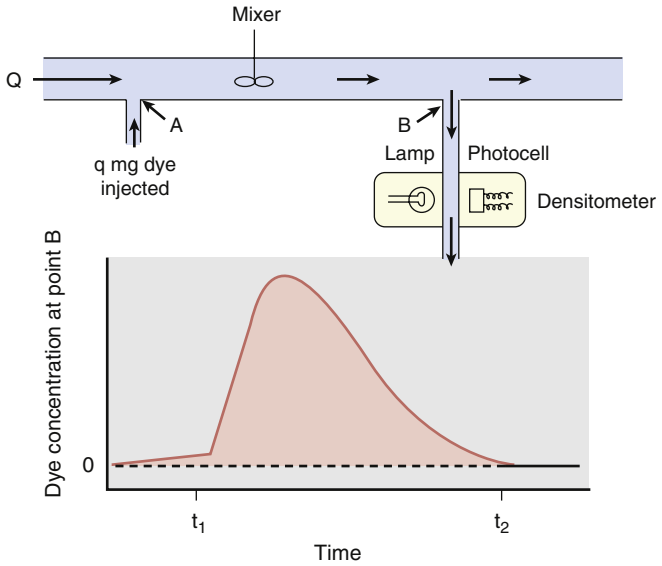

Figure 20-8. Illustration demonstrates the principle of determining cardiac output with the indicator dilution technique. This model assumes that there is no recirculation. A known amount of dye *(q)* is injected at point *A* into a stream flowing at $\dot{Q}$ (mL/min). A mixed sample of the fluid flowing past point *B* is withdrawn at a constant rate through a densitometer. The change in dye concentration over time is depicted in a curve. Flow may be measured by dividing the amount of indicator injected upstream by the area under the downstream concentration curve. *(From Berne RM, Levy MN: The cardiac pump. In* Cardiovascular physiology, *ed 8. St. Louis, 2001, Mosby, pp 55-82.)*

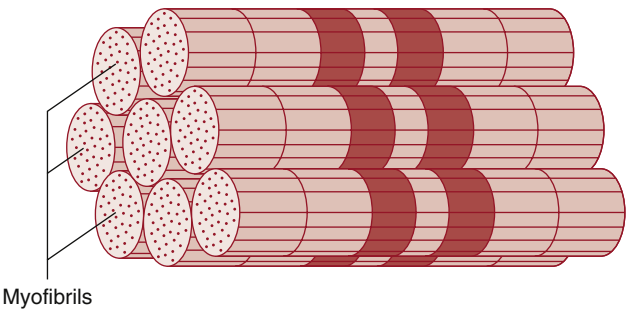

Figure 20-9. Organization of cardiomyocytes. Fifty percent of cardiomyocyte volume is made up of myofibrils; the remainder consists of mitochondria, nucleus, sarcoplasmic reticulum, and cytosol.

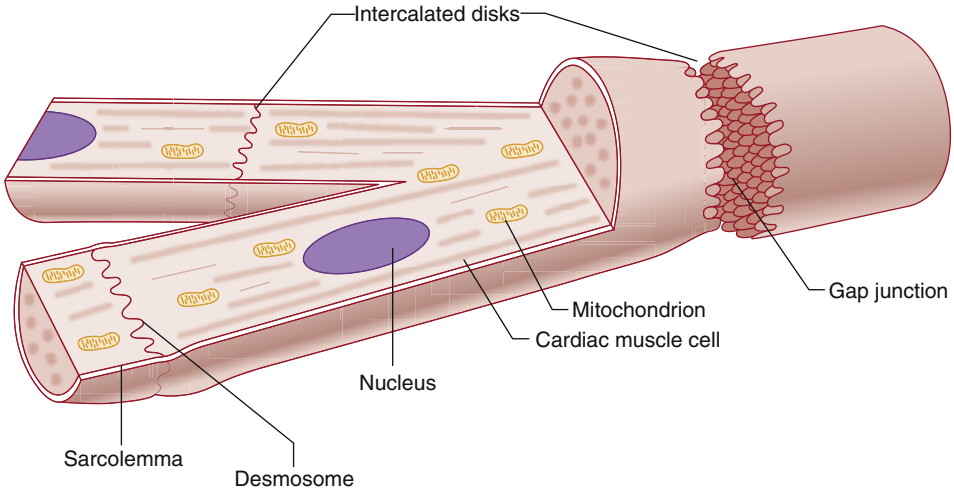

Figure 20-10. The sarcolemma that envelops cardiomyocytes becomes highly specialized to form the intercalated disks where ends of neighboring cells are in contact. The intercalated disks consist of gap junctions and *spot* and *sheet* desmosomes.

their breakdown by matrix metalloproteins contributes to the mechanical properties and function of the heart.[6]

CARDIOMYOCYTE STRUCTURE AND FUNCTION

Individual contracting cardiomyocytes are large cells between 20 μm (atrial cardiomyocytes) and 140 μm (ventricular cardiomyocytes) in length. Approximately 50% of the cell volume in a contracting cardiomyocyte is made up of myofibrils, and the remainder consists of mitochondria, nucleus, sarcoplasmic reticulum (SR), and cytosol. The myofibril is the rodlike bundle that forms the contractile elements within cardiomyocytes. Within each contractile element are contractile proteins, regulatory proteins, and structural proteins. Contractile proteins make up approximately 80% of the myofibrillar protein, with the remainder being regulatory and structural proteins.[16,17] The basic unit of contraction is the sarcomere (see discussion under "Contractile Elements" later in this chapter).

The sarcolemma, or the outer plasma membrane, separates the intracellular and extracellular space. It surrounds the cardiomyocyte and invaginates into the myofibrils through an extensive tubular network known as *transverse tubules* or *T tubules*, and it also forms specialized intercellular junctions between cells.[18,19]

Transverse or T tubules are in close proximity to an intramembranous system and the SR, which plays an important role in the calcium (Ca^{2+}) metabolism that is critical in the excitation-contraction coupling (ECC) of the cardiomyocyte. The SR can be further divided into the longitudinal (or network) SR and the junctional SR. The longitudinal SR is involved in the uptake of Ca^{2+} for the initiation of relaxation. The junctional SR contains large Ca^{2+}-release channels (ryanodine receptors [RyRs]) that release SR Ca^{2+} stores in response to depolarization-stimulated Ca^{2+} influx through the sarcolemmal Ca^{2+} channels. The RyRs are not only Ca^{2+}-release channels, but they also form the scaffolding proteins that anchor many of the key regulatory proteins.[20]

Mitochondria are immediately found beneath the sarcolemma, wedged between myofibrils within the cell. They contain enzymes that promote the generation of adenosine triphosphate (ATP), and they are the energy powerhouse for the cardiomyocyte. In addition, mitochondria can also accumulate Ca^{2+} and thereby contribute to the regulation of the cytosolic Ca^{2+} concentration. Nearly all of the genetic information is found within the centrally located nucleus. The cytosol is the fluid-filled microenvironment within the sarcolemma, exclusive of the organelles and the contractile apparatus and proteins.

Cardiac muscle cells contain three different types of intercellular junctions: gap junctions, *spot* desmosomes, and *sheet* desmosomes (or fasciae adherens) (Fig. 20-10).[18,21] Gap junctions are responsible for electrical coupling and the transfer of small molecules between cells, whereas desmosome-like junctions provide mechanical linkage. The adhesion sites formed by spot desmosomes anchor the intermediate filament cytoskeleton of the cell; those formed by the fasciae adherens anchor the contractile apparatus. Gap junctions consist of clusters of plasma membrane channels directly linking the cytoplasmic compartments of neighboring cells. Gap junction channels are constructed from connexins, a multigene family of conserved proteins. The principal connexin isoform of the mammalian heart is connexin 43; other connexins, notably connexins 40, 45, and 37, are also expressed but in smaller quantities.[20,21]

The conducting cardiomyocytes, or Purkinje cells, are cells specialized for conducting propagated action potentials. These cells have a low content of myofibrils and a prominent nucleus, and they contain an abundance of gap junctions. Cardiomyocytes can be functionally separated into (1) the excitation system, (2) the ECC system, and (3) the contractile system.

Excitation System

The cellular action potential originating in the specialized conduction tissue is propagated to individual cells where it initiates the intracellular event that leads to the contraction of the cell through the sarcolemmal excitation system.

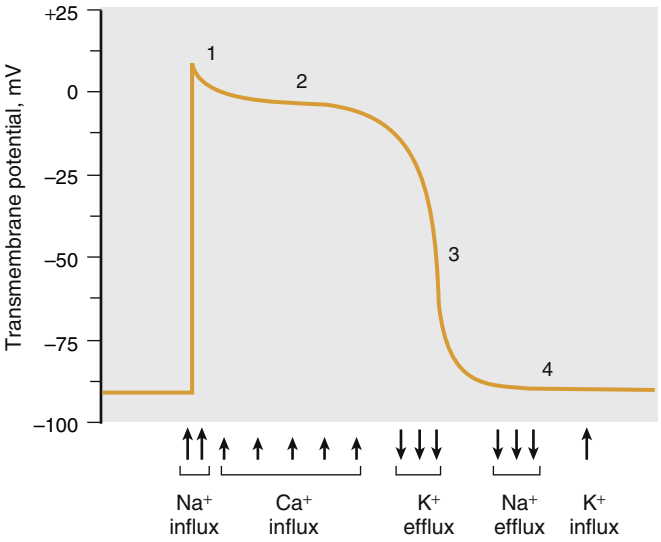

Figure 20-11. Phases of cellular action potentials and major associated currents in ventricular myocytes. The initial phase (0) spike and overshoot (1) are caused by a rapid inward sodium (Na^+) current, the plateau phase (2) by a slow calcium (Ca^{2+}) current through L-type Ca channels, and repolarization (phase 3) by outward potassium (K^+) currents. Phase 4, the resting potential (Na^+ efflux, K^+ influx), is maintained by Na^+-K^+-adenosine triphosphatase (ATPase). The Na^+-Ca^{2+} exchanger is mainly responsible for extrusion of Ca^{2+}. In specialized conduction system tissue, spontaneous depolarization takes place during phase 4 until the voltage resulting in opening of the Na channel is reached. *(From LeWinter MM, Osol G: Normal physiology of the cardiovascular system. In Fuster V, Alexander RW, O'Rourke RA, editors:* Hurst's the heart, *ed 10. New York, 2001, McGraw-Hill, pp 63-94.)*

Action Potential. Ion fluxes across plasma membranes result in depolarization (attaining a less negative membrane potential) and repolarization (attaining a more negative membrane potential). They are mediated by membrane proteins with ion-selective pores. Because these ion channel proteins open and close the pores in response to changes in membrane potential, the channels are voltage gated. In the heart, sodium (Na^+), potassium (K^+), Ca^{2+}, and chloride (Cl^-) channels contribute to the action potential.

The types of action potential in the heart can be separated into two categories: (1) fast-response action potentials, which are found in the His-Purkinje system and atrial or ventricular cardiomyocytes; and (2) slow-response action potentials, which are found in the pacemaker cells in the SA and AV nodes. A typical tracing of an action potential in the His-Purkinje system is depicted in Figure 20-11.[8] The electrochemical gradient for K^+ across the plasma membrane is the determinant for the resting membrane potential. Mostly as a result of the influx of Na^+, the membrane potential becomes depolarized, which leads to an extremely rapid upstroke (phase 0). As the membrane potential reaches a critical level (or threshold) during depolarization, the action potential is propagated. The rapid upstroke is followed by a transient repolarization (phase 1). Phase 1 is a period of brief and limited repolarization that is largely attributable to the activation of a transient outward K^+ current, i_{to}. The plateau phase (phase 2) occurs with a net influx of Ca^{2+} through L-type Ca^{2+} channels and the efflux of K^+ through several K^+ channels—the inwardly rectifying i_k, the delayed rectifier i_{k1}, and i_{to}. Repolarization (phase 3) is brought about when an efflux of K^+ from the three outward K^+ currents exceeds the influx of Ca^{2+}, thus returning the membrane to the resting potential. Very little ionic flux occurs during diastole (phase 4) in a fast-response action potential.

In contrast, during diastole (phase 4), pacemaker cells that show slow-response action potentials have the capability of spontaneous diastolic depolarization and generate the automatic cardiac rhythm. Pacemaker currents during phase 4 are the result of an increase in the three inward currents and a decrease in the two outward currents. The three inward currents that contribute to spontaneous pacemaker activity include two carried by Ca^{2+}, i_{CaL} and i_{CaT}, and one that is a mixed cation current, I_f.[22] The two outward currents are the delayed rectifier K^+ current, i_k, and the inward rectifying K^+ current, i_{k1}. When compared with the fast-response action potential, phase 0 is much less steep, phase 1 is absent, and phase 2 is indistinct from phase 3 in the slow-response action potential.[23] In SA node cells, the pacemaker I_f current is the principal determinant of duration diastolic depolarization, and it is encoded by four members of the hyperpolarization-activated cyclic nucleotide-gated gene (HCN1-4) family.[24]

During the cardiac action potential, movement of Ca^{2+} into the cell and Na^+ out of the cell creates an ionic imbalance. The Na^+-Ca^{2+} exchanger restores cellular ionic balance by actively transporting Ca^{2+} out of the cell against a concentration gradient while moving Na^+ into the cell in an energy-dependent manner.

Excitation-Contraction Coupling

Structures that participate in cardiac ECC include the sarcolemma, transverse tubules, SR, and myofilaments (Fig. 20-12, *A*).[25] The process of ECC begins with depolarization of the plasma membrane and spread of electrical excitation along the sarcolemma of cardiomyocytes.

The ubiquitous second messenger Ca^{2+} is the key player in cardiac ECC (see Fig. 20-12, *B*).[23] Cycling of Ca^{2+} within the structures that participate in ECC initiates and terminates contraction. Activation of the contractile system depends on an increase in free cytosolic Ca^{2+} and its subsequent binding to contractile proteins.

Ca^{2+} enters through plasma membrane channels concentrated at the T tubules, and such entry through L-type Ca^{2+} channels (dihydropyridine receptors) triggers the release of Ca^{2+} from the SR.[26] This evokes a *Ca^{2+} spark*. Ca^{2+} sparks are considered to be the elementary Ca^{2+} signaling event of ECC in heart muscle. A Ca^{2+} spark occurs with the opening of a cluster of SR RyRs to release Ca^{2+} in a locally regenerative manner. It, in turn, activates the Ca^{2+}-release channels and induces further release of Ca^{2+} from subsarcolemmal cisternae in the SR and thus leads to a large increase in intracellular Ca^{2+} (iCa^{2+}). These spatially and temporally patterned activations of localized Ca^{2+} release, in turn, stimulate myofibrillar contraction. The increase in iCa^{2+}, however, is transient inasmuch as Ca^{2+} is removed by (1) active uptake by the SR Ca^{2+} pump adenosine triphosphatase (ATPase), (2) extrusion of Ca^{2+} from the cytosol by the Na^+-Ca^{2+} exchanger, and (3) binding of Ca^{2+} to proteins.[27] Ca^{2+} sparks have also been implicated

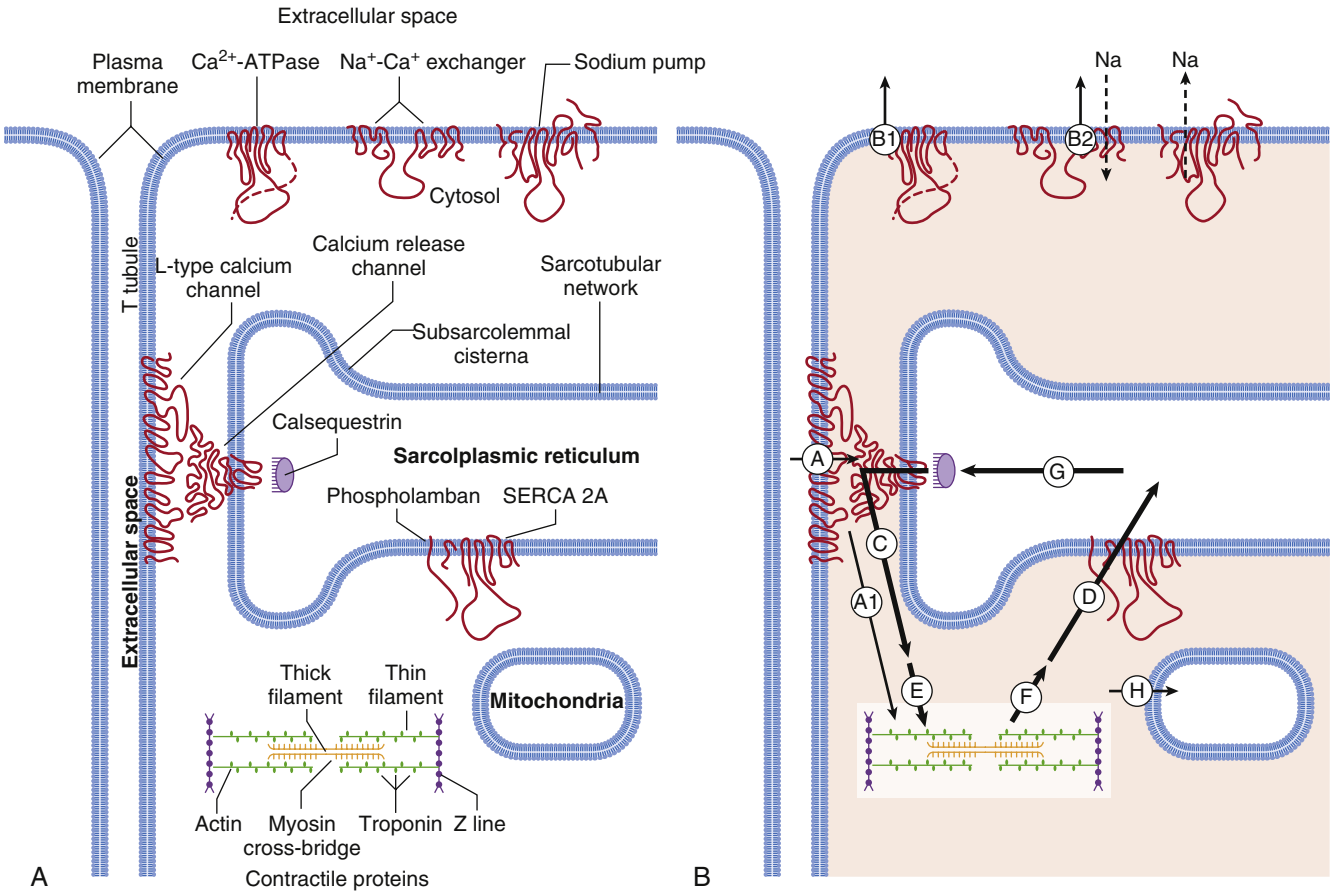

Figure 20-12. A, Diagram depicts the components of cardiac excitation-contraction coupling. Calcium pools are noted in **bold** letters. **B,** Extracellular (*arrows A, B1, B2*) and intracellular calcium flux (*arrows C, D, E, F,* and *G*) are shown. The thickness of the *arrows* indicates the magnitude of the calcium flux, and the vertical orientations describe their energetics: *downward-pointing arrows* represent passive calcium flux, whereas *upward-pointing arrows* represent energy-dependent calcium transport. Calcium entering the cell from extracellular fluid through L-type calcium channels triggers the release of calcium from the sarcoplasmic reticulum. Only a small portion directly activates the contractile proteins (*arrow A1*). *Arrow B1* depicts active transport of calcium into extracellular fluid by means of the plasma membrane calcium adenosine triphosphatase (Ca^{2+}-ATPase) pump and the sodium-calcium (Na^{+}-Ca^{2+}) exchanger. Sodium that enters the cell in exchange for calcium (*dashed line*) is pumped out of the cytosol by the sodium pump. SR regulates calcium efflux from the subsarcolemmal cisternae (*arrow C*) and calcium uptake into the sarcotubular network (*arrow D*). *Arrow G* represents calcium that diffuses within the SR. Calcium binding to (*arrow E*) and dissociation from (*arrow F*) high-affinity calcium-binding sites of troponin C activate and inhibit interactions of the contractile proteins. *Arrow H* depicts movement of calcium into and out of mitochondria to buffer the cytosolic calcium concentration. *SERCA 2A,* Sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase. *(From Katz AM: Calcium fluxes. In* Physiology of the heart, *ed 3. Philadelphia, 2001, Lippincott-Raven, pp 232-233.)*

in pathophysiologic diseases such as hypertension, cardiac arrhythmias, heart failure, and muscular dystrophy.[28-30]

The SR provides the anatomic framework and is the major organelle for the cycling of Ca^{2+}. It is the depot for iCa^{2+} stores. The cyclic release plus reuptake of Ca^{2+} by the SR regulates the cytosolic Ca^{2+} concentration and couples excitation to contraction. The physical proximity between L-type Ca^{2+} channels and RyRs at the SR membrane makes Ca^{2+}-induced Ca^{2+} release to occur easily. The *foot* region of the RyR is the part that extends from the SR membrane to the T tubules, where the L-type Ca^{2+} channels are located.[17,27,31]

The SR is also concerned with the reuptake of Ca^{2+} that initiates relaxation or terminates contraction. The sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) pump is the ATP-dependent pump that actively pumps the majority of the Ca^{2+} back into the SR after its release. SERCA makes up close to 90% of all of the SR proteins and is inhibited by the phosphoprotein, phospholamban, at rest. Phospholamban is an SR membrane protein that is active in the dephosphorylated form. Phosphorylation by a variety of kinases as a result of β-adrenergic stimulation or other stimuli inactivates phospholamban and releases its inhibitory action on SERCA. Positive feedback ensues and leads to further phospholamban phosphorylation and greater SERCA activity. Active reuptake of Ca^{2+} by SERCA then promotes relaxation.[17,27,31]

Once taken up into the SR, Ca^{2+} is stored until it is released during the next cycle. Calsequestrin and calreticulin are two storage proteins in the SR. Calsequestrin is a highly charged protein located in the cisternal component of the SR near the T tubules. Because it lies close to the Ca^{2+}-release channels, the stored Ca^{2+} can be quickly discharged for release once the Ca^{2+}-release channels are stimulated. Cytosolic Ca^{2+} can also be removed by extrusion through the sarcolemmal Ca^{2+} pump and the activity of the Na^{+}-Ca^{2+} exchanger. The protein, calmodulin, is an important *sensor* and regulator of iCa^{2+}.[19]

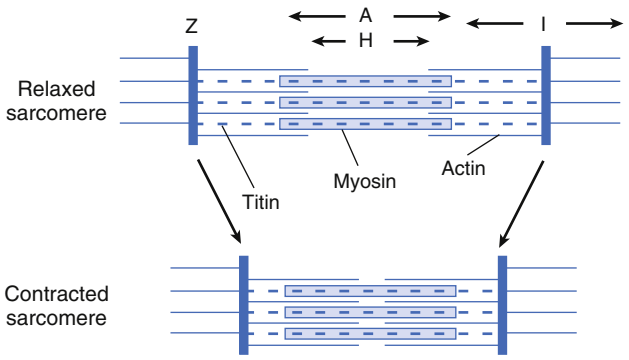

Figure 20-13. The basic unit of contraction is the sarcomere. A contracted and relaxed sarcomere is depicted. Z lines are located at the ends of the sarcomere. The A band is the site of overlap between myosin and actin filaments. The I band is located on either side of the A band and contains only actin filament. The H zone is located in the center of the A band, and only myosin is present.

Contractile System

Contractile Elements. The basic working unit of contraction is the sarcomere. A *sarcomere* is defined as the distance between Z lines (*Z* is an abbreviation for the German word, *Zuckung*, meaning *contraction*), which join the sarcomeres in series. Each sarcomere consists of a central A band that is separated by one half of an I band from the Z lines on each side because the Z line bisects the I band. A schematic representation is depicted in Figure 20-13.[8] Within each sarcomere are two principal contractile proteins (see the next section, "Contractile Proteins") and one noncontractile protein, titin.[27] The two contractile proteins are actin, the thin filament, and myosin, the thick filament. Actin filaments and titin are both tethered to the Z line, but the thick myosin filaments do not actually reach the Z lines. Titin, the third filament protein, tethers the thick-filament myosin to the Z line. The Z lines at the two ends of the sarcomere are brought closer together during contraction as the thick-filament myosin heads interact with the thin actin filaments and slide over each other.[32,33]

Familial hypertrophic cardiomyopathy is an inherited autosomal dominant sarcomeric disease[34] that is the most common cause of sudden death in otherwise healthy individuals. Its clinical features are left ventricular hypertrophy and myocyte and myofibrillar disarray. Mutations in at least eight different genes encoding sarcomere proteins have been identified to be the molecular basis for the disorder. These genes are β-cardiac myosin heavy chain, cardiac troponin T (TnT), α-tropomyosin, cardiac myosin-binding protein C, essential or regulatory myosin light chain, cardiac troponin I (TnI), α-cardiac actin, and titin.[34]

Contractile Proteins. The contractile apparatus within the cardiomyocyte consists of contractile and regulatory proteins.[19,35,36] The thin-filament actin and the thick-filament myosin are the two principal contractile proteins. Actin contains two helical chains. Tropomyosin, a double-stranded α-helical regulatory protein, winds around the actin array and forms the backbone for the thin-filament actin. The thick-filament myosin is made up of 300 myosin molecules. Each myosin molecule has two functional domains: the body or filament and the bilobar myosin head. The myosin head is made up of one heavy chain and two light chains. The heavy head chain has two domains: the larger one interacts with actin at the actin cleft and has an ATP-binding pocket where myosin ATPase is located, and the other smaller one is flexible and attached to the two light chains. The regulatory troponin heterotrimer complex is found at regular intervals along tropomyosin. The heterotrimer troponins are made up of troponin C (TnC), the Ca^{2+} receptor; TnI, an inhibitor of actin-myosin interaction; and TnT, which links the troponin complex to tropomyosin. Tropomodulin is another regulatory protein. It is located at the end of the thin-filament actin and caps the end to prevent any excessive elongation of the thin filament.[32,33]

Myocyte Contraction and Relaxation. At rest, cross-bridge cycling and generation of force do not occur because either the myosin heads are blocked from physically reacting with the thin filament or they are only weakly bound to actin (Fig. 20-14).[16] Cross-bridge cycling is initiated on binding of Ca^{2+} to TnC, which increases TnC-TnI interaction and decreases the inhibitory TnI-actin interaction. These events, which ensue from the binding of Ca^{2+} to TnC, lead to conformational changes in tropomyosin and permit attachment of the myosin head to actin. Cross-bridging involves the detachment of the myosin head from actin and a reattachment of myosin to another actin on hydrolysis of ATP by myosin ATPase. Binding of ATP to the nucleotide pocket of the myosin head leads to the activation of myosin ATPase,[31-33] ATP hydrolysis, and changes in the configuration of the myosin head, all of which facilitate binding of the myosin head to actin and the generation of the power stroke of the myosin head. Based on this model, the rate of cross-bridge cycling is dependent on the activity of myosin ATPase.[36] Turnoff of cross-bridge cycling is largely initiated by the decrease in cytosolic Ca^{2+}.

Myocyte relaxation is an energy-dependent process because restoration of cytosolic Ca^{2+} to resting levels requires the expenditure of ATP. The decrease in cytosolic Ca^{2+} occurs through active reuptake of Ca^{2+} into the SR by SERCA and extrusion of Ca^{2+} by the Na^{+}-Ca^{2+} exchanger. This activity results in the release of Ca^{2+} binding to TnC and the separation of the myosin-actin cross-bridge. Myocyte relaxation is dependent on the kinetics of cross-bridge cycling, the affinity of Ca^{2+} for TnC, and the activity of the Ca^{2+}-reuptake mechanisms. Relaxation is enhanced by the increased kinetics of cross-bridge cycling, decreased Ca^{2+} affinity for TnC, and increased activity of Ca^{2+}-reuptake mechanisms.[27]

Titin is a giant stringlike protein that acts as the third filament within the sarcomere. A single titin molecule spans one half of the sarcomere. Structurally, titin consists of an inextensible anchoring segment and an extensible elastic segment. Its two main functions involve muscle assembly and elasticity. Titin is the principal determinant of the passive properties of the myocardium at small ventricular volumes.[37]

The Frank-Starling relationship states that an increase in end-diastolic volume results in enhanced systolic function.[38,39] At the cellular level, the key component for the Frank-Starling relationship is a length-dependent shift

in Ca^{2+} sensitivity.[40-42] Several possible mechanisms for this change in Ca^{2+} sensitivity have been implicated, including Ca^{2+} sensitivity: (1) as a function of myofilament lattice spacing, (2) involving positive cooperativity in cross-bridge binding to actin, and (3) dependence on a strain of the elastic protein titin.[36,40]

Cytoskeleton Proteins. The cytoskeleton is the protein framework within the cytoplasm that links, anchors, or tethers structural components inside the cell.[16,19] Microfilaments (actin filaments), microtubules, and intermediate filaments are three classes of cytoskeleton proteins found in the cytoplasm. Microfilament proteins are actin filaments, either sarcomeric or cortical, depending on their location. Sarcomeric actin filaments are the thin filaments in the contractile machinery that have been previously described. Cortical actin filaments are found below the plasma membrane at the cell surface and are linked to several other microfilament proteins, including dystrophin, vinculin, and ankyrin. Microtubules assemble by polymerization of the α- and β-dimers of tubulin. They play a major role in intracellular transport and cell division.[43] Attachment of the ends of microtubules to cellular structures causes the microtubules to expand and contract, thereby pulling and pushing these structures around the cell. The intermediate filaments are relatively insoluble. They have been demonstrated to be important in normal mitochondrial function and behavior. The desmin intermediate filament in cardiomyocytes connects the nucleus to the plasma membrane and is important in the transmission of the stress and strain of contractile force between cells.[44] The cytoskeleton provides the organization of microenvironments within the cell for enzyme and protein activity and interaction.

Whereas familial hypertrophic cardiomyopathy is a genetic sarcomeric disease, familial dilated cardiomyopathy

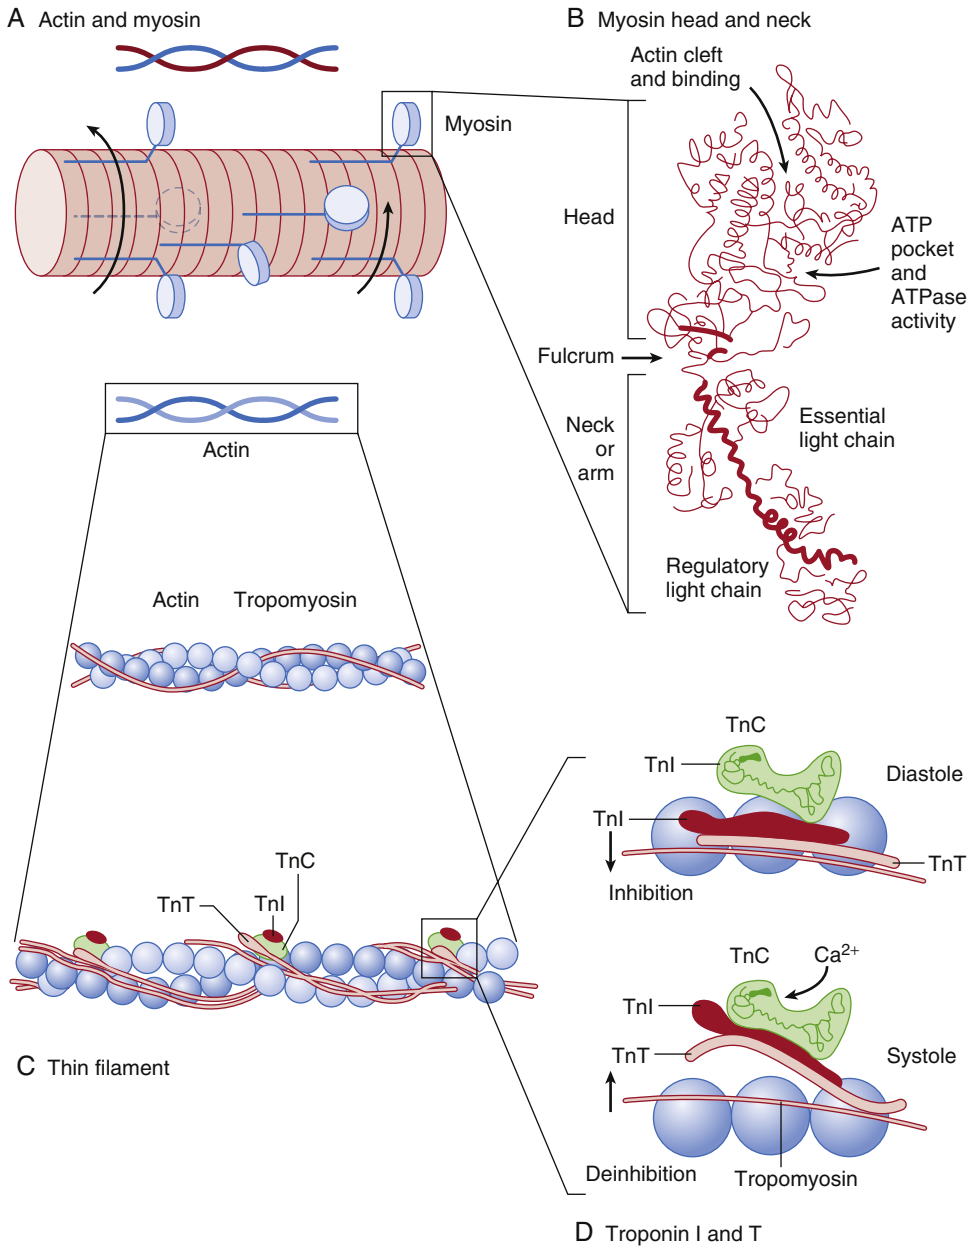

Figure 20-14. Molecules of the contractile system, troponins C, I, and T (TnC, TnI, and TnT). *ATP*, Adenosine triphosphate; *ATPase*, adenosine triphosphatase. *(From Opie LH: Ventricular function. In* The heart. Physiology from cell to circulation, *ed 4. Philadelphia, 2004, Lippincott-Raven, pp 209-231.)*

(FDCM) is a disease of cytoskeleton proteins. The genetic basis of FDCM includes two genes for X-linked FDCM (dystrophin, G4.5) and four genes for the autosomal dominant form (actin, desmin, lamin A/C, and δ-sarcoglycan).[16]

CONTROL OF CARDIAC FUNCTION

NEURAL REGULATION OF CARDIAC FUNCTION

The two limbs of the autonomic nervous system provide opposing input to regulate cardiac function.[45] The neurotransmitter of the sympathetic nervous system is norepinephrine, which provides positive chronotropic (heart rate), inotropic (contractility), and lusitropic (relaxation) effects. The parasympathetic nervous system has a more direct inhibitory effect in the atria and has a negative modulatory effect in the ventricles. The neurotransmitter of the parasympathetic nervous system is acetylcholine. Both norepinephrine and acetylcholine bind to seven-transmembrane–spanning G protein–coupled receptors to transduce their intracellular signals and affect their functional responses (Fig. 20-15).[46] At rest, the heart has a tonic level of parasympathetic cardiac nerve firing and little, if any, sympathetic activity. Therefore, the major influence on the heart at rest is parasympathetic. During exercise or stress, however, the sympathetic neural influence becomes more prominent.

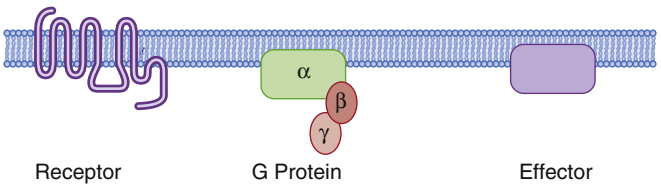

Figure 20-15. General scheme for a G protein–coupled receptor consisting of receptor, the heterotrimeric G protein, and the effector unit. *(Reprinted with permission from Bers DM: Cardiac excitation-contraction coupling,* Nature *415:198-205, 2002. Copyright MacMillan Magazines Ltd.)*

Parasympathetic innervation of the heart is through the vagal nerve. Supraventricular tissue receives significantly more intense vagal innervation than do the ventricles. The principal parasympathetic target neuroeffectors are the muscarinic receptors in the heart.[47,48] Activation of muscarinic receptors reduces pacemaker activity, slows AV conduction, directly decreases atrial contractile force, and exerts inhibitory modulation of ventricular contractile force. A total of five muscarinic receptors have been cloned.[49] M_2 receptors are the predominant subtype found in the mammalian heart. In the coronary circulation, M_3 receptors have been identified. Moreover, non–M_2 receptors have also been reported to exist in the heart. In general, for intracellular signaling, M_1, M_3, and M_5 receptors couple to $G_{q/11}$ protein and activate the phospholipase C–diacylglycerol–inositol phosphate system. On the other hand, the M_2 and M_4 receptors couple to the pertussis toxin–sensitive G protein, $G_{i/o}$, to inhibit adenylyl cyclase. M_2 receptors can couple to certain K^+ channels and influence the activity of Ca^{2+} channels, I_f current, phospholipase A_2, phospholipase D, and tyrosine kinases.

In contrast to vagal innervation, sympathetic innervation of the heart is more predominant in the ventricle than in the atrium. Norepinephrine released from sympathetic nerve terminals stimulates adrenergic receptors (adrenoreceptors [AdRs]) located in the heart. The two major classes of ARs are α and β, both of which are G protein–coupled receptors that transduce their intracellular signals by means of specific signaling cascades (Fig. 20-16).

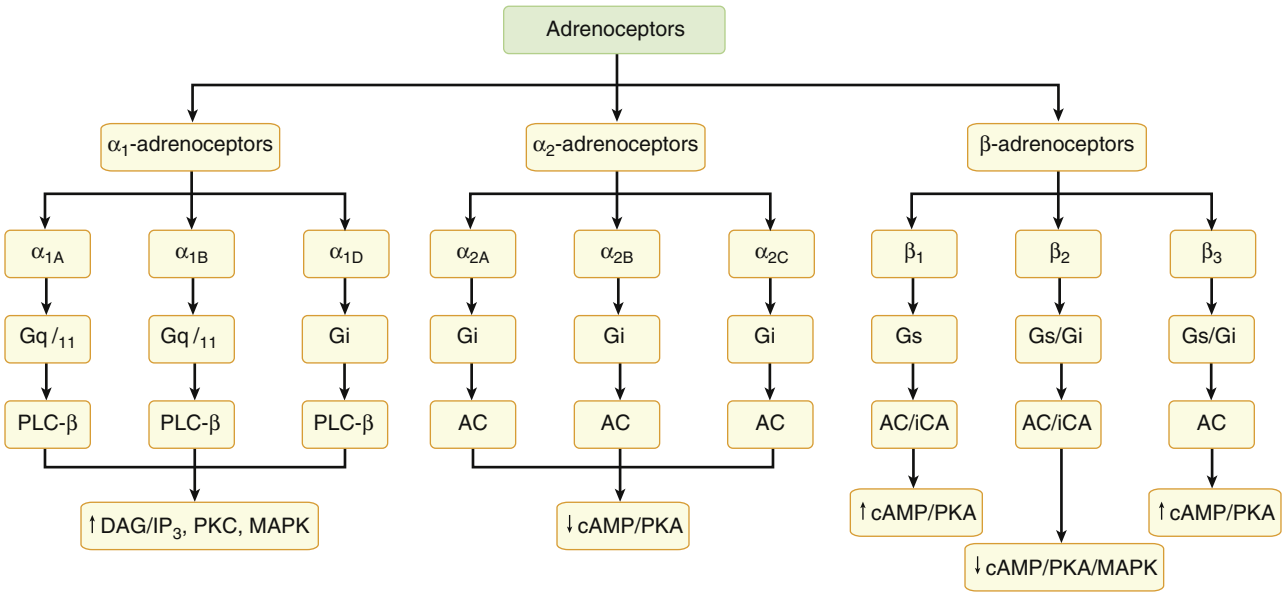

Figure 20-16. Adrenoceptor signaling cascades involving G proteins and effectors are adenylyl cyclase (AC), L-type calcium current (iCA), and phospholipase β (PLC-β) in the heart. The intracellular signals are diacylglycerol (DAG), inositol 1,4,5-triphosphate (IP_3), protein kinase C (PKC), cyclic adenosine monophosphate (cAMP), protein kinase A (PKA), and mitogen-activated protein kinase (MAPK). *$Gq/_{11}$*, Heterotrimeric G protein; *Gi*, inhibitory G protein; *Gs*, stimulatory G protein.

β-ARs can be further divided into subpopulations of β_1, β_2, and β_3.[50] Although most mammalian hearts contain β1-ARs and β_2-ARs, β_3-ARs also exist in many mammalian ventricular tissues. The relative contribution of each β-AR subtype to modulation of cardiac function varies among species. In humans, β_1-ARs are the predominant subtype in both the atria and ventricles, but a substantial proportion of β_2-ARs are located in the atria, and approximately 20% of β_2-ARs are found in the LV. Much less is known about β_3-ARs, but they do exist in the human ventricle. Despite the fact that the β_1-AR population is more intense than the β_2-AR population, the cardiostimulant effect is not proportional to the relative densities of these two subpopulations, which is largely attributable to the tighter coupling of β_2-ARs than β_1-ARs to the cyclic adenosine monophosphate (cAMP) signaling pathway. Both β_1-ARs and β_2-ARs activate a pathway that involves the stimulatory G protein (Gs), activation of adenylyl cyclase, accumulation of cAMP, stimulation of cAMP-dependent protein kinase A, and phosphorylation of key target proteins, including L-type Ca^{2+} channels, phospholamban, and TnI.

Although traditional teaching is that both β_1-ARs and β_2-ARs are coupled to the G_s-cAMP pathway, more recent experimental evidence indicates that β_2-ARs also couple to the inhibitory G protein (Gi) to activate non–cAMP-dependent signaling pathways. Additionally, β_2-ARs can couple to G protein–independent pathways to modulate cardiac function. β-AR stimulation increases both contraction and relaxation, as summarized in Figure 20-17.

The two major subpopulations of α-ARs are α_1 and α_2. α_1-ARs and α_2-ARs can be further subdivided into different subtypes. α_1-ARs are G protein–coupled receptors and include the α_{1A}, α_{1B}, and α_{1D} subtypes. The α_1-AR subtypes are products of separate genes and differ in structure, G protein coupling, tissue distribution, signaling, regulation, and function. Both α_{1A}-ARs and α_{1B}-ARs mediate positive inotropic responses. However, the positive inotropic effect mediated by α_1-ARs is believed to be of minor importance in the heart. α_1-ARs are coupled to phospholipase C, phospholipase D, and phospholipase A_2; they increase iCa^{2+} and myofibrillar sensitivity to Ca^{2+}.

Cardiac hypertrophy is primarily mediated by α_{1A}-ARs.[51,52] Cardiac hypertrophic responses to α_1-AR agonists involve activation of protein kinase C and mitogen-activated protein kinase through G_q-signaling mechanisms. Three subtypes of α_2-ARs are recognized: α_{2A}, α_{2B}, and α_{2C}. In the mammalian heart, α_2-ARs in the atrium play a role in the presynaptic inhibition of norepinephrine release. These prejunctional α_2-ARs are believed to belong to the α_{2C} subtype.

Neural regulation of cardiac function involves a complex interaction between the different classes and subpopulations of adrenoceptors and their signaling pathways. Targeted therapeutics in cardiovascular medicine involve the clinical application and manipulation of a basic understanding of adrenoceptor pharmacology.

HORMONES AFFECTING CARDIAC FUNCTION

Many hormones have direct and indirect actions on the heart (Table 20-1). Hormones with cardiac actions can be synthesized and secreted by cardiomyocytes or produced by other tissues and delivered to the heart. They act on specific receptors expressed in cardiomyocytes. Most of these hormone receptors are plasma membrane G protein–coupled receptors (GPCRs). Non-GPCRs include the natriuretic peptide receptors, which are guanylyl cyclase–coupled receptors, and the glucocorticoid and mineralocorticoid receptors, which bind androgens and aldosterone and are nuclear zinc finger transcription factors. Hormones can have activity in normal cardiac physiologic function or are active only in pathophysiologic conditions, or both situations can apply. Most of the new information regarding the action of hormones in the heart has been derived from the endocrine changes associated with chronic heart failure.[53]

Cardiac hormones are polypeptides secreted by cardiac tissues into the circulation in the normal heart. Natriuretic peptides,[54,55] aldosterone,[56] and adrenomedullin[57] are hormones secreted by cardiomyocytes. Angiotensin II, the effector hormone in the renin-angiotensin system, is also produced by cardiomyocytes.[58,59] The

TABLE 20-1 **ACTIONS OF HORMONES ON CARDIAC FUNCTION**

Hormone	Receptor	Cardiac Action	Increase (+) or Decrease (–) With CHF
Adrenomedullin	GPCR	+Inotropy/+chronotropy	+

renin-angiotensin system is one of the most important regulators of cardiovascular physiology. It is a key modulator of cardiac growth and function. Angiotensin II stimulates two separate receptor subtypes, AT_1 and AT_2, both of which are present in the heart. AT_1 receptors are the predominant subtype expressed in the normal adult human heart. Stimulation of AT_1 receptors induces a positive chronotropic and inotropic effect. Angiotensin II also mediates cell growth and proliferation in cardiomyocytes and fibroblasts and induces the release of the growth factors aldosterone and catecholamines through the stimulation of AT_1 receptors. Activation of AT_1 receptors is directly involved in the development of cardiac hypertrophy and heart failure, as well as adverse remodeling of the myocardium. In contrast, AT_2 receptor activation is counterregulatory and generally antiproliferative. Expression of AT_2 receptors, however, is relatively scant in the adult heart because they are most abundant in the fetal heart and decline with development. In response to injury and ischemia, AT_2 receptors become upregulated. The precise role of AT_2 receptors in the heart remains to be defined.

The beneficial effects of blockade of the renin-angiotensin system with angiotensin-converting enzyme inhibitors in the treatment of heart failure have been attributed to an inhibition of AT_1-receptor activity. In addition to the renin-angiotensin system, other cardiac hormones that have been shown to play pathogenic roles in the promotion of cardiomyocyte growth and cardiac fibrosis, development of cardiac hypertrophy, and progression of congestive heart failure include aldosterone,[56] adrenomedullin,[60-62] natriuretic peptides,[54,55] angiotensin,[63-65] endothelin,[66] and vasopressin.[67,68]

Increased stretch of the myocardium stimulates the release of atrial natriuretic protein (ANP) and B-type natriuretic protein (BNP) from the atria and ventricles, respectively. Both ANP and BNP bind to natriuretic peptide receptors to generate the second messenger cyclic guanosine monophosphate and represent part of the cardiac endocrine response to hemodynamic changes caused by pressure or volume overload. They also participate in organogenesis of the embryonic heart and cardiovascular system.[54,55] In patients with chronic heart failure, increases of serum ANP and BNP levels are a predictor of mortality.[69]

Adrenomedullin is a recently discovered cardiac hormone that was originally isolated from pheochromocytoma tissue. It increases the accumulation of cAMP and has direct positive chronotropic and inotropic effects.[57,60,61] Adrenomedullin, with interspecies and regional variations, has also been shown to increase nitric oxide production, and it functions as a potent vasodilator.

Aldosterone is one of the cardiac-generated steroids, although its physiologic significance remains to be defined. It binds to mineralocorticoid receptors and can increase the expression or activity (or both) of cardiac proteins involved in ionic homeostasis or the regulation of pH, such as cardiac Na^+/K^+-ATPase, the Na^+-K^+ cotransporter, Cl^--bicarbonate (HCO_3^{2+}), and the Na^+-hydrogen (H^+) antiporter.[56] Aldosterone modifies cardiac structure by inducing cardiac fibrosis in both ventricular chambers and thereby leads to impairment of cardiac contractile function.

Other hormones such as the growth hormone,[70] thyroid hormones,[71] and sex steroid hormones (see the following text) can also have cardiac effects through direct actions of nuclear receptors or indirect effects.

Sex Steroid Hormones and the Heart

Cardiac contractility is more intense in premenopausal women than in age-matched men, and withdrawal of hormone replacement therapy in postmenopausal women leads to a reduction in cardiac contractile function. The gender dimorphism in heart function and its adaptive responses to injury and disease states are partly mediated by sex steroid hormones.

The most extensively studied sex steroid hormones are estradiol-17β (E2) and its bioactive metabolites. They bind and act on the two subtypes of estrogen receptors (ERs) in the heart: ERα and ERβ. Progesterone and testosterone (two other sex steroid hormones) and the enzyme aromatase, which converts testosterone to estrogen, are much less well investigated. Progesterone and testosterone bind and act on their respective progesterone receptors and androgen receptors in the heart. Sex steroid hormones interact with their receptors to affect postsynaptic target cell responses and to influence presynaptic sympathoadrenergic function. Cardiomyocytes are not only targets for the action of sex steroid hormones, but they are also the source of synthesis and the site of metabolism of these hormones.[72]

E2 is derived from testosterone and is primarily metabolized in the liver to form hydroxyestradiols, catecholestradiols, and methoxyestradiols. Estradiol metabolism also takes place in vascular smooth muscle cells, cardiac fibroblasts, endothelial cells, and cardiomyocytes. Cardiomyocytes express nuclear steroid hormone receptors that modulate gene expression and nonnuclear receptors for the nongenomic effects of sex steroid hormones. They interact with many different coregulators to confer tissue and temporal specificity in their transcriptional actions. These cell-specific coactivator and corepressor proteins are known as estrogen-related receptors.[73] Sex steroid hormones can activate rapid signaling pathways without changing gene expression (Fig. 20-18). One such example is stimulation of vascular endothelial nitric oxide synthase to mediate vascular dilatation. Estrogen's vasodilatory effect might explain the lower systolic blood pressures of premenopausal women when compared with age-matched men. In men, aromatase-mediated conversion of testosterone to estrogen maintains normal vascular tone. In addition to sex steroid hormone stimulation of nuclear or nonnuclear receptors, sex steroid hormone receptors could also induce rapid signaling of growth factor pathways in the absence of ligands.

Gender differences exist in cardiac electrophysiologic function. The modulatory actions of estrogen on Ca^{2+} channels might be responsible for sex-based differences in repolarization of the heart, such as the faster resting heart rate of women, as well as the increased propensity of women to have prolonged QT syndrome.[74] Estrogen, through the activation of ERβ, confers protection after ischemia and reperfusion in murine models of myocardial infarction. In contrast, testosterone, in the same model, has the opposite effect. Aromatase also has protective effects, probably through its action to increase estrogen and to decrease testosterone.

Gender differences in cardiac physiology should include consideration of the cellular physiology of sex steroid hormones in males and females; intrinsic differences in the physiology of cardiomyocytes, vascular smooth muscle cells, and endothelial cells between males and females; and gender-based differences in the autonomic modulation of cardiac physiology.

CARDIAC REFLEXES

Cardiac reflexes are fast-acting reflex loops between the heart and the central nervous system (CNS) that contribute to regulation of cardiac function and the maintenance of physiologic homeostasis. Specific cardiac receptors elicit their physiologic responses by various pathways. Cardiac receptors are linked to the CNS by myelinated or unmyelinated afferent fibers that travel along the vagus nerve. Cardiac receptors are in the atria, ventricles, pericardium, and coronary arteries. Extracardiac receptors

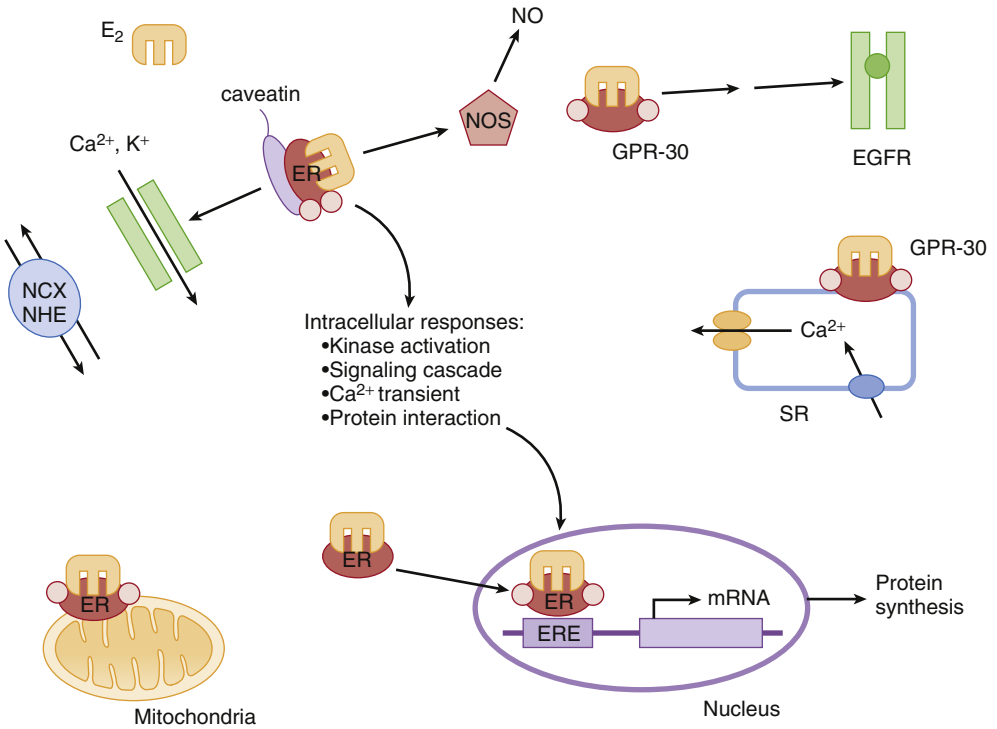

Figure 20-18. Signaling mechanism of nuclear and nonnuclear localized estrogen receptor (ER) and the estrogen-binding receptor, GPR-30. Nuclear ER influences the transcription of target genes by binding to an ER-response element (ERE) within the promotor region of target genes. *E_2*, Estrogen; *EGFR*, epidermal growth factor receptor; *NCX*, Na^+-Ca^{2+} exchanger; *NHE*, Na^+-H^+ exchanger; *NO*, nitric oxide; *NOS*, nitric oxide synthase, *SR*, sarcoplasmic reticulum. *(From Du XJ, Fang L, Kiriazis H: Sex dimorphism in cardiac pathophysiology: experimental findings, hormonal mechanisms, and molecular mechanisms,* Pharmacol Ther *111:434-475, 2006.)*

are located in the great vessels and carotid artery. Sympathetic and parasympathetic nerve input is processed in the CNS. After central processing, efferent fibers to the heart or the systemic circulation will provoke a particular reaction. The response of the cardiovascular system to efferent stimulation varies with age and duration of the underlying condition that elicited the reflex in the first instance.

Baroreceptor Reflex (Carotid Sinus Reflex)

The baroreceptor reflex is responsible for the maintenance of arterial blood pressure. This reflex is capable of regulating arterial pressure around a preset value through a negative-feedback loop (Fig. 20-19).[75,76] In addition, the baroreceptor reflex is capable of establishing a prevailing set point for arterial blood pressure when the preset value has been reset because of chronic hypertension. Changes in arterial blood pressure are monitored by circumferential and longitudinal stretch receptors located in the carotid sinus and aortic arch. The nucleus solitarius, located in the cardiovascular center of the medulla, receives impulses from these stretch receptors through afferents of the glossopharyngeal and vagus nerves. The cardiovascular center in the medulla consists of two functionally different areas; the area responsible for increasing blood pressure is laterally and rostrally located, whereas the area responsible for lowering arterial blood pressure is centrally and caudally located. The latter area also integrates impulses from the hypothalamus and the limbic system. Typically, stretch receptors are activated if systemic blood pressure is greater than 170 mm Hg. The response of the depressor system includes decreased sympathetic activity, leading to a decrease in cardiac contractility, heart rate, and vascular tone. In addition, activation of the parasympathetic system further decreases the heart rate and myocardial contractility. Reverse effects are elicited with the onset of hypotension.

The baroreceptor reflex plays an important beneficial role during acute blood loss and shock. However, the reflex arch loses its functional capacity when arterial blood pressure is less than 50 mm Hg. Hormonal status and therefore sex differences may alter baroreceptor responses.[77] Furthermore, volatile anesthetics (particularly halothane) inhibit the heart rate component of this reflex.[78] Concomitant use of Ca^{2+}-channel blockers, angiotensin-converting enzyme inhibitors, or phosphodiesterase inhibitors will lessen the cardiovascular response of raising blood pressure through the baroreceptor reflex. This lessened response is achieved by either their direct effects on the peripheral vasculature or, more importantly, their interference with CNS signaling pathways (Ca^{2+}, angiotensin).[79] Patients with chronic hypertension often exhibit perioperative circulatory instability as a result of a decrease in their baroreceptor reflex response.

Chemoreceptor Reflex

Chemosensitive cells are located in the carotid bodies and the aortic body. These cells respond to changes in pH status and blood O_2 tension. At an arterial partial O_2 pressure (PaO_2) of less than 50 mm Hg or in conditions of acidosis, the chemoreceptors send their impulses along the sinus nerve of Hering (a branch of the glossopharyngeal nerve) and the tenth cranial nerve to the chemosensitive area of the medulla. This area responds by stimulating the respiratory centers and thereby increasing ventilatory drive.

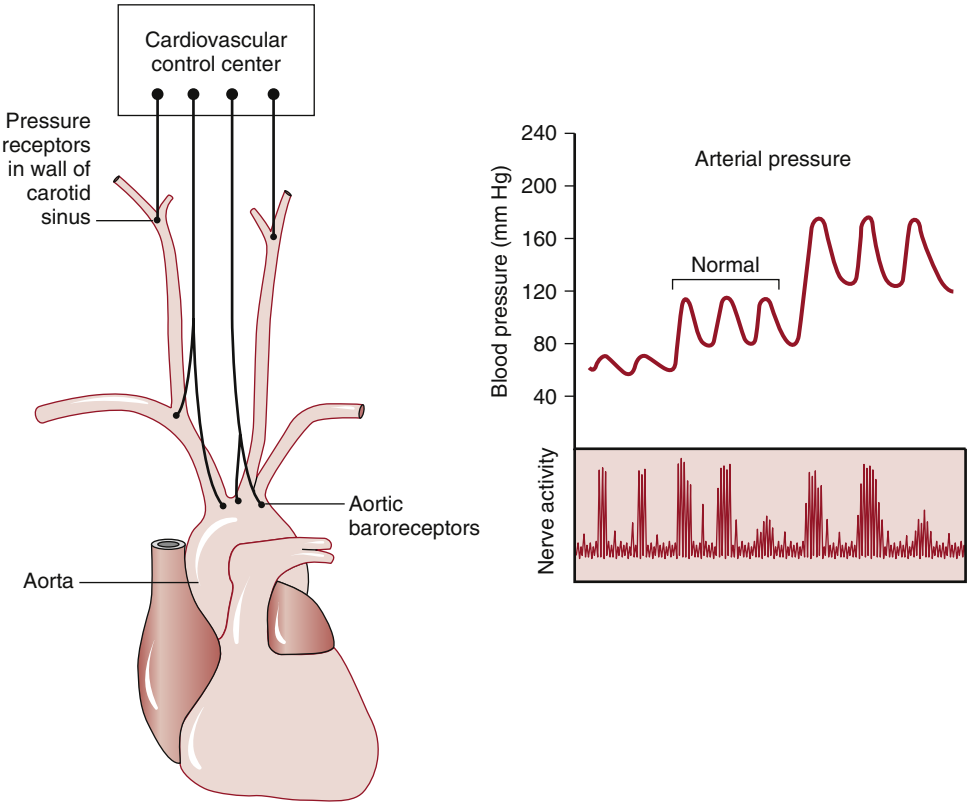

Figure 20-19. Anatomic configuration of the baroreceptor reflex. Pressure receptors in the wall of the carotid sinuses and aorta detect changes in arterial pressure in the circulation. These signals are conveyed to afferent receptive regions of the medulla through the Hering and vagus nerves. Output from effector portions of the medulla modulates peripheral tone and heart rate. The increase in blood pressure results in increased activation of the reflex (*right*), which affects a decrease in blood pressure. *(From Campagna JA, Carter C: Clinical relevance of the Bezold-Jarisch reflex,* Anesthesiology *98:1250-1260, 2003.)*

In addition, activation of the parasympathetic system ensues and leads to a reduction in heart rate and myocardial contractility. In the case of persistent hypoxia, the CNS will be directly stimulated, with a resultant increase in sympathetic activity.

Bainbridge Reflex

The Bainbridge reflex[80-82] is elicited by stretch receptors located in the right atrial wall and the cavoatrial junction. An increase in right-sided filling pressure sends vagal afferent signals to the cardiovascular center in the medulla. These afferent signals inhibit parasympathetic activity, thereby increasing the heart rate. Acceleration of the heart rate also results from a direct effect on the SA node by stretching the atrium. The changes in heart rate are dependent on the underlying heart rate before stimulation.

Bezold-Jarisch Reflex

The Bezold-Jarisch reflex responds to noxious ventricular stimuli sensed by chemoreceptors and mechanoreceptors within the left ventricular wall by inducing the triad of hypotension, bradycardia, and coronary artery dilatation.[75] The activated receptors communicate along unmyelinated vagal afferent type C fibers. These fibers reflexively increase parasympathetic tone. Because it invokes bradycardia, the Bezold-Jarisch reflex is thought of as a cardioprotective reflex. This reflex has been implicated in the physiologic response to a range of cardiovascular conditions such as myocardial ischemia or infarction, thrombolysis, or revascularization and syncope. Natriuretic peptide receptors stimulated by endogenous ANP or BNP may modulate the Bezold-Jarisch reflex. Thus the Bezold-Jarisch reflex may be less pronounced in patients with cardiac hypertrophy or atrial fibrillation.[83]

Valsalva Maneuver

Forced expiration against a closed glottis produces increased intrathoracic pressure, increased central venous pressure, and decreased venous return. Cardiac output and blood pressure will be decreased after the Valsalva maneuver. This decrease will be sensed by baroreceptors and will reflexively result in an increase in heart rate and myocardial contractility through sympathetic stimulation. When the glottis opens, venous return increases and causes the heart to respond by vigorous contraction and an increase in blood pressure. This increase in arterial blood pressure will, in turn, be sensed by baroreceptors, thereby stimulating the parasympathetic efferent pathways to the heart.

Cushing Reflex

The Cushing reflex is a result of cerebral ischemia caused by increased intracranial pressure. Cerebral ischemia at the medullary vasomotor center induces initial activation of the sympathetic nervous system. Such activation will lead to an increase in heart rate, arterial blood pressure, and myocardial contractility in an effort to improve cerebral perfusion. As a result of the high vascular tone, reflex bradycardia mediated by baroreceptors will ensue.

Oculocardiac Reflex

The oculocardiac reflex is provoked by pressure applied to the globe of the eye or traction on the surrounding structures. Stretch receptors are located in the extraocular muscles. Once activated, stretch receptors will send afferent signals through the short- and long-ciliary nerves. The ciliary nerves will merge with the ophthalmic division of the trigeminal nerve at the ciliary ganglion. The trigeminal nerve will carry these impulses to the gasserian ganglion, thereby resulting in increased parasympathetic tone and subsequent bradycardia. The incidence of this reflex during ophthalmic surgery ranges from 30% to 90%. Administration of an antimuscarinic drug such as glycopyrrolate or atropine reduces the incidence of bradycardia during eye surgery (also see Chapter 84).

Chapter 21

Gastrointestinal Physiology and Pathophysiology

MATTHIAS F. STOPFKUCHEN-EVANS • SIMON GELMAN

Key Points

- The functional role of the gastrointestinal (GI) tract is the digestion and absorption of nutrients. These processes are facilitated by the integrated movement of luminal contents (food, digestive enzymes, secretions) along the gastroenteral tube from the mouth to the anus.
- The wall structure of the GI tract consists of a few layers. Main layers of the GI tract are the serosa, muscularis (longitudinal and circular muscle layers), submucosa, and mucosa. The mucosa has three components: a single layer of epithelial cells (epithelium), the lamina propria, and the muscularis mucosae.
- The regulation of digestion and absorption is principally the result of the in-depth networking between the enteric mucosal membrane, the enteric nervous system, and the autonomic nervous system. The enteric nervous system contains two main plexuses: the submucosal plexus, which controls mainly absorption, secretion, and mucosal blood flow; and the myenteric plexus, which regulates tone and tonic contractions of the intestinal wall.
- Motility plays a vital role in regulating speed and intensity of absorption through regulation of transit time and exposure of nutrients to the mucosal brush border.
- Achlorhydria, such as chronic proton pump inhibitor or histamine antagonist use or the removal of much of the oxyntic region of the stomach (gastrectomy, bariatric surgery), results in a profound offset of the balance between digestive and protective secretion and can result in severe depletion of nutrients and vitamins over time.
- Manipulation of the intestines leads to a cascade of neural and inflammatory responses that propagate through the entire gut. The main pathophysiologic event in postoperative ileus is the neuroimmune interaction, which is the bidirectional communication between the immune system within the GI tract as well as the entire body and the autonomic nervous system, including the enteric nervous system.
- The main purpose of the GI blood flow is to deliver nutrients and hormones to the gut, to remove metabolic waste from the gut, and to maintain the mucosal barrier to prevent transepithelial migration of antigens, toxic chemicals, and pathogenic microbiota.
- Approximately 70% of the total blood volume is in the veins. The splanchnic system receives 25% of cardiac output and contains approximately one third of the total blood volume. Approximately 1 L of blood can be recruited from the splanchnic vasculature into the systemic circulation when needed.
- Hemodynamic changes observed during capnoperitoneum are the result of the complex interaction between anesthesia, surgical insult, the patient's position, carbon dioxide, and an increase (followed by a reduction at the end of surgery) in intra-abdominal pressure and oxidative stress, which plays an important role in the overall response to this procedure. It is not surprising that some authors are replacing the term *minimally invasive surgery* with the more precise term *minimal-access surgery.*

The gastrointestinal (GI) tract constitutes approximately 5% of the total human body mass but receives 25% of the cardiac output. The main functions of the GI tract include motility, digestion, absorption, excretion, and circulation (blood flow and blood volume regulation). Other important functions have been studied extensively only for the past few decades. These functions include local and general immunity and the overall role of the GI tract in inflammatory responses, including the resolution of inflammation. These multiple functions require sophisticated integration and regulation; information from the body and the environment must be sensed and processed into appropriate command centers, and then necessary activities are initiated. The structure and regulatory mechanisms of the GI tract fulfill these requirements.

The walls of the GI tract are multilayered (Fig. 21-1). The main layers are (from outermost to inmost) the serosa, muscularis (longitudinal and circular muscle layers), submucosa, and the mucosa. The mucosa has three components (from innermost to outermost): a single layer of epithelial cells (epithelium), the lamina propria, and the muscularis mucosae. Every organ along the GI tube has a generally similar structure; however, the specifics are remarkably different and mainly have to do with the mucosa. GI epithelial cells turn over every 3 days, undergoing divisions and differentiation, followed by programmed death (apoptosis). The contents of the GI tract are sensed by the epithelium, where the enteric reflexes originate. Secretion of enzymes, absorption of nutrients, and excretion of waste products occur through the epithelium.

Beneath the epithelium is a membrane called the *lamina propria*. It contains blood vessels and nerve endings as well as immune and inflammatory cells that are part of the host defense mechanisms. Beneath the lamina propria, there is a thin layer of smooth muscle called the *muscularis mucosa,* which is responsible for movement of the villi. Beneath the mucosa is a tangled network of nerve cell bodies called the *submucosal plexus*, which transmits information from the epithelial cells to the enteric and central nervous systems. Beneath the mucosa, two layers of smooth muscle provide gut motility. The one closer to the mucosa is a layer of circular muscle with contractions that decrease the diameter of the intestinal lumen. The outer layer of smooth muscle is longitudinal, and its contractions shorten the length of the intestinal segment. Between these two smooth muscle layers is the myenteric plexus, consisting of nerves regulating the function of the gut smooth muscle.

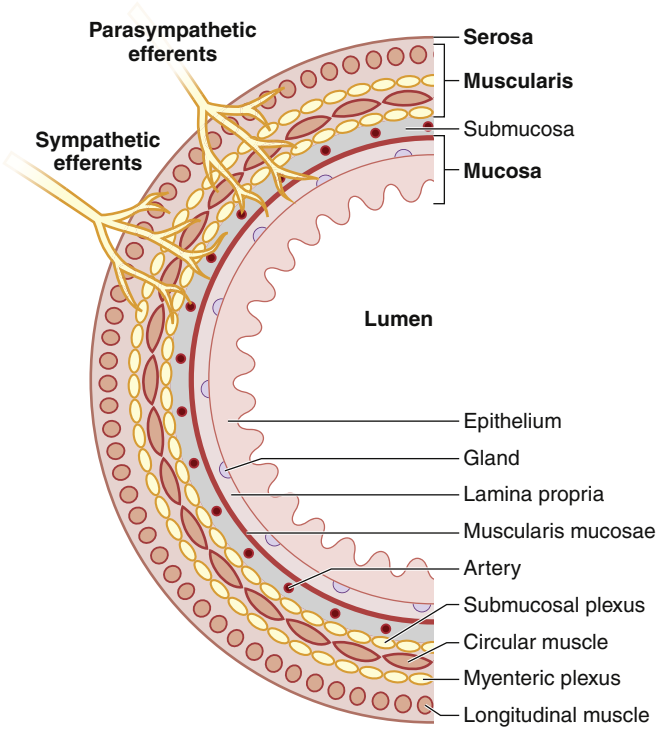

Figure 21-1. The gut wall.

REGULATION OF GASTROINTESTINAL FUNCTION

Four modes of communication control the GI system: endocrine, neurocrine, paracrine, and juxtacrine (immune) regulation. Endocrine regulation is important in integrating the function of the GI organs in their response to a meal. Barrett compares endocrine regulation to a radio broadcast.[1] When a hormone is released, it affects many receptors throughout the GI system and beyond. On the other hand, neurocrine regulation transmits information over long distances, but the communication is narrow and precise, traveling from the end of the nerve fiber to release neurotransmitters that activate the appropriate receptor and then affects the effector. For its specificity, neurocrine communication has been compared with the telephone rather than the radio.[1] Paracrine and juxtacrine (immune) regulation are usually effective in the immediate vicinity of the mediator release. These modes are analogous to live conversations among a few individuals,[1] such as a conference call, to extend Barrett's metaphor**.** In paracrine communication, certain substances are released from cells other than nerves. Such substances provide additional (sometimes redundant) regulation of GI functions, including motility. Juxtacrine or immune communications are achieved with the release of substances from the mucosal immune system. These immune cells are activated by pathogenic microorganisms during invasion of the mucosa by pathogens or antigenic substances and release chemical mediators that include histamines, prostaglandins, and cytokines. Mast cells are particularly important in these processes, and their density is high in the lamina propria. Paracrine and immune regulation involve the release of different mediators.

INTESTINAL MUCOSAL IMMUNOLOGY

The inner surface of the GI tract is really a continuation of the exterior of the body and provides an entrance to the body for microbes and toxic compounds. To protect the body, the intestine has developed a highly effective immune defense system, in effect making the GI tract the largest lymphoid organ in the body.[1] The intestinal immune system can distinguish between harmful and

benign antigens within food. The mucosal immune system is composed of mucosa-associated lymphoid tissues and is one of the most powerful barriers to invasion by pathogens. The system includes nonimmunologic barriers such as acid in the stomach and other digestive secretions and enzymes. The immune host defense barriers include innate and adaptive or acquired immune systems. The innate mucosal immune system responds quickly to pathogens by expressing pattern recognition receptors that detect molecules in pathogenic microbes. For example, lipopolysaccharide and peptidoglycan are often present within pathogenic microbes. The innate system senses these chemicals, activating and releasing chemotactic molecules that stimulate the influx of other inflammatory cells, including microphages and neutrophils. These activated cells facilitate microbial killing by releasing a variety of toxic products such as oxygen free radicals. These inflammatory mediators are important in host-defense mechanisms against microbes, but they also may traumatize nearby uninfected tissues. The innate immune system generates cytokines that facilitate the response and activation of the adaptive immune system, which recognizes components of microorganisms, antigens within microorganisms, as well as abnormal host cells. Such recognition is mediated by specific receptors expressed on lymphoid cells and T and B cells. The B cells secrete antibodies specific for a given antigen; this process is facilitated by T cells, which release cytokines (transforming growth factor β) and interleukins (IL-4, IL-5, and IL-6). Antibodies produced by B cells activate other classes of cells, such as natural killer (NK) cells, which link the adaptive and innate branches of the intestinal immune system. NK cells destroy particles and microbes that have been opsonized or coated with antibodies specific for the NK cell surface components

NK cells also release cytotoxic compounds that are independent of adaptive responses. Transport of antigens and microbes through epithelial cells to lymphoid cells for destruction by the immune system is accomplished by epithelial M cells; they provide an opening in the epithelial barrier through vesicular transport.[2]

Glycocalyx is a general term describing the glycoproteins, mucosaccharides, and other compounds located at the apical part of epithelial cells. The functions of the glycocalyx include protection of the cellular membrane from chemical injury. The glycocalyx also enables the immune system to recognize and selectively attack foreign organisms. It coats the endothelial cells within blood vessels and prevents leukocytes from rolling. When the glycocalyx is damaged by inflammation, its permeability increases, leading to loss of water, electrolytes, and proteins during many inflammatory conditions, including the perioperative period. The amount of water lost from the circulation in this way can reach 1 L.[3]

NEUROCRINE REGULATION OF MOTILITY

Motility refers to the contractions of the muscles of the GI tract that move ingested material from the mouth to the anus. During this long trip, the particles of the ingested mass are reduced in size and mixed with GI secretions. The GI tract is innervated by the autonomic nervous system, which includes the extrinsic nervous system with its sympathetic and parasympathetic branches and the enteric nervous system.

EXTRINSIC SYMPATHETIC INNERVATION

Preganglionic sympathetic fibers that innervate the GI tract originate in the spinal cord at the T5-L2 segments. The ganglionic presynaptic fibers leave the spinal cord, enter the sympathetic chain of ganglia (celiac ganglion and a few mesenteric ganglia), synapse with postganglionic neurons, and travel to the gut, terminating at the neurons of the enteric nervous system. The main neurotransmitter in the sympathetic innervation of the GI tract is norepinephrine. Vasoactive intestinal polypeptide (VIP) also plays a role in transmission of sympathetic signals. The main physiologic action of the sympathetic nervous system is inhibitory; strong sympathetic stimulation can stop the movement of food through the GI tract.

EXTRINSIC PARASYMPATHETIC INNERVATION

Preganglionic parasympathetic nerves arise from cell bodies in the medulla and in the sacral region of the spinal cord. They synapse mainly in the cells of the enteric nervous system. The multiple afferent nerves that travel within the vagus and pelvic nerves provide information to the brain and spinal cord for integration. Vagus fibers provide innervation to the esophagus, stomach, pancreas, small intestine, and the first half of the large intestine. The sacral parasympathetic nerves originate in the sacral segments of the spinal cord and within the pelvic nerves, innervating the lower part of the large intestine, sigmoid, rectal, and anal regions. The main physiologic effect of the parasympathetic influence is activation of the GI functions. The main parasympathetic neurotransmitter is acetylcholine (ACh).

INTRINSIC INNERVATION (ENTERIC NERVOUS SYSTEM)

The GI tract has its own independent nervous system—the enteric nervous system; it is often called the *little brain* because it functions independently from the central nervous system to control GI tract functions such as motility, secretion, and blood flow.[1] The motor apparatus consists of enteric neurons, interstitial cells of Cajal (ICCs), and smooth muscle cells.[4] The enteric nervous system receives information concerning the physiologic status of the intestine instantly, integrating it and effecting necessary changes in the function of the smooth muscle and other structures within the GI tract. This information is also transmitted to the central nervous system, which modulates it with the adaptive plasticity of mostly vagal brainstem circuits and sends signals back to the enteric nervous system, modifying the functional result. This process ensures that extrinsic factors such as stress or the time of day are incorporated as well.

The enteric nervous system contains two main plexuses (see Fig. 21-1). The outer plexus is located between

the longitudinal and circular muscular layers and is called the *myenteric plexus*, or *Auerbach plexus*. The inner plexus is located within submucosa and is called the *submucosal plexus*, or *Meissner plexus*. The motility of the GI tract is mainly controlled by the myenteric plexus. ICCs are pacemaker cells that generate intrinsic electrical activity. ICCs reside within the myenteric plexus and are functionally connected with smooth muscle cells via gap junctions. ICCs are densely associated with enteric nerve terminals and are interposed between them and the smooth muscle syncytium. The submucosal plexus controls mainly absorption, secretion, and mucosal blood flow.[5] Sympathetic and parasympathetic fibers are connected with the myenteric and submucosal plexuses. Stimulation of the myenteric plexus mainly increases the tone or tonic contraction of the intestinal wall, mediated by neurotransmitters within the enteric nervous system. ACh and tachykinins such as substance P are excitatory, whereas VIP and nitric oxide (NO) are inhibitory.

There are reflexes that occur within the enteric nervous system. Many are bidirectional, connecting the spinal cord or brainstem with the GI tract. Activation of sympathetic neurons and norepinephrine do not directly affect the basic myogenic tone of the GI tract, but instead reduce the amount of ACh released from intrinsic cholinergic neurons.[6] The sympathetic neurons also constrict the sphincters. Both mechanisms (reducing ACh release and constricting sphincters) retard the transit of intestinal content along the digestive tract. There are many sympathetic enteric reflexes. Distention of the distal ileum or the colon leads to inhibition of motility within the proximal ileum, slowing down gastric emptying to protect the duodenum from excessive exposure to the highly acid gastric contents.[6] The main neurotransmitter within the excitatory nerves is ACh, which activates muscarinergic receptors. Inhibitory nerves release predominantly NO, although other inhibitory neurotransmitters include VIP and adenosine triphosphate (ATP). Sympathetic inhibitory effects within the enteric nervous system are achieved by norepinephrine.

Decreases in motility are mediated partially by the inhibition of ACh release from enteric cholinergic neurons, secondary to α_2 adrenoceptor activation.[6] This effect is supplemented by direct relaxation of the intestinal muscles by activation of β-adrenergic receptors. Sphincter muscles (unlike nonsphincter muscles) have excitatory α and inhibitory β-adrenergic receptors. Development of dystrophic and degenerative processes in sympathetic efferent fibers innervating the GI tract have been observed in diabetic sympathetic neuropathy,[6] leading to more rapid transit of food through the distal small intestine.

Nervous control of GI motility is complex and includes communication from the central nervous system to the periphery; it also messages from the GI tract to the central nervous system. The role of the enteric nervous system within the GI tract cannot be overestimated.

TRAVEL AND MIXING OF FOOD IN THE GASTROINTESTINAL TRACT

There are two main types of movement within the GI tract: mixing movements (which keep the intestinal contents well mixed at all times) and propulsive movements (which move the GI contents along the tract, allowing necessary time for digestion and absorption). The propulsive movements result from periodic contractions of certain segments of the GI tract (peristalsis). The distention of intestinal segments is the most important stimulus of peristalsis.

SWALLOWING AND THE MOTILITY OF THE ESOPHAGUS

The pharynx is divided into three regions: nasopharynx, oropharynx, and hypopharynx. Muscles in the nasopharynx prevent food from moving into the nasal passages during swallowing. The oropharynx pushes the food bolus backwards and down into the esophagus. The hypopharynx is located between the base of the tongue and the cricoid cartilage; it contains the upper esophageal sphincter. The functional coordination between muscles during swallowing is regulated by the swallowing center in the brain.

There are two phases of swallowing, the first of which is the initiatory voluntary stage. When the food is ready to be swallowed, it is voluntarily squeezed and rolled posterior into the pharynx by the pressure of the tongue upwards and backwards against the palate. Next, the process becomes automatic and cannot stop. During the second phase, the food is passed through the pharynx into the esophagus. At the beginning, the soft palate moves upwards to close the posterior nares, preventing the reflux of food into the nasal cavities. Next, the combined action of muscles within the larynx and the neck prevents the movement of the epiglottis upwards, protecting the opening of the larynx and trachea. This stage of swallowing takes approximately 1 or 2 seconds, during which the swallowing center specifically inhibits the respiratory center of the medulla.

The function of the esophagus is not dependent on gravity; food can be moved from the mouth to the stomach even if a person is standing on his or her head.[1] Food enters the esophagus and enters the stomach with two waves of peristalsis. The first wave moves the main part of the food; the second wave takes the remaining part of the food to the stomach. There is an upper esophageal sphincter, which is also called the *pharyngoesophageal sphincter*. This sphincter constricts after food moves to the esophagus, preventing it from moving back into the pharynx. The upper esophageal sphincter produces pressure of approximately 60 mm Hg. At the distal end of the esophagus, approximately 2 to 5 cm above the junction with the stomach, the esophageal circular muscle thickens and functions as the gastroesophageal or lower esophageal sphincter; this sphincter can produce pressure between 20 and 40 mm Hg.

The many enteric neurons within the esophagus sense the presence of food and coordinate local reflexes, supplementing central control of swallowing and esophageal peristalsis. Sensory afferents transmit the signals to the dorsal vagal complex, which activates the somatic and vagal efferents terminating on the striated muscle in the upper third of the esophagus or on the nerves of the enteric nervous system. The enteric nervous system

releases ACh (which contracts the muscle) or NO or VIP (which induce relaxation).

The lower esophageal sphincter contracts in response to distention; the response is mainly myogenic. However, neurohumoral substances (ACh and gastrin) are also released in concert with the ingestion of the meal. Relaxation of this sphincter allows food to enter the stomach and it is mediated mainly by VIP. The lower esophageal sphincter is controlled by myogenic mechanisms, neurohumoral factors, and neural regulation from both the central nervous system as well as the enteric plexus.

Difficulty swallowing is called *dysphagia*. Dysphagia is a frequent problem, especially among the elderly, and increases the risk of aspiration, choking, and malnutrition. Approximately 13% of patients in hospitals and 60% of patients in nursing homes have some degree of dysphagia.[1] Anatomic reasons for dysphagia include diverticula, hiatal hernia, the formation of fibrosis, and scarring of the esophagus as a consequence of reflux disease. Causes of functional dysphagia include stroke and other neurologic diseases.

One of the most common dysfunctions of the lower esophagus is heartburn, which is caused by the reflux of gastric acid and can result in injury to the esophageal mucosa. The acid in the esophagus is partially neutralized by bicarbonate contained in the swallowed saliva; however, with progression of reflux, the stomach contents (including acid) stay in the esophagus longer than under normal conditions, and gastroesophageal reflux disease develops. The activity of the gastroesophageal sphincter and the pressure of the esophageal sphincter are both reduced in critically ill patients.[7,8] Gastroesophageal sphincter tone decreases reflexively when cricoid pressure is applied to awake patients.[9] Remifentanil infusion, with or without a propofol bolus, reduces the decrease in gastroesophageal barrier pressure caused by cricoid pressure.[10]

MOTILITY OF THE STOMACH

The stomach functions as a homogenizer, mechanically breaking down ingested food into an emulsion of small particles. The proximal stomach (i.e., the cardia, fundus, and corpus**)** functions primarily as a reservoir. The distal stomach consists of the distal portion of the body of the stomach, the antrum, and the pylorus that controls the amount and size of food particles entering the duodenum. The stomach is shaped like a sac rather than a tube. The muscle layers are thick and contract in different directions. There are three main motor functions of the stomach. The first function is the storage of large quantities of food. The stomach can easily accommodate about 1500 mL of contents without a significant increase in intragastric pressure. This process is called *receptive relaxation* and is mediated by a vagovagal reflex; vagotomy abolishes this reflex. The second function of the stomach is mixing food with gastric secretions until it forms a semifluid mixture called *chyme*. The third function is slow emptying of the stomach into the small intestine. Solid food tends to be retained in the proximal stomach, while liquids are distributed throughout the stomach. Liquids are emptied faster than solids. Gastric emptying of solids is a two-stage process: an initial retention period during which solids are broken down to approximately 2 mm diameter followed by a generally linear emptying phase.[5] It takes approximately 3 to 4 hours to empty solids from the stomach into the duodenum. Characteristics of the food within the stomach affect the pace of stomach emptying; for example, isotonic saline leaves the stomach the fastest, while lipids empty slowly.

Vagal afferents provide information from mechanosensitive and chemosensitive receptors to the nucleus tractus solitarius of the dorsal motor nucleus in the brain. Gastric motility is controlled by intrinsic (myenteric plexus) and extrinsic neural regulation. Extrinsic control regulates motility via parasympathetic nerves carried by the vagus. Stimulation of the vagus increases the number and force of contractions, while sympathetic nerves usually inhibit contractions. The hormones gastrin and motilin increase frequency and strength of contractions, while gastric inhibitory polypeptide inhibits them.

Sympathetic innervation reaches the stomach through the splanchnic nerve. The main neurotransmitter there is norepinephrine, which functions as an inhibitor at the postganglionic level within the enteric ganglia. Myenteric neurons provide coordination for gastric motility.

The effectiveness of such complex innervation and interconnectedness is illustrated by the fact that distention of the duodenum leads to a decrease in the tone of the gastric fundus. Such reflexes and actions depend on the characteristics of the contents of the duodenum. For example, an increase in fat or protein within the duodenal lumen slows gastric emptying until the duodenum is able to process additional nutrients. Colon distention also leads to relaxation of the stomach. Cholecystokinin (CCK) is considered one of the main neurotransmitters mediating retrograde signaling from the intestines to the stomach. CCK is released from the mucosa of the jejunum in response to fatty substances in the intestinal contents. CCK constricts the gallbladder, expelling bile into the small intestine and inhibiting stomach motility. The combination of these two functions leads to slower movement and longer exposure of the intestinal contents to digestive enzymes.

The motility of the stomach is organized to accomplish the orderly emptying of the contents into the duodenum. When the stomach is filled with a meal, the pylorus is closed for a prolonged period and opens for short periods to let only small amounts of food enter the duodenum. The specific chemical composition of a meal can also prolong constriction of the pylorus to prevent food from entering the duodenum prematurely. This feature is used in the formulation of medications; pills can be coated with a substance that is sensed by the gastric chemoreceptors and through enteric reflexes prevents the pylorus from relaxing for a relatively long period (referred to as *slow-release pills*).

The emptying of the stomach is regulated by neural mechanisms (the reflex is a reaction to the distention of the stomach) and hormonal mechanisms (release of gastrin from the mucosa of the stomach). The pyloric tone is regulated by inhibitory and excitatory vagal pathways and also by myenteric ascending and descending reflexes. The main mediator of pyloric relaxation is NO, which is formed through both extrinsic and intrinsic pathways.

Suppressed gastric motility and slow gastric emptying aggravate and increase the risk of gastroesophageal reflux. This condition often develops in critically ill patients. Delayed transit has been observed following administration of opioids and during the postoperative period.[7,11] Retrograde flow of gastric contents is observed frequently.[11,12] Gastroparesis can result from abnormalities in the intrinsic and extrinsic innervation of the GI tract. Vagal neuropathy is an important cause of gastroparesis in patients with diabetes.[13] Gastric emptying can be slowed to 1 kcal/min from the 2 to 3 kcal/min seen in healthy humans.[7]

Slow gastric emptying was observed in approximately half of critically ill patients receiving mechanical ventilation.[14] Hyperglycemia and increased intracranial pressure are associated with delayed gastric emptying. Administration of dopamine and other catecholamines stimulates β-adrenergic receptors, reduces intestinal motility, and slows gastric emptying. Erythromycin and metoclopramide accelerate gastric emptying in critically ill patients and can be effective as prokinetic drugs in this population.[15]

MOTILITY OF THE SMALL INTESTINE

The proximal part of the small intestine is called the *jejunum* and the distal part is called the *ileum*, with total length approximately 6 m. There are two layers of smooth muscle within the intestinal wall (see Fig. 21-1). Slow intestinal motility serves several purposes: mixing of the contents with digestive enzymes; further reduction of particle size, increasing their solubility; circulation of the contents to ensure optimal exposure to the intestinal cell membrane; and finally, propulsion of the contents through the small intestine into the colon. A number of reflexes are involved in these activities; they occur within the intrinsic or extrinsic neurons or both. For example, the peristaltic reflex depends on the enteric nervous system. The intestinal reflex depends on the extrinsic neural connection; when one of the areas of intestines is distended, contractile activity in the rest of the intestines is inhibited. The section of the extrinsic nerves abolishes this reflex.

Two types of contractions occur within the small intestines to serve particular purposes: mixing contractions and propulsive contractions. Periodic contractions of the same segment of intestine help to blend the chyme with the intestinal secretions. Peristaltic contractions occur in segments of the intestine in a well-regulated order that pushes the chyme along the GI tract. The constriction of the ileocecal valve keeps the chyme in the ileum to facilitate absorption and to prevent the contents of the large intestine from entering. The ileocecal valve contracts when the colon is distended; this reflex is mediated by sympathetic input from the splanchnic nerve.

The smooth muscles of the intestine provide for "two steps forward, one step back"—that is, retaining the intestinal contents long enough to assure the extraction of useful substances.[1] One of the mechanisms involved is segmentation. When two nearby areas contract, a segment of the small intestine becomes isolated. Next, a contraction in the middle of this segment occurs, further dividing it. Each of the two smaller segments is then divided by other contractions. Both circular and longitudinal muscles shorten and relax in concert to achieve this effect. Segmentation is controlled by the enteric nervous system; specifically, the myenteric plexus receives input from other neurons within the plexus, from receptors located in the mucosa and muscle layers, and from the central nervous system by way of the parasympathetic and sympathetic nerves. Plexus neurons in turn provide integrated output to the smooth muscle cells as well as to epithelial cells and probably to endocrine and immune cells.

Extrinsic innervation is provided by the vagus and by nerve fibers from the superior mesenteric ganglia. The main contracting neurotransmitters of this system are ACh and substance P; VIP and NO are inhibitory. However, intestinal motility is mainly regulated by intrinsic innervation. The main function of extrinsic innervation is to modulate the motility pattern established by the "little brain" of the enteric nervous system. In addition, many circulating compounds are involved in regulation of intestinal motility, including epinephrine (released from adrenal glands), secretin, and glucagon, which inhibit contractions, whereas serotonin (contained in the wall of the small intestine), gastrin, motilin, and insulin stimulate them.

Vomiting is the forceful expulsion of intestinal and gastric contents through the mouth. An increase in tone of the autonomic nervous system usually precedes and accompanies vomiting. The symptoms are nausea, salivation, sweating, rapid breathing, and sometimes an irregular heartbeat. During vomiting, the pressure gradient between different areas of the intestines and stomach can reach 200 mm Hg, and often the stomach partially slides through the hiatus in the diaphragm into the thorax. Vomiting is usually a protective mechanism to eliminate toxic compounds; however, prolonged vomiting can lead to fluid and electrolyte imbalance. Transit of contents through the small intestine can be substantially faster in critically ill patients than in healthy individuals.[16] Faster transit decreases absorption and contributes to malnutrition.[7]

MOTILITY OF LARGE INTESTINE

The colon (large intestine) is a reservoir for waste and indigestible material prior to elimination through defecation. The colon (the GI tract distal to the ileocecal junction) is anatomically divided into the cecum; ascending, transverse, and descending colon; sigmoid; the rectum; and the anal canal. Unlike the small intestines, the main function of the colon is to extract electrolytes and remaining water from the intestinal contents, to transfer the contents to the rectum, and then promote the urge to defecate. Distention of the colon contracts the ileocecal sphincter, whereas distention of the ileum relaxes it; both actions are mediated by enteric nerves. Relaxation of the ileocecal sphincter and increase in contractile activity of the ileum occur shortly after eating. This gastroileal reflex is mediated by GI hormones, mainly gastrin and CCK; both hormones increase contractions of the ileum and relax the ileocecal sphincter.

Most movements within the colon are segmental; they move the contents back and forth, exposing them to absorptive surfaces. The contractions generate intraluminal pressure between 10 and 50 mm Hg and are of either short or long duration. Short-duration contractions occur mainly within the circular muscle and create waves of contraction approximately 8 seconds long, effecting local mixing. Long-duration contractions last 20 to 60 seconds and can propagate the contents for a short distance.

The motility of the large intestine is controlled almost entirely by the enteric nervous system; the major effect of regulation is inhibitory. Cells of the myenteric plexus receive the input from receptors within the intestines as well as from extrinsic nerves. Both parasympathetic and sympathetic branches of the autonomic nervous system are involved in the regulation of colon motility. Pelvic nerves enter the colon near the rectosigmoid junction and then travel along the colon proximally and distally. The distal rectum and anal canal are innervated by sympathetic fibers from the hypogastric plexus. The external anal sphincter striated muscle is innervated by somatic pudendal nerves. The main neurotransmitters involved in the innervation of the large intestine include ACh, substance P, NO, VIP, and ATP. Transmission between pudendal nerves and the external anal sphincter is mediated by ACh.

Movement of the colon mass into the rectum leads to the beginning of defecation. Filling and distention of the rectum causes relaxation of the internal anal sphincter, mediated by release of VIP and NO from intrinsic nerves. This effect is offset by the simultaneous increase of the tone of the external anal sphincter. This action not only allows postponement of defecation until an appropriate time; it also prevents leakage.

Defecation is controlled by extrinsic and intrinsic nerves. The sensation of distention and voluntary control of the external anal sphincter are mediated by nerves within the spinal cord and the cerebral cortex.

GASTROINTESTINAL TRACT AND EMOTIONS

Experiments using magnetic resonance imaging (MRI) and other methods have demonstrated the relationships amongst eating, overall quality of food, and emotions. The design of one such experiment included ratings of hunger, mood, and feeling of fullness; then the subjects were exposed to musical and visual cues intended to induce sadness. At the same time nutrients were infused into the stomach. It was found that induced sadness was attenuated by fatty acid infusion; increased neural activity in the part of the brain processing emotions was also observed.[17]

Gut-brain communications are also influenced by enteric microflora. Ingestion of probiotic bacteria influences emotional state by modulating subunits of receptors of the neurotransmitter γ-aminobutyric acid. Probiotic bacteria are beneficial in stress-related disorders, such as anxiety and depression, and during the course of common comorbidities and some bowel disorders.[18] It seems that the connections between GI function and emotional state have been discussed for centuries: expressions such as "butterflies in the stomach" or "I do not have the stomach for this" were probably not created by chance.

POSTOPERATIVE ILEUS

The following description of postoperative ileus (POI) and its pathophysiology includes only the uncomplicated course of changes in motility of the GI tract after laparotomy or surgery, or both, on GI organs. Not included are descriptions of any unexpected complications (e.g., perforations, peritonitis, bleeding) during the postoperative period. Such complications would have additional pathophysiologic features necessitating different additional treatments.

The main pathophysiologic event in POI is neuroimmune interaction, which is based on bidirectional communication between the immune system within and outside the GI tract (including mast cells, macrophages, and other leukocytes) on one hand and the autonomic nervous system (which includes afferents, efferents, and the enteric nervous system) on the other.[19] The course of uncomplicated POI lasts approximately 3 to 4 days and consists of two phases: the early neurogenic phase and the second inflammatory phase.[19] Manipulation of the intestines is the main factor initiating POI. However, many additional factors contribute to its development, including anesthesia, postoperative pain, and opioids.

The early, neurogenic phase of POI begins with the manipulation of the intestine, which leads to almost complete cessation of GI motility. This effect is mediated via adrenergic innervation. Afferent splanchnic nerves convey the information from the manipulated intestine to the spinal cord. After synapsing within the spinal cord, the efferent fibers convey the information back to the GI organs. These signals also travel through the afferents to the hypothalamus, specifically to the nucleus tractus solitarii and the paraventricular and supraoptic nuclei**.** This pathway activates secretion of corticotropin-releasing factor (CRF). CRF activates neurons in the supraoptic nucleus of the hypothalamus, from which the information travels distal to the spinal cord to the synaptic preganglionic neurons. Activation of the postganglionic neurons inhibits motility of the GI tract. This early phase of POI usually lasts approximately 3 to 4 hours after surgery. The late, inflammatory phase of POI also starts with the manipulation of the intestines, which leads to influx of leukocytes into the traumatized segments of the intestine. This increases the overall sympathetic tone, including the activation of sympathetic efferents. Sympathetic activation within the myenteric plexus contributes to the increased influx of leukocytes into the manipulated segment of the intestine (Fig. 21-2).

Trauma of serosa and activation of sympathetic neurons within the myenteric plexus lead to activation of phagocytosis[20] and an increase in the release of cytokines and chemokines, which further increases the influx of leukocytes first into the manipulated segment of the intestine and later into the entire GI tract.

Degranulation of mast cells and release of their mediators within the traumatized segment increases permeability and facilitates translocation of intraluminal

bacteria, exacerbating the inflammatory process. Mast cells are highly effective in recruiting neutrophils and eliminating bacteria within the peritoneal cavity. Some data suggest that substance P and calcitonin gene–related peptide (CGRP) released from activated afferent nerves are involved in the triggering of mast cell degranulation. During the process, released histamines and proteases have been found in the peritoneal fluid after intestinal manipulation.[21,22] Thus, mast cells and macrophages play central roles in the inflammatory process leading to POI.

The neural response to surgical manipulation of the intestines is important in initiating POI, but becomes less important during the inflammatory phase. POI still develops after small intestine transplantation despite the transplanted intestine being completely denervated.[23]

Under normal conditions, macrophages are located at the level of the myenteric plexus (between the longitudinal and circular muscle layers) and the intestinal serosa.[20] The products released from cells damaged during manipulation of the intestine (which includes ATP and others), and particularly the products of mast cell degranulation, activate muscularis phagocytes.[24] Cytokines and chemokines released thereafter activate resident macrophages.[25]

Pharmacologic or genetic manipulation leading to depletion of resident macrophages leads to a decrease in release of inflammatory mediators and decreases the recruitment of leukocytes into the muscularis. Thus, resident macrophages are activated by direct manipulation of the intestines, which activate muscular phagocytes. Released cytokines reinforce the inflammatory process. Preoperative treatment with antibiotics

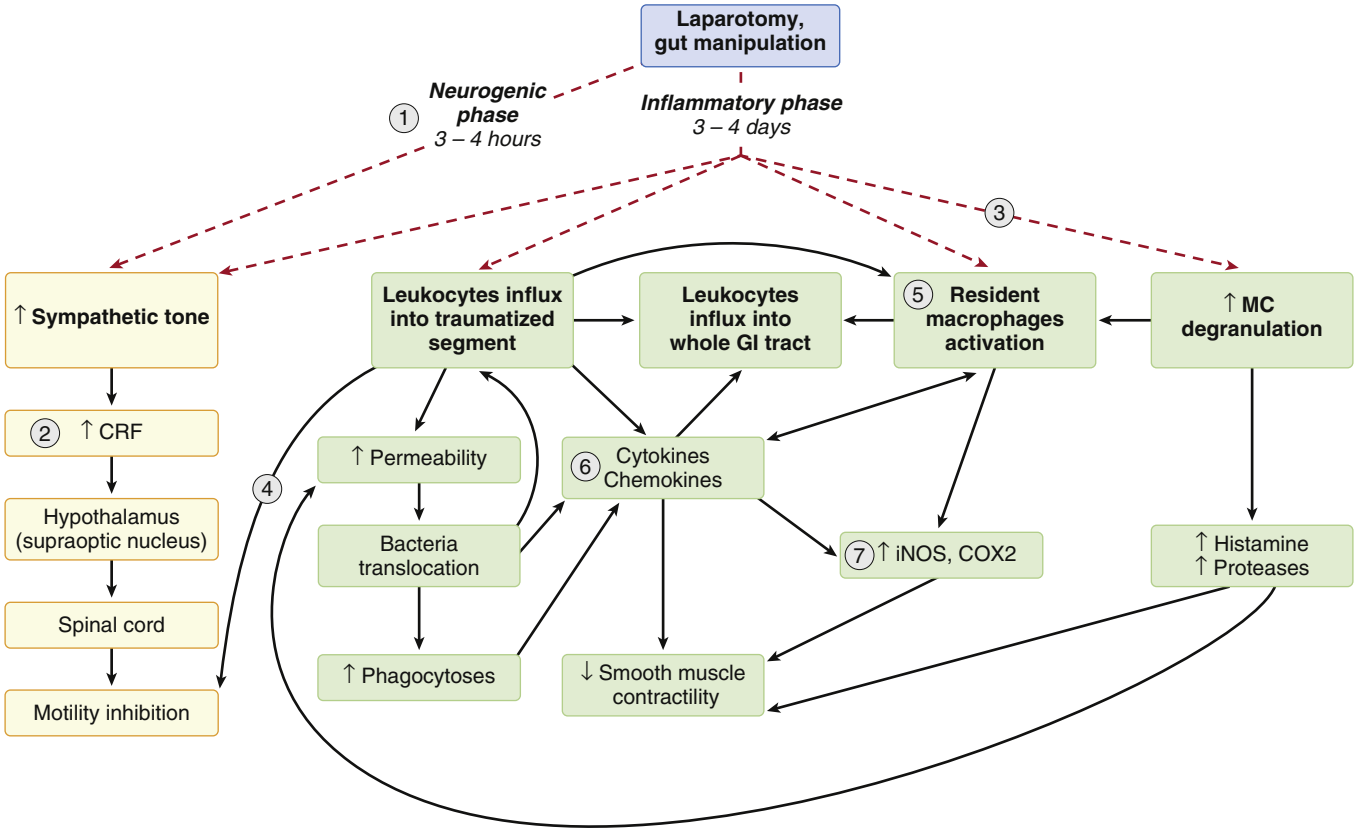

Figure 21-2. Pathophysiology of postoperative ileus (POI). The key feature in the development of POI is the crosstalk between the immune system (mast cells, macrophages, and other leukocytes) and the autonomic nervous system (afferents, efferents, and myenteric plexus). The diagram incorporates main events. The majority of important afferents and efferents are not depicted; see text for explanation. (1) The manipulation of the intestines leads to activation of sympathetic nervous system. Neural pathways involve afferents from the gut, synapses in the spinal cord, and efferents traveling back to the gut directly or through the enteric nervous system. (2 and 3) Released CRF together with substance P initiate MC degradation; the following effects are depicted in the diagram. (4) Manipulation of the intestines triggers the influx of leukocytes in the manipulated segment immediately impairing the smooth muscle function within the segment. (5) Resident macrophages located in serosa and between circular and longitudinal muscle layers close to myenteric plexus are activated directly by manipulation of the intestinal segment leading to an increase in iNOS and COX-2 and directly inhibiting function of the smooth muscles by production of nitric oxide and prostaglandins, particularly PGE-2. (6) Released cytokines tumor necrosis factor α, IL-1β, and IL-6, chemokines MCP-1 and macrophage inflammatory protein-1α (MIP-1α) upregulate adhesion molecules (ICAM-1) in the endothelium and increase further the influx of leukocytes. Neuroinput into this process is illustrated by the decrease in inflammation and POI symptoms during sympatholytic influences, including thoracic epidural anesthesia. (7) Influx of leukocytes triggers neural pathways and inhibits motility illustrating the importance of the crosstalk between neural and immunity or inflammatory systems during the development of POI. *CRF*, corticotropin-releasing factor; *MC*, mast cells.

modifies the overall inflammatory process within the intestines.

The influx of leukocytes into the muscularis starts approximately 3 hours after manipulation of the intestines; during the next 24 hours, the influx increases in the manipulated segment of the intestine and the entire GI tract. These events in turn induce iNOS and cyclooxygenase-2 (COX-2) in the resident macrophages. Thus, the inflammatory process that includes influx of leukocytes into the muscularis of the intestinal wall is one of the main mechanisms responsible for the late inflammatory phase of POI. The up-regulation of iNOS and COX-2 in the resident macrophages inhibits motility in the inflamed intestines[26,27]; therefore, the prevention and treatment of POI can include the blockade of iNOS and COX-2. Preoperative administration of antibiotics decreases the overall inflammatory process and can reduce POI.

Pharmacologic or electrical stimulation of the vagus reduces macrophage activation and attenuates POI.[28] Stabilizing mast cells, administering antibodies to IL-12, or inhibiting Th_1 cell migration were also effective in reducing POI symptoms.[29] Ganglion antagonists such as hexamethonium significantly ameliorate the inhibition of intestinal motility during POI.[30] Thoracic epidural anesthesia placed below T12 does not affect the course of POI; however, if it is administered above T12, attenuation of POI has been observed.[31] Thoracic epidural anesthesia promotes GI motility by blockade of afferent nerves, blockade of thoracolumbar sympathetic efferent nerves, unopposed parasympathetic efferent nerves, reduced need for postoperative opioids, increased GI blood flow, and systemic absorption of local anesthetics.[31] These observations show clearly that both neural and inflammatory mechanisms (and interactions between them) play an important role in the pathogenesis of POI.

Manipulation of the intestines leads to a cascade of neural and inflammatory responses. Leukocyte influx into manipulated segments is associated with release of cytokines and chemokines that initiate and potentiate the recruitment of leukocytes into the intestinal segment and then into the entire GI tract. Motility is decreased in the inflamed intestine by increased production of NO and COX-2. These events and the activation of inhibitory adrenergic neural signals are responsible for the course of POI (see Fig. 21-2).

SECRETION

OVERVIEW

Initially, the secretory function of the GI tract supports the digestion of a swallowed bolus of food to promote the absorption of nutrients, electrolytes, and vitamins contained in food. It also protects the GI tract from ingested bacteria. Next, the secretion of hormones, peptides, and mediators not only regulates the intake of food through intensive crosstalk with the central nervous system; it also ensures the optimal digestion and absorption of luminal content by modulating digestive secretion and its rate of delivery throughout the intestinal tract. It regulates mucosal proliferation, maturation and regeneration, and modulates immune function. The integral secretory activity of the GI tract controls food ingestion, its digestion, absorption, and the advancement through the intestine to optimize extraction of vital nutrients, vitamins, and electrolytes while ensuring the maintenance of homeostasis of the complex ecosystem of the GI tract, the integrity of its own structure by adapting to the ever changing needs of quiescence during night and fasting, and the dynamics of food processing during digestion.

DIGESTIVE SECRETION

Hydrochloric Acid Secretion

Hydrochloric acid is secreted in the stomach by parietal cells found in the oxyntic region (Fig. 21-3) and facilitates digestion and absorption of proteins, iron, electrolytes, and certain medications such as thyroxin.[32] Hydrochloric acid also controls ingested bacteria and sterilizes food. Hydrochloric acid production and secretion must be tightly regulated, because too much gastric acid is detrimental to the stomach itself or the adjacent esophagus and duodenum and it might overwhelm self-protective measures causing significant pathology (gastric ulcers, duodenal ulcers, esophagitis, intestinal metaplasia [Barrett esophagus], and ultimately gastric or esophageal cancer). Too little gastric acid can lead to malabsorption of essential vitamins and electrolytes or increase the risk for intestinal infections and modification of the enteral ecosystem by bacterial overgrowth. The chronic use of acid-suppressing drugs, such as histamine-2 receptor antagonists or proton pump inhibitors (PPIs), can also increase the risk for community-acquired pneumonia.[33] Electrolyte abnormalities, such as hypomagnesemia and low vitamin B_{12} levels, should be anticipated with long-term use of such medications. An increased risk of fractures has been noted as well when gastric hydrochloric acid is reduced chronically by means of a PPI.[34] Lastly, when administered with clopidogrel, a GP2b/3a receptor inhibitor frequently used as an antiplatelet agent after stent placement, PPIs are thought to reduce the efficacy of clopidogrel in various but clinically significant degrees.[35]

Acid secretion is a complex and highly integrated process involving hormonal, paracrine, and enteric as well as central neuronal pathways that are modulated by both local and central feedback loops (Fig. 21-4). The cephalic phase of acid secretion is initiated by sensory inputs such as the thought, sight, smell, taste, or sound of food. The cephalic phase contributes about 50% of the overall acid response to a meal.[5] GI peptides such as ghrelin and leptin can act directly in the brain or indirectly by acting on the abundant afferent neurons that terminate in the spinal cord or the brain stem. The mechanical and chemical milieu is monitored continuously by as many as 16,000 afferent vagal neurons that convey information to the nucleus tractus solitarius in the medulla and the paraventricular nucleus in the hypothalamus. Only 6000 efferent preganglionic neurons originating from

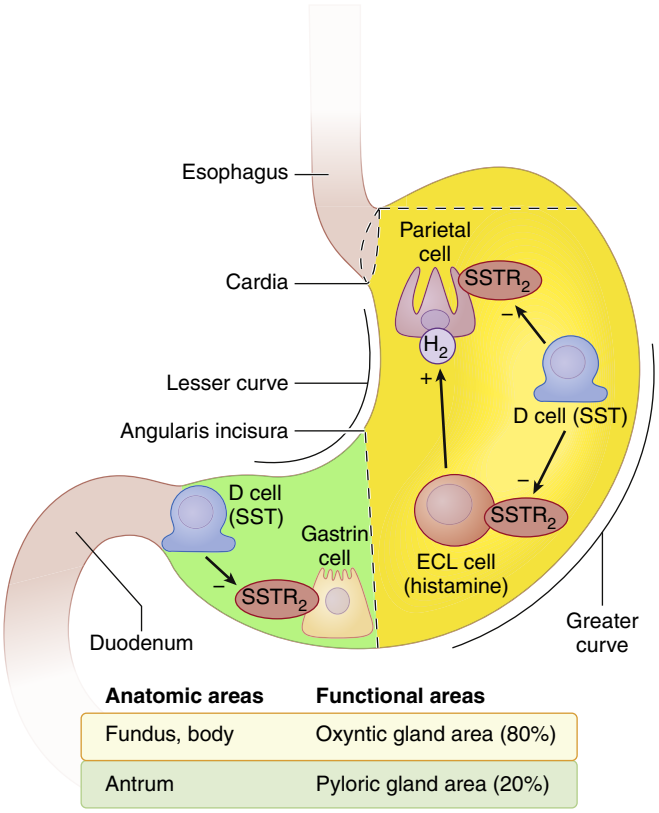

Figure 21-3. Functional gastric anatomy. The stomach consists of three anatomic (fundus, corpus or body, and antrum) and two functional (oxyntic and pyloric gland) areas. The hallmark of the oxyntic gland area is the parietal cell. The hallmark of the pyloric gland area is the gastric (G) cell. Somatostatin (SST)-containing D cells are structurally and functionally coupled to their target cells: parietal, enterochromaffin-like (ECL), and gastric cells. SST, acting via $SSTR_2$ receptors, tonically restrains acid secretion. This restraint is exerted directly on the parietal cell and indirectly by inhibiting histamine secretion from ECL cells and gastrin secretion from G cells. H_2, histamine H_2 receptor. *(Redrawn from Functional Gastric Anatomy from Schubert ML: Regulation of gastric acid secretion. In Johnson LR, Ghishan FK, Kavnitz JD, et al, editors:* Physiology of the gastrointestinal tract, *vol 2, ed 5. Boston, 2012, Academic Press.)*

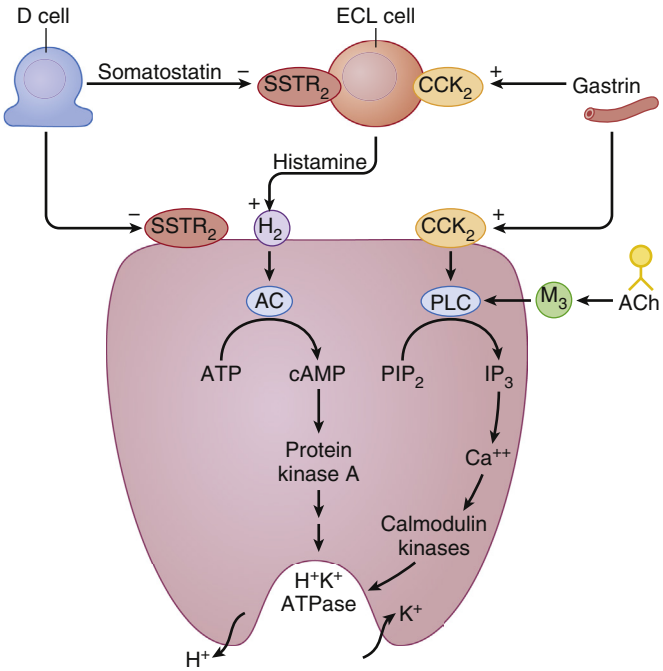

Figure 21-4. Model illustrating parietal cell receptors and signaling pathways. The principal stimulants of acid secretion at the level of the parietal cell are histamine (paracrine), gastrin (hormonal), and acetylcholine (ACh; neurocrine). Histamine, released from enterochromaffin-like (ECL) cells, binds to H_2 receptors coupled to activation of adenylate cyclase, which converts cytosolic adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). Increases in cAMP activate cAMP-dependent protein kinases (protein kinase A) that phosphorylate various intracellular proteins that ultimately trigger acid secretion. Gastrin, released from G cells, binds to CCK_2 receptors on ECL and parietal cells that are coupled to activation of phospholipase C with conversion of phosphatidylinositol bisphosphate (PIP_2) to inositol triphosphate (IP_3). IP_3 in turn induces release of cytosolic calcium (Ca^{2+}), which activates various calcium-dependent enzymes, such as calmodulin kinases, that ultimately trigger acid secretion. The acid-stimulatory effects of gastrin are mediated primarily via release of histamine from ECL cells. ACh, released from intramural neurons, binds to M3 receptors that are coupled to an increase in intracellular calcium via similar signaling pathways as described earlier for gastrin. The intracellular cAMP- and calcium-dependent signaling systems activate downstream protein kinases ultimately leading to fusion and activation of H^+K^+-ATPase, the proton pump. Somatostatin, released from oxyntic D cells, is the principal inhibitor of acid secretion. Somatostatin, acting via the $SSTR_2$ receptor, inhibits the parietal cell directly and indirectly by inhibiting histamine release from ECL cells. +, Stimulatory; –, inhibitory. *(Redrawn from Schubert ML: Regulation of gastric acid secretion. In Johnson LR, Ghishan FK, Kavnitz JD, et al, editor:* Physiology of the gastrointestinal tract, *vol 2, ed 5. Boston, 2012, Academic Press.)*

the nucleus ambiguus and the dorsal motor nucleus of the vagus nerve are switched over to postganglionic neurons in the wall of the stomach and duodenum and with decreasing density in the mid and distal gut.[36] These neurons stimulate acid secretion either directly or indirectly by inhibiting somatostatin secretion and by stimulating histamine and gastrin. Overall, acid secretion is supported by paracrine histamine release from oxyntic enterochromaffin-like (ECL) cells, gastrin release from pyloric G cells, and ACh release from postganglionic intramural neurons. Histamine and either ACh or gastrin act synergistically at the parietal cell and potentiate hydrochloric acid release. Somatostatin is released from oxyntic and pyloric D cells in a paracrine fashion; this represents the major inhibitor of acid secretion. Synthetic somatostatin (octreotide) is used therapeutically among other treatments in acute bleeding peptic ulcer disease.

Bicarbonate Secretion and Mucus Barrier

Mucus and bicarbonate secretions, particularly in the stomach and the duodenum, represent the first line of defense against the hostile and acidic luminal milieu. Mucin is secreted from epithelial cells and polymerizes into large multimers to form a gel. Together with surfactant phospholipids and bicarbonate, it covers the epithelial cell surface and creates a steep pH gradient across the unstirred mucus layer. The hydrophobic luminal surface of this glycoprotein matrix is probably the major

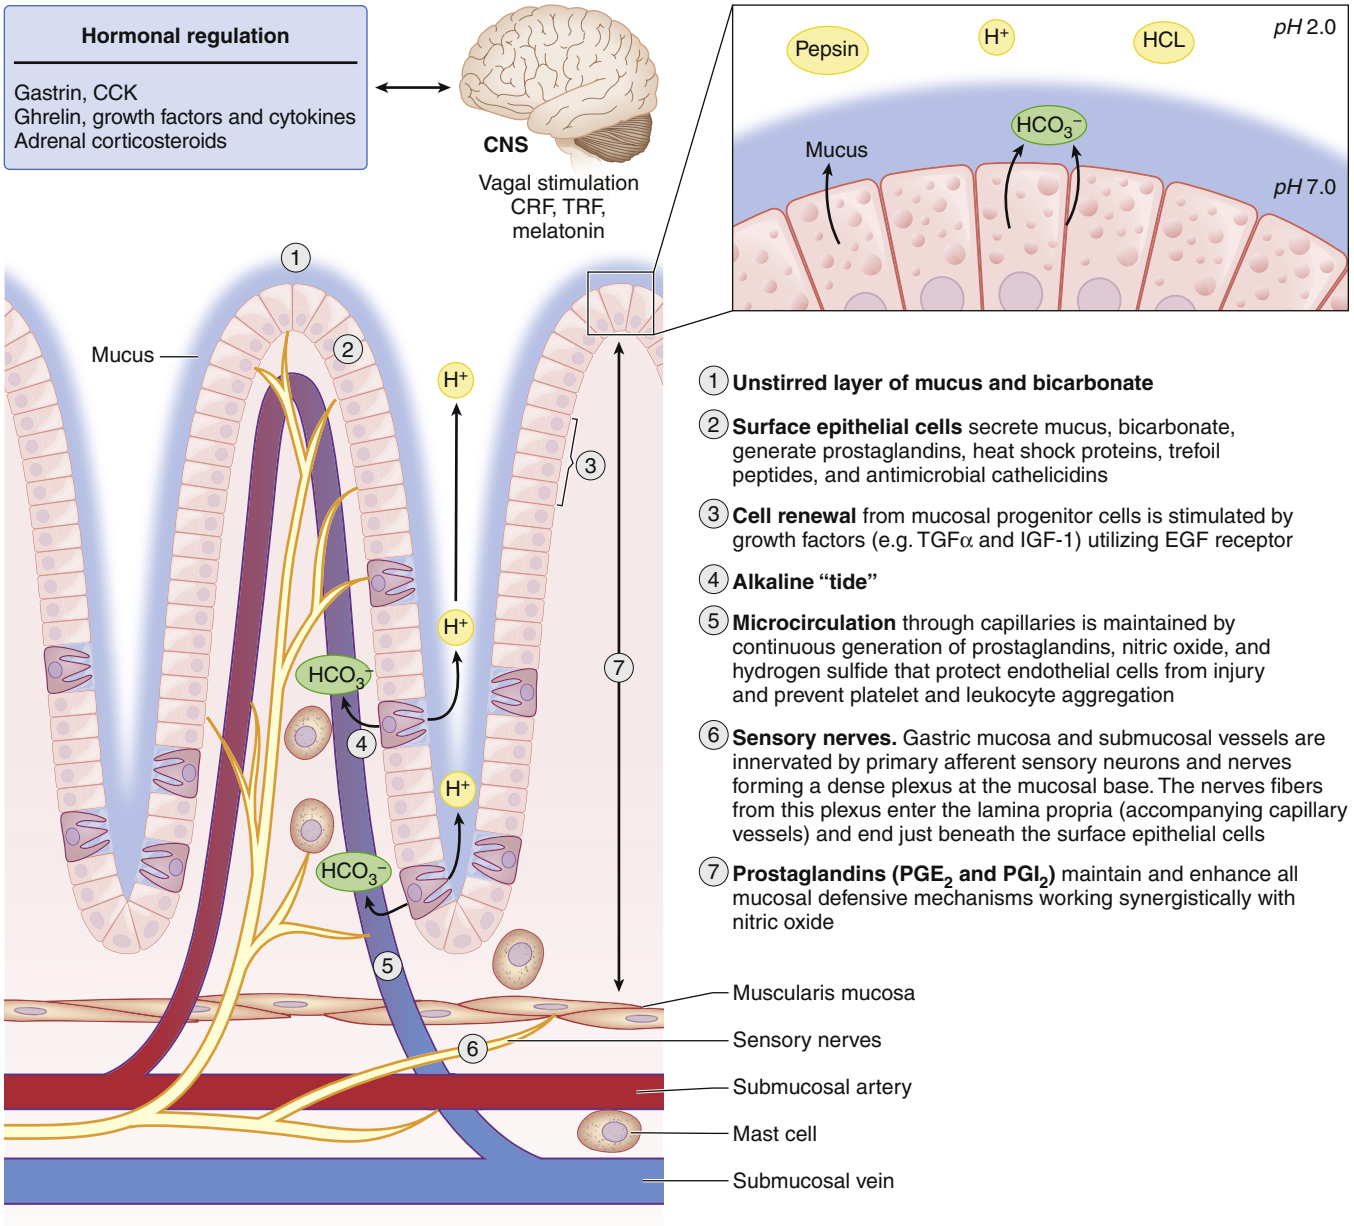

Figure 21-5. Gastric mucosal defense. Schematic diagram of the mucus–bicarbonate barrier of the acid-secreting gastric mucosa. *(Redrawn from Laine L, Takeuchi K, Tarnawski A: Gastric mucosal defense and cytoprotection: bench to bedside,* Gastroenterology *135:41, 2008.)*

reason for this gradient. Trefoil family peptides (TFFs) are stored in mucosal cells in the stomach (gastric pit and surface mucus cells) and in the duodenum (small and large intestinal goblet cells) and are secreted into the mucus gel, where TFFs increase viscosity and elasticity. In addition, TFFs are believed to play a pivotal role in mucosal cell differentiation and regeneration and add to the regulatory signals of acid production. Mucus secretion is stimulated by gastrin, secretin, prostaglandin E_2, and cholinergic agents. Ulcerogenic substances such as nonsteroidal antiinflammatory drugs (NSAIDs), aspirin, and bile salts dissolve the mucus gel and phospholipid layer and lead to mucosal injury (Fig. 21-5). Parietal cells in the oxyntic region of the stomach maintain a tandem production of equivalent numbers of hydrogen and bicarbonate ions. This astonishing and simplistic yet sophisticated principle results in self-regulation.[37] The more hydrochloric acid is produced, the more bicarbonate is secreted into the interstitium and fenestrated capillaries in the gastric glands from which it diffuses into the mucus layer, where it neutralizes hydrogen ions that have diffused into it from the gastric lumen. The driving force for bicarbonate diffusion is the rate of its neutralization in the mucus layer by hydrogen ions; however, most bicarbonate from parietal cells is secreted in the urine. The increase in blood and urine pH after a meal is known as the *alkaline tide*.[38]

Duodenal HCO_3^- secretion is stimulated by a wide variety of agonists (e.g., CCK, ghrelin, serotonin, uroguanylin) and is a much stronger and more sustained

occurrence compared with that of the stomach. Exposure of the duodenal mucosa to luminal acid results in a significant but segmental increase in bicarbonate secretion by mucosal enterocytes and by submucosal Brunner glands. This increase is augmented by a concomitant increase in PGE_2 secretion, which also stimulates bicarbonate secretion. The autonomic nervous system plays an important role in this acid-induced secretory response. The capsaicin-sensitive transient receptor potential vanilloid receptor 1 resides in the lamina propria, senses acidosis, and stimulates bicarbonate secretion. Local humoral factors such as melatonin, vasoactive intestinal peptide, and NO prove to be involved in up-regulation of bicarbonate secretion following exposure to luminal acid. Cystic fibrosis transmembrane conductance regulator (CFTR) is an ATP-binding cassette–class transporter ion channel for chloride and thiocyanate movement across epithelial cell membranes. In states of hypotonicity or low intracellular Cl^-, CFTR switches its selectivity from chloride to HCO_3^-.[39] At least three forms of the apical solute carrier (Slc-26) anion transporter family are expressed in the duodenum and contribute to HCO_3^- secretion.[40]

Prostaglandins (PGE_2, PGI_2) stimulate and facilitate mucosal defense by inhibiting acid secretion and by stimulating mucus, bicarbonate, and phospholipid secretion. They increase mucosal blood flow and support epithelial regeneration and mucosal healing. Prostaglandins (PGs) inhibit mast cell activation, leukocyte adhesion, and platelet adhesion to the vascular endothelium. The inhibition of cyclooxygenase (COX)-mediated PG synthesis by NSAIDs leads to gastroduodenal ulceration and is mainly a systemically mediated effect regardless of the route of NSAID administration. Gastric mucosal integrity at baseline is supported by COX-1–mediated PG synthesis. COX-1 is expressed in many tissues whereas COX-2 is rapidly induced in response to growth factors or cytokines. Only the combined inhibition of COX-1 and -2 causes mucosal damage, whereas mucosal blood flow decreases after selective COX-1 and COX-1/2 inhibition but not with COX-2 selective inhibition. The absence of PG renders hormonal, paracrine or neurocrine pathways (TRPV-1, afferent fibers, NO, CGRP) that stimulate mucus gel secretion ineffective, which underlines the importance of PG, especially in the up-regulation of mucus gel production and secretion. Interestingly, PG depletion results in vagus nerve–dependent gastric hypermotility and subsequent reduction of mucosal blood flow and neutrophil recruitment in the endothelium with the onset of oxygen-radical production.[38]

REGULATORY SECRETION

Hormones, Paracrine, and Neurocrine Compounds

Five peptides are considered GI hormones.[32] They are released following a stimulus, such as a meal, and act at a different location in the GI tract altering its function. This effect is maintained even if no nervous connections exist between the area where the hormone is released and the area where it acts. Hormones are chemically identified and reliably elicit the same functional change when injected into the blood stream. Secretin, gastrin, CCK, gastrin inhibitory peptide and motilin are today established gastrointestinal hormones.[32]

Histamine and somatostatin are released in close proximity to and reach their respective targets by diffusion and therefore represent paracrine agents.

Neurotransmitters are ACh, gastrin-releasing peptide (GRP), vasoactive intestinal peptide, and pituitary adenylate cyclase-activating polypeptide (PACAP). They are released from nerve terminals, and they reach their target receptors by traversing the synaptic cleft. Table 21-1 summarizes postpyloric compounds and their respective primary actions.

Gastrin is the major regulator for hydrochloric acid secretion in the stomach. It promotes mucosal proliferation and maturation, and it modulates innate mucosal immune function. Gastrin is secreted as precursor peptides by G cells in the antrum of the stomach and the duodenum. G cells are the hallmark of the pyloric gland mucosa in the antrum of the stomach. Gastrin is also produced, although in much smaller amounts, in the small intestine, colon, and pancreas. Gastrin release is stimulated by ACh, GRP, PACAP, secretin, serotonin, β_2/β_3-adrenergic agonists, calcium, luminal protein, capsaicin, alcoholic beverages made by fermentation, and bacterial lipopolysaccharide. Galanin, adenosine, and somatostatin inhibit gastrin release from G cells. Gastrin stimulates ECL cells and parietal cells directly via the CCK-2 receptor, which increases intracellular Ca^{2+} through the phospholipase C pathway. Gastrin is metabolized by the kidney, the intestine, and the liver and is found in higher plasma concentrations in patients with impaired renal function. At least two negative feedback loops regulate gastrin release. One loop is activated by intragastric acidity, which releases somatostatin via sensory CGRP neurons, and the second is a direct stimulus by gastrin to release somatostatin. Long-term use of medications that raise gastric pH can lead to hypergastrinemia.[41]

CCK-2 receptors are also found on oxyntic progenitor cells, implying that gastrin is also involved in differentiation, growth, and migration of parietal cells. Gastrin stimulates mucosal proliferation and increases the parietal and ECL cell mass, probably through the release of growth factors.

Gastrin modulates innate immune function through CCK-2 receptors that are found on macrophages in the intestinal lamina propria, peripheral blood mononuclear cells, and polymorphonuclear monocytes within the stroma of colorectal cancers. Proinflammatory actions appear to dominate with stimulation of chemotaxis, adherence, and phagocytosis at sites of active inflammation. In the mesenteric venous system, gastrin promotes leukocyte adherence and extravasation. CCK-2 receptor–expressing intestinal endothelial cells up-regulate their production of vascular cell adhesion molecule 1 (VCAM-1) and P-selectin glycoprotein ligand-1 (P-selectin) following a gastrin stimulus. Therefore, gastrin appears to act as a chemoattractant and recruits inflammatory cells to sites of inflammation within the GI tract.[41]

TABLE 21-1 **IMPORTANT FEATURES OF POSTPYLORIC PEPTIDES**

Peptide	Location	Hormone (H), Neuropeptide (N)	Secretagogues	Primary Activities
Secretin	"S" cells—small intestine	H	Luminal acid, fat	Bicarbonate secretion by biliary pancreatic ductular epithelium, Brunner's glands
Somatostatin (SRIF)	"D" cells—entire GI tract, nerves, and nerve plexuses	H, N	Luminal acid, dietary nutrients	Central inhibitor of gut hormone secretion, nutrient absorption, and exocrine secretion
Vasoactive intestinal polypeptide (VIP)	Superior and inferior mesenteric ganglia, Meissner's and Auerbach's plexuses	N	Unresponsive to meal	Smooth muscle relaxant
Pituitary adenylate cyclase activity peptide (PACAP)	Nerve fibers; myenteric and submucosal ganglia	N	Unresponsive to meal	Physiologic function not proved; relaxes colonic smooth muscle, stimulates pancreatic exocrine secretion
Neurotensin	"N" cells—cells in ileum and colon; myenteric plexus	H, N	Dietary fat	Physiologic functions not proved; influences pancreatic, gastric, and intestinal secretion
Neuropeptide Y (NPY)	Submucosal and myenteric plexuses; nerve fibers of entire GI tract; highest level in lower esophageal sphincter	N	Unresponsive to meal	Regulates GI blood flow, motility, and secretion
Motilin	"M" or "Mo" cells in duodendum	H	Cyclic elevations in plasma motilin during fasting stage; dietary fat in human increases plasma motilin	Stimulation of phase III–MMC contractions
Peptide YY (PYY)	"L" cells of terminal ileum and colon; nerve cell bodies and fibers of stomach; intestinal myenteric and submucosal plexuses	H, N	Mixed meal in humans, luminal fat	Enterogastrone; ileal break; reduces gastric and intestine motility, gastric acid, and pancreatic secretion

GI, Gastrointestinal; *MMC,* migrating myoelectric complex.

Enteroendocrine I–type cells in the duodenum secrete CCK into the blood stream following a meal rich in fat and protein. This secretion stimulates gallbladder contractions and exocrine pancreatic secretion and inhibits further food intake, delays gastric emptying, and increases the travel time along the GI tract via CCK-receptor-1 acting on afferent vagal fibers. Overall, CCK promotes the optimal digestion of fat and protein in the small intestine and currently represents the most important anorexigenic signal in the complex control of food intake and in the long-term energy balance.[42] In addition, CCK has been found to act as an endogenous antiopioid and promotes the development of acute opioid tolerance.[43]

Secretin is released by S cells that line the mucosa of the small intestine in decreasing density from the duodenum to the ileum. It is released when the luminal pH in the duodenum falls to less than 4.5. Its major action is the stimulation of pancreatic and biliary duct cells to secrete bicarbonate.[1] In addition, secretin reduces the gastrin response to food intake, slows gastric emptying, and decreases colonic motility. Secretin is used to aid in the diagnosis of Zollinger-Ellison syndrome, a condition in which an often malignant neuroendocrine tumor produces gastrin. Elevated serum gastrin levels increase further by up to 100% after a secretin challenge.[32] Gastrin-inhibitory peptide or glucose-dependent insulinotropic peptide is a member of the secretin family; it is secreted by K cells, stimulates pancreatic insulin release, and decreases gastric acid release. Luminal carbohydrates, protein, and fat are triggers for the release of gastric inhibitory polypeptide. It also slows gastric emptying and reduces gastric motility.[32] Motilin is cyclically released in the small intestine during the fasting state; it promotes the "migrating motor complex," which is a phased peristaltic wave through the entire intestine

believed to serve a preparatory function to accommodate the next meal.[1]

Gastral histamine is mainly released from ECL cells that are found on the base of oxyntic glands. Some histamine is also released from mast cells. ECL cells, but not mast cells, contain L-histidine decarboxylase, which catalyzes the production of histamine from L-histidine, the major source for histamine in ECL cells. Four subtypes of histamine receptors exist and all of them are G-protein coupled. Parietal cells exhibit the histamine-2 receptor. Histamine release is stimulated by gastrin, PACAP, VIP, ghrelin, epinephrine, norepinephrine, and transforming growth factor alpha. Somatostatin, CGRP, PGE_1 and PGE_2, peptide YY, galanin, and interleukin-1β inhibit histamine secretion.[36]

ACh is released from postganglionic intramural neurons in the gastric body and fundus; it stimulates acid secretion directly by acting on M_3-ACh receptors on parietal cells and indirectly by inhibiting somatostatin release via M_2- and M_4-ACh receptors on D cells.[36]

Gastrin-releasing peptide (GRP) receptors are found on G cells and stimulate gastrin among other peptides.

PACAP is a regulatory peptide found in the gastric mucosa and released from enteric nervous system neurons. Its receptors are found on ECL and D cells. Whether it increases acid secretion or inhibits it depends on confounding factors such as calcium entry and the relative weight of ECL cell–derived histamine release versus D cell–derived somatostatin release.

NO acts as a neurotransmitter, intracellular messenger, and signaling molecule, and it appears to have a dose-dependent effect on net acid secretion.

Ghrelin

Ghrelin is present mainly within the oxyntic mucosa and to a lesser extent within the pyloric mucosa in A-like or Gr cells. These cells represent 20% to 30% of gastric neuroendocrine cells and produce approximately 80% of the body's ghrelin. It is released when the stomach does not contain calories and circulates systemically when fasting to stimulate appetite. ACh, glucagon, secretin, endothelin, and gastric inhibitory polypeptide stimulate ghrelin secretion as well. Ghrelin promotes food intake and appetite. It increases gastric motility, hydrochloric acid secretion, insulin secretion, and promotes adipogenesis. Ghrelin release decreases with intragastric calories, intravenous fat and dextrose, insulin, CCK, somatostatin, GRP, and IL-1β. Ghrelin stimulates growth hormone release in the pituitary gland.[41] The sustained weight loss after bariatric surgery or total gastrectomy is thought to be maintained by loss of ghrelin-secreting cells, 65% of which reside in the stomach. Additionally, ghrelin antagonists might be able to induce weight loss by reducing appetite. Offsetting the hormonal balance that regulates appetite (ghrelin, leptin, GLP-1) by removing parts of the stomach together with a significant drop in ghrelin-secreting cells can put patients at risk for addiction after bariatric surgery, because these mediators affect dopamine release in the addiction circuitry in the brain.[44]

IMMUNOMODULATORY SECRETION

Paneth Cells

Paneth cells reside at the base of Lieberkühn crypts in the small intestine and display a unique histologic morphology with their extensive endoplasmic reticulum and Golgi network.[45] Paneth cells secrete host defense proteins and peptides (e.g., α-defensins that modulate composition of small intestinal microflora, secretory phospholipase A2, lysozyme, lipopolysaccharide-binding protein, REG3-γ, xanthine oxidase, matrix metalloprotease 7, CD95 ligand, immunoglobulin A, CD1d, CRIP, CD15, and several proinflammatory mediators such as IL-17A, tumor necrosis factor α, IL-1β, and lipokines). As a result, these cells play various roles in innate mucosal immunity and maintenance of homeostasis in the lower GI tract. Paneth cells are particularly sensitive to endoplasmic reticulum stress and unfolded protein responses, which if unresolved, leads to apoptosis and disruption of crypt homeostasis with the result of increased sensitivity to ileitis and colitis.[45]

DIGESTION AND ABSORPTION

OVERVIEW

Digestion ensues in the mouth after the ingestion of food. Saliva lubricates the food bolus and mixes into the food as it is chewed. This action moistens the food and facilitates swallowing. Enzymes that are contained in saliva begin the breakdown of carbohydrates (α-amylase) and lipids (lipase). In addition, saliva protects the oral cavity by buffering and by diluting noxious substances, hot or cold liquids, or food. Saliva exhibits additional protective functions by its antibacterial compounds (lactoferrin, secretory immunoglobulin A). Salivary glands are highly effective in producing saliva and are under control of the autonomic nervous system. Muscarinergic receptors and β-adrenergic receptors of salivary glands are mostly stimulated by the parasympathetic as well as by the sympathetic nervous system. Antidiuretic hormone (ADH) and aldosterone decrease sodium and increase potassium concentrations; however, they do not affect the rate of saliva production.

The digestive process in the stomach begins with simple hydrolysis. The stomach secretes hydrochloric acid, which acidifies the luminal environment, denaturizes protein, and sterilizes the meal. Proteolytic enzymatic digestion begins in the stomach. Pepsin is secreted as an inactive precursor (pepsinogen), which is activated by autocatalytic cleavage in the low pH environment. Pepsin activity is optimal at low pH. This is referred to as *luminal digestion*.[32] As the bolus of food passes into the small intestine, membrane digestion ensues. Food contacts the small intestinal brush border and is further hydrolyzed by enzymes anchored in the apical membrane of the epithelial surface.

The small intestine with its brush border is the major area of digestion and absorption of all major dietary compounds, whereas the colon principally absorbs electrolytes and most of the remaining water that passes the ileocecal valve.

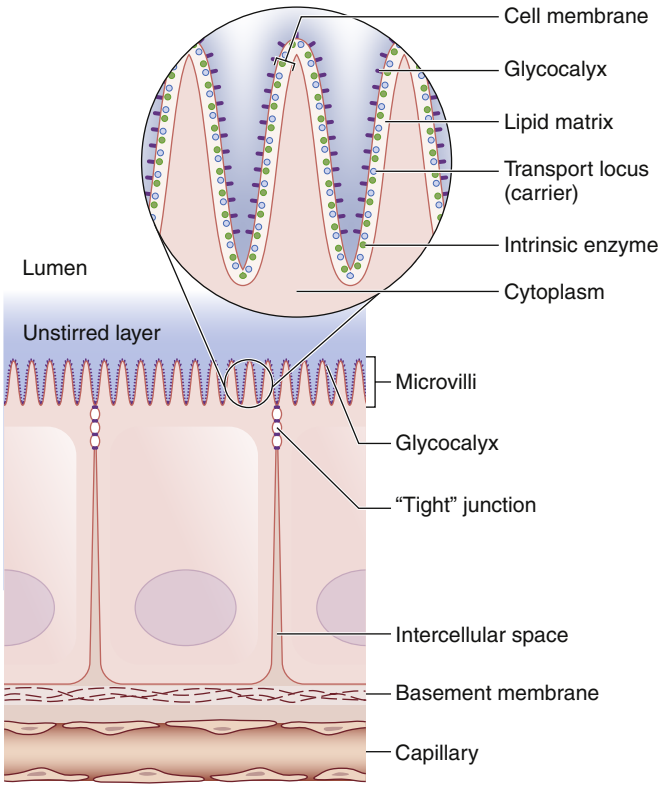

Figure 21-6. Mucosal barrier. Solutes moving across the enterocyte from the intestinal lumen to the blood must traverse an unstirred layer of fluid, a glycocalyx, the apical membrane, the cytoplasm of the cell, the basolateral cell membrane, the basement membrane, and finally the wall of the capillary of the lymphatic vessel. Microvilli are morphologic modifications of the cell membrane that comprise the brush border. The importance of this region in the digestion and absorption of nutrients is depicted by the enlarged microvillus *(inset)*, which illustrates the spatial arrangement of enzymes and carrier molecules. *(Redrawn from Johnson LR:* Gastrointestinal physiology: Mosby physiology monograph series*, ed 7. Philadelphia, 2006, Mosby.)*

The intestinal epithelial monolayer is composed mainly of four different cell types: absorptive enterocytes, mucus-secreting goblet cells, enteroendocrine cells, and Paneth cells. All cells are renewed continuously from pluripotent progenitor cells that reside in the Lieberkühn crypts. See Figure 21-6 for a schematic arrangement of the epithelium in villi and crypts and an illustration of its mucous barrier.

The intake of nutrients and water occurs through several mechanisms such as pinocytosis, passive diffusion, facilitated diffusion, and active transport.[32] Luminal tight junctions between apposing enterocytes seal the endothelium mechanically but are relatively leaky for ions and water in certain regions of the intestine. Digestive and absorptive processes are adaptable to functional changes within the intestine. Small bowel resections or bypasses are well tolerated because the remaining gut is able to compensate. An exception is the terminal ileum, which is the only area where bile salts and vitamin B_{12} are absorbed.

Sugars

Carbohydrates comprise approximately 50% of our daily ingested calories. Half of these calories are in the form of starch, a high-molecular-weight compound made of amylose and amylopectin. α-Amylase from salivary glands and from the pancreas luminally digests starch in the mouth and the small intestine. Amylase is inactivated by acid; therefore, only limited digestion of starch occurs in the stomach. Brush border hydrolases further break down starch and other carbohydrates into their monosaccharides. Those are absorbed throughout the small intestine passively either by paracellular diffusion facilitated by tight junction plasticity or by the passive facilitated diffusion using Glucose Transporters (GLUTs of the SLC2 gene family) at the brush border. More importantly, monosaccharides are absorbed into the enterocytes by the active sodium glucose symporter or cotransporter (SGLTs of the SLC5 gene family). Glucose and galactose are accumulated within the enterocyte and eventually exit at the basolateral membrane into the blood by either facilitated transport (GLUT2) or exocytosis.[46] The capacity to absorb sugars in the small intestine is extremely high**.** Usually, all monosaccharides are absorbed by the time they reach the mid ileum. Chemoreceptors and osmoreceptors within the brush border of the proximal small intestine sense luminal carbohydrate content and regulate the contact time of ingested sugars by modifying motility and gastric emptying.[32] The rate of carbohydrate-containing solutes leaving the stomach is inversely related to the carbohydrate content. The higher the carbohydrate load, the slower it is delivered into the duodenum with approximately 200 kcal/hr delivered to the duodenum.[5]

Proteins

Proteins are denaturized by hydrochloric acid and luminally digested by pepsin in the stomach. Pepsin is released as a precursor by the chief cells. Ingestion of a meal with protein in the stomach and low gastric pH (as more hydrochloric acid is secreted in response to protein in the meal) triggers pepsin release. With transition of the chyme to the duodenum, its polypeptide and fat content triggers CCK release from duodenal enteroendocrine cells (I cells), which stimulates the secretion of peptidases (trypsinogen, chymotrypsinogen, proelastase, procarboxypeptidase) from the pancreas in inactive precursor forms; they are activated by enterokinase in the brush border of duodenal enterocytes. Furthermore, membrane-bound digestion of peptides to free amino acids, and more importantly small dipeptides and tripeptides, occurs at the brush border, where absorption follows by secondary active transport processes along transmembrane ion gradients. The activity for dipeptide and tripeptide absorption is highest in the more proximal small intestine, whereas free amino acids are more efficiently absorbed more distally in the ileum. This activity coincides with a noticeable increase in brush border–bound proteases towards the ileum. Most protein is absorbed in the small intestine. Although able to absorb protein, the colon plays only a minor role in the uptake of amino acids derived from food. It can be involved in the absorption of dipeptides and tripeptides from bacterial proteins.[47] Enterocytes demonstrate high cytosolic peptidase activity that further hydrolyzes small peptides so that ultimately about 90% of all absorbed peptides exit the enterocyte at the basolateral membrane in the form of amino acids.

Lipids

Lipids are highly heterogeneous macromolecules and represent the most dense source of calories in the human diet. Lipids present predominantly as triacylglycerols (TAGs), phospholipids, and sterols; they are inherently insoluble in water and tend to form ester linkages. Digestion of lipids is a refined and efficient process that is intimately associated with the absorption of lipid-soluble vitamins. It involves three steps: emulsification, enzymatic hydrolysis, and the creation of water-soluble products of lipolysis that allows lipids to be absorbed.[32] The stomach mixes and churns lipids with hydrochloric acid, releases lipase in its corpus and fundus, and regulates the advancement of chyme into the duodenum. CCK is secreted to slow gastric motility and emptying when significant amounts of lipids reside in the small intestine. CCK also promotes the release of bile salts into the duodenum. With the exception of short-chain fatty acids, there is no absorption of lipids in the stomach.[32] In the small intestine, bile salts, phosphatidylcholine, fatty acids (FA), and other compounds emulsify lipids into small fat droplets of approximately 1 μm in diameter to allow enzymatic hydrolysis. Because products of lipolysis are poorly soluble in water, they are built together with lipid-soluble vitamins (vitamins A, D, E, and K) into micelles, which have a hydrophobic core but a hydrophilic surface.

CD36, a member of the class B scavenger receptor family of cell surface proteins, is found abundantly on the apical membrane of villi enterocytes of the proximal small bowel, where most FA absorption occurs. CD36 knockout animals shift absorption of FA to the more distal small bowel, where it is CD36 independent. Chylomicron production, however, is greatly impaired when CD36 is absent. Polymorphisms of the CD36 gene are relatively common and result in high blood FA levels and accelerated cardiovascular disease.[48] TAG is hydrolyzed to two FAs and monoacylglycerol and is subsequently reassembled to TAG in the endoplasmic reticulum of the enterocyte before moving as a prechylomicron transport vesicle into the Golgi apparatus. There, the chylomicrons mature and are subsequently released into the lymph and blood streams. This multistep process is usually accomplished quickly, and 500 g of fat can be processed daily. Fat-soluble vitamins are solubilized into micelles before absorption occurs by passive diffusion (vitamins A, D, E, food-derived K) into the enterocyte. Bacterially derived vitamin K is absorbed by an active process. The eventual distribution of vitamins throughout the body is achieved by embedding them (mostly unaltered) into chylomicrons, which demonstrates that the absorption of fat-soluble vitamins in fact depends on fat absorption.[32]

Intestinal lipid metabolism could have a significant effect on overall metabolic homeostasis in the body. High fatty intake and intestinal lipid metabolism disturbances can lead to hyperlipidemia and accelerated cardiovascular disease.[48]

WATER TRANSPORT

The GI tract handles 8 to 9 L of water in a 24-hour period; only the kidneys filter and process more water. Approximately 2 L are ingested with daily food and liquid intake, the remaining 6 to 7 L are derived in combination from the following: secretory products from salivary glands (1.5 L), gastric juices (2.5 L), pancreatic enzymes and bicarbonate-containing fluids (1.5 L), and bile salts (0.5 L). Most water is reabsorbed in the small intestine (7.5 to 9 L),[1,49] which illustrates that especially in the stomach and small intestine, water is secreted and absorbed at the same time, with a net flow in either direction depending on the location and the physiologic state. Compared with the small intestine, the colonic mucosa has a lower paracellular permeability and tighter epithelium with higher electrical resistance; therefore, it is relatively impermeable for water. It reabsorbs the remainder, leaving approximately 100 mL/day of hypertonic water for excretion with the feces. Hence, water flow in the colon is mostly absorptive and has to occur against substantial osmotic and hydraulic resistance imposed by the luminal content.[49] The colonic crypts are suggested to be the site where water is absorbed, because they are surrounded by a hypertonic milieu created by solute absorption (mostly sodium). A fenestrated sheath formed by myofibroblasts maintains the osmotic gradient and patency of the crypts as water is "sucked" into the pericryptal space.[49]

Mechanisms of Water Transport

The longstanding paradigm states that water moves across membranes driven by either osmotic forces created by active salt transport or hydrostatic pressure differences. The observation that water can be secreted or absorbed in the absence of both forces puzzles scientists even today and supports the theory of a dedicated active transport mechanism for water across GI epithelial membranes. The role of aquaporin water channels or water pumps such as the sodium/glucose co-transporter 1 is being investigated but remains elusive. Currently, the most widely accepted model, the "standing gradient model," assumes that sodium is actively transported into the hypertonic lateral intercellular space (LIS) between cells, resulting in transcellular movement of water into the LIS and isotonic transfer of fluid into the capillary circulation. However, the apical and basolateral membranes prove to be water permeable, and the osmotic gradient in the LIS is small and essentially immeasurable. The observation that most water transfer occurs through the cell rather than across intercellular tight junctions has led to the "revised standing gradient model" and the emergence of several other theories.[49]

Sodium and Potassium Transport

Sodium is absorbed by four mechanisms. It diffuses passively, either transcellular or paracellular, following electrochemical gradients and Starling forces. There is an active countertransport with H^+, cotransport with organic solutes such as sugars and amino acids, and cotransport with Cl^-. The luminal sodium content in the duodenum is equilibrated to plasma through net water secretion or absorption. The sodium content in the enterocyte is kept low as the basolateral Na^+, K^+-activated adenosine triphosphatase (ATPase) continues to move Na^+ out and K^+ into the cell. Advancing aborally, Na^+ and Cl^- concentrations decrease in the jejunum and further in the ileum, reaching their respective minima in the colon where luminal

Na^+ concentrations are as low as 35 to 40 mEq/L. Chloride is conserved in the colon and is exchanged for HCO_3^- which stems from the hydration of CO_2 by carbonic anhydrase.[32] Potassium is absorbed passively throughout the small intestine and is secreted actively in the colon.

There is little regulation of water and electrolyte absorption in the intestine, which simply absorbs what is presented. However, adrenergic (α-receptor) or anticholinergic stimuli increase absorption, whereas cholinergic and anti-adrenergic stimuli decrease it. Serotonin, dopamine, endorphins, and enkephalins alter the net transport across the epithelium and enhance secretion over absorption. Exogenous opiates such as morphine or codeine enhance absorption in the small and large intestine and increase transition time.[32]

In contrast to the small intestine, the large intestine is able to increase sodium absorption by decreasing sodium concentration in fecal water to as little as 2 mEq/L in a response to plasma sodium depletion or mineralocorticoid secretion. Simultaneously, the potassium secretion is stimulated. Aldosterone improves the sodium permeability of the brush border membrane by activating more sodium channels and increasing the number of sodium pump molecules in the basolateral membrane of the enterocyte. Osmotic retention of fluid in the gut and the increase in fecal water content is achieved by polyvalent ions such as magnesium sulfate ($MgSO_4$), which are only incompletely absorbed.[32] This principle is used when the bowel is "prepared" for endoscopies or colorectal surgery. For the latter, it has been suggested that this practice be abandoned because there is no benefit; moreover, the disturbances of electrolyte and water homeostasis may be significant.[50]

Calcium, Magnesium, and Phosphorus

Calcium, magnesium, and phosphorus stem from dietary sources and are essential elements required for multiple functions and structural tasks. Serum levels are tightly regulated, and the intestine along with kidney and bone play a major role in the homeostasis of those elements. Parathyroid hormone and vitamin D are the major regulating signals among a complex network of membrane transporters, associated proteins, and soluble mediators.[51] The ratio of absorbed to ingested calcium varies with age, level of Ca^{2+} intake, physiologic state (i.e., pregnancy), and GI factors, such as transit time of chyme along the gut, proportion of soluble form of calcium, and the rate of transport across the intestinal epithelium.[51] Solid food containing calcium must be digested first to make soluble calcium available. Overall, approximately 25% of all ingested calcium is enterically absorbed in the nonpregnant state by passive paracellular and active, ion-channel dependent transcellular pathways. When luminal calcium concentration is high, most of it is passively absorbed through the tight-junction regulated paracellular pathway. The major ion-channel protein responsible for transcellular calcium absorption is TRPV6. Several models have been proposed to explain how calcium can diffuse into the cytoplasm of the enterocyte, traverse it, and exit at the basolateral membrane without upsetting the tightly regulated intracellular calcium concentration. The "facilitated diffusion model" assumes binding of free calcium to an intracellular buffering protein and basolateral exclusion via a P-type ATPase with high affinity to Ca^{2+}. The "ER tunneling model" and the "vesicular transport model" suggest transport through the endoplasmic reticulum and exocytosis of calcium through vesicles, respectively, or Na^+/Ca^{2+} exchangers and Ca^{2+} ATPases.[51]

Phosphorus plays an important role in bone structure and as inorganic phosphate and phosphate esters in cell physiology. Phosphorus is extracted efficiently from food in the intestine, which maintains phosphate levels within a narrow range. Absorption occurs mostly in the duodenum and in the jejunum by passive paracellular diffusion and by active transcellular transport, which can be up-regulated when phosphate intake is reduced.

Magnesium is absorbed mostly in the small intestine by passive, gradient-driven, paracellular diffusion that is regulated by luminal magnesium concentration in a curvilinear fashion, which is probably the result of tight junction plasticity. [51] Similar to calcium and phosphorus, magnesium is also absorbed apically by an active transcellular transport involving TRP family of ion channels. Vitamin D_3 increases the capacity of both pathways and hence represents the major regulatory signal in intestinal calcium absorption and overall calcium homeostasis.

Iron

Iron is absorbed mainly in the proximal small intestine; less prominent sites include the stomach, ileum, and colon. Iron must be reduced before being transported across apical surfaces by the intestinal iron transporter-1 and stored as ferritin in mature enterocytes when iron stores in the body are filled. If iron stores are low, iron is exported from enterocyte storage via ferroportin 1 to bind to transferrin in interstitial fluid and plasma. This is regulated by liver-derived hepcidin, which is up-regulated by hemochromatosis protein.

Water-Soluble Vitamins

Dietary vitamin B_1 (thiamine) is mainly phosphorylated and thus needs to be hydrolyzed at the brush border before absorption through a mechanism in the small intestine that is pH dependent and mediated by an electroneutral carrier.[52] Another source of thiamine is the bacterial flora in the large intestine that synthesizes free thiamine to be used by enterocytes for their own metabolism in addition to adding to the body's supply. Prolonged vomiting and alcoholism are common causes for vitamin B_1 deficiency.

Vitamin B_2 (riboflavin) from dietary and bacterial sources in the large intestine is absorbed similarly to vitamin B_1 utilizing a Na^+-independent, carrier-mediated mechanism, whereas vitamin B_3 is absorbed only from dietary sources. Vitamin B_5 (pantothenic acid) and vitamin B_6 (pyridoxine) are hydrolyzed before they are absorbed in the small intestine.

Conjugated vitamin B_9 (folate) polyglutamates carry multiple negative charges, represent a large molecule, and are hydrophobic—all features that hinder absorption. Hence, folate hydrolases at the brush border hydrolyze it to its monoglutamate before it can be absorbed. Again, large intestine bacterial flora supplies folate locally to the colonic mucosa and supports its structural integrity.

Deficiencies in bacterially derived folate are being linked to malignant diseases of the colonic mucosa.[52]

Vitamin B_{12} (cobalamin) absorption requires the acidic gastric environment to isolate it from food to make it available for intrinsic factor to bind. Intrinsic factor is a glycoprotein secreted by parietal cells in the stomach. Cellular and functional gastric integrity is therefore vital for the cobalamin–intrinsic factor complex formation. This complex is recognized by the cubam receptor in the small intestine, which binds the complex and internalizes it into the enterocyte. Lack of intrinsic factor (e.g., atrophic gastritis, *Helicobacter pylori* infection) or decreased acid secretion (e.g., long-term antacid use) can render the patient deficient in vitamin B_{12}. In those patients, the use of NO, a potent and irreversible methionine synthase inhibitor, should be limited because it can cause acute vitamin B_{12} deficiency neuropathy and hyperhomocysteinemia.

Vitamin C is derived solely from the diet, and there is no bacterial source in the large intestine. Both luminal uptake and exit across the basolateral membrane involve concentrative, carrier-mediated, Na^+-dependent mechanisms.[52]

GASTROINTESTINAL BLOOD FLOW

This section discusses issues concerning control of regional blood flow within the GI tract and regulation of blood volume within the splanchnic vasculature.

ANATOMY

Celiac, superior mesenteric, and inferior mesenteric arteries leave the aorta and deliver arterial blood to the organs of the GI tract (Fig. 21-7). The celiac artery supplies the stomach, the proximal part of the duodenum, part of the pancreas, and the liver through the hepatic artery. The superior mesenteric artery delivers arterial blood to the remaining parts of the pancreas and duodenum, the jejunum and ileum, and the colon. The inferior mesenteric artery supplies blood to the remaining part of the colon and rectum, except the very distal part of the rectum, which is supplied by rectal arteries branching off the internal iliac artery.

The GI tract is richly supplied by blood. Blood flow to the stomach is approximately 11 mL/min per 100 g of tissue; in the small intestine it is 30 to 70 mL/min per 100 g[1]; and in the colon it is 8 to 35 mL/min per 100 g. For comparison, in resting skeletal muscle it is 2 to 5 mL/min per 100 g, whereas in the brain it is approximately 55 mL/min per 100 g.

Basic oxygen consumption in the GI tract is relatively low, between 1.5 and 2 mL/min per 100 g.[53] In comparison, in the liver it is up to 6 mL/min per 100 g; in the brain, it is 3.5 mL/min per 100 g; and in the heart it depends on heart rate and physical activity, reaching 7 to 9 mL/min per 100 g of tissue.

GASTRIC BLOOD FLOW

The celiac artery branches into smaller arteries, then into arterioles in the muscular layer and submucosa.

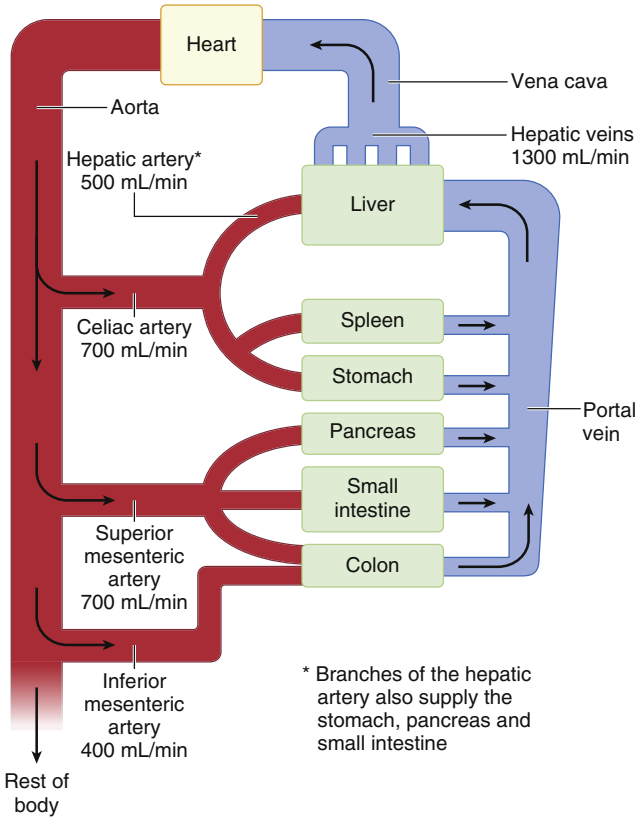

Figure 21-7. The schematic representation of the splanchnic circulation. Values of blood flow per gastrointestinal organs are identified. *(Redrawn with permission from Barrett KE:* Gastrointestinal physiology: Lange physiology series. *New York, 2005, McGraw-Hill.)*

Submucosal arterioles branch into capillaries at the base of the gastric glands and then travel to the luminal surface of the mucosa, forming a capillary network. The mucosal capillaries drain into venules that form venous plexuses in the submucosa. The muscular and mucosal blood flows are regulated independently according to tissue metabolism. Of the total blood flow through the stomach, 75% is distributed to the mucosa and 25% to the muscularis, although the distribution between muscular and mucosal layers is almost entirely dependent on their function at any particular moment.

INTESTINAL BLOOD FLOW

The three large arteries mentioned earlier (see Fig. 21-7) branch into smaller arteries, form arcades, and anastomose one with another, creating collateral flow. This is why an occlusion of one artery within the arcade does not usually lead to necrosis of tissue within the GI tract. These arcades give branches into the submucosal and mucosal layers. The blood flows to the different layers of the intestinal walls (mucosa, submucosa, and muscularis) through the arteriolar plexus within the submucosa. After flowing into arterioles and capillaries and exchanging metabolites through capillary walls, the blood flows through venules and larger veins. These veins enter the mesentery in parallel to the mesenteric arteries within the arcades, eventually forming three final preportal

veins: splenic, superior mesenteric, and inferior mesenteric. The splenic vein drains blood from the spleen, stomach, and pancreas; the superior mesenteric vein from small intestine and parts of the colon and pancreas; and the inferior mesenteric vein collects blood from the descending colon, sigmoid colon, and upper rectum. These three preportal veins combine to form the portal vein, from which blood flows through the liver and then enters the systemic circulation through hepatic veins and the inferior vena cava.

GASTROINTESTINAL BLOOD FLOW REGULATION

The main purpose of the GI blood flow is to deliver nutrients and hormones to the gut, to remove metabolic waste from the gut, and to maintain the mucosal barrier to prevent transepithelial migration of antigens, toxic chemicals, and pathogenic microbiota.[54] The blood flow within the GI tract varies over a wide range depending on need. GI organs periodically have high requirements for oxygen and therefore blood flow; for example, during food ingestion, the blood flow within the GI organs increases. On the other hand, the blood flow to the GI organs can decrease considerably to supply active muscles during physical exercise or to maintain viability of vitally important organs, such as the brain and heart, during blood loss. Such needs require a wide range of blood flow and sophisticated regulation. GI blood flow is regulated by extrinsic and intrinsic mechanisms that include the enteric nervous system.

Extrinsic control of the splanchnic circulation is achieved by activation of the sympathetic nervous system. The preganglionic sympathetic neurons are located mainly in the thoracolumbar area of the spinal cord at the T1-L2 level. The axons of the sympathetic preganglionic neuron synapse in celiac, superior mesenteric, or inferior mesenteric ganglia.[53] Blood vessels in GI organs are richly innervated by sympathetic and parasympathetic nerve fibers, which release neurotransmitters to affect vascular tone and blood flow. An increase in sympathetic discharge is usually associated with a constriction of the vessels and a decrease in blood flow. Although the parasympathetic nervous system is not directly involved in regulation of GI blood flow, vasodilating neurotransmitters can activate the appropriate receptors directly and indirectly through ACh. Compounds such as ACh, VIP, and the neuropeptide substance P are released from parasympathetic nerve fibers, and they can mediate vasodilation via NO. Parasympathetic fibers dilate vessels indirectly by stimulating the function of the GI organs. Many vasodilating and vasoconstricting substances affect GI blood flow. The main vasodilating factors include prostaglandins, adenosine, NO, bradykinin, VIP, and substance P. Vasoconstricting factors include mainly catecholamines that activate α-adrenergic receptors, the renin-angiotensin system, and vasopressin.

Intrinsic regulation of GI blood flow includes pressure-induced flow autoregulation, response to acute venous hypertension, reactive hyperemia, functional hyperemia, hypoxic vasodilation, and other internal factors. Overall, intrinsic regulation of blood flow is responsible for adjustment of blood flow to the demand at any time via myogenic, metabolic, or hormonal mechanisms.

Blood flow autoregulation is the ability of an organ to maintain relatively constant blood flow despite changes in blood pressure. Such regulation is strong in the heart and brain but much weaker in the GI organs. For example, a 50% decrease in blood pressure results in minimal changes in cerebral blood flow, whereas blood flow through the intestines is decreased by approximately 25%.

An increase in venous pressure is often used in experimental models to determine whether the regulation of flow is myogenic or metabolic in nature. If an increase in venous pressure is associated with an increase in arterial tone, vascular resistance, precapillary sphincter tone, and decrease in capillary density, the regulation is assumed to be myogenic. Otherwise, the control is assumed to be metabolic.[55]

Reactive hyperemia is defined as an increase in blood flow above baseline after temporary occlusion of an artery; it probably serves the need to repay oxygen debt after temporary oxygen deprivation and results, at least partially, from the accumulation of vasodilating metabolites (e.g., adenosine) produced by the preceding ischemia.

Stimulation of sympathetic nerves or an intra-arterial norepinephrine infusion leads to severe vasoconstriction and a decrease in intestinal blood flow. However, regardless of whether the infusion or stimulation continues, the blood flow partially returns to baseline level in a few minutes. This so-called autoregulatory escape is observed only in arterial but not in venous smooth muscle; it is not affected by β-adrenergic receptor antagonists or by muscarinergic antagonists. The mechanism most likely to be responsible for this phenomenon is the accumulation of different vasodilating factors during hypoperfusion. Adenosine and VIP have been implicated more often than other vasodilating compounds.

The metabolic mechanism of blood flow regulation assumes that an increase in oxygen demand or decrease in oxygen delivery, or both, decreases tissue oxygen tension and releases vasodilating metabolites. A decrease in oxygen content in arterial blood is associated with an increase in GI blood flow and capillary recruitment, even in a denervated intestinal preparation. A decrease in hematocrit is also associated with an increase in tissue blood flow. Oxygen deprivation leads to intracellular ATP breakdown and adenosine release, causing vasodilation. Adenosine has been shown to be a powerful vasodilator in the small intestine.[53]

An increase in function is associated with an increase in oxygen demand and a subsequent increase in blood flow. For example, an increase in acid secretion by the stomach induced by pentagastrin is associated with an increase in portal blood flow and in oxygen extraction. Similar responses have also been observed in other organs of the GI tract.[53] Functional (postprandial) hyperemia following food ingestion can increase blood flow within the small intestine by as much as 230% and can last 4 to 7 hours depending on the nature and quantity of the meal.[53] Redistribution of blood flow within the intestinal wall toward mucosa and submucosa has been observed. Many factors regulating the blood flow to the intestinal

mucosa are metabolic and include oxygen, pH, carbon dioxide, and adenosine. Other mediators include vasopressin, catecholamines, NO, VIP, substance P, histamine, prostaglandins, and bradykinin.[53]

An increase in intestinal motility (and associated increase in oxygen demand) drastically reduces the higher vascular resistance produced by elevated venous pressure**.** This change implies that metabolic factors play a more important role than myogenic mechanisms do in the regulation of GI flow.[55]

The enteric nervous system (as a part of intrinsic regulation) also plays a role in regulation of GI blood flow, particularly in the distribution of blood within the intestinal wall. The mucosa of the GI tract receives about 80% of total resting blood flow of the gut.[54] Such high blood flow is needed to meet the requirements of the gut for motility, secretion, and absorption. The submucosal plexus is the main control for blood flow within the gut, and vasoconstriction results primarily from activation of sympathetic efferents. Epinephrine increases blood flow through the GI tract mainly by activation of β_2-adrenergic receptors.

Vasodilation within the mucosa is controlled by three different types of neurons:

1. Extrinsic primary afferent neurons
2. Efferent neurons of the parasympathetic nervous system
3. Enteric neurons within the submucosal plexus[56]

The main afferent neurotransmitters are CGRP, substance P, and NO. Their release in the afferent pathways is associated with vasodilation of arterioles within the submucosa. These vasodilating signals are conducted through the sympathetic nervous system within the ganglia, where ACh is the main neurotransmitter.

Parasympathetic vasodilator pathways (within the vagus) include cholinergic mechanisms that probably play relatively minor roles: the gastric vasodilation caused by stimulation of the vagus nerve remains unchanged after atropine administration.[56] Parasympathetically mediated vasodilation is achieved through the myenteric plexus (where ACh is also the main neurotransmitter) and then, after synapsing there, the signals travel to the arterioles, where the main neurotransmitters are VIP and ACh.[56] ACh induces vasodilation by activating muscarinic receptors; their stimulation leads to release of NO within the arteriolar endothelium.[56]

Finally, arteries and arterioles in the submucosa and mucosa dilate in response to signals from enteric neurons that originate in the submucosal but not in the myenteric plexus; neither extrinsic denervation nor removal of the myenteric plexus alters these vasodilating effects, which are mediated by serotonin (5-hydroxytryptamine, 5-HT). In the submucosal plexus, afferent input is transmitted to the efferent reflex limb of the arch, which is composed of cholinergic vasodilator neurons; such reflex-mediated dilation of submucosal arterioles is blocked by atropine.

There are many interactions between enteric and sympathetic vasomotor neurons.[6,56] During exercise, portal blood flow may decrease by 80%, reaching only 20% of baseline. Such a decrease can be counteracted by ingestion of a meal. Superior mesenteric blood flow is reduced 43% by exercise but increased 60% by ingestion of a meal. When exercise was combined with a meal, the blood flow was actually increased by 40%, demonstrating that metabolic and humoral demands often override other influences.[57]

GASTROINTESTINAL MICROCIRCULATION

The mesenteric microcirculation is composed of isolated small microcirculatory units. Such units branch from the marginal arteries that are themselves branches of mesentery arcades. The blood flows within microvessels from arterioles to capillaries and then drains to low-flow venules, which then form high-flow venules of larger diameters. Some high-flow venules have direct anastomoses to other high-flow or low-flow venules.[58] The density of functioning capillaries depends on two factors working in concert: an increase in blood flow and the accumulation of the end products of cellular metabolism.

SPLANCHNIC BLOOD VOLUME

Splanchnic vasculature can be thought of as a devoted employee: it serves the boss (the body) enthusiastically and completely, sometimes sacrificing its own needs. Changes in the blood flow in one or another system generally serve the needs of a particular organ. However, alterations in the blood volume within the splanchnic veins serve overall hemodynamics rather than the GI organs themselves. Regulation of blood flow through the GI organs and the liver is described separately herein and in Chapters 22 and 23, respectively. However, regulation of blood volume within the GI organs and the liver has a common purpose: to maintain stable systemic hemodynamics. Therefore, the regulation of splanchnic blood volume as a whole is fully described in this chapter.

Approximately 70% of total blood volume is in the veins.[59] The splanchnic system receives 25% of cardiac output and contains approximately one third of the total blood volume.[59,60] Approximately 1 L of blood can be recruited from the splanchnic vasculature into the systemic circulation when needed (Table 21-2). Because veins are 30-fold more compliant than arteries, drastic changes in the blood volume within the splanchnic veins are associated with relatively small changes in the intravenous

TABLE 21-2 DISTRIBUTION OF BLOOD VOLUME AMONG ORGANS AND AMOUNT OF BLOOD THAT CAN BE RECRUITED FROM THEM

	Total (mL)	Mobilized (mL)
Liver	600	300
Spleen	700	600
Intestine	350	150
Total	**1650**	**1050**
Lungs	500	50
Skin	100	50
Muscle	850	250
Total	**3100**	**1400**

pressure. Moreover, splanchnic veins can accumulate or lose a large amount of blood without significant change in systemic hemodynamic variables, such as blood pressure and cardiac output.

Definitions of at least two physiologic variables are needed for understanding the function of the compliant (splanchnic) veins in blood volume regulation. *Unstressed volume* is the volume of blood when transmural pressure equals zero. *Stressed volume* is the volume within the venous system under transmural pressures above zero. These two volumes cannot be measured directly; instead they are determined by extrapolation of the pressure-volume line to zero pressure[60] (Fig. 21-8). The difference between total volume and unstressed volume equals stressed volume. At rest, approximately one third of the total blood volume is stressed, and approximately 70% is unstressed, located mainly within the splanchnic venous system. The analogy with a tub can be helpful in understanding the relationship between stressed and unstressed volumes (Fig. 21-9).

The relationship between stressed and unstressed volumes explains why patients with up to 10% to 12% of blood volume loss maintain systemic hemodynamics without significant changes in heart rate, blood pressure, or central venous pressure (CVP). However, further blood loss, even if relatively small, leads to severe deterioration of hemodynamics. As the first 10% of blood volume is lost, compensation occurs mainly by moving unstressed volume into stressed volume. If the mechanism of transfer of blood from unstressed to stressed volume is already exhausted (no unstressed volume is left), further blood loss leads to decompensation.

Let us imagine that the heart is stopped, leading to cessation of blood flow. Pressure would be the same in all parts of the circulation, and is referred to as *mean circulatory filling pressure* (MCFP).[61] When the heart starts pumping again, the pressure in the aorta, arteries, capillaries, and finally in the small veins distal to capillaries increases, pushing blood back to the heart. Because arterial resistance is high (compared with other parts of the vasculature), the pressure in these small veins becomes the driving force for venous return and is called *pivotal pressure*; it turns out that this pressure is equal to the MCFP.[59,60]

It is the unstressed volume from which blood is mobilized into circulation (into stressed volume) when it is

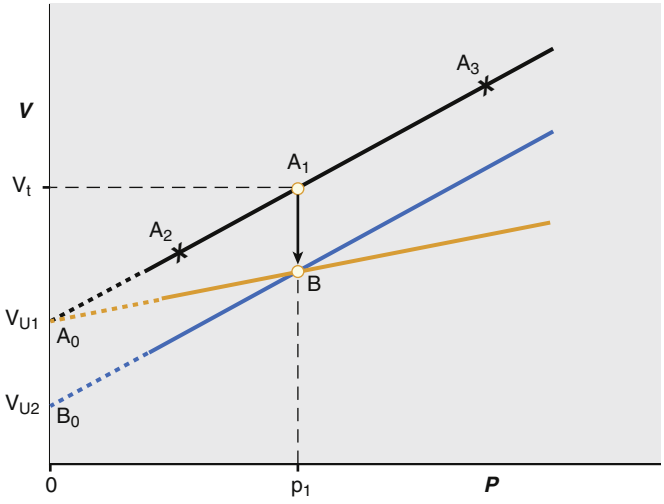

Figure 21-8. Venous capacitance and compliance, stressed and unstressed volumes. Point A1 represents volume of blood in veins at intramural pressure p_1. Points A2 and A3 represent change in volume induced by change in pressure within the veins. The *thick black line* represents baseline compliance. Point A_0 is obtained by extrapolation of the thick black line until it crosses the *y* axis; this point (A_0) represents volume of blood at transmural pressure zero, which is unstressed volume (Vu_1). The difference between total volume (Vt) and Vu_1 is stressed volume (Vs). When a certain amount of blood is mobilized from the veins, point A_1 moves to point B; the veins contain less blood at the same intramural pressure p_1. Removal of the volume of blood between points A_1 and B may be associated with no change in the slope of the pressure-volume relation (*blue line*); this means that venous compliance did not change, but capacity did. Point B_0 (*blue line extrapolated to the y-axis*) represents decreased unstressed volume (from Vu_1 to Vu_2). However, the pressure-volume relation within the veins might look like the *brown line*. The same amount of blood is mobilized (from point A1 to B), but Vu did not change. The *brown line* crossed the *y* axis at the same point A_0; the mobilized blood was recruited by a decrease in compliance rather than from a decrease in Vu. *(Redrawn with permission from Gelman S: Venous function and central venous pressure. A physiologic story.* Anesthesiology *108:735, 2008.)*

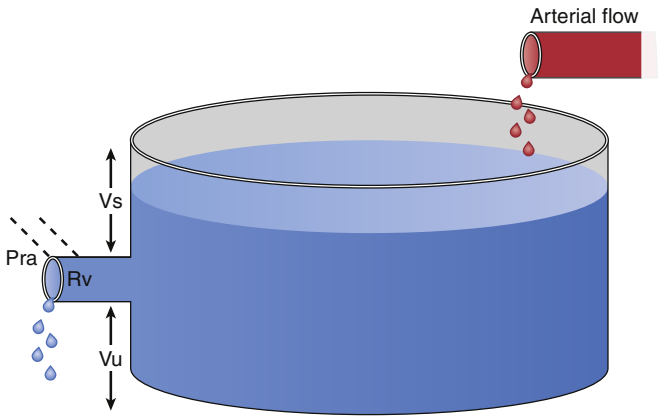

Figure 21-9. Stressed and unstressed volumes—tub analogy. Water in a tub represents total blood volume. A hole in the wall of the tub between the surface of the water and the bottom of the tub divides total volume into stressed (Vs) and unstressed (Vu) volumes, above and below the hole, respectively. The water leaves the tub through the hole at a certain rate that depends on the diameter of the hole (which would reflect venous resistance [VenR]), and on the height of the water above the hole, representing Vs. The larger the Vs, the higher the flow through the hole. The water between the hole and the bottom of the tub does not affect the flow of water through the hole; this is the Vu, which is a sequestered volume that does not directly participate in the rate of water flow (venous return). With the same amount of water in the tub (total blood volume in the venous system) the relationship between Vs and Vu can be changed by moving the hole up or down. Moving the hole down represents venoconstriction and increases Vs (and venous return). The distal end of the tube, attached to the hole in the tub wall, represents central venous pressure (CVP). The higher the distal end, the higher the CVP and the lower the pressure gradient for venous return, and vice versa. The inflow tap represents the arterial flow. The hydraulic disconnect between the tap and the tub represents functional disconnection between the two (arterial flow and the venous system) due to high arterial resistance. *(Redrawn with permission from Gelman S: Venous function and central venous pressure. A physiologic story,* Anesthesiology *108:735, 2008.)*

needed. Under physiologic conditions, the stressed volume is the main factor determining the MCFP (pivotal venous pressure) and (indirectly) venous return. Stressed volume, in turn, is determined by total blood volume and the arterial and venous tone within the splanchnic vasculature. The two-compartment model of the venous system helps to explain the relationships among stressed and unstressed volumes, MCFP, and venous return[60] (Fig. 21-10).

During sympathetic stimulation, the smooth muscles of the vasculature contract to produce vasoconstriction, leading to a decrease in flow through the arteries. When arteries are constricted, the blood flow into the veins through capillaries is decreased, lowering intramural (intraluminal) pressure within these veins. This decrease in intramural pressure leads to a passive recoil of the venous walls around the decreased volume and pressure, producing a short-lasting increase in flow out of the veins and an increase in venous return. The volume shifted out of the splanchnic vasculature stays in the main basic circuit (Fig. 21-11, see Fig. 21-10) until splanchnic arterial tone returns to baseline. In many instances active venoconstriction also occurs, squeezing blood out of the veins (reinforcing passive recoil) and increasing venous return and cardiac output.

In a canine model, an induced hemorrhage to lower blood pressure below 50 mm Hg was compensated for by three mechanisms: (1) transcapillary fluid shift from different tissues (one third of this volume), (2) shift of blood from passive elastic recoil of the veins, mainly splanchnic veins (an additional third of the lost volume), and (3) actively constricted capacitance vessels mediated by an increase in sympathetic discharge.[59] This means that approximately two thirds of the compensation for severe blood loss comes from the veins, mainly the splanchnic veins, regardless of whether it comes passively from venous recoil or actively from sympathetically mediated venoconstriction. The passive change in blood volume within the splanchnic veins is more typical of the intestines, whereas active venous constriction is more prominent within the liver.[62]

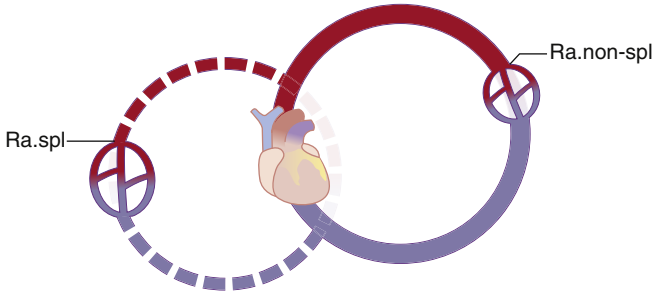

Figure 21-10. Two-compartment model of venous system. (*Two circuits* represent two compartments; the *solid red and blue lines* represent arterial and noncompliant venous compartments (the main, basic circuit). *Dashed red and blue lines* represent arterial and compliant (splanchnic) venous compartments. The compartment with compliant veins is outside the main circuit. Therefore, changes in arterial or venous resistance in compliant compartment do not directly affect arterial or venous resistance in the main circuit with noncompliant veins. *Thickness of the lines* reflects the amount of flow within the vessels under normal conditions. The *size of the junctions* between arteries and veins reflects the blood volumes contained in the two circuits. *(Adapted with permission from Gelman S: Venous function and central venous pressure. A physiologic story,* Anesthesiology *108:735, 2008.)*

ROLE OF α-ADRENERGIC AND β-ADRENERGIC RECEPTORS IN BLOOD VOLUME REGULATION

The splanchnic veins have a high population of α_1- and α_2-adrenergic receptors and are much more densely innervated than the corresponding arteries; this explains their more vigorous response to sympathetic stimulation compared to arteries.[60,63] Because of its high compliance and rich population of α-adrenergic receptors, the splanchnic venous system is the most effective blood reservoir in the body, capable of mobilizing (and accommodating) large amounts of blood. Low-frequency stimulation of sympathetic nerves or an infusion of α-adrenergic agonists at small doses leads to constriction of veins (particularly splanchnic veins) and shift of blood volume from the splanchnic vasculature to the systemic circulation. This "auto-transfusion" helps to maintain hemodynamics during situations such as blood loss, increase in intra-abdominal or intrathoracic pressure, general anesthesia, and positive-pressure breathing. Small doses of α-adrenergic agonist probably do not constrict arteries or jeopardize tissue perfusion; in many situations, this treatment can be preferable to infusion of extra blood volume.[64]

ROLE OF HEPATIC VEINS IN SPLANCHNIC BLOOD VOLUME REGULATION

An increase in resistance in the distal part of the splanchnic venous system might lead to sequestration of blood within the liver and more proximal part of the splanchnic venous vasculature. Therefore, a decrease in resistance to venous outflow within the liver or hepatic veins facilitates blood volume shift from the splanchnic vasculature into the inferior caval veins and right atrium, thereby increasing venous return. Activation of α-adrenergic receptors increases this resistance,[65] whereas activation of β_2-adrenergic receptors decreases it, facilitating a volume

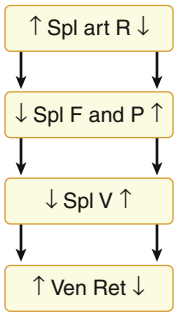

Figure 21-11. Role of splanchnic arteries in splanchnic blood volume (Spl V) regulation. An increase in resistance in the splanchnic arteries leads to a decrease in splanchnic venous flow and pressure within the splanchnic veins that leads to a decrease in splanchnic volume and subsequently to an increase in venous return. Decrease in resistance within splanchnic arteries leads to opposite chain of events. *Spl art R*, splanchnic arterial resistance; *Spl F+P*, splanchnic flow and pressure within the splanchnic veins.

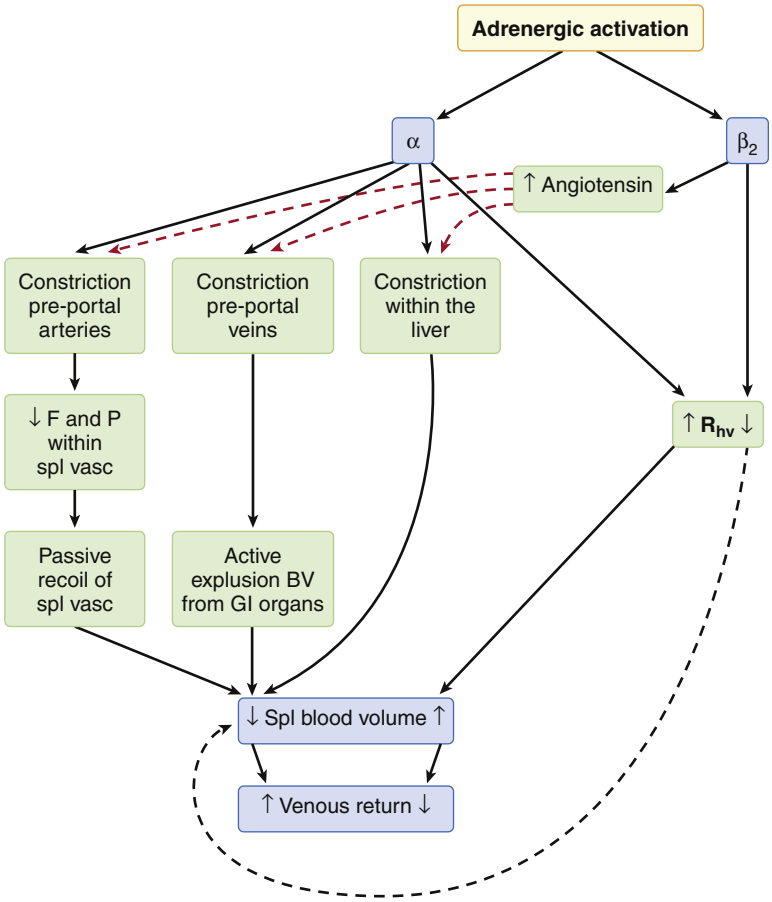

Figure 21-12. Effect of adrenergic activation on splanchnic blood volume regulation. ↑, increase; ↓, decrease; α, α-1 (including peripheral α-2) adrenergic receptors. β-2, β-2 adrenergic receptors; *BV*, blood volume; *GI*, gastrointestinal; *Rhv*, resistance in hepatic veins; *Spl vasc*, splnchnic vasculature; *Ven Ret*, venous return.

shift. A decrease in venous capacity (a shift of blood volume out of the splanchnic veins) induced by relatively small doses of α-adrenergic receptor agonists has a more dramatic effect than an increase in resistance within the hepatic veins (Fig. 21-12). However, large doses of α-adrenergic agonists can lead to sequestration of blood within the liver and decrease in venous return.[66] The combination of α- and β_2-adrenergic agonists can be useful in the treatment of hypotension in normovolemic patients, because it would facilitate the shift of blood volume from the splanchnic veins into the systemic circulation more effectively than an α-adrenergic agonist alone. Such a combination would decrease venous capacity, decrease resistance in the distal splanchnic venous system, and more effectively recruit unstressed volume into stressed volume. In cases of hypovolemia, the ability to recruit unstressed volume is diminished (or even absent, because unstressed volume has been completely mobilized), and an increase in blood pressure can be achieved only by administration of large doses of α-adrenergic agonists, which would lead to constriction of arteries, decreasing tissue blood flow, and tissue ischemia; therefore, the hypovolemia must be resolved as soon as possible.

ROLE OF REFLEXES IN SPLANCHNIC BLOOD VOLUME REGULATION

Increasing carotid sinus pressure from 50 to 200 mm Hg was associated with a volume increase within the splanchnic vasculature of approximately 50%.[60] Thus, when carotid sinuses and other arterial baroreceptors "sense" a decrease in blood pressure, sympathetic tone immediately increases, leading to an increase in arterial resistance throughout the body, including the splanchnic arteries. The latter is reinforced by concomitant constriction of splanchnic veins; both result in passive and active expulsion of blood from the splanchnic venous system. This expulsion leads to a decrease in unstressed volume and an increase in stressed volume, MCFP (or pivotal venous pressure), and both venous return and cardiac output; blood pressure returns toward normal values. Opposite changes occur when blood pressure increases. This reflex serves important functions in blood pressure regulation. General anesthesia impairs this reflex and significantly modifies such responses, decreasing the ability of the body to compensate for changes in blood pressure.

ROLE OF THE SPLEEN IN SPLANCHNIC BLOOD VOLUME REGULATION

Atrial natriuretic peptide (ANP) is released by atrial myocytes when the atrial wall is stretched. ANP increases the glomerular filtration rate by dilating the preglomerular and constricting the postglomerular vessels. Such an action is associated with a decrease in plasma volume and an increase in hematocrit values. Because this effect is almost completely abolished by splenectomy, we know that the major effect of ANP is achieved through

the spleen.[67] During ANP administration splenic venous blood flow is lower than arterial flow and venous hematocrit values are higher than arterial ones, indicating a loss of fluid from the splenic vascular bed. Thus, ANP has direct effects on the splenic microvasculature and intrasplenic hemodynamics to promote filtration of fluid out of the organ. NO affects splenic hemodynamics in concert with ANP; namely, NO decreases the arteriolar resistance within the intrasplenic microvasculature, increasing intracapillary pressure and fluid filtration. In conclusion, different mediators regulate the blood flow and filtration of fluid within the spleen, often leading to an increase in the filtration of fluid and an increase in hematocrit values within the splenic venous blood.

PATHOPHYSIOLOGIC VIGNETTES OF SPLANCHNIC CIRCULATION

Splanchnic Blood Volume During Aortic Cross-Clamping

Clamping of the aorta at the diaphragmatic level considerably decreases blood flow to the splanchnic organs. This decrease leads to a passive recoil of the splanchnic veins and a shift of blood volume from the splanchnic system into systemic circulation. Associated surgical stress and an increase in sympathetic discharge add an active component of venoconstriction. This is why in experimental conditions the clamping of the aorta at the diaphragmatic level is most often associated with an increase in venous return and cardiac output.[60,68] In the clinical setting, such an increase is rare because, unlike the experimental situation, other events that develop during surgical intervention affect volume shifts in different directions. A few examples are different depths of anesthesia, blood loss, and concomitant use of vasoactive drugs, including epidural anesthesia.

On the other hand, clamping of the aorta distal to celiac and mesenteric arteries is usually not associated with an increase in venous return and cardiac output, first because the leg veins are not compliant and therefore contain a relatively small amount of blood. Second, this volume usually shifts into the more compliant splanchnic veins (increasing the unstressed volume) rather than to the heart, which would increase venous return. This is why, even without serious blood loss, clamping of the aorta distal to the arteries supplying blood to splanchnic organs often decreases cardiac output (Fig. 21-13).

Effects of Increased Intra-abdominal Pressure on Gastrointestinal Blood Flow and Splanchnic Blood Volume

Spontaneous inspirations are associated with shifts of the diaphragm downwards, compression of the splanchnic vasculature, and shift of blood volume from the splanchnic system into the systemic circulation.[69] At the same time, venous flow from the lower extremities through the inferior caval vein decreases. During expiration the diaphragm shifts upwards, decreasing the flow from the splanchnic veins and increasing flow from the legs. More drastic increases in intra-abdominal pressure occur during other physiologic actions, such as defecation, coughing, and physical exercise. These changes occur acutely and are short in duration. Acute nonphysiologic increases occur during hemorrhage, perforation of a hollow organ within the abdominal cavity, pneumoperitoneum, and other abnormal states. Some conditions such as pregnancy and accumulation of ascites are associated with a relatively slow increase in intra-abdominal pressure. A drastic increase in intra-abdominal pressure might lead to abdominal compartment syndrome, which presents as a life-threatening hemodynamic instability and usually occurs when intra-abdominal pressure exceeds 25 mm Hg. Pneumoperitoneum induced for laparoscopic surgery decreases blood flow through the intra-abdominal organs.[70] Such increased intra-abdominal pressure compresses the GI organs and squeezes blood from the GI vasculature into the systemic circulation, increasing the stressed volume until the intra-abdominal pressure is normalized.

Any flow through the hepatic veins is maintained by the stressed blood volume within the splanchnic vasculature. In other words, the intravascular pressure within the splanchnic system must be higher than the intra-abdominal pressure, which is the perivascular pressure. When intra-abdominal pressure starts to increase, intravascular pressure increases with it, and stressed volume flows out of the splanchnic system through the hepatic veins, raising the intra-abdominal pressure by 5 mL/cm of fluid. A simultaneous increase in pressure within the inferior caval vein at the level of hepatic veins momentarily stops blood flow through the femoral veins. However, that high pressure also increases flow from the hepatic vein entry and delays the compression of the inferior caval vein by high intra-abdominal pressure. This increased pressure gradient from the inferior caval vein pressure to the right atrial pressure increases flow through the inferior caval vein and venous return, helping to counteract the effects of the compression of the inferior caval vein and possible decrease in preload.[69]

The final effect of these alterations depends on (1) the degree of the increase in intra-abdominal pressure (the larger the increase, the higher the probability of a decrease in venous return); (2) the baseline blood volume; and (3) the ability to develop sympathetically mediated vascular responses. If there is not enough blood volume within the splanchnic veins, or if intra-abdominal pressure is too high to be compensated for by the existing stressed volume, flow through the hepatic vein and then venous return will begin to decrease (Fig. 21-14). Thus, an increase in stressed volume is needed to overcome the increase in impedance to the venous return.[69] Such responses require activation of the sympathetic nervous system. An increase in concentrations of other vasoconstricting compounds such as vasopressin and endothelin, as well as activation of the renin-angiotensin system and release of aldosterone, adrenocorticotropic hormone (ACTH), and cortisol have been also observed.[70] These responses are reflected in increases in CVP, pulmonary wedge pressure, mean pulmonary arterial pressure, and systemic and pulmonary vascular resistances. Mean arterial pressure is usually slightly increased or decreased, cardiac output might be decreased or maintained.[71] A study of patients with American Society of

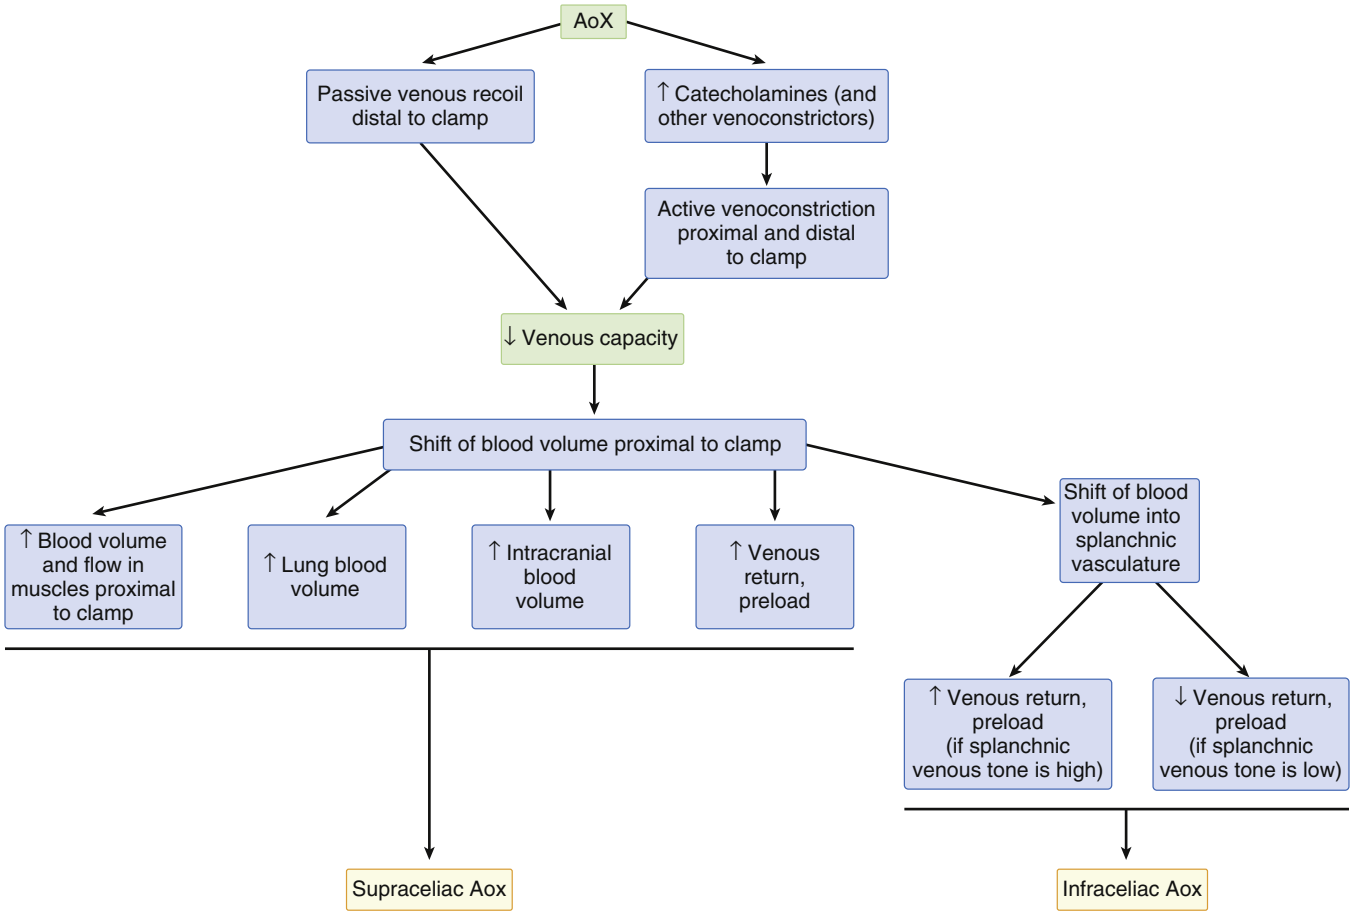

Figure 21-13. Blood volume redistribution during aortic cross-clamping. This scheme depicts the reason for the decrease in venous capacity, which results in blood volume redistribution from the vasculature distal to aortic occlusion to the vasculature proximal to aortic occlusion. If the aorta is occluded above the splanchnic system, the blood volume travels to the heart, increasing preload and blood volume in all organs and tissues proximal to the clamp. However, if the aorta is occluded below the splanchnic system, blood volume can shift into the splanchnic system or into the vasculature of other tissues proximal to the clamp. The distribution of this blood volume between the splanchnic and nonsplanchnic vasculature determines changes in preload. ↑, increase; ↓, decrease; *AoX*, aortic cross-clamping. *(Redrawn with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping,* Anesthesiology *82:1026, 1995.)*

Anesthesiologists (ASA) physical status I and II showed that an increase in intra-abdominal pressure to 15 mm Hg was associated with increases in left and right ventricular end-diastolic area by 65% and 45%, respectively. The ejection fraction of both ventricles decreased by approximately 18%.[72] The reverse Trendelenburg position might improve the hemodynamics.[72]

Release of pneumoperitoneum and simultaneous drastic decrease in intra-abdominal pressure lead to opposite shifts in blood volume and possible hemodynamic instability (vasodilation, shift of blood volume into splanchnic veins, decrease in stressed volume and venous return, hypotension) and ischemia-reperfusion injury. The latter might lead to an increase in splanchnic free radical production, an increase in capillary permeability, and bacterial translocation from the intestine into the bloodstream.[70]

The hemodynamic changes observed during pneumoperitoneum with carbon dioxide are the result of the complex interaction of anesthesia, surgical insult, the patient's position (Trendelenburg or reverse Trendelenburg), carbon dioxide, and an increase (followed by a reduction at the end of surgery) in intra-abdominal pressure as well as oxidative stress, which plays an important role in the overall response to this procedure.[73] It is not surprising that some authors are replacing the term *minimally invasive surgery* with the more precise term *minimal-access surgery*. Fortunately, an increase in intra-abdominal pressure that does not cause it to reach 12 to15 mm Hg is usually well tolerated by most patients.

Splanchnic Blood Volume in Congestive Heart Failure

The majority of patients with congestive heart failure do not demonstrate an increase in body weight, but they do show volume overload and an associated decrease in cardiac output.[74] Some authors speculate that because the density of adrenergic terminals in veins is more than fivefold higher than in arteries,[63] and because vasomotor response induced by sympathetic stimulation is greater in veins than in arteries, the pathogenesis of congestive heart failure involves increases in sympathetic discharge, constriction of splanchnic vasculature, and translocation of blood volume into the systemic circulation.[74] Those researchers believe that this is the main mechanism

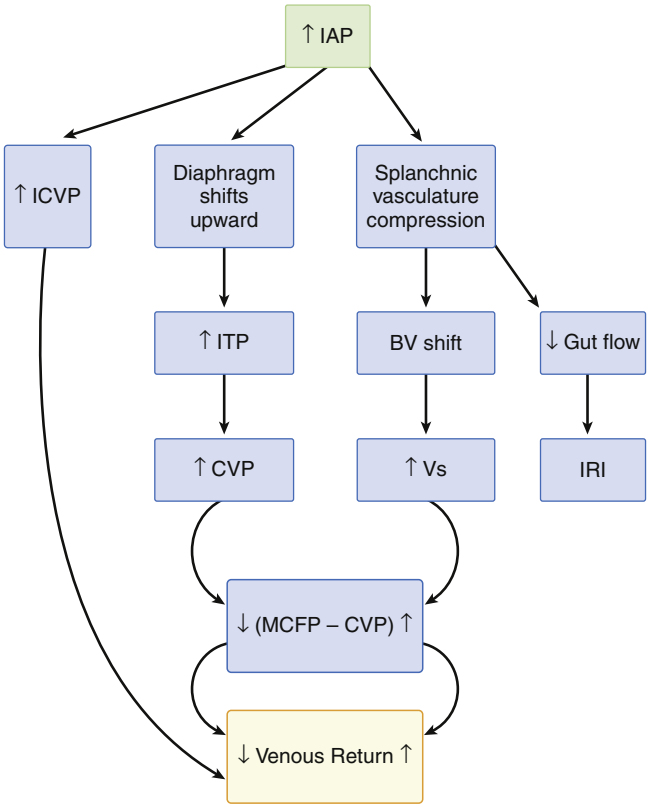

Figure 21-14. Hemodynamic responses to an increase in intra-abdominal pressure (IAP). ↑, Increase; ↓, decrease; *BV*, blood volume; *CVP*, central venous pressure; *ICVP*, inferior caval venous pressure; *IRI*, ischemia-reperfusion injury; *ITP*, intrathoracic pressure; *MCFP*, mean circulatory filling pressure; *Ven Ret*, venous return; *Vs*, stress volume.

responsible for congestive heart failure. It seems likely though that when the heart (myocardium) is able to handle an increased preload, such a translocation of blood volume does not lead to cardiac failure. However, when the myocardium is not able to handle this additional volume, congestive heart failure can ensue. Moreover, such an increase in preload (as a result of sympathetic activation) can be a compensatory mechanism necessary to maintain acceptable cardiac output. Different types of vasodilators can be used to treat cardiac failure.[75] Vasodilators (which decrease afterload and preload) should be administered carefully, because in cardiac failure an increased preload might be needed to maintain adequate cardiac output. In other words, a particular increase in stressed volume might be needed to maintain the heart at an appropriate position on the Starling curve (to the right of normal).

Role of Gastrointestinal Blood Flow in Gastroduodenal Mucosal Ulceration

Many compounds secreted within the stomach are ulcerogenic, the most important being hydrochloric acid and pepsin. Acute ulceration results from inflammatory response to physical or thermal trauma, shock, sepsis, and some others including emotional stress; these are called *stress ulcers*. These ulcers usually occur in the proximal, acid-secreting portion of the stomach.[76] The process starts with disturbances in microcirculation and focal ischemia. Focal ischemia can be observed as pallor and hyperemia, followed by petechiae and shallow ulcerations that progress to mucosal stress ulcers. Stress ulcers are superficial, limited only to the mucosa, and usually heal without serious consequences.

The etiology and course of drug-related ulcers are similar to those of stress ulcers. Aspirin and other NSAIDs can initiate that process. These drugs produce an imbalance between vasodilating and vasoconstricting prostaglandins, disturbing microcirculation within the mucosa that can be followed by ulceration.

The main pathogenetic factor in stress ulcers and in drug-related ulcers is a temporary decrease in gastric mucosal blood flow that can result in complications such as bleeding, endotoxemia, and sepsis. The role of blood flow and overall pathogenesis of stress ulcers has been well described.[76]

Splanchnic Circulation in Sepsis

Decrease in blood flow to the gut in general and to the intestinal mucosa in particular is the key event in the pathogenesis of sepsis and septic shock. Examination of the intravital microcirculation during sepsis reveals vascular wall edema, local hemorrhages, arteriole-venule shunting, reverse flow in capillaries and venules, blood flow redistribution within microunits, leukocyte-endothelial interaction, and transmigration through the capillary walls.[58] Reduction in blood velocity within the venules is closely correlated with the number of leukocyte-epithelium adhesions.[58] This disturbance in microcirculation is called *leukocyte adhesion stenosis*, because it is characterized by slowed capillary blood flow and a pattern of stop-and-go and no-flow venules; next, it progresses to leukocyte-endothelium adhesions within the lumen of the arterioles.[58] Thus, the microcirculation is severely disturbed and heterogeneous. Some micro-areas are hyperperfused and others are hypoperfused; arteriovenous shunting of blood is increased. This often is associated with a relatively normal or even increased total blood flow, but severely decreased nutritive blood flow to the intestinal walls, particularly to the mucosa. During sepsis, metabolic demand for oxygen within the intestines is increased, and nutritive blood flow is decreased despite profound vasodilation.

Sepsis is associated with severe inflammatory response leading to an increase in permeability and impaired immunologic barrier function within the intestines. Ischemia, increased permeability, and impaired intestinal barrier play an important role in subsequent amplification of distant organ dysfunction.[77] The use of dopamine and some other catecholamines might increase blood pressure and cardiac output, but also can increase arteriovenous shunting without any improvement in nutritive flow and microcirculation of GI organs. Such therapy often is ineffective and can actually exacerbate sepsis.[78] Despite an increase in oxygen delivery, the intramucosal pH, which is a marker of tissue oxygenation, decreases. The term *oxygen delivery* might not precisely reflect oxygen content in the arterial blood and flow (cardiac output). *Oxygen output* might be a better term, because in reality this oxygen is not delivered to cells, but bypasses them via arteriovenous shunting. The lack of oxygen uptake might

result not only from arteriovenous shunting, but in part from the inability of cells to consume oxygen because of impaired intracellular metabolism. In that case, "delivered" oxygen is not absorbed.

Effects of Spinal and Epidural Anesthesia on Gastrointestinal Blood Flow and Volume

The degree of arterial hypotension induced by spinal or epidural anesthesia is directly related to the extent of the blockade, the dose of local anesthetic used, and baseline hemodynamics.[79] Lumbar epidural anesthesia leads to arterial and venous dilation at the segments affected by the anesthetic. The constriction of the proximal part of the splanchnic vasculature shifts blood volume from the splanchnic system into the systemic circulation and usually results in preservation of stressed volume and blood pressure. Thoracic epidural anesthesia is associated with pronounced mesenteric vasodilation and arterial hypotension, whereas intestinal blood flow and oxygen consumption are maintained**.** A study using labeled red cells demonstrated that epidural anesthesia with sensory block at T4-T5 increased blood volume in both the intrathoracic and splanchnic vasculature.[80] The addition of a vasoconstrictor decreased volume within the splanchnic region, but increased volume within the thorax. The authors estimated that the use of a vasoconstrictor during thoracic epidural anesthesia led to a shift of approximately 1 L of blood from the splanchnic area into the thoracic and systemic circulation.[80]

Infusion of fluid or the use of adrenergic agonists apparently increases stressed volume. Infusion of fluid increases total (stressed and unstressed) blood volume, whereas adrenergic agonists move existing blood volume from unstressed to stressed. In many situations, the use of α-adrenergic agonists might be more beneficial than infusion of fluid.[64] Because veins are much more sensitive to adrenergic stimulation than arteries are, small doses of α-adrenergic agonists in normovolemic patients would constrict veins (increasing stressed volume) without affecting arteries or jeopardizing tissue perfusion.

Chapter 22

Hepatic Physiology and Pathophysiology

PHILLIP S. MUSHLIN • SIMON GELMAN

Key Points

- Roughly 30% of cardiac output flows through the liver by a dual blood supply. The portal vein delivers 75% of total hepatic blood flow; the hepatic artery provides the rest. Each vessel delivers half of the total hepatic oxygen supply.
- Hepatic sinusoids are the capillaries of the liver. Postsinusoidal vessels are a major source of total hepatic vascular resistance. The liver has a highly compliant, distensible vasculature that is central to its role as an important, rapidly accessible reservoir of blood volume. Without this reservoir function, mild losses of intravascular volume can result in severe hypotension.
- The liver is integral to the monocyte-macrophage system. Kupffer cells reside in hepatic sinusoids; they filter the venous effluent of the gastrointestinal tract; and they avidly remove bacteria and other harmful substances, preventing their entry into the systemic circulation.
- The acinar concept describes the functional microvascular unit of the liver. Each acinus has three circulatory zones. Blood perfusing zone 1 is rich in O_2 and nutrients; zone 3 hepatocytes are perfused with effluent blood from zones 1 and 2, which is relatively O_2 poor.
- The hepatic arterial buffer response (HABR) induces a compensatory increase of hepatic arterial flow, thereby preserving hepatic O_2 delivery despite decreases of total hepatic blood flow. Pathologic disruptions of HABR increase the susceptibility of the liver to hypoxic injury.
- The liver metabolizes cholesterol to bile acids, which is the only means of eliminating cholesterol from the body. Hepatocytes secrete bile acids, which flow through a series of hepatobiliary ducts that drain into the duodenum via the common bile duct.
- Bile salts are amphipathic molecules with detergent-like properties; they emulsify lipophilic substances, promoting their enteric absorption. Enterocytes of the terminal ileum efficiently take up bile acids and return them to hepatocytes via the portal blood. Hepatocytes can then take up and secrete a single bile acid molecule many times; this gut–liver connection is called the enterohepatic circulation.
- The liver is the epicenter of intermediary metabolism and energy homeostasis. Depletion of liver glycogen during prolonged fasting, for example, promotes hepatic gluconeogenesis, enabling the liver to nourish glucose-dependent tissues. Starvation accelerates the oxidation of fatty acids and formation of ketoacids, which are released from the liver and used as energy substrates by most of the extrahepatic tissues.
- Hepatocytes oxidize myriad substances by cytochrome P450–mediated reactions; they also attach endogenous polar substrates to hydrophobic molecules. Such products, being more hydrophilic than their unconjugated precursors, are more readily excreted in the urine or feces.
- The liver has a vital role in nitrogen metabolism. Ammonia is highly toxic to the central nervous system and can be eliminated only by the liver. Hepatocytes are uniquely equipped with the urea cycle enzymes required to metabolize ammonia to urea, which is readily excreted and much less toxic than ammonia.

Key Points—cont'd

- The liver produces almost all of the plasma proteins, except γ-globulins. Albumin is the most abundant plasma protein; it is the main determinant of plasma oncotic pressure and an essential plasma transporter of exogenous substances and endogenous compounds, such as unconjugated bilirubin and free fatty acids.
- Hepatocytes synthesize most of the molecular participants in coagulation pathways; they also modify vitamin K–dependent proteins—such as factors II, VII, IX, and X; protein C; and protein S—enabling their participation in the coagulation cascade.
- Standard liver chemistry tests—which are useful for detecting and monitoring hepatic and biliary disorders—lack the specificity and sensitivity needed to identify any specific disease. For diagnostic purposes, results of such tests must be interpreted in clinical context and often with supplemental radiologic and endoscopic information.
- Cirrhosis-induced portal hypertension produces a hyperdynamic circulation: systemic blood pressure is slightly below normal, cardiac output increases, and total peripheral resistance decreases. Portosystemic shunting occurs, circumvents the hepatic filtering mechanism, and thereby allows drugs, nitrogenous waste, and toxins to enter the central circulation.
- The onset of cirrhosis-induced portal hypertension is a pivotal event; it coincides with loss of the huge physiologic reserve of the healthy liver. Additional liver injury leads to life-threatening pathophysiologic derangements, including variceal hemorrhage, hepatic encephalopathy, and the hepatorenal and hepatopulmonary syndromes. The only definitive treatment for end-stage hepatic disease is liver transplantation.

OVERVIEW

The liver is the most versatile and largest internal organ in the human body, comprising 2% of the total mass of healthy adults and 5% of neonates. The liver is an essential part of the gastrointestinal tract that filters, excretes, and modifies an enormity of gut-derived substances. It is also a key component of the monocyte-macrophage system; Kupffer cells within liver sinusoids avidly remove bacteria and other harmful substances from portal blood, preventing their entry into the systemic circulation. The liver is the most vascular organ in the body; it has a unique dual blood supply and receives nearly 30% of the total cardiac output. Because of its highly compliant, distensible vasculature, the liver serves as a rapidly exchangeable blood reservoir that promotes homeostasis of the circulating blood volume. Moreover, the liver is the epicenter of intermediary metabolism and energy homeostasis; it is uniquely equipped to meet the nutritional needs of tissues throughout the body during times of both feast and famine. The liver plays an indispensable role in the excretion of endogenous wastes—most notably, ammonia and bilirubin—and eliminates a wide range of xenophobic substances, including most of the drugs and toxins that enter the body. For these reasons, a fundamental understanding of hepatic physiology is a prerequisite for health care providers. Liver disease, particularly when severe, has pervasive clinical ramifications and imposes complex therapeutic challenges.

HEPATIC ANATOMY

TRADITIONAL ANATOMY

The liver looks like a reddish-brown boomerang and occupies the entire right subcostal space, most of the epigastrium, and part of the left subcostal space. Being highly malleable, the liver allows its less pliable neighbors to determine its topography. For example, on its posterior surface, the liver shows imprints of the inferior vena cava and diaphragmatic attachments, such as the coronary and triangular ligaments and the interstitial matrix at the bare area of the liver. The superior hepatic surface conforms to the underside of the diaphragm.

Topologic landmarks, which are at the core of traditional anatomy, provide the basis for separating the liver into four lobes, known as the left, right, caudate, and quadrate lobes. The liver, when viewed from its anterior, superior surface, reveals only the right and left lobes separated by the falciform ligament. The posterior-inferior hepatic surface provides the best vantage for viewing the relative positions of the four lobes. On this surface, the left and right lobes are separated by the left sagittal fossa (ligamenta venosum and teres hepatis). The quadrate and caudate lobes are not well delineated, but can be envisaged as follows: First, the midline boundary—the porta hepatis (transverse fissure) forms the posterior border of the quadrate lobe and the anterior border of caudate lobe. Second, the right-side boundary—for the quadrate lobe

it is the gallbladder fossa; for the caudate lobe it is the inferior vena cava. Third, the left-side boundary—for the quadrate lobe it is the ligamentum teres (umbilical vein fossa); for the caudate lobe it is the ligamentum venosum fissure (ductus venosus fossa).[1]

Knowledge of surface anatomy is indispensable for those who perform procedures involving the liver. Recent and marked advances in liver surgery—particularly with hepatic transplantation—have prompted the development of new classification systems of hepatic anatomy. This chapter provides a brief overview of the concepts of segmental anatomy, which focus on the spatial relationships among blood vessels and bile ducts within the liver. More specifically, physiologic anatomy seeks to identify singular portions of the liver (segments) that can be resected without compromising the viability of neighboring hepatic segments.[2,3]

PHYSIOLOGIC ANATOMY

Physiologic anatomy—also referred to as functional or segmental anatomy—separates the liver into independent, self-sufficient segments. Each segment is equipped with its own afferent blood supply and conduits to drain blood and bile from its parenchyma (Fig. 22-1).[4] At present, no system of physiologic anatomy is universally accepted, largely because of the considerable variability that exists in the interindividual anatomy of the portal vein, hepatic artery, and bile ducts. The Couinaud classification, which is in widespread clinical use, is depicted in Figure 22-1 and shows the general principles of segmental anatomy. The primary focus of the Couinaud system is on third-generation branches of the portal vein. This classification, similar to most others in common use, partitions the liver into eight physiologic segments (see Fig. 22-1).[2,4]

Advanced imaging techniques (e.g., contrast-enhanced helical computed tomography [CT]) are commonly used to determine the real anatomy of each patient's liver (Fig. 22-2).[5] These scans provide accurate correlative information about the topology and unique physiologic anatomy of the patient's liver.[4] Accordingly, liver operations (e.g., resection of tumors, repair of traumatic injuries), planned and guided by the principles of physiologic anatomy, result in lower rates of perioperative morbidity and mortality.

HEPATIC ARCHITECTURE

Portals for Hepatic Blood and Bile Flow

The hilum of the liver (porta hepatis) is where the afferent blood vessels enter and bile ducts exit the liver. The two main afferent blood vessels divide into first-order branches—the left and right portal veins and the left and right hepatic arteries. These vascular branches ramify and traverse the hepatic stroma in tandem. Their final branches—which are located within portal tracts—drain their blood into the liver sinusoids (hepatic capillaries). After perfusing the liver parenchyma, this blood drains into central hepatic veins (also called terminal hepatic venules). These tiny veins coalesce successively, giving rise to larger venous vessels that ultimately unite to form the right main, middle, and left main hepatic veins that connect directly to the inferior vena cava.

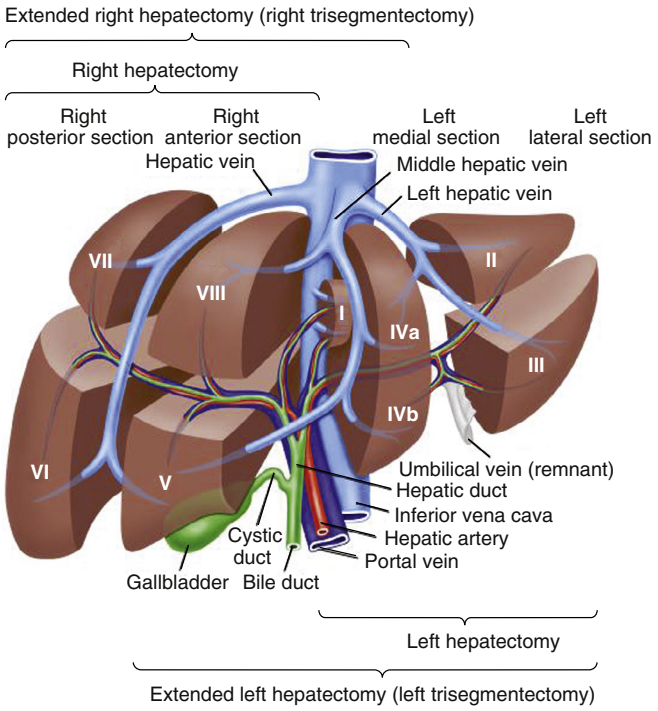

Figure 22-1. Schematic depiction of Couinaud segmental liver anatomy and the normal portal venous structures. *Bracketed text* shows hepatic segments resected during partial hepatectomies. *(Modified from Venook AP, Curley SA: Management of potentially resectable colorectal cancer liver metastases. Available at: http://www.uptodate.com/contents/management-of-potentially-resectable-colorectal-cancer-liver-metastases).*

Liver Lobule

The lobule is the basic anatomic unit of the liver (Fig. 22-3). An idealized classic liver lobule is a hexagonal prism that has six vertically aligned portal canals (see Fig. 22-3) at its apices and a terminal hepatic venule at its center. The portal canals contain a connective tissue matrix, nerve fibers, lymphatic vessels, and a portal triad, which consists of a bile ductule and the final branches of the portal vein and hepatic artery. Liver lobules are tiny; each has a circumference of 3 mm and is several millimeters in length. The human liver contains 50,000 to 100,000 lobules.

Liver Acinus: The Microvascular Unit of the Liver

The liver acinus is considered the functional microvascular unit of the liver. The acinus, as defined by Rappaport in the 1950s, is the parenchyma around terminal afferent portal and arterial vessels that supply blood to this group of hepatocytes. Figure 22-4 shows the three heterogeneous circulatory zones: zone 1 is periportal, zone 2 is the midzone, and zone 3 is pericentral. Blood supplied to zone 1, which is near the origin of the sinusoid, is rich in oxygen and nutrients. In contrast, zone 3, at the periphery of the acinus, receives blood that is O_2 poor because this blood has already perfused hepatocytes of zones 1 and 2 before it reaches zone 3.

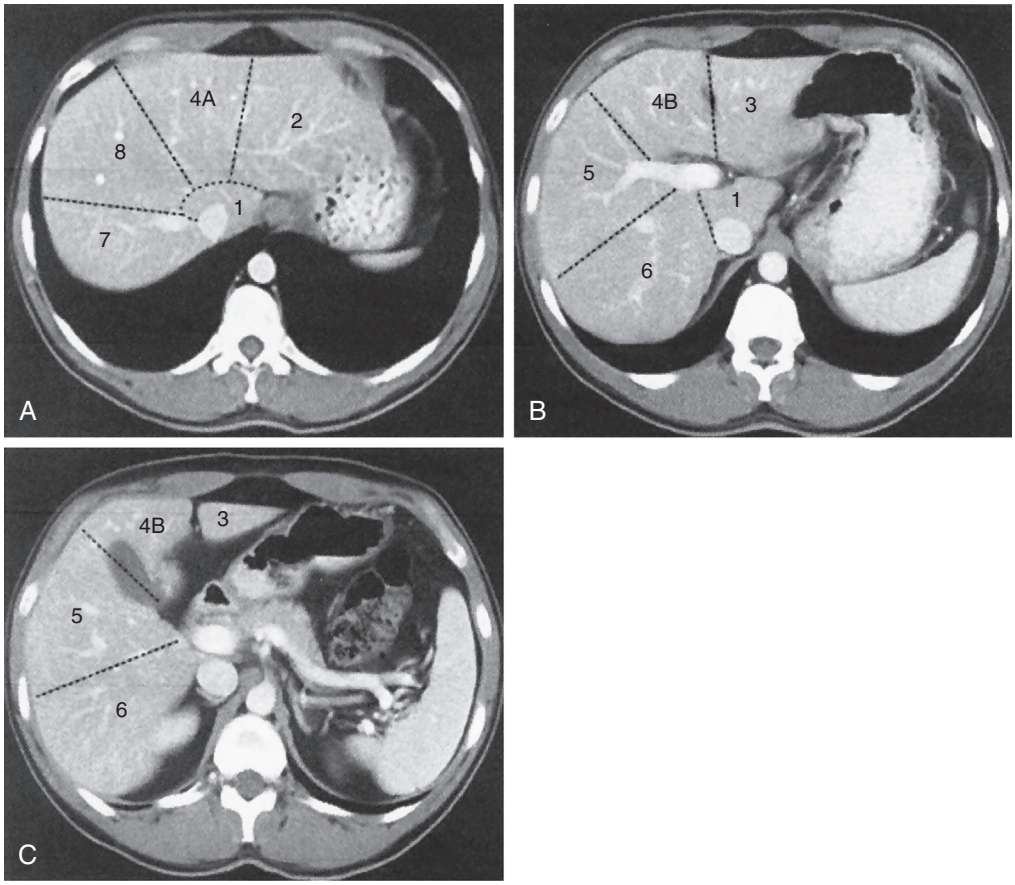

Figure 22-2. Segmental anatomy of the liver is demonstrated at three levels on contrast-enhanced CT images. **A,** At the level of the hepatic veins, the caudate lobe (segment 1) is seen posteriorly, embracing the vena cava. Segment 2 is separated from segment 4A by the left hepatic vein. Segment 4A is separated from segment 8 by the middle hepatic vein and segment 8 is separated from segment 7 by the right hepatic vein. **B,** At the level of the portal vein bifurcation, segment 3 is visible as it hangs inferiorly in its anatomic position and is separated from segment 4B by the umbilical fissure. Note that segment 2 is not visible at this level. Terminal branches of the middle hepatic vein separate segment 4B from segment 5 and terminal branches of the right hepatic vein separate segment 5 from segment 6. Note that Sements 4A, 8, and 7 are not visible at this level. Segment 1 is seen posterior to the portal vein and embracing the vena cava. **C,** Below the portal bifurcation, one can see the inferior tips of segments 3 and 4B. The terminal branches of the middle hepatic vein and the gallbladder mark the separation of segment 4B from segment 5. Segments 5 and 6 are separated by the distal branches of the right hepatic vein. Note how the right liver hangs well inferior to the left liver. *(From Townsend CM Jr, Beauchamp D, Evers BM, et al:* Sabiston textbook of surgery, *ed 19. Philadelphia, 2012, Saunders, Chap 54, Fig 54-6.)*

The microvascular architecture of the acinus allows increases in the efficiency of substrate usage and excretion of waste products.[6,7] Urea cycle enzymes are localized in zones 1 and 2. Hepatocytes within these zones convert amino acids to ketoacids and ammonia; the urea cycle (high capacity, low affinity) captures the ammonia and incorporates it into urea. Any ammonia that eludes the urea cycle is likely to encounter glutamine synthetase, which is expressed only in zone 3. This enzyme facilitates the capture of ammonia within the glutamine substrate. If glutamine substrate were present in zones 1 or 2, it would compete with urea cycle enzymes for ammonia and thereby decrease the liver's capacity to eliminate ammonia. By having glutamine synthetase localized in zone 3, pericentral hepatocytes more efficiently scavenge the ammonia that would otherwise reach the central circulation.

Periportal hepatocytes have the highest density of mitochondria and are the major site of oxidative metabolism and glycogen synthesis. In contrast, pericentral hepatocytes—which have an abundance of smooth endoplasmic reticulum, reduced nicotinamide adenine dinucleotide phosphate (NADPH), and cytochrome P450 (CYP) proteins—are the major site of anaerobic metabolism and xenobiotic biotransformation. Not surprisingly, pericentral hepatocytes bear the brunt of injuries induced by reactive xenobiotic metabolites or hypoxic episodes. The clinical message is that ischemic injury or necrosis of the centrilobular region decreases the liver's capacity to excrete many drugs and other xenobiotics.[4]

A Conceptual Alternative to the Acinar Concept

An alternative to the acinar concept, which is based on the angioarchitecture of the liver,[8] has recently been gaining popularity.[9] This concept divides the portal and hepatic venous systems into a conducting portion—which delivers and drains blood from the parenchyma—and a parenchymal portion, which is the basis for the primary lobule. Recent studies of hepatic enzymes and

pathologic processes suggest the presence of a continuous periportal network around portal tracts and terminal afferent vessels and a distinct concentric perivenous area around the central vein; such data support the idea that the liver architecture more closely resembles the classic lobule more than it does the acinus.[9]

Types of Liver Cells

Sinusoidal Endothelial Cells. Sinusoidal endothelial cells are different from the endothelium in the rest of the body. The large (~100 to 200 nm in diameter) pores between the cells are called fenestrae. The fenestrae permit passage of relatively large particles out of the blood; these include albumin with bound ligands, such as lipids and lipoproteins. But the fenestrae do not let red and white blood cells and platelets penetrate the sinusoidal endothelium. Another unusual feature of sinusoidal endothelium is that these cells lack basement membrane. This feature also increases the endothelium permeability to solute from the bloodstream. Thus, sinusoidal endothelium does not have a serious barrier to efflux of albumin and other molecules of similar size.

Kupffer Cells. The structure and function of Kupffer cells are similar to those of macrophages. Kupffer cells line the sinusoidal endothelium on the bloodstream side, have very high phagocytic properties, and represent the first line of host defense.[10]

Hepatic Epithelial Cells. The term *hepatocyte* is commonly used to denote the liver parenchymal cells. They are highly polarized epithelial cells and serve as the metabolic factories of the liver.[11] They have heterogeneous plasma membranes with three distinct specialized domains. For example, plasma membrane domains that face the hepatic sinusoids (called basolateral or sinusoidal membranes) are in direct contact with the perisinusoidal space of Disse; in contrast, apical domains of hepatocellular membranes that make up the lumina of the tiny channels (bile canaliculi) convey to bile ductules and ducts.

Lobular or acinar zonation is an important concept that explains morphologic and metabolic differences among hepatocytes based on their relative proximities to portal regions versus central veins. Hepatocytes close to portal regions are called zone 1 hepatocytes. They receive blood that is relatively high in O_2; the main function of these cells is detoxification and secretion. In conditions of compromised liver function, cells in zone 2 and 3 can be recruited; they represent the "anatomic reserve." Different zones determine the susceptibility of hepatocytes to injury. Hepatocytes in zone 3 are more sensitive to hypoxia; on the other hand, ischemia-reperfusion injury is more dramatic in zone 1. The histologic analysis of liver samples may help in diagnosis of the source of hepatic injury.

Hepatocytes can regenerate. After surgical removal of part of the liver, the remaining hepatocytes proliferate by undergoing mitosis. In animal models, up to 70% of total liver mass can be regenerated.[11]

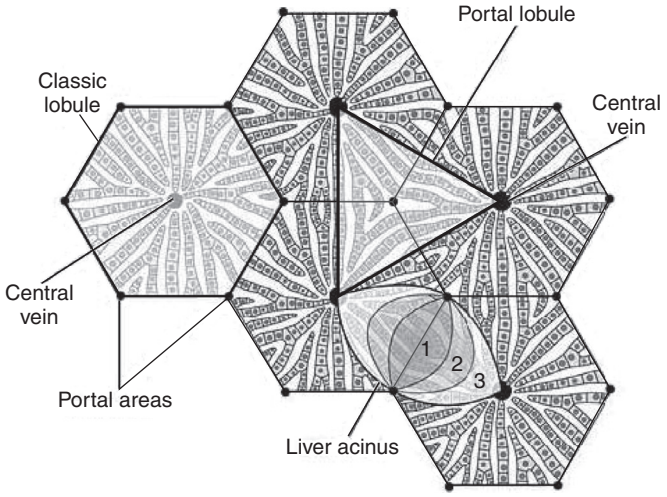

Figure 22-3. Schematic classifications of liver units: liver lobule, portal lobule, and liver acinus. Lobular units have well demarcated central structures (central vein or portal canal), whereas the liver acinus (zones *1, 2, 3*; see Fig. 22-4) contains a central axis derived from two adjacent classic lobules. *(From Henrickson R, Kaye GI, Mazurkiewicz J: Liver and gallbladder. In Henrickson R, Kaye GI, Mazurkiewicz, editors:* NMS Histology, *ed 3. Philadelphia, 1997, Lippincott Williams & Wilkins.)*

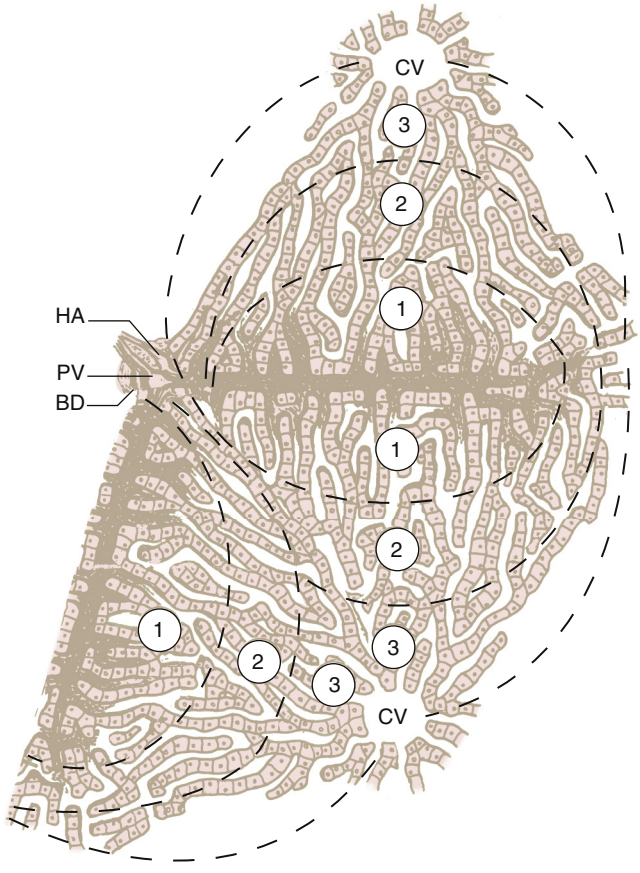

Figure 22-4. Blood supply of a liver acinus. Oxygen tensions and nutrient levels within sinusoids continuously decrease as blood flows from zone *1* through zone *3*. The lower part of this figure shows zones *1, 2,* and *3* of a neighboring acinus. *BD,* Bile ductule; *CV,* central vein; *HA,* hepatic artery; *PV,* portal vein. *(From Jones AL: Anatomy of the normal liver. FUNCTIONS OF THE LIVER

RESERVOIR FOR BLOOD VOLUME AND BLOOD FILTER

Vasculature of the Liver

The liver is the most vascular organ in the body; it receives nearly one third of the total cardiac output (1 mL of blood/1 g of liver) through a unique dual blood supply. Approximately 75% of the total hepatic blood flow arrives by the portal vein, and the remaining 25% is from the hepatic artery. Each of the two vessels brings half of the total O_2 content supplied to the liver. The hepatic artery has its origin at the celiac trunk of the abdominal aorta (Fig. 22-5).[1,12]

The portal vein—formed by the union of superior mesenteric and splenic veins—conveys the effluent venous blood from splanchnic organs, including the stomach, intestines, pancreas, and spleen. In other words, the portal veins transmit to the liver the entire venous drainage of the preportal splanchnic beds.[4,13]

Hepatic Blood Flow

Regulation of Hepatic Blood Flow. Intrinsic and extrinsic mechanisms play important roles in the regulation of hepatic blood flow. Intrinsic mechanisms—such as the hepatic arterial buffer response (HABR), metabolic control, and pressure-flow autoregulation—work independently of neurohumoral factors.

Intrinsic Regulation

Hepatic Arterial Buffer Response. The HABR is the most important intrinsic mechanism.[14] With an intact HABR, changes in portal venous flow cause reciprocal changes in hepatic arterial flow. That is, when portal venous flow decreases, the HABR compensates by increasing hepatic arterial flow and vice versa. The HABR mechanism involves the synthesis and washout of adenosine (i.e., a vasodilator) from periportal regions.[14,15] When portal venous flow decreases, adenosine accumulates in the periportal regions, which lowers arteriolar resistance and thereby increases hepatic arterial flow. Conversely, when portal venous flow increases, adenosine is washed out of the periportal regions, which increases arteriolar resistance and decreases hepatic arterial flow. At a maximum, the HABR can double hepatic arterial flow. Therefore, it cannot fully restore hepatic blood flow when portal venous flow falls by more than 50%. Yet, because hepatic arterial blood carries more O_2 than does portal venous blood, the HABR more effectively preserves hepatic O_2 supply than does hepatic blood flow. Various disorders (e.g., endotoxemia, splanchnic hypoperfusion) may decrease or even abolish the HABR and render the liver more vulnerable to hypoxic injury.[16-18]

Metabolic Control. Many constituents of blood affect hepatic arterial and portal venous blood flow. Decreases in O_2 tension or the pH of portal venous blood typically lead to increases in hepatic arterial flow. Postprandial hyperosmolarity increases hepatic arterial and portal venous flow. The underlying metabolic and respiratory status (e.g., hypercapnia, alkalosis, arterial hypoxemia) also modulate the distribution of blood flow within the liver.

Pressure-Flow Autoregulation. Pressure-flow autoregulation enables tissue-specific regulators to govern organ blood flow despite fluctuations in systemic arterial pressure.

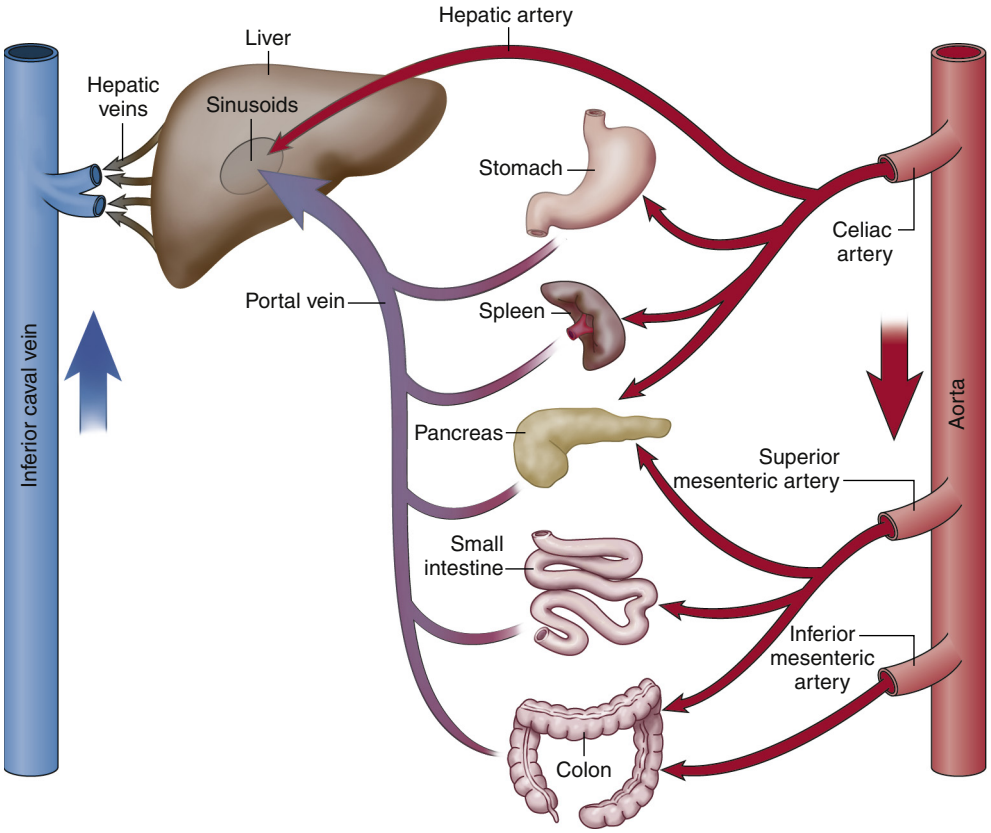

Figure 22-5. The splanchnic circulation. *(Redrawn from Gelman S, Mushlin PS: Catecholamine induced changes in the splanchnic circulation affecting systemic hemodynamics.* Anesthesiology *100:434-439, 2004.)*

The mechanism involves myogenic responses of vascular smooth muscle to stretch. For example, a hypertensive episode increases transmural pressure, thereby stretching arterial smooth muscle. The resultant increase in myogenic tone (i.e., vasoconstriction) prevents the increases in organ blood flow that would otherwise occur. Conversely, transient hypotension lowers transmural pressure and myogenic tone (i.e., vasodilation), which helps sustain organ perfusion during systemic hypotension. Decreases in systemic blood pressure, as often occur during anesthesia, typically lead to a proportional decrease in portal blood flow and often are compensated by an increase in hepatic arterial blood flow; anesthesia with volatile anesthetic decreases this response in a dose-related fashion.

Extrinsic Regulation

Neural Control. Fibers of the vagus, phrenic, and splanchnic nerves (postganglionic sympathetic fibers from T5 through T11) enter the liver at the hilum; they course through the liver alongside the afferent hepatic blood vessels and bile ducts. When sympathetic tone decreases, splanchnic reservoir volume increases. On the other hand, sympathoadrenal stimulation translocates blood volume from the splanchnic reservoir to the central circulation. Within seconds of splanchnic nerve stimulation, up to 80% of the hepatic blood volume (400 to 500 mL) could be transferred to the central circulation in dogs. The hepatic arterial bed has α_1-, α_2-, and β_2-adrenergic receptors, whereas the portal vein has only α-receptors (Fig. 22-6).[12,19]

Humoral Control. Glucagon induces dose-dependent relaxation of hepatic arterial smooth muscle and blocks the effects of physiologic vasoconstrictors on the hepatic artery. By contrast, angiotensin II constricts the hepatic arterial and portal venous beds. Pharmacologic doses of angiotensin II can cause hepatic blood flow to plummet because of its ability to markedly decrease both mesenteric arterial and portal venous flow. Vasopressin, on the other hand, elevates splanchnic arterial resistance, but it lowers portal venous resistance. Because of its vascular profile, vasopressin may have efficacy in treating portal hypertension.[4]

BIOCHEMICAL AND PHYSIOLOGIC ROLES OF THE LIVER

The liver removes particles from the portal blood, which usually contains numerous colonic bacteria that cross the wall of the intestine under normal circumstances. This "blood cleansing" is performed by Kupffer cells.[10]

The liver also has abundant specialized pathways and detoxifies gut-derived substances using CYP450 pathways and other enzymes. It converts xenobiotics, toxins, and other substances into harmless compounds. The effectiveness of many drugs is significantly decreased when taken orally because they are absorbed in the gastrointestinal (GI) tract, reach the liver through the portal blood, and are metabolized there. Their effectiveness is decreased by first-pass metabolism.

Hepatic metabolism of xenobiotics is achieved in two phases. The first phase is metabolism that includes oxidation and other reactions mediated by CYP450s. The second phase includes the esterification reaction that links the metabolites to other molecules such as sulfate, glucuronic acid, amino acids, and others. The liver metabolizes and synthesizes proteins, carbohydrates, lipids, and many other compounds.

Protein Metabolism

The liver plays a central role in the production and breakdown of amino acids, peptides, and proteins. Hepatocytes metabolize amino acids to ketoacids, glutamine, and ammonia by transamination and oxidative deamination

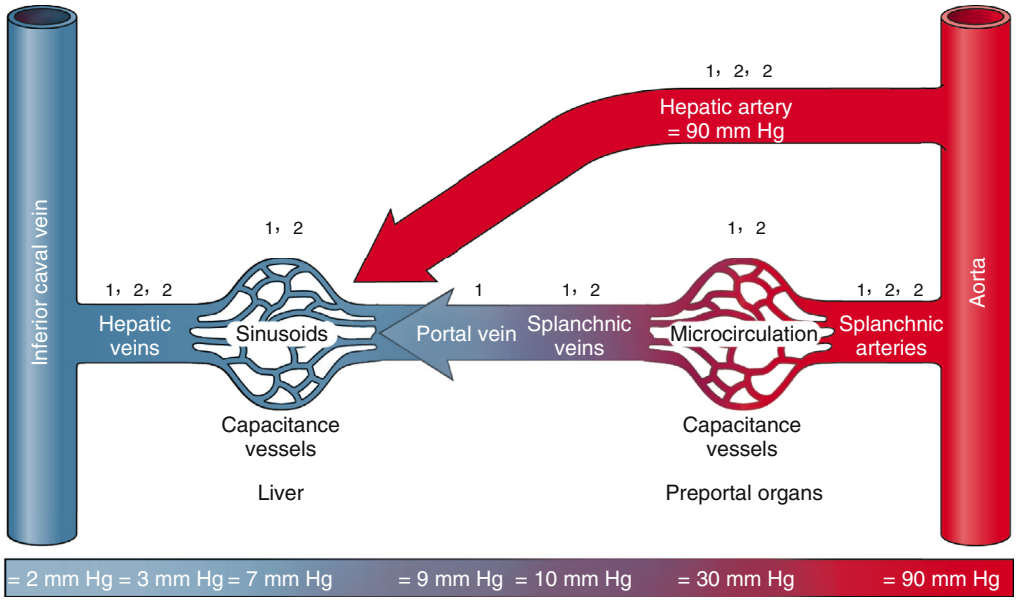

Figure 22-6. Adrenoceptor subtypes (α_1, α_2, β_2) and intravascular pressure within the splanchnic circulation. The splanchnic arteries represent the arterial supply to all preportal organs; the splanchnic veins represent the pooled venous blood from all these organs *(Redrawn from Gelman S, Mushlin PS: Catecholamine induced changes in the splanchnic circulation affecting systemic hemodynamics.* Anesthesiology *100:434-439, 2004.)*

reactions. The Krebs-Henseleit cycle is the major pathway for removing ammonia and other nitrogenous wastes from the body. This pathway captures nitrogen in the form of urea. Thus, with a failing liver (and normal renal function), blood urea nitrogen remains low, whereas nitrogenous wastes such as ammonia accumulate in blood and other tissues.

Liver-derived proteins have an impact on every organ in the body. Such proteins include procoagulants, hormones, cytokines, chemokines, acute-phase reactants, and transport proteins. The most abundant of them is albumin, which accounts for roughly 15% of the liver's total protein production. Healthy adults produce 12 to 15 g of albumin every day; the total-body pool of albumin has a mass of about 500 g. Factors that modulate the synthesis of albumin include plasma oncotic pressure, dietary amino acids, and hormones. The main regulator of intravascular albumin is oncotic pressure. Albumin binds to and transports a wide variety of substances—free fatty acids, unconjugated bilirubin, hormones, xenobiotics, and metals. In this way, albumin affects the biologic activity and clearance of a multiplicity of substances.[4]

Carbohydrate Metabolism

The liver is the epicenter of carbohydrate metabolism. Whether the liver is a net producer or consumer of glucose depends on many factors, including the neuroendocrine milieu (i.e., insulin, catecholamines, glucagon) and glucose concentration in sinusoidal blood. Hepatic production of glucose is inversely related to glycogen production by the liver. In the fed state, hepatocytes polymerize glucose and store it as glycogen; in the unfed state, hepatocytes depolymerize glycogen to glucose and release it into the bloodstream. Regulation of glycogen metabolism involves two rate-limiting enzymes: (1) glycogen synthase, which catalyzes the synthesis of glycogen from monomers of uridine diphosphate (UDP) glucose, and (2) glycogen phosphorylase, which catalyzes the sequential cleavage of glycogen to monomers of glucose 1-phosphate.

When liver glycogen stores are depleted the body depends on hepatic gluconeogenesis to replenish blood glucose. Substrates for gluconeogenesis include (1) lactate; (2) glycerol from the hydrolysis of triglycerides; and (3) glucogenic amino acids such as alanine and glutamine, which are derived from protein catabolism in skeletal muscle. Endocrine modulators of gluconeogenesis include glucagon, catecholamines, and insulin. Both glucagon and catecholamines stimulate gluconeogenesis. Glucagon works via cyclic adenosine monophosphate (cAMP)-dependent protein kinase, and catecholamines use both cAMP-dependent and cAMP-independent mechanisms. By contrast, insulin inhibits gluconeogenesis, and it blocks the stimulatory effects of catecholamines and glucagon on this pathway.

The four main functions of the liver in carbohydrate metabolism are glycogen storage, conversion of galactose and fructose to glucose, gluconeogenesis, and formation of many biochemical compounds from the intermediate products of carbohydrate metabolism. The liver removes excess glucose from the blood and returns it as needed. This function is often called glucose buffer function of the liver.[11]

Lipid Metabolism

The liver produces, takes up, retains, releases, and oxidizes fatty acids in accord with nutritional and endocrine influences. Dietary fatty acids absorbed in the small intestines reach the liver by blood and the lymphatics, mainly in the form of chylomicrons. When replete with glycogen, hepatocytes convert glucose to fatty acids and may store them as triglycerides (fat). Thus, the major sources of intrahepatic fatty acids include (1) free fatty acids extracted from blood, (2) de novo lipogenesis, (3) hydrolysis of cytoplasmic triglycerides, and (4) hepatocellular uptake and metabolism of blood-borne lipoproteins.

Esterification and β-oxidation pathways have pivotal roles in the hepatic disposition of fatty acids. Esterification of glycerol and fatty acids produces triglycerides—the main storage form of free fatty acids. The liver may either retain triglycerides or package them into lipoproteins, primarily very-low-density lipoproteins (VLDLs), for transport to other tissues. Free fatty acids regulate VLDL production, but endocrine and nutritional factors govern VLDL secretion. β-Oxidation is the pathway of fatty acid catabolism. Glucagon activates this pathway, whereas insulin inhibits it. β-Oxidation sequentially cleaves fatty acids to yield monomers of acetyl coenzyme A (acetyl-CoA). It is a building block for lipids (i.e., triglycerides, phospholipids, cholesterol) and a product of the oxidative breakdown of fatty acids and carbohydrates. Mitochondria oxidize acetyl groups to yield carbon dioxide, water, and adenosine triphosphate (ATP). If more acetyl-CoA is produced than the tricarboxylic acid cycle can handle, the surplus is metabolized to ketone bodies—namely, acetoacetate, β-hydroxybutyrate, and acetone.[7] Hepatocytes cannot extract energy from ketones, however, because they lack ketoacyl-CoA transferase (acetoacetate:succinyl-CoA transferase). This enzyme exists in all organs except the liver. Thus, ketones are an important extrahepatic energy source during catabolic states, most notably starvation. Insulin modulates ketogenesis by inhibiting lipolysis in adipocytes. Stress-induced ketosis is typically a self-limited process because ketones stimulate the release of insulin, thereby limiting availability of substrate (fatty acid) for hepatic ketogenesis.[20] Without insulin, this feedback loop is nonexistent and diabetic ketoacidosis may ensue.[77]

Thus, the liver plays an important role in lipid metabolism. An example is its major role in the high rate of fatty acid biotransformation that supplies energy for functions throughout the body. On the other hand, the liver converts amino acids and intermediate products of carbohydrates into fats and transports them to the adipose tissues.

GUT–LIVER INTERACTIONS: THE ENTEROHEPATIC CIRCULATION

Bile: Its Composition and Its Role in Enteric Absorption

Bile is a heterogeneous solution of variable composition; its main constituents are conjugated bile salts, cholesterol, phospholipids, conjugated bilirubins, and electrolytes.[21] After its release from the common bile duct into the duodenum, bile alkalinizes intestinal contents and its

detergent-like chemical properties promote the emulsification, absorption, and digestion of hydrophobic dietary lipids, including saturated long-chain fatty acids and fat-soluble vitamins. Furthermore, bile plays an indispensable role in the excretion of potentially toxic endogenous wastes and xenobiotics.[22]

Bile consists of a micellar solution in which bile acids, products of hepatocytes produced by the metabolism of cholesterol, form mixed micelles with phosphatidylcholine.[21] These mixed micelles solubilize molecules that would otherwise have minimal aqueous solubility, such as cholesterol itself and a variety of xenobiotics. In addition to its role in providing for excretion of hydrophobic waste products, bile also plays an important role in the digestion and absorption of lipids ingested in the diet. Bile acids form mixed micelles with the products of lipid digestion, increasing the rate at which they can diffuse across the aqueous environment of the gastrointestinal lumen. Although bile acids are not essential for the uptake of most fatty acids, which have appreciable aqueous solubility, they do markedly increase the efficiency of this process. On the other hand, in patients suffering from cholestasis, deficiencies of fat-soluble vitamins can occur.[23]

The liver transforms cholesterol into bile salts that are secreted by the liver as a vehicle to facilitate fat digestion and absorption; bile salts also allow the excretion of lipid-soluble waste products of metabolism and xenobiotics. Bile acids recycle several times daily from the intestine to the liver in the enterohepatic circulation; in their conjugated forms, they are actively reabsorbed in the terminal ileum, thereby generating a recycling pool of bile acids.[23]

Bile Formation and Intrahepatic Bile Flow

Bile secretion originates in pericentral hepatocytes and flows centrifugally through tiny channels that parallel the sinusoids. Hepatocytes around the sinusoids secrete bile acids into bile canaliculi that flow in a direction opposite to that of afferent blood. Bile canaliculi drain into small bile ductules that coalesce serially to form larger bile ducts. Ducts of liver segments unite and eventually form the right and left main hepatic bile ducts. The union of these two ducts is the common hepatic duct, which descends through the porta hepatis, where it combines with the cystic duct to create the common bile duct.

BILE PRODUCTION AND THE ENTEROHEPATIC CIRCULATION: GASTROINTESTINAL–HEPATIC INTERACTIONS

The liver produces 200 to 500 mg of primary bile acids per day, using cholesterol as the substrate. Chenodeoxycholic acid and cholic acid are the most important primary bile acids. These bile acids travel from the liver through the intestine. They are reabsorbed from either the terminal ileum or the colon, where bacterial enzymes metabolize them into secondary bile acids. Both types of bile acids enter the mesenteric venous blood and reach the liver sinusoids via the portal vein. Specific transporters on hepatocellular membranes internalize these bile acids, which are then conjugated with hydrophilic substrates (such as glycine or taurine); this facilitates their ATP-dependent secretion into bile canaliculi. Through this series of events, roughly 95% of bile acids are conserved and recycled via the enterohepatic circulation.

The bile acids activate lipases (bile acid dependent), promote micelle formation, and enable the intestinal uptake of fat-soluble vitamins, cholesterol, and other lipids. Bile acids also facilitate the excretion of numerous lipophilic substances, including exogenous compounds such as xenobiotics and endogenous molecules such as bilirubin, cholesterol, and steroid hormonal derivatives.

Bile salts also regulate lipid metabolism. Bile salts produce their regulatory effects by binding to and activating the farnesoid X receptor (FXR). When activated, hormone nuclear receptors (such as FXR) are transferred from cytoplasm to the nucleus; they bind to hormone response elements on DNA to induce either expression or transrepression of specific gene products. An important effect of FXR activation is the decrease in the transcription of cholesterol 7α-hydroxylase (CYP7A1), which catalyzes the rate-limiting step in the conversion of cholesterol to bile salts. Bile salts modulate plasma lipid levels by regulating the expression of lipoprotein receptors that enable hepatocytes to remove lipoprotein cholesterol from the bloodstream.

Cholesterol is so hydrophobic that the body is unable to excrete it without first increasing its water solubility. Remarkably, hepatocytes metabolize cholesterol to bile acids, creating amphipathic molecules that solve two problems. First, amphipathic metabolites of cholesterol are readily excreted in the bile. Second, such bile acid metabolites retain the hydrophobic regions of cholesterol while also containing newly added hydrophilic groups. Therefore, cholesterol metabolism yields effective detergents that facilitate enteric emulsification and digestion and absorption of dietary lipids, including long-chain fatty acids and fat-soluble vitamins.[11]

SYNTHESIS OF PROCOAGULANTS, ANTICOAGULANTS, AND FIBRINOLYTIC FACTORS

Hepatocytes make most of the procoagulants, with notable exceptions such as factors III (tissue thromboplastin), IV (calcium), and VIII (von Willebrand factor). The liver also makes protein regulators of coagulation and the fibrinolytic pathways. Such regulators include protein S, protein C, protein Z, plasminogen activator inhibitor (PAI), and antithrombin III. Protein Z facilitates the degradation of factor Xa, and protein S is a cofactor of activated protein C that inactivates factor Va and VIIIa complexes; a deficiency of protein S increases the risk for venous thrombosis. PAI-1 is an indirect inhibitor of fibrinolysis. This serine protease inhibitor blocks the effects of plasminogen activators, such as urokinase and tissue plasminogen activator, to convert plasminogen to plasmin; a deficiency of PAI increases the risk for uncontrolled fibrinolysis. To summarize, hepatocytes make most of the procoagulants and many proteins that modulate the consumption of clotting factors.[24]

Vitamin K Cofactor and γ-Carboxylation

Vitamin K–dependent proteins include factors II, VII, IX, and X and proteins C and S. Such proteins undergo

a vitamin K–dependent, posttranslational modification. This process involves carboxylation of the γ-position of glutamate residues at the amino terminus, which produces the amino acid carboxyglutamate.[20,25] This modification (termed γ-carboxylation) creates procoagulants capable of forming complexes with calcium or other divalent cations. Thus, γ-carboxylated procoagulants are primed for activation to serine proteases (e.g., via extrahepatic phospholipids) that participate in the clotting cascade.[20,26]

The γ-carboxylation pathway, which contains two steps, accounts for the anticoagulant effect of warfarin.[26] The first involves vitamin K–dependent γ-carboxylation of precursor proteins, during which vitamin K cofactor (naphthol hydroquinone) is oxidized to 2,3-epoxide vitamin K. In the second stage, vitamin K cofactor is regenerated via vitamin K 2,3-epoxide reductase. Warfarin blocks the second stage by inhibiting vitamin K epoxide reductase and thereby trapping vitamin K in the epoxide form. The eventual result is depletion of vitamin K cofactor, which shuts down the γ-carboxylation pathway.

Warfarin inhibits γ-carboxylation soon after its enteric absorption, but its anticoagulant effect takes at least 1 day to develop. This paradox reflects the slow clearance of blood-borne prothrombin complexes (i.e., half-life of ~14 hours) and the insensitivity of prothrombin time (PT) as a test for decreasing blood levels of procoagulants. As a rule, the PT will remain normal until the prothrombin complex in blood is less than 70% below the lower limit of normal.

Therapeutic use of vitamin K may help uncover the cause of an unexplained prolongation in PT. For example, PT abnormalities caused by malnutrition or warfarin are correctable with enteral or parenteral vitamin K therapy. When PT abnormalities result from malabsorption syndromes, parenteral vitamin K is superior to oral therapy. However, if PT abnormalities result from liver dysfunction (i.e., acute hepatitis, cirrhosis), vitamin K will be ineffective because the problem is not a deficiency of vitamin K but rather a deficiency of hepatic procoagulants.

SYNTHESIS AND DEGRADATION OF HEME: CYTOCHROMES, PORPHYRINS, AND BILIRUBIN

Heme synthesis begins with the condensation of glycine and succinyl-CoA to produce 5-aminolevulinic acid (ALA). This reaction, catalyzed by ALA synthase, is the rate-limiting step in the heme pathway. Heme inhibits ALA synthase and thereby regulates its own synthesis. ALA is made in mitochondria; it diffuses into the cytoplasm and encounters ALA dehydratase. This enzyme joins two ALA molecules together to form porphobilinogen (PBG). PBG molecules are positioned in a linear arrangement by PBG deaminase to form hydroxymethylbilane (HMB). HMB is transformed to uroporphyrinogen III, which is the precursor of coproporphyrinogen III. The latter is taken up by mitochondria and converted by coproporphyrinogen oxidase and protoporphyrin oxidase to protoporphyrin IX. In the final step of the pathway, ferrochelatase catalyzes the formation of a complex of ferrous iron and protoporphyrin IX to produce heme.[27,28]

Bilirubin Production and Excretion

The main source of serum bilirubin is heme metabolism. Healthy adults make approximately 300 mg of bilirubin daily, 80% of which is derived from phagocytosis of senescent erythrocytes by macrophages in the spleen, liver, and bone marrow. These reticuloendothelial cells extract protein from hemoglobin and convert heme to bilirubin.[29,30] The first step is rate limiting. Heme oxygenase, with O_2 as a substrate, oxidatively cleaves the porphyrin macrocycle of heme to yield biliverdin-IXα, carbon monoxide, and free divalent iron in equimolar amounts.

Most of the endogenous carbon dioxide production is derived from heme oxygenase reactions. Thus, the biologic importance of heme oxygenase may extend beyond the breakdown of heme. To clarify, carbon dioxide roles include regulation of vascular tone (vasodilator), platelet aggregation, vascular myocyte proliferation, and neurotransmitter release. Furthermore, carbon dioxide exerts cytoprotective, antiapoptotic, and antioxidant effects in organs throughout the body. Biliverdin also confers protection from oxidative stress[31]; it is rapidly converted to bilirubin by cytoplasmic reductases.[32]

After release from reticuloendothelial cells, bilirubin becomes tightly bound to plasma albumin. Hepatocytes avidly extract this bilirubin from albumin. They produce conjugates of bilirubin (through the action of glucuronic acid and bilirubin UDP-glucuronosyltransferase) and secrete these conjugates into canalicular bile. Although the gut excretes most of this bilirubin, a small amount returns to the liver in the enterohepatic circulation. Thus, the bloodstream normally has a modicum of bilirubin conjugates, which arrive directly by the enterohepatic circulation or indirectly from the bile ducts and lymphatics.

Porphyrias. Porphyrinogens exposed to O_2 are readily oxidized to the corresponding porphyrins. Accumulation of porphyrins in tissues leads to porphyrias. Porphyrias are rare, genetic diseases characterized by aberrations in heme production. Patients with these disorders are typically asymptomatic until some stressor (exogenous or endogenous) induces a porphyric crisis.[33]

The clinical syndrome includes recurrent, dramatic, and occasionally fatal neurologic reactions, accompanied by abdominal pain (90%) and dark urine (80%). Acute intermittent porphyria is the most common porphyria. Its prevalence in the general population is about 1 in 10,000, but it may reach 1 in 500 in psychiatric patients. Acute intermittent porphyria has a fivefold higher frequency in women than in men. Substances known to trigger porphyric crises include sex hormones, glucocorticoids, cigarette smoke, and various medications, most notably barbiturates and other CYP inducers.[29,34]

REGULATOR OF HEMATOGENOUS ENDOCRINE MEDIATORS

The liver is the largest gland in humans, and it plays important roles in the metabolism of hormones and hormone-binding proteins.[35] Hepatocytes produce a wide variety of endocrine substances, including angiotensinogen, thrombopoietin, and insulin-like growth factor I (IGF-I).[36] They take up thyroxine (T_4), the major product

of the thyroid gland, and may activate it to triiodothyronine (T_3) or inactivate it. The liver inactivates many other hormones, including aldosterone, antidiuretic hormone, estrogens, androgens, and insulin. Nearly half of the insulin released by the pancreas may not reach the systemic circulation because of hepatic degradation.

MODULATOR OF IMMUNE AND INFLAMMATORY PROCESSES

The liver is the largest reticuloendothelial organ in the human body. Hepatic macrophages (Kupffer cells) account for nearly 10% of the total liver mass. Kupffer cells protect and defend the body against foreign intrusions. Before splanchnic venous blood enters the central circulation, it is filtered by Kupffer cells, which degrade toxins, process antigens, and phagocytose bacteria.[10,37] In addition, Kupffer cells are important modulators of inflammation[38]; they attenuate inflammatory responses by removing inciting substances from the bloodstream; but they can also induce and intensify inflammation by producing and releasing proinflammatory mediators and recruiting neutrophils to the liver.[38] Among these mediators are various cytokines, chemokines, leukotrienes, proteases, nitroradicals, and reduced O_2 species. If not properly controlled, these same mediators can induce or aggravate injuries to parenchymal and other liver cells.[38,39] For example, because of their low glutathione content, endothelial cells of the sinusoids and terminal hepatic veins are highly vulnerable to oxidative stress and drug-induced vascular injury. Stellate cells reside mainly in the perisinusoidal spaces and are the liver's major source of matrix deposition. When activated by oxidative stress or toxic chemicals, stellate cells may be transformed to collagen-synthesizing myofibroblasts, which can cause extensive fibrosis of the liver (e.g., methotrexate-induced hepatic fibrosis).

METABOLISM AND EXCRETION OF ENDOGENOUS AND XENOBIOTIC MOLECULES

The myriad chemical reactions that hepatocytes use to eliminate drugs fit into three broad categories (or phases). Phase 1 metabolism uses CYP and mixed-function oxidases to increase the polarity of drugs. Phase 2 metabolism increases the polarity of drugs (or their metabolites) by conjugating them with endogenous water-soluble substrates. Phase 3 elimination uses energy-dependent transporters to excrete drugs into canalicular bile. The hepatic clearance of drugs involves at least one of these phases.[40-42]

Phase 1 Metabolism

Phase 1 reactions (e.g., oxidations, reductions, hydrolysis) convert drugs to more polar compounds by inserting polar groups (e.g., hydroxide, amine, sulfhydryl) or removing nonpolar groups. Generally, the products of phase 1 metabolism are more readily excreted in bile or urine than are their precursors. Such products also may be substrates for phase 2 conjugations.

Microsomal Oxidases and Cytochrome P450. More than 90% of drug biotransformations involve microsomal oxidases and hemoproteins of the CYP gene superfamily. The human liver has more than 20 different CYP isozymes that mediate redox reactions in diverse pathways, including steroid, lipid, and bile salt metabolism. Zone 3 (centrilobular) has the highest total CYP content. In fact, the acinar location of specific isozymes of CYP may clarify relationships between drug metabolism and liver injury. For example, centrilobular necrosis is the classic acetaminophen-induced injury; the probable explanation is that CYP2E—the CYP isoform involved in acetaminophen metabolism—is localized in zone 3.

CYP reactions generate metabolites that are highly reactive and potentially toxic. In brief, the CYP reaction cycle begins with O_2 binding to heme iron; this O_2 becomes activated after receiving an electron from a flavoprotein reductase—NADPH:hemoprotein oxidoreductase (CYP). Insertion of activated O_2 into lipophilic molecules (e.g., xenobiotics) produces substrates for mixed-function oxidase reactions. These oxidases transfer a singlet oxygen (atom) from O_2 to the target molecule; another substrate (e.g., NADPH) simultaneously delivers electrons that reduce the residual oxygen singlet, thereby enabling its incorporation into water. To summarize, oxidases promote the formation of highly active chemicals, including reduced O_2 species and free radical intermediates, which can cause or aggravate liver injury.[4]

Phase 2 Metabolism. Phase 2 reactions conjugate xenobiotics (or their metabolites) with endogenous hydrophilic molecules such as glucuronic acid, acetate, sulfates, amino acids, and glutathione.[40,43] Many conjugations involve glucuronic acid and UDP-glucuronosyltransferase. Other conjugations are catalyzed by sulfatases, glutathione-*S*-transferases, acetyl-*N*-transferases, or amino acid *N*-transferases. When compared with their precursors, conjugated xenobiotics are usually less efficacious, less toxic, more hydrophilic, and more readily excreted in bile or urine.

Phase 3 Elimination. Phase 3 reactions involve specific molecular transporters known as ATP-binding cassette (ABC) transport proteins that facilitate the excretion of xenobiotics and endogenous compounds. These proteins use ATP hydrolysis to drive molecular transport. Major ABC transport proteins include cystic fibrosis transmembrane conductance regulator, canalicular copper transporters, and multidrug resistance protein (MDR). MDR-1 (formerly referred to as P-glycoprotein) resides on the canalicular surfaces of hepatocytes and enables biliary excretion of cationic compounds, including anticancer drugs.[44,45]

Another family of ABC proteins—multidrug resistance–related protein (MRP)—excretes conjugated molecules. MRP-1, located on the lateral surfaces of hepatocytes, can transport drug conjugates into the sinusoids. MRP-2 (formerly termed canalicular multispecific organic anion transporter [cMOAT]), on the canalicular surfaces of hepatocytes, secretes conjugates of drugs and endogenous wastes (e.g., bilirubin diglucuronide, glutathionyl-leukotriene conjugates) into canalicular bile. Thus, dysfunction of ABC transport proteins can disrupt the flow of bile, impair excretion of xenobiotics and endogenous compounds, and induce cholestatic liver injury.[46,47]

Demographic Factors Affecting Metabolic Rates and By-products

Dose-related responses to drugs often vary considerably within individuals and populations. Much of this variability is due to the heterogeneity of drug disposition and metabolism, which is mainly influenced by genetic and environmental factors. Genetics control the expression of CYP isozymes. Environmental factors (e.g., drugs, other chemicals) modify genetic expression and thereby alter drug biotransformation.[40-42] Numerous conditions and disorders are capable of altering the production of CYP proteins. For example, obesity, fasting, and diabetes mellitus may lead to up-regulation of CYP2E1.[40-42] On the other hand, conditions that may result in down-regulation of CYP include systemic inflammatory disorders, fever, nitrogen-free solutions, nitrogen-rich solutions, and hepatic cirrhosis. Hypothyroidism and hypopituitarism may selectively down-regulate CYP1A and CYP3A4, respectively.[41,42]

Pharmacokinetics

Perfusion models of drug elimination generally focus on three major parameters: intrinsic hepatic clearance, hepatic blood flow, and protein binding. The intrinsic hepatic clearance of a drug divided by hepatic blood flow is the drug's extraction ratio; this provides a measure of the relative efficiency with which the liver extracts or eliminates a given drug.[48] Box 22-1 shows a compilation of drugs with high and low extraction ratios.[4,49] Such information enables general rules to be made about pharmacologic categories and intrinsic clearances. For example, hepatocytes are efficient extractors of calcium channel blockers, β-adrenoceptor blockers (except atenolol), opioid analgesics, tricyclic antidepressants, and organic nitrates. On the other hand, the liver poorly extracts warfarin, aspirin, alcohol, and many anticonvulsants. For drugs with a low extraction ratio, hepatic elimination rates are capacity limited. Such rates often change when protein binding or intrinsic hepatic clearance changes, but they are insensitive to fluctuations in hepatic blood flow. For drugs with a high extraction ratio, hepatic elimination rates are flow dependent. These elimination rates are highly dependent on and directly related to liver blood flow; they are unaffected by changes in either protein binding or the activity of drug-metabolizing enzymes (Table 22-1).[4]

BOX 22-1 *Drugs Efficiently Versus Poorly Extracted From Blood Flowing Through the Liver*

Efficiently Extracted Drugs	Poorly Extracted Drugs
Amitriptyline	Acetaminophen
Desipramine	Amobarbital
Imipramine	Antipyrine
Labetalol	Aspirin
Lidocaine	Clindamycin
Meperidine	Diazepam
Metoprolol	Digitoxin
Morphine	Ethanol
Nortriptyline	Hexobarbital
Pentazocine	Phenobarbital
Propoxyphene	Phenytoin
Propranolol	Tolbutamide
Ranitidine	Valproic acid
Verapamil	Warfarin
Zidovudine	

EVALUATION OF THE LIVER

CLINICAL ASSESSMENT

The only clues to liver disease may be mild, nonspecific symptoms, such as loss of appetite, easy fatigability, malaise, altered sleep patterns, or subtle changes in personality. The history addresses major risk factors for liver disease: (1) alcoholism; (2) illicit drug use; (3) sexual promiscuity; (4) blood transfusions; (5) occupational exposure to hepatotoxins; (6) prior bouts of jaundice, particularly after anesthesia; and (7) genetic diseases, such as hemochromatosis, α_1-antitrypsin deficiency, and Wilson disease. Clinical findings consistent with liver disease include nonspecific symptoms (as just mentioned), pruritus, abdominal pain, indigestion, and changes in urine or stool color. The physical examination focuses on stigmata of advanced liver disease, such as icterus, jaundice, ascites, spider angiomas, xanthelasma, encephalopathy, palmar erythema, and fetor hepaticus.

STANDARD LABORATORY TESTS

Standard test panels used to evaluate hepatobiliary status are often referred to as liver function tests (Table 22-2).[4,50,51] To be precise, this terminology is a misnomer because none of the tests measure any specific liver function. Instead, they point to broad categories of hepatobiliary pathology: hepatitis, hepatobiliary dysfunction, or insufficient protein synthesis. These categories include large subsets of diseases—for example, all possible causes of hepatitis.

Detection of Hepatocellular Injury

Aminotransferases. Hepatocellular injury is the usual cause of elevated serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), formerly termed serum glutamic-pyruvic transaminase (SGPT) and serum glutamic-oxaloacetic transaminase (SGOT), respectively. Both enzymes are involved in gluconeogenesis. They catalyze the transfer of an amine group to α-ketoglutarate to yield glutamate and either pyruvate (by ALT) or oxaloacetate (by AST). ALT is mainly a cytoplasmic liver enzyme. In contrast, cytoplasmic and mitochondrial isozymes of AST are found in most extrahepatic tissues, including the heart, skeletal muscle, brain, kidney, pancreas, adipose tissue, and blood. It is rare to encounter concomitant elevations in AST and ALT when the liver is normal and disease free. In those rare instances, the elevations in AST and ALT levels would most likely result from muscle injury.[51]

Elevated ALT and AST levels are sometimes described in qualitative terms: mild (100 to 249 International Units/L), moderate (250 to 999 International Units/L), large (1000 to 1999 International Units/L), and extreme

(>2000 International Units/L). Mild elevations in AST and ALT may arise from any disorder that injures hepatocytes. Common causes include steatosis, medications, alcohol consumption, hemochromatosis, cholestasis, chronic viral hepatitis, neoplasms, and cirrhosis. Moderate ALT and AST elevations are characteristic of acute viral hepatitis, drug-induced liver injury, and flare-ups of chronic liver disease (e.g., viral hepatitis, steatohepatitis). Large elevations often reflect acute hepatitis superimposed on chronic active liver disease. Extreme elevations signify massive hepatic necrosis. Typical causes are fulminant viral hepatitis, severe drug-induced liver injury (e.g., from acetaminophen), shock liver or hypoxic hepatitis, and, in rare instances, autoimmune hepatitis or acute biliary obstruction.[51]

Ratios of aminotransferases may hold keys to the diagnosis of hepatic disorders. For example, when both AST and ALT are elevated, an AST-to-ALT ratio higher than 4 is characteristic of Wilson disease, ratios between 2 and 4 are typical of alcoholic liver disease, and a ratio below 1 suggests nonalcoholic steatohepatitis (without cirrhosis). When elevations of AST and ALT are mild, ratios above 2 are consistent with alcoholic liver disease or cirrhosis of any etiology.[51] If the ratio is elevated and ALT is normal, the elevation in AST is most likely from an extrahepatic source of AST. Although concomitant elevations in AST and ALT are a reliable indicator of hepatocellular injury, aminotransferase levels by themselves seldom reveal the extent of liver damage. For instance, patients with florid liver failure can have normal enzyme levels when the liver damage is so extensive that too few viable hepatocytes remain to bring about increases in ALT or AST. In addition, chronic, smoldering liver diseases such as hepatitis C can destroy the liver, slowly and silently, without overt increases in ALT or AST.

Lactate Dehydrogenase. Elevated serum lactate dehydrogenase (LDH) levels may reflect hepatocellular injury, extrahepatic disorders, or both. Extreme increases signify massive liver damage, which may result from fulminant viral hepatitis, drug-induced liver failure, or hypoxic hepatitis. Prolonged, concurrent elevations in LDH and alkaline phosphatase (AP) suggest malignant infiltration of the liver. Notable extrahepatic disorders that cause moderate elevations in LDH include hemolysis, rhabdomyolysis, tumor necrosis, renal infarction, acute cerebrovascular accident, and myocardial infarction. Such disorders cause more pronounced LDH elevations in patients with acute

TABLE 22-1 FLOW-DEPENDENT VERSUS CAPACITY-LIMITED ELIMINATION OF DRUGS BY THE LIVER

Type of Hepatic Elimination	Extraction Ratio (ER)	Rate of Hepatic Drug Metabolism
Flow-dependent elimination	High ER: At clinically relevant concentrations, most of the drug in the afferent hepatic blood is eliminated on first pass through the liver.	Rapid: Because drugs with a high ER are metabolized so rapidly, their hepatic clearances roughly equal their rates of transport to the liver (i.e., hepatic blood flow).
Capacity-limited elimination (also referred to as dose-dependent, nonlinear, saturable, or zero-order elimination)	Low ER: Hepatic elimination of these drugs is determined by their plasma concentration.	Slow: When the capacity of the liver to eliminate a drug is less than the dosing rate, a steady state is unachievable; plasma levels of drug will continue to rise unless the dosing rate is decreased. Drug clearance has no real meaning in such settings.

TABLE 22-2 LIVER BLOOD TESTS AND THE DIFFERENTIAL DIAGNOSIS OF HEPATOBILIARY DISORDERS

	Predominant Abnormality		
Blood Test	Bilirubin Overload (Hemolysis)	Hepatocellular Injury	Cholestasis
Aminotransferases	Normal	Increased: May be normal or decreased in advanced stages	Normal: May be increased in advanced stages
Serum albumin	Normal	Decreased: May be normal in acute fulminant hepatic failure	Normal: May be decreased in advanced stages
Prothrombin time*	Normal	Prolonged	Normal: May be prolonged in advanced stages
Bilirubin (main form present)	Unconjugated (also mild increase in conjugates)	Conjugated	Conjugated
Alkaline phosphatase	Normal	Normal: May be increased by hepatic infiltrative disease	Increased
γ-Glutamyl transpeptidase 5′-nucleotidase	Normal	Normal	Increased
Blood urea nitrogen	Normal: May be increased by renal dysfunction	Normal: May be decreased by severe liver disease and normal kidney function	Normal
BSP/ICG (dye)	Normal	Retention of dye	Normal or retention of dye

BSP/ICG, Bromsulphalein and indocyanine green.
*Used interchangeably with the international normalized ratio.

liver injury (e.g., severe preeclampsia). An elevation in LDH that is due solely to hepatocellular injury is typically accompanied by elevations in AST and ALT. Thus, LDH rarely yields information about liver injury beyond that already provided by AST and ALT.[51]

Glutathione-*S*-Transferase. Glutathione-*S*-transferase (GST) is a sensitive and specific test for some patterns of drug-induced liver injury. The enzyme has a brief plasma half-life (90 minutes) and is released rapidly into the circulation after hepatocellular injury. Thus, serial GST measurements can reveal the time course of hepatic injury, from its onset to its resolution. In contrast to AST and ALT, which reside in acinar zone 1, GST localizes in acinar zone 3 (centrilobular region).[52] The zone contains the hepatocyte population with the highest susceptibility to injury from hypoxia or reactive drug metabolites. Accordingly, GST would be more sensitive than AST or ALT as a marker of centrilobular necrosis in its incipient stages.

Assessment of Hepatic Protein Synthesis

Serum Albumin. Serum albumin yields information about hepatocellular function (i.e., protein synthesis) and is used to evaluate chronic liver disease, with notable caveats. First, hypoalbuminemia has many causes besides low rates of albumin synthesis; examples include renal losses of albumin, increased albumin catabolism, expansion of plasma volume, and maldistribution of total body albumin. In fact, the total body mass of albumin (in the exchangeable pool) is often normal in patients with liver cirrhosis, ascites, and hypoalbuminemia.[53] Second, no clear relationship exists between serum albumin and the instantaneous rate of albumin synthesis because plasma albumin has a half-life of nearly 3 weeks. Thus, if hepatic protein synthesis came to an abrupt and permanent halt, this change would not be reflected as a decrease in the serum albumin level for at least a few days.

Prothrombin Time. When compared with albumin, liver-derived procoagulants have short half-lives, which range from 4 hours for factor VII to 4 days for fibrinogen. Plasma levels of such procoagulants start to descend shortly after the liver begins to fail. PT (or the international normalized ratio [INR]) is widely used to evaluate and monitor patients with acute liver dysfunction. A prolonged PT secondary to liver failure generally reflects a low blood level of factor VIIa, which has the shortest plasma half-life of hepatic coagulant factors.[51] Besides diagnostic utility, PT is used as a prognostic indicator. It is a common parameter of models or algorithms designed to facilitate timely, yet correct, decisions about the need for liver transplantation. In this regard, PT is of value for patients with drug-induced liver failure or those with active liver disease and a surgical condition that needs immediate attention.

Detection of Cholestatic Disorders

Alkaline Phosphatase. Serum AP is used to screen for disorders of the liver or biliary tree, including hepatitis, malignancies, and cholestatic diseases. Because AP isoenzymes exist in plasma membranes throughout the body, AP lacks specificity for hepatobiliary disease.[51] Mild, transient increases in AP may occur in up to a third of those subjected to routine laboratory testing. Major sources of AP include bone, intestine, kidney, leukocytes, placenta (third trimester of gestation), and neoplasms. Increased metabolic activity in one or more of these tissues may lead to elevations in AP. Increased serum AP usually reflects increased production or release of AP rather than decreased clearance of AP.

The AP elevations in cholestatic disorders may reflect the action of bile salt on the plasma membranes of hepatocytes. Serum AP may remain normal for a couple of days after the onset of biliary obstruction, not increasing until hepatocytes produce (and release) more AP. Because it has a half-life of nearly a week, serum AP may remain elevated for days after bile flow is restored.[51] Extreme increases in AP suggest (1) a major block in biliary flow as a result of disorders such as primary biliary cirrhosis and choledocholithiasis or (2) a hepatic malignancy (primary or metastatic) that is compressing small intrahepatic bile ducts.

Serum Bilirubin. Serum bilirubin is the most widely used test for hepatic excretory dysfunction. Total bilirubin is normally below 1 mg/dL, but up to 10% of healthy adults have higher levels, mainly in the form of unconjugated bilirubin. This is usually a benign condition (Gilbert syndrome) that reflects genetically low levels of bilirubin UDP-glucuronosyltransferase. Serum bilirubin levels above 4 mg/dL are readily detectable on physical examination as jaundice—a yellowish discoloration of body tissues. But with natural light, scleral icterus can be discerned at bilirubin levels of 3 mg/dL or even lower.[51]

Bilirubin is normally absorbed by hepatocytes, conjugated there with glucuronide, and transported across the bile canaliculi. Conjugated bilirubin is transported into the bile; both conjugated and unconjugated bilirubin can pass from hepatocytes into the plasma. Conjugation of bilirubin increases its solubility. Bilirubin is deconjugated and then metabolized by bacteria within the colon and converted into urobilinogen, which also can be passed into the urine.

Conjugated hyperbilirubinemia generally results from one or two fundamental problems: (1) flow of bile is blocked within the hepatobiliary tree, or (2) hepatocytes produce more bilirubin conjugates than they can efficiently transport into the canalicular space. Massive hemolysis causes unconjugated and conjugated hyperbilirubinemia. Increases in unconjugated bilirubin occur because hepatocytes are presented with more bilirubin than they can conjugate. Increases in conjugated bilirubin result because hepatocytes conjugate bilirubin faster than hepatocellular transporters can secrete them into canalicular bile. Bilirubinuria usually reflects conjugated hyperbilirubinemia. The kidneys readily excrete bilirubin conjugates, whereas unconjugated bilirubin, which binds tightly to plasma albumin, is neither filtered nor excreted by normal kidneys.[51,54]

Clinically it is important to distinguish conjugated from unconjugated bilirubin. Any bilirubin in the urine (which is easily diagnosed by color) must be conjugated because only conjugated bilirubin can pass through the kidney and be excreted in the urine. Jaundice without bilirubin in the urine can be due to overproduction of

bilirubin, impaired hepatic uptake, or impaired conjugation. Bilirubin in the urine suggests hepatobiliary disease (i.e., extrahepatic or intrahepatic cholestasis) or genetic defect in the excretion of bilirubin[11] (Fig. 22-7).

Thus, a patient with severe jaundice and no bilirubin in the urine suggests an increase in circulating bilirubin resulting from the unconjugated form. This is usually during the increase in heme production that overwhelms the conjugation pathway or when the process of conjugation is impaired. Hemolysis is one of the most common reasons for such a condition. Conjugated hyperbilirubinemia (jaundice and bilirubin in the urine) occurs because some of the bilirubin dissociates from albumin; the associated increase in water solubility of conjugated bilirubin leads to it being able to pass through the kidney into the urine. This means that bilirubin is formed within the hepatocytes but cannot be transported into the bile; a typical example is cholestasis.

Testing for Specific Diseases

Targeted testing is used to identify specific hepatic or biliary diseases. Examples include (1) serologic testing to identify viral, microbial, and autoimmune causes[55,56]; (2) genetic testing to diagnose heritable metabolic disorders; and (3) tumor marker assays to detect hepatic malignancies.

Identifying viral markers—antibodies, antigens, and genetic material—is the key for diagnosis of hepatitis from hepatotropic viruses (A, B, C, E) and herpesviruses such as cytomegalovirus and Epstein-Barr virus. Patients infected with hepatitis B or C virus often have markers of immune pathology, including anti–smooth muscle antibodies, antinuclear antibodies, and mixed cryoglobulins.[57] Autoimmune hepatitis and hepatitis A virus infection are commonly associated with anti–asialoglycoprotein receptor antibodies. Autoimmune cholangitides have distinctive serologic profiles.[58] For example, antimitochondrial antibodies usually develop with primary biliary cirrhosis[56,59-61] but are typically absent with primary sclerosing cholangitis. Characteristic findings of primary sclerosing cholangitis include anti–smooth muscle and antinuclear antibodies.[56,62,63]

Markers for hepatic malignancy include α-fetoprotein (AFP) and des-γ-carboxylated prothrombin.[64-67] As a test for hepatocellular carcinoma (HCC), plasma AFP is highly specific, with a sensitivity that ranges from 50% to 90%, depending on population subgroups.[66] Another test for HCC is the plasma γ-carboxylated prothrombin level. HCC cells usually make procoagulants without γ-carboxylating them.[64,67] High levels of des-γ-carboxylated, vitamin K–dependent proteins occur in up to 91% of patients with HCC. In at least two thirds of these patients, levels are above 300 ng/mL, which far exceeds the typical value in patients with liver cirrhosis or acute hepatitis. After surgical removal of HCC, levels of des-γ-carboxylated factors begin to decrease. Subsequent increases suggest tumor recurrence.[68]

QUANTITATIVE LIVER TESTS

Total hepatocellular mass can be estimated by measuring the clearance of a substance that is avidly extracted by the liver, such as bromsulphalein and indocyanine green (ICG). However, these are rough estimations because clearance is subject to many influences and unknown factors. For example, hepatic clearance of highly extracted substances (1) changes in direct proportion to variations in liver blood flow, (2) is altered by extrahepatic retention or clearance of the substance, and (3) may be affected by anomalous hepatobiliary function.

Drug-metabolizing capacity of the liver can be measured by several methods, such as caffeine clearance, galactose elimination capacity, aminopyrine breath test, antipyrine clearance, and monoethylglycinexylidide (MEGX).[51,69-72] Techniques are available for measuring caffeine clearance noninvasively. For example, patients take an oral dose of caffeine (150 to 300 mg), and caffeine metabolites in saliva are measured for up to 24 hours. MEGX is an invasive method that has recently gained popularity for measuring liver blood flow in critically ill patients. Fifteen minutes after an intravenous injection of lidocaine (1 mg/kg), a blood sample is obtained and assayed for MEGX, the major metabolite of lidocaine. Currently, quantitative tests are in the domain of research tools; when compared with standard liver chemistry tests, they are expensive and time consuming, with no compelling evidence of being superior, either diagnostically or prognostically.

MEASUREMENT OF LIVER BLOOD FLOW

Methods used to measure hepatic blood flow fall into three broad categories: clearance techniques, indicator dilution techniques, and direct measurements.

Clearance Techniques

Extraction methods using the indirect Fick principle closely approximate hepatic blood flow and are valid for substances with high intrinsic hepatic clearance and total body clearance. Such substances include ICG dye, propranolol, lidocaine, and colloidal particles. Constant infusion of ICG is among the most reliable extraction methods. Hepatocytes take up nearly all of the ICG infused and excrete it unchanged in bile. Clearance methods also may be based on the ability of Kupffer cells to avidly phagocytose radiolabeled colloidal particles such as gold 198.

After injecting such particles, the area under the initial curve (of radioactivity versus time) can be computed to obtain a valid measurement of hepatic blood flow—assuming that the reticuloendothelial system is functioning normally.[73] The bottom line is that severe liver disease renders clearance techniques unreliable because of indeterminable disease-related effects on liver blood flow and hepatic capacity to eliminate substances. The latter decreases in direct proportion to the loss of hepatocellular mass.[74]

Indicator Dilution Techniques

Unlike clearance methods, measurements of liver blood flow by indicator dilution techniques are unaffected by liver disease. After a radiolabeled indicator (e.g., iodinated albumin) is injected into the spleen, hepatic flow is computed from indicator dilution curves. These curves are obtained by continuous sampling from one of the hepatic veins or by external γ-scintillation counting. For this technique to be valid, the indicator must be uniformly mixed on injection and resistant to hepatic clearance.[4]

Direct Measurements

Electromagnetic flow probes provide direct measurements of blood flow through the hepatic artery or portal vein. However, the surgical procedures used to implant the probes can themselves alter hepatic blood flow. Thus, the probes are often left in place after the implantation procedure and blood flow is subsequently measured by telemetry.

RADIOLOGIC AND ENDOSCOPIC METHODS

Radiologic and endoscopic techniques offer therapeutic alternatives to surgery. Endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTHC) are used to evaluate hepatobiliary disorders. ERCP provides intraductal access to the biliary tree and pancreatic duct. Its main use is to diagnose and treat extrahepatic biliary disorders such as gallstones, tumors, inflammatory strictures, and postsurgical anastomotic leaks. Successful endoscopic papillotomy can obviate surgical removal of stones in the common bile duct.[75] ERCP is less invasive than surgery, but it too can lead to major complications, most notably pancreatitis. Radionuclide and ultrasonic scanning detect space-occupying lesions of the hepatobiliary tree.[75,76] PTHC provides a means of evaluating the intrahepatic bile ducts of patients with unexplained intrahepatic cholestasis or jaundice. Dilated intrahepatic bile ducts on PTHC indicate mechanical blockage of intrahepatic ducts. When no such blockage exists, the most likely cause of intrahepatic cholestasis is hepatic parenchymal disease.

Esophagogastroscopy is an important technique for evaluating and treating submucosal varices in patients with cirrhosis and portal hypertension. Splenoportography provides information about the status of the splenic and portal veins. Portal venography using three-dimensional CT with a multidetector row technique can render vascular maps that are superior to those obtained by classic angiography.[77] Such vascular maps show the extent and location of portosystemic collateral communications, which may include abnormalities in gastric, paraumbilical, and abdominal wall veins; esophageal varices; and splenorenal and gastrorenal shunts.

HEPATIC PATHOPHYSIOLOGY

PATTERNS OF LIVER PATHOLOGY

Cholestatic Disease

Cholestasis is impaired biliary flow and has a complex pathogenesis.[78] The usual cause of intrahepatic cholestasis, whether inherited or acquired, is dysfunction of the bile transporter.[79,80] In contrast, extrahepatic cholestasis most often results from mechanical blockage of the biliary tree. With cholestasis, high blood levels of biliary constituents are found, including hepatocellular enzymes (AP, γ-glutamyl transferase, 5′-nucleotidase, leukocyte alkaline phosphatase), immunoglobulin A, cholesterol, and various forms of bile salts and bilirubin. The most toxic of these is unconjugated bilirubin; high concentrations of unconjugated bilirubin cause membrane dysfunction and disrupt major metabolic pathways such as the tricarboxylic acid cycle and oxidative phosphorylation. Patients with cholestatic syndromes typically have marked increases in serum bile salts but normal or slightly elevated serum bilirubin. The clinical findings in cholestatic syndromes depend on the severity of the cholestatic disorder and its pathogenesis. Pruritus is a hallmark feature and results mainly from retained bile salts.[81] As cholestatic disorders increase in severity, jaundice develops. The stool becomes lighter in color and the urine darkens as bile pigments are diverted from the gut to the kidney for excretion. Some of the rest of the pathogenesis and symptomatology is often similar to that observed in hepatic cirrhosis.

Impairment can take place within the liver or distally within the biliary tract.[82] Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are classic examples of cholestasis. PBC is progressive inflammatory destruction of the cholangiocytes that line the bile ductus, and the disease is more common in women than men. PSC is associated with inflammation, and fibrosis of intrahepatic and extrahepatic bile ducts is more often

seen in men. It represents a severe inflammatory process and is often observed together with inflammatory bowel disease. Both PBC and PSC are associated with genetic and immunologic defects. Despite some differences between PBC and PSC, the end results are the same—bile ducts are destroyed, preventing bile from exiting the liver.

Obstructive Jaundice

A common reason for obstructive jaundice is gallstones. If gallstones block one of the hepatic ducts, the unobstructed side of the liver will increase its function to produce the necessary amount of bile. If the obstruction goes untreated, that part of the liver does not drain bile and the toxic effects of the retained bile eventually cause atrophy. If a gallstone occludes the common hepatic duct, bile cannot leave the liver and jaundice develops.

MECHANISMS OF CELL DEATH

Necrosis

Hepatocellular death often results from hypoxia or anoxia. Hypoxia decreases intracellular ATP. This stimulates breakdown of glycogen and anaerobic glycolysis, which raises lactic acid levels and lowers intracellular pH. Sudden precipitous decreases in ATP initiate a series of events that may culminate in hepatocellular necrosis. Such events include abrupt failure of the energy-dependent ion pumps that regulate intracellular fluid and electrolyte homeostasis. Plasma membranes become dysfunctional, and hepatocytes swell rapidly and then rupture and extrude their contents. This cellular debris, which contains hepatic enzymes and reactive chemicals such as aldehydes, lipid peroxides, and eicosanoids, incites an inflammatory response. The release of cytokines and chemoattractants recruits circulating neutrophils to the liver and augments the hepatic inflammation.[83]

Apoptosis

In contrast to necrosis, apoptosis is an energy-dependent process.[84] Most agents of liver disease (toxins, viruses, oxidants) can activate proapoptotic intracellular signaling pathways or proapoptotic cell-surface receptors such as Fas, tumor necrosis factor receptor (TNFR), and other members of the TNFR superfamily. Apoptosis has several ultrastructural hallmarks, including (1) a shrunken cell and nucleus; (2) condensed, marginated nuclear chromatin; (3) blebs on the plasma membrane; and (4) apoptotic bodies, which consist of membrane-bound cellular fragments and intact organelles. Epithelial and mesenchymal cells engulf the apoptotic bodies, and their lysosomes digest and recycle the contents of apoptotic bodies, such as intact mitochondria and nucleic acids. Apoptosis and necrosis may be related events at opposite ends of a spectrum of overlapping morphologic and mechanistic cell death processes.[84-86]

OXIDATIVE STRESS AND THE GLUTATHIONE SYSTEM

Hepatocytes continuously produce reactive O_2 species. During aerobic metabolism, mitochondria work nonstop transferring electrons from reduced substrates to O_2. This process involves the tetravalent reduction of O_2; the reduced O_2 atoms are incorporated into water. However, small amounts of O_2 undergo univalent or divalent reductions that give rise to superoxide and hydrogen peroxide. Nonparenchymal cells in the liver—Kupffer cells, endothelial cells, polymorphonuclear leukocytes, and macrophages—also can generate large amounts of reduced O_2 species and nitroradicals.[87]

In health, hepatocytes have many ways to keep oxidant concentrations within a safe range. Their defenses against oxidative injury include (1) micronutrients, such as vitamins C and E; (2) metal-sequestering proteins, such as ferritin; (3) enzymes that dispose of reactive O_2 species, such as catalase and superoxide dismutase; (4) enzymes that detoxify lipid peroxides, such as glutathione peroxidase; and (5) thiol-rich peptides, most notably glutathione (γ-glutamyl-cysteine-glycine). Glutathione is the single most important intracellular antioxidant.

The liver is the main site of glutathione synthesis. Accordingly, hepatocytes have high cytoplasmic concentrations of glutathione, ranging from 5 to 10 mmol/L.[40] Glutathione serves as a cofactor for major enzymes involved in the elimination of oxidants—notably glutathione peroxidase and thiol-disulfide exchangers. Glutathione peroxidase plays a key role as a detoxifier of organic peroxides and free radicals. Another enzyme, glutathione *S*-transferase, helps eliminate toxic electrophiles by attaching them to the free thiol of reduced glutathione (GSH). GSH also participates in nonenzymatic detoxification reactions, which yield oxidized glutathione and mixed disulfides of glutathione and protein.

ISCHEMIA-REPERFUSION INJURY

Ischemia-reperfusion injury results from both hypoxia during an ischemic episode and cytotoxic events during reperfusion.[88,89] Reperfusion induces the production of highly reactive chemicals that can cause necrosis or apoptosis, such as superoxide, hydrogen peroxide, and hydroxyl radicals. After relatively brief ischemic intervals, most of the injury is due to reperfusion. With more prolonged ischemia, hypoxia accounts for a larger fraction of the overall injury from ischemia-reperfusion.

Role of Xanthine Dehydrogenase/Xanthine Oxidase

The liver and intestines contain large amounts of xanthine dehydrogenase/xanthine oxidase (XDH/XO).[90] XDH catalyzes the rate-limiting step in nucleic acid degradation by using nicotinamide adenine dinucleotide (NAD) rather than O_2 as the electron acceptor. Thus, no O_2 radicals are produced in healthy tissue. However, ischemic conditions transform XDH to XO. Because XO reactions involve O_2, they produce free radicals. During reperfusion, XO-derived oxidants increase the production and release of leukotriene B_4 and platelet-activating factor, which promote neutrophil adherence and migration. When activated, neutrophils can wreak havoc on the microvascular circulation as they release proteases and physically disrupt the endothelial barrier. Liver injury, independent of the cause, imperils extrahepatic tissue because damaged hepatocytes spew out XO and other

inflammatory mediators. XO enters the bloodstream and binds to vascular endothelial cells in many organs. Endothelial cells produce superoxide, which reacts with nitric oxide (NO) to form peroxynitrite ($OONO^-$).[91] $OONO^-$ is intensely reactive and can increase the severity of injuries to local and remote tissues.[91]

Therapeutic agents that may confer protection from ischemia-reperfusion–induced injury include (1) antioxidants, (2) O_2 radical scavengers such as superoxide dismutase and dimethyl sulfoxide, (3) inhibitors of leukocyte adherence and migration, and (4) inhibitors of XO. For example, laboratory studies show that allopurinol (inhibits XO) treatment before induction of ischemia-reperfusion prevents the usual ischemia-reperfusion–related increases in microvascular permeability and epithelial cell necrosis.[4]

Hepatic Injury From Liver Transplantation

Preservation Injury. The University of Wisconsin solution protects the donor liver for approximately 24 hours. However, use of this solution for more than 24 hours may lead to microcirculatory disturbances (e.g., leukocyte and platelet adhesion) after liver transplantation. The adverse effects result from (1) depletion of hepatocellular antioxidants over time and (2) biochemical changes that lead to a profusion of reactive oxidants during reperfusion of the transplanted liver. Hypothermic preservation solutions also induce apoptotic changes in endothelial cells, which may engineer their destruction after graft implantation.

The pathogenesis of ischemia-reperfusion injury is complex.[91-94] Characteristic events include (1) Kupffer cell activation; (2) XO formation[95]; (3) profusion of oxidants—superoxide, NO, $OONO^-$) and hydroxyl radicals; (4) release of proinflammatory cytokines into the bloodstream; and (5) destruction of endothelial cells.[96]

BACTERIAL, VIRAL, AND IMMUNE INJURY

Endotoxins are lipopolysaccharide complexes of the outer membranes of gram-negative bacteria. All endotoxins have a common lipid component (lipid A), a core R antigen, and variable polysaccharide regions, which are bacterial strain–specific O-antigens. Lipid A binds to high-density lipoproteins in blood and other tissues, and it mediates the biologic actions common to endotoxins. Endotoxins bind more extensively to Kupffer cells than to hepatic parenchyma. They can induce hepatocellular or cholestatic injury directly or indirectly by activation of Kupffer cells and release of proinflammatory mediators (e.g., cytokines, eicosanoids). Like endotoxins, viruses may cause direct and indirect hepatocellular injury. Hepatotropic viruses and some herpesviruses can induce cytokine production, leading to lymphocyte- or macrophage-dependent cytotoxicity. Antigens on hepatocellular membranes may be primary targets of cell-mediated injury. Antibodies to such antigens are often increased selectively in patients with autoimmune hepatitis and primary biliary cirrhosis. Other potential antigenic foci for cell-mediated cytotoxicity include liver-specific lipoproteins and hepatic lectins, which may be targets in hepatitis B and other liver diseases.[4]

DRUG-INDUCED LIVER INJURY

Adverse reactions to drugs fall into two general categories: dose-related toxicity and idiosyncratic drug-induced injury. The former is predictable and develops in all individuals with escalation of the drug dose. The latter is a rare event, inducible with subclinical doses of the drug; it is most likely an immune-mediated injury that occurs in just a tiny fraction of those receiving the drug. Although obvious differences exist between the two categories of drug reactions, remarkable similarities also exist. For example, both categories involve covalent binding of drugs (or their metabolites) to endogenous macromolecules. This binding can lead to inactivation of important enzymes, depletion of intracellular antioxidants, and peroxidation of membrane lipids. The body's response to such molecular perturbations determines whether a drug-induced injury is categorized as dose related or idiosyncratic. When drug-induced subcellular damage induces immune sensitization, reexposure to even a very low dose of the sensitizing drug can cause severe liver injury (e.g., halothane hepatitis).[4]

The hepatotoxic effects of drugs and environmental substances usually involve CYP-mediated production of oxidants such as reduced O_2 species, carbon-based radicals, and nitroradicals. Examples include (1) carbon tetrachloride metabolism by CYP, which yields trichloromethyl radical—a highly toxic intermediate that induces centrilobular necrosis, and (2) metabolism of nitrofurantoin or other aromatic compounds, which generates free radical intermediates that induce hepatic injury. Similar to CYP of the smooth endoplasmic reticulum, mitochondrial electron transporters transform xenobiotics to reactive metabolites. For example, the nitroradicals that are formed during cocaine or nitrofurantoin metabolism reduce O_2 via flavoprotein reductases to yield superoxide and other oxidizing species. Redox cycling, as occurs with anthracycline chemotherapeutics and imidazole antimicrobials, is yet another source of toxic oxidizing species.

Oxidant formation during drug metabolism contributes to or causes liver injury by weakening the antioxidant defenses of hepatocytes. For example, acetaminophen and bromobenzene cause dose-related decreases in hepatocellular GSH, rendering the liver increasingly susceptible to necrosis. This increases the likelihood of oxidants damaging (1) proteins and enzymes, (2) phospholipids in membranes, and (3) nucleotides via activation of proteases, phospholipases, and endonucleases. Oxidative stress also can induce pathologic increases in cytosolic calcium by increasing Ca^{2+} uptake by hepatocytes while inducing release of Ca^{2+} from the endoplasmic reticulum or mitochondria. These events can lead to apoptosis, necrosis, or both.[4,84]

Drug-Induced Apoptosis

Apoptotic pathways can be activated by drug-induced mitochondrial injury.[84,97] The sequence of events may be (1) drug metabolism produces oxidants and depletes GSH; (2) oxidants induce mitochondrial injury, with release of cytochrome *c* and initiation of the mitochondrial membrane permeability transition; and (3) caspase is activated and triggers apoptosis.

Alcohol-Induced Disease

Alcoholism (five or more drinks per day) induces several patterns of liver injury—notably steatosis (fatty liver), alcoholic hepatitis, and cirrhosis. Steatosis develops in nearly everyone who drinks excessively, but cirrhosis develops in only 10% to 20% of these individuals. In contrast to the general population, people with alcoholic liver disease have a higher prevalence of health-related disorders—malnutrition, immune incompetence, and fluid and electrolyte imbalance. Such individuals are at increased risk for postoperative morbidity secondary to hemorrhage, sepsis, or cardiopulmonary decompensation (from alcoholic or cirrhotic cardiomyopathy).

Characteristic pathologic findings of alcoholic liver disease include (1) acetaldehyde-induced subcellular injury, (2) abnormalities in metabolism, (3) microvascular hypoxia, (4) increased O_2 and nitrogen radical formation, and (5) depletion of antioxidant defenses. Alcohol metabolism is integral to the pathology of alcoholic liver disease.[98-100] The rate-limiting step in ethanol metabolism is catalyzed by alcohol dehydrogenase (ADH).[101] This polymorphic zinc metalloenzyme has more than 20 different isozymes.[102] Although ADH activity exists in many tissues, hepatocytes metabolize more than 95% of the alcohol consumed. Genetic polymorphisms of ADH explain much of the variability in the relationship between ethanol consumption (dose) and liver disease (response). For example, the risk for alcoholic cirrhosis developing relates directly to polymorphisms at the *ADH2* gene locus (i.e., high frequency of the *B* allele). The oxidative metabolism of alcohol forms reduced nicotinamide adenine dinucleotide (NADH); these compounds inhibit the oxidation of fatty acids and 3-carboxyl acid cycles, promoting lipogenesis. Tumor necrosis factor-α (TNF-α) produced by Kupffer cells plays an important role in the genesis of alcoholic hepatitis.[103]

Hypoxic Liver Injury Resembles Alcohol-Induced Liver Injury

Hepatic injuries from hypoxic episodes and ingestion of ethanol are similar in many respects. Hypoxic injuries promote the release of proinflammatory cytokines, TNF-α, and interleukin-1 (IL-1) and IL-6. These signaling molecules lead to increased expression of adhesion molecules, decreased velocity and increased margination of neutrophils, increased platelet adherence, and decreased hepatic blood flow. Hepatoenteric ischemia releases cytokines and XO and leads to activation of complement. This intensifies the local inflammation and can induce systemic inflammatory responses, with subsequent pulmonary and cardiac injury.

Similarly, alcoholic-related liver injury promotes the release of proinflammatory mediators. Alcohol ingestion can markedly increase hepatic O_2 consumption, which would predispose to hypoxic injury. The earliest manifestations of ethanol-induced injury occur in acinar zone 3 (the centrilobular region), which has the highest ADH content and the lowest O_2 supply.

CIRRHOSIS AND PORTAL HYPERTENSION

Cirrhosis of the liver is a chronic condition that results from persistent hepatic injuries and is characterized by perturbations of the normal liver architecture by fibrotic scar tissue and regenerative nodules. The possible causes of cirrhosis include alcoholism, nonalcoholic steatohepatitis, viral hepatitides, and genetic disorders. Cirrhosis often progresses in an insidious, indolent manner. Hepatic fibrosis and vascular distortions cause continual, cumulative losses of liver function. Patients may remain unaware of their condition until approximately 70% of their liver is destroyed—that is, the innate and abundant physiologic reserves of the liver are depleted, and the body can no longer compensate for additional losses of viable hepatocytes.

The early clinical manifestations of cirrhosis include anorexia, abdominal discomfort, fatigue, weakness, nausea, vomiting, and jaundice. As the severity of cirrhosis increases, its signs and symptoms become overt; a common and serious complication is portal hypertension, which results in myriad and pervasive abnormalities that affect every tissue in the body. The most ominous changes include ascites, portosystemic shunting, renal and pulmonary dysfunction, hepatic encephalopathy, and gastroesophageal varices, which are associated with devastating events, including massive hemorrhage, sepsis, renal failure, coma, and death.

Pathogenesis of Portal Hypertension

Characteristic features of cirrhosis-induced portal hypertension include elevated resistance to sinusoidal blood flow, increased flow of blood through preportal vessels, and high rates of blood flow through portocaval collateral vessels.[104]

The complex pathogenesis of cirrhosis-induced portal hypertension has been explained using both "backward" and "forward" metaphors, which are not mutually exclusive. According to the backward concept, proliferation of perisinusoidal fibrous tissue leads to increased resistance to portal venous flow. Based on the physics of blood flow (i.e., pressure = flow × resistance), such an increase in resistance at a constant rate of portal venous flow increases portal venous pressure.

On the other hand, when portal hypertension is caused solely by prehepatic increases in portal venous resistance, such as that produced by experimental narrowing of the portal vein, the resultant changes include (1) increased mesenteric vascular resistance, (2) decreased mesenteric blood flow, (3) decreased splanchnic venous O_2 saturation, and (4) increased arteriovenous O_2 content gap in the mesenteric blood. Such changes are in diametric opposition to those associated with cirrhosis-induced portal hypertension. Yet, patients with liver cirrhosis have elevated blood levels of endogenous vasodilators, widespread arteriovenous shunt formation, and high cardiac output with low total peripheral resistance. Therefore, the forward concept could explain some portion of the portal pressure elevation that is caused by cirrhosis-induced changes in the systemic and splanchnic arterial circulation.

Cirrhosis-induced portal hypertension results from both increased intrahepatic vascular resistance (as a result of the development of fibrosis) and increased blood flow through the portal vein and hepatic artery. The deposition of collagen within the liver is the main mechanism

responsible for the increase in resistance within the liver as cirrhosis develops. In other words, the decrease in total cross-sectional area of hepatic sinusoids is one of the main reasons behind the increase in resistance to portal flow.[105] Fibrosis and tissue injury lead to endothelial dysfunction and intrahepatic vasoconstriction with development of intrahepatic vascular shunts between afferent and efferent vessels within the liver.[106,107]

An increase in portal pressure is one of the most important causes of hyperactivity in endothelial cells within the splanchnic and systemic circulation. The intestinal microcirculation is the first part of the vasculature to sense an increase in portal pressure. Responses follow from the arteries in the splanchnic and then the systemic circulation. An increase in splanchnic blood flow is the result of a decrease in splanchnic (mesenteric and splenic) arterial resistance.[105] Both local and systemic neurogenic and biochemical mechanisms contribute to the development of hyperdynamic circulatory syndrome, which is defined as the combination of decreased vascular resistance, increased cardiac output, and increased circulating blood volume.

NO has an indisputable role in the pathogenesis of hemodynamic disorders in liver cirrhosis. Chronic administration of a nitric oxide synthase (NOS) inhibitor may completely normalize the parameters of hyperdynamic circulation but only partially decrease the degree of mesenteric vasodilation.[108,109] This implies that other vasodilators participate in the decrease in mesenteric vascular resistance.

Prostacyclin (PGI_2) is a powerful vasodilator produced by endothelial and epithelial cells. Its production has been well documented in patients with liver cirrhosis.[105] CO, endocannabinoids, neuropeptide Y, and bradykinin are the endogenous vasodilators with the most important vasodilatory roles in patients with liver cirrhosis and portal hypertension. Other endogenous vasodilating factors include glucagon, histamine, vasoactive intestinal polypeptide, substance P, cholecystokinin, estrogen, ammonia, endotoxins, adenosine, and biliary acids. These numerous powerful compounds are responsible for the persistent vasodilation seen in advanced liver cirrhosis. A reduction in the release of some endogenous vasoconstrictors also may play a role in the development of vasodilation; for example, in patients with advanced liver disease, a decrease in vasopressin concentrations has been demonstrated.[110]

Collateral vessels connecting portal and systemic circulation are formed through the enlargement of preexisting vessels and angiogenesis.[111] These collaterals further increase already elevated portal blood flow and aggravate the symptoms of portal hypertension.[111]

An increase in the production of NO derived from endothelial nitric oxide synthase (eNOS) is responsible not only for vasodilation but also for thinning of arterial walls in the splanchnic systemic circulation. Arterial thinning is an important factor in the pathogenesis of hepatic cirrhosis. Treatment with a NOS inhibitor significantly improves wall thickness and attenuates hyperdynamic circulatory syndrome.[112,113]

Overall, hemodynamic disorders in patients with cirrhosis result not only from elevated levels of vasodilatory molecules but also from increased production of vasoconstrictive mediators. For example, by lowering arterial blood pressure, vasodilators trigger baroreceptor-mediated increases in sympathetic nervous system tone, activate the renin-angiotensin-aldosterone system, and promote the release of antidiuretic hormone. In addition, cyclooxygenase-1 production increases, increasing formation of PGH_2 and thromboxane A_2, which in turn augments vasoconstrictive responses to α-adrenergic stimulation.[114] The release of thromboxane A_2 by activated Kupffer cells along with endothelin-1 (ET-1), a potent vasoconstrictor produced by sinusoidal endothelial cells, is a major contributor to increases in portal pressure.[115] It is interesting to note that endothelins also participate in an autocrine loop that counteracts the development of liver fibrosis. Thus, administration of endothelin receptor antagonists as potential therapeutic agents could cause more harm than benefit in patients with liver cirrhosis.[105]

Vascular structures within cirrhotic livers can originate from preexisting sinusoids (in the postnecrotic area of connective tissue) or from pathologic angiogenesis.[116] The angiogenesis develops along two pathways. The first is the process of wound healing typical of fibrogenic chronic liver disease. It is characterized by overexpression of cytokines and several growth factors, such as platelet-derived growth factor, transforming growth factor-β1 (TGF-β1), fibroblasts, and others. The second is the neoangiogenesis that is stimulated in hepatic tissue by a progressive increase in tissue O_2 deprivation. This mechanism is enhanced by an increase in the contribution of the hepatic artery to sinusoidal blood flow, which becomes even more arteriole-like. Hepatocytes adjust to the high O_2 tension and bring about changes in the structure of sinusoids, leading to impairment in the diffusion of O_2 from the sinusoids to the hepatocytes, followed by up-regulation of proangiogenic pathways.[117] Persistent injury of hepatocytes eventually creates a vicious circle—hypoxia promotes angiogenesis, then fibrogenesis and cirrhosis, and back to hypoxia.[118]

The hepatic venous pressure gradient, which is the difference between wedge hepatic venous pressure and free hepatic venous pressure, is considered one of the most important determinants of the progression of hepatic cirrhosis and portal hypertension.[118] The normal hepatic venous pressure gradient is approximately 3 to 5 mm Hg; above 10 to 12 mm Hg, chronic liver disease becomes a serious systemic disorder with potentially life-threatening complications. Under these conditions, both systemic and extrahepatic collateral circulation develop enough to allow gut-derived antigenic matter to enter the systemic circulation. This leads to activation of the innate immune system and increased release of vasoactive compounds, particularly NO.[119] Reinforced and aggravated dilation within the splanchnic vasculature leads to sequestration of blood volume within the splanchnic vascular bed, producing both splanchnic hypervolemia and central hypovolemia.[118]

The described changes are associated with a failure of one of the most important functions of the liver, namely detoxification of potentially harmful compounds, including bacterial end products from the splanchnic and systemic circulation.[120]

Thus, splanchnic vasodilation results from the following mechanisms: (1) increased splanchnic arterial NO production; (2) release of other vasodilating compounds (e.g., endocannabinoids, CO, prostaglandins, glucagon, and others); (3) decreased ability of the splanchnic vasculature to constrict; (4) development of mesenteric angiogenesis mediated by vascular epithelial growth factors; and (5) development of portosystemic connections as a result of dilation of preexisting blood vessels, vascular remodeling, and angiogenesis.[111,121] These collaterals lead to even further increases in the already elevated portal venous blood flow, which exacerbates portal hypertension.[111]

Cardiovascular Dysfunction

The pathophysiologic changes within the splanchnic vasculature form the basis of subsequent changes in systemic hemodynamics. Hyperdynamic circulation (low total peripheral resistance, high cardiac output, and increased blood volume) is a hallmark of cirrhosis and portal hypertension.[122] Generally, systemic arterial pressure is slightly below normal, the heart rate is mildly increased, and central filling pressure is normal. Mixed venous O_2 saturation is elevated, and the arteriovenous O_2 content gap is low. Overall, the hemodynamic profile resembles a peripheral arteriovenous fistula. Indeed, advanced liver disease causes extensive, widespread arteriovenous communications (collateral vessels) within the splanchnic organs, lungs, muscle, and skin. As discussed earlier, high blood flow through these collateral vessels results from cirrhosis-induced increases in endogenous vasodilators.[123-127] Endogenous vasodilators also explain why severe liver disease diminishes cardiovascular responses to physiologic and pharmacologic vasoconstrictors. The main pathophysiologic feature for an anesthesiologist to keep in mind is that these patients are in a constant state of vasodilation, their vasoconstriction is impaired, and their response to vasoconstrictors is decreased. They exhibit both central hypovolemia (within the main, fast compartment of the vasculature) and splanchnic hypervolemia (within the secondary, slower circuit), and mobilization of blood from unstressed to stressed volume is also impaired (see Chapter 21, Figs. 21-9 to 21-11).

Control of Circulatory Volume and Renal Dysfunction

Renal dysfunction typically develops in patients with cirrhosis and portal hypertension. The glomerular filtration rate (GFR) steadily decreases, and the renal tubules avidly retain sodium, with no overt glomerular or tubular injury. Urinalysis is unremarkable except for a low sodium level.

Avid renal retention of sodium is integral to the pathophysiology of cirrhosis and portal hypertension. Volume receptors that detect low effective plasma volume stimulate the sympathetic nervous system and lead to release of renin from the kidney.[128-130] This increases the production of angiotensin II and aldosterone, which enhances renal tubular uptake of sodium. Blood norepinephrine levels are inversely correlated with renal blood flow. Both norepinephrine and angiotensin II redistribute intrarenal blood flow in a manner that increases retention of sodium by the kidney. Additional factors that may augment sodium retention include the kallikrein-kinin system and some potent renal vasoconstrictors, such as $F_{2\alpha}$-isprostanes[131] and ET-1. Renal vasoconstrictors are likely inducers of the renal dysfunction that accompanies cirrhosis and ascites.[132] Under such conditions, endogenous vasodilators (e.g., prostaglandins) become increasingly important to counteract intense vasoconstriction and protect renal blood flow. Accordingly, inhibitors of prostaglandin synthesis can significantly decrease renal blood flow and GFR, increasing the risk for acute renal injury.

The main causes of acute renal failure (ARF) in this patient population are prerenal failure and acute tubular necrosis (ATN). Prerenal failure usually results from hypovolemia, sepsis, or type 1 hepatorenal syndrome (HRS).[133-139] End-stage liver disease puts patients at high risk for systemic hypovolemia as a result of (1) the formation of profuse ascites,[132] (2) aggressive diuretic therapy, (3) gastrointestinal hemorrhage, and (4) sequestration of blood in the splanchnic vasculature. Therapy for prerenal ARF focuses on restoration of blood volume and renal blood flow. The most common cause of ATN is prerenal ARF—when it is protracted and severe enough to cause ischemic renal tubular injury. Other causes of ATN include nephrotoxic substances such as radiocontrast agents and nonsteroidal antiinflammatory drugs. Unlike prerenal ARF, no specific therapy exists for ATN; treatment is mainly supportive.[135,140,141]

Prerenal failure secondary to type 1 HRS has a poor prognosis. In many instances, the only effective therapy is liver transplantation. Interventions that may transiently improve renal performance in such patients include (1) intravenous vasoconstrictors, notably terlipressin, norepinephrine, and midodrine, in combination with octreotide, and (2) devices or procedures that support the liver, such as a molecular adsorbent recirculation system or transjugular intrahepatic portosystemic shunt.[135,140-143]

Thus, systemic vasodilation leads to a decrease in effective blood volume, a decrease in cardiac output followed by an increase in antidiuretic hormone production, sympathetic nervous system stimulation, and activation of the renin-angiotensin-aldosterone system. All this leads to sodium and water retention and finally to formation of ascites. In more extreme situations it is associated with severe renal arterial vasoconstriction, decrease in renal blood flow, and HRS.[144]

Pulmonary Dysfunction

Hepatopulmonary syndrome is presented as a defect in arterial oxygenation induced by dilation in the pulmonary vascular bed in the setting of hepatic cirrhosis.[145]

Pulmonary vasculature undergoes changes similar to those observed in the systemic circulation. Severe dilation of the pulmonary vasculature, intrapulmonary arteriovenous shunts, portopulmonary shunts, and decreased hypoxic pulmonary vasoconstriction can cause severe ventilation-perfusion abnormalities in the lung. Pulmonary vasodilation and increased flow through intrapulmonary shunts leads to increased passage of mixed venous blood from pulmonary arteries to pulmonary veins. An increase in wall thickness of small

veins and particularly capillary walls limits the alveolar-capillary diffusion. Atelectasis or restrictive pulmonary pathophysiology secondary to ascites or pleural effusion can further aggravate pulmonary function. Erythrocyte 2,3-diphosphoglycerate levels often increase and shift the oxyhemoglobin dissociation curve rightward. Ventilation-perfusion mismatching occurs because of atelectasis or restrictive pulmonary pathophysiology secondary to ascites or pleural effusion.

Orthodeoxia (a decrease in arterial oxygenation in standing position) is one of the characteristic symptoms of hepatopulmonary syndrome. Shunt flow, which cannot adjust easily to activation of baroreceptors through the sympathetic nervous system, leads to severe decrease in pulmonary flow and orthodeoxia, often associated with shortness of breath.[145]

Hematologic Dysfunction

Coagulopathies and other hematologic abnormalities are common with end-stage liver disease. Anemia often develops for many reasons, including gastrointestinal bleeding, hemolysis, hypersplenism, malnutrition, vitamin deficiencies, bone marrow depression, and plasma volume expansion. As the liver begins to fail, it cannot make enough vitamin K–dependent procoagulants. When factor VII drops by 70% of the normal level, the PT becomes prolonged. Thrombocytopenia and thrombopathy develop as a result of (1) splenic sequestration syndrome, (2) bone marrow suppression secondary to alcoholism or medications such as interferon, or (3) platelet destruction from immune-mediated, platelet-associated IgG. Dysfibrinogenemia—the activation of fibrinolysis—may develop. Laboratory results typically include increased D-dimer levels, increased fibrin degradation products, and normal or nearly normal fibrinogen levels. However, before attributing any fibrinolytic disorder to liver failure, it is essential to conduct a thorough search for all possible reversible causes of disseminated intravascular coagulation.

Gastrointestinal Complications

Gastrointestinal hemorrhage is always a concern; nearly a third of cirrhosis-related deaths are due to ruptured esophagogastric varices.[146] Portal hypertensive gastropathy, esophageal varices, or gastric varices develop in most patients with cirrhosis and portal hypertension.[147] Hemorrhage from esophageal varices occurs more often than hemorrhage from gastric varices, but the latter is generally more severe than the former. Variceal size is a good predictor of when varices will rupture, and rates of variceal enlargement parallel the severity of liver disease. Less than 2 years after cirrhosis and portal hypertension are diagnosed, 20% to 30% of patients experience a variceal hemorrhage.[147] The first hemorrhage is acutely lethal in approximately 7% of cases, with a 6-week mortality rate of approximately 30%. Untreated survivors of variceal hemorrhage have a 60% chance of rebleeding within 2 years; if this should occur, the death rate would be 40% to 50%.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis is another complication of hepatic cirrhosis. Impaired intestinal transport of food resulting in bacterial overgrowth in cirrhotic patients is probably one of the most important causes of bacterial translocation.[144,148] Observations that prokinetic drugs decrease intestinal overgrowth and bacteria translocation support this notion.[149] Mucosal hypoxia as a consequence of portal hypertension, vascular stasis, and intestinal mucosal congestion, combined with alteration in systemic immune defense systems, leads to development of bacterial peritonitis.[144]

Endocrinopathies

Because the liver produces, processes, and metabolizes many endocrine substances, advanced liver disease leads to endocrine abnormalities. For example, plasma levels of glucagon and growth hormone increase with liver disease and contribute to insulin resistance. Insulin-like growth factor–1 decreases in children with liver disease and adversely affects their growth and development. Gonadal dysfunction develops in men and women because of disruptions in the metabolism of sex hormones. Men undergo feminization, with the development of gynecomastia, testicular atrophy, infertility, and impotence. In women, oligomenorrhea, amenorrhea, and infertility are common.

Hepatic Encephalopathy

Hepatic encephalopathy is a complex neuropsychiatric syndrome that develops in 50% to 70% of patients with cirrhosis. Pathophysiologic phenomena that contribute to the syndrome include (1) hepatobiliary dysfunction, (2) decreased hepatic blood flow, and (3) extrahepatic diversion of portal venous flow through collateral vessels (i.e., portocaval blood flow). Various gut-derived chemicals, including mercaptans, phenols, ammonia, short-chain fatty acids, and manganese, may play a role in the pathogenesis of hepatic encephalopathy. Central nervous system depression may result from false neurotransmitters (e.g., octopamine) or endogenous ligands that increase central inhibitory outflow, such as activators of γ-aminobutyric acid and benzodiazepine receptors. Other possible contributors to encephalopathy are disruptions of the blood-brain barrier and defective cerebral energy metabolism. The pathogenesis and management of hepatic encephalopathy are described in detail elsewhere.

Pathogenesis of Ascites

Cirrhosis-induced portal hypertension leads to massive increases in total body water, edema, and ascites formation.[150] The problem can be traced to excessive sodium retention by the kidney (Fig. 22-8).[1,151] However, the principal driver of the sodium retention is unclear. One explanation—the overflow model—is that hepatic cirrhosis gives rise to chemicals that stimulate the kidney to retain sodium. A second explanation—the underfill model—is that renal retention of sodium is a normal physiologic response to a low effective blood volume.

The essence of the overflow model is that excessive renal retention of sodium causes intravascular volume to expand, with two major and direct consequences: (1) plasma oncotic pressure decreases, with the liver unable to produce sufficient albumin to correct the hypoalbuminemia, and (2) portal hydrostatic pressure increases (i.e., portal hypertension). The combination of low oncotic pressure and portal hypertension accelerates the formation

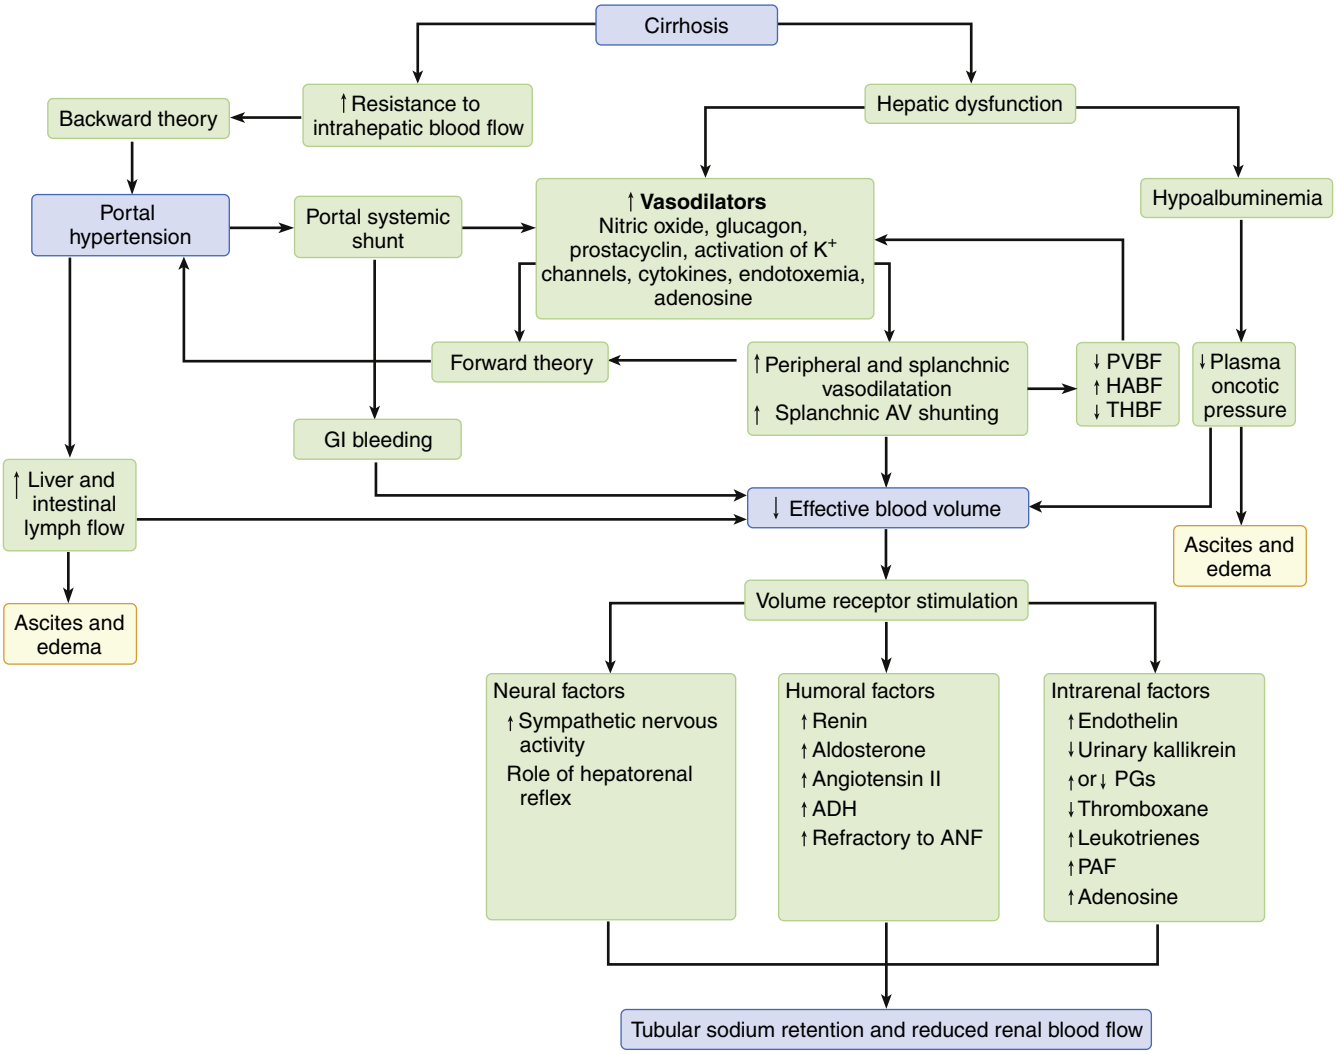

Figure 22-8. Schematic of pathways for cirrhosis-induced portal hypertension: the forward and backward theories. Cirrhosis and portal hypertension induce circulatory changes that decrease effective blood volume. This activates volume receptors and stimulates neurohumoral and intrarenal reflexes, which decreases renal blood flow and increases renal retention of sodium. *ADH,* antidiuretic hormone; *ANF,* atrial natriuretic factor; *AV,* arteriovenous; *HABF,* hepatic arterial blood flow; *PAF,* platelet-activating factor; *PGs,* prostaglandins; *PVBF,* portal venous blood flow; *THBF,* total hepatic blood flow. *(Reprinted with permission from Mushlin PS, Gelman S: Anesthesia and the liver. of edema and ascites. A pivotal assumption of the overflow model is that a cirrhosis-induced mediator causes normal kidneys to retain sodium and water despite an overfilled intravascular compartment. At present, no such mediator (or process) has been identified.

The underfill model recognizes that homeostatic reflexes work in concert with the kidney to tightly regulate intravascular volume. This model posits that cirrhosis causes the effective plasma volume to decrease, which activates homeostatic mechanisms to retain sodium and water. That is, with decreases in arterial volume, whether from arterial dilation or low cardiac output, the kidney is instructed to retain sodium and water. Cirrhosis-induced decreases in effective plasma (or arterial) volume can result from arterial dilation, intravascular volume depletion, or both. Although the latter has many possible causes, edema and ascites formation from unbalanced Starling forces are sufficient to significantly decrease intravascular volume. The overflow and underfill models are not mutually exclusive; a primary defect in sodium excretion could be the major factor in earlier stages of cirrhosis, whereas a low effective plasma volume could be the more important factor in progression to end-stage liver disease.

Chapter 23

Renal Physiology, Pathophysiology, and Pharmacology

DAVID MCILROY • ROBERT N. SLADEN

Key Points

- To cross the filtration barrier between plasma and tubular fluid, a molecule must pass in succession through the endothelial fenestrations, glomerular basement membrane, and epithelial slit diaphragm. The capillary endothelium restricts the passage of cells, but the basement membrane filters plasma proteins. All three layers contain negatively charged glycoproteins, which retard the passage of other negatively charged proteins. Thus, the filtration barrier is size selective and charge selective.
- A primary determinant of glomerular filtration rate (GFR) is glomerular filtration pressure, which depends not only on renal artery perfusion pressure but also on the balance between afferent and efferent arteriolar tone. In the presence of decreased afferent arteriolar pressure or blood flow, low levels of catecholamines, angiotensin, and arginine vasopressin (AVP) induce preferential efferent arteriolar constriction, which maintains glomerular filtration pressure. This is reflected by an increase in calculated filtration fraction (FF), which is the GFR expressed as a fraction of the renal plasma flow (RPF). High levels of catecholamines and angiotensin (but not AVP) increase afferent arteriolar tone and decrease glomerular filtration pressure (and GFR) out of proportion to RPF, with a consequent reduction in FF.
- Tubuloglomerular feedback may be a primary mechanism in renal autoregulation. When GFR is increased, distal tubular NaCl delivery is enhanced. The increase in chloride is sensed by the macula densa, triggering release of renin from the adjacent afferent arteriole. Angiotensin is elaborated and arteriolar constriction ensues, which decreases GFR. When the thick ascending loop becomes ischemic, reabsorption of NaCl ceases, the ability of the tubule to concentrate urine is lost, and theoretically, intractable polyuria should result. However, the increased delivery of NaCl to the macula densa may be the trigger for angiotensin-mediated arteriolar constriction, which decreases GFR, induces oliguria, conserves intravascular volume, and protects the organism from dehydration—so-called acute renal success. Autoregulation enables the kidney to maintain solute and water regulation independently of wide fluctuations in arterial blood pressure. Urinary flow rate is not subject to autoregulation. Tubular water reabsorption determines urinary flow rate and is closely related to the hydrostatic pressure in the peritubular capillaries. Hypotension of any cause results in decreased urinary flow rate that may be correctable only when arterial blood pressure is restored toward normal.
- The tubule has an enormous capacity for reabsorption of water and NaCl. Each day, 180 L of protein-free glomerular ultrafiltrate is formed, of which almost 99% of the water and 99% of the sodium is reabsorbed. Many other filtered substances are completely reabsorbed, but some, such as glucose, have a maximum rate of tubular reabsorption (tubular maximum). Once this rate is exceeded, glycosuria results, increasing in proportion to the filtered load. The ability of the kidney to concentrate urine is dependent on the interaction of at least three processes: (1) generation of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling, (2) concentration and then dilution of tubular

KEY POINTS—cont'd

fluid in the loop of Henle, and (3) the action of antidiuretic hormone (now known as arginine vasopressin) in increasing water permeability in the last part of the distal tubule and collecting ducts. The juxtaglomerular apparatus consists of three groups of specialized tissues. In the afferent arteriole, modified fenestrated endothelial cells produce renin; in the juxtaposed distal tubule, cells of the macula densa act as chemoreceptors; and in the glomerulus, mesangial cells have contractile properties. Together these provide an important regulating system for arterial blood pressure, salt, and water homeostasis.

- Two mutually dependent but opposing neurohormonal systems maintain blood pressure, intravascular volume, and salt and water homeostasis. The sympathoadrenal axis, the renin-angiotensin-aldosterone system, and AVP defend against hypotension and hypovolemia by promoting vasoconstriction and salt and water retention. The prostaglandins and natriuretic peptides defend against hypertension and hypervolemia by promoting vasodilation and salt and water excretion.
- Hypothalamic osmoreceptors are sensitive to increases in serum osmolality of as little as 1% above normal. The threshold for AVP secretion (and sensation of thirst) is between 280 and 290 mOsm/kg. Even mild dehydration results in rapid antidiuresis, and urine osmolality can increase from 300 to 1200 mOsm/kg as plasma AVP levels rise from 0 to 5 pg/mL. Decreases in intravascular volume also stimulate AVP secretion, mediated by stretch receptors with vagal afferents from the left atrium and pulmonary veins.
- Serum creatinine reflects the balance between creatinine production from muscle and creatinine excretion by the kidney, which is dependent on GFR. Creatinine generation rate varies with muscle mass, physical activity, protein intake, and catabolism. However, when these processes are in equilibrium and renal function is stable, serum creatinine is a useful marker of GFR. The relationship between serum creatinine and GFR is inverse and exponential. A doubling of the serum creatinine implies a halving of GFR. However, limited sensitivity and specificity for renal injury combined with the delayed rise in creatinine that follows an acute reduction in GFR may limit the clinical utility of serum creatinine.
- Given the widely acknowledged limitations associated with traditional markers of renal injury, recent interest has focused on developing novel biomarkers to enable early detection of renal injury. Many candidate markers are currently under investigation to evaluate their validity and potential clinical utility. However, they remain investigational at the current time, and serum creatinine remains the imperfect gold standard for clinically relevant AKI.
- With an incidence of 20% to 25% following cardiac surgery, perioperative acute kidney injury (AKI) is associated with an increased incidence of adverse outcomes, including hospital mortality. Potential mechanisms are complex and multifactorial and may include ischemia-reperfusion injury, up-regulation of inflammatory cascades, endothelial dysfunction, multiple sources of embolic injury, and multiple nephrotoxins, including recent radiocontrast exposure and cardiopulmonary bypass–related hemolysis with associated hemoglobinuria.
- All anesthetic techniques and drugs tend to decrease GFR and intraoperative urine flow. Some drugs also decrease renal blood flow (RBF), but filtration fraction is usually increased, implying that angiotensin-induced efferent arteriolar constriction limits the decrease in GFR. However, these effects are much less significant than those caused by surgical stress or aortic cross-clamping and usually resolve promptly after emergence from anesthesia. Any anesthetic technique that induces hypotension will result in decreased urine flow because of altered peritubular capillary hydrostatic gradients, even if renal autoregulation is preserved (as is usually the case during anesthesia).
- Clinically significant renal injury with the use of low-flow sevoflurane anesthesia has not been reported in patients, even with moderate preexisting renal dysfunction. The relationship among compound A formation, biochemical injury, and clinically relevant renal dysfunction remains unclear and unproven. Nonetheless, the

KEY POINTS—cont'd

current U.S. Food and Drug Administration (FDA) guidelines, which recommend a fresh gas flow of at least 2 L/minute when using sevoflurane for longer than 2 MAC (minimal alveolar concentration of anesthetic)-hours to limit exposure to compound A, should be followed. Regardless of the position of an aortic cross-clamp, RBF may be significantly decreased during surgical manipulation of the aorta, presumably because of direct compression or reflex spasm of the renal arteries. After release of a suprarenal cross-clamp, RBF increases above normal (reflex hyperemia), but GFR may remain depressed to one third of control for up to 2 hours. After 24 hours, GFR may still be only two thirds of control. Urine flow may be maintained despite marked impairment of tubular functions (concentrating ability, sodium, and water conservation), resembling an attenuated form of acute tubular necrosis. Cross-clamp times longer than 50 minutes have been associated with prolonged depression of GFR and transient azotemia (also see Chapter 69).

- No intervention has proven effective for prevention or treatment of perioperative AKI. Although several therapies have shown some benefit in selected studies or meta-analyses (e.g., fenoldopam, goal-directed therapy), meaningful conclusions can be made only with additional large trials to clarify the potential role of such interventions.

The kidneys contain approximately 2×10^6 nephrons, each of which consists of a glomerulus and a tubule, which empties into a collecting duct. These functional units collectively enable the kidneys to maintain a remarkably stable interior milieu, despite large fluctuations in fluid and solute intake. Together they regulate intravascular volume, osmolality, and acid-base and electrolyte balance and excrete end products of metabolism and drugs. Urine is formed by the combination of glomerular ultrafiltration and tubular reabsorption and secretion. The nephron also elaborates hormones that contribute to fluid homeostasis (renin, prostaglandins, kinins), bone metabolism (1,25-dihydroxycholecalciferol), and hematopoiesis (erythropoietin). The function of the nephron is closely integrated with the vascular supply of the kidney (Fig. 23-1).

THE GLOMERULUS (RENAL CORPUSCLE)

The glomerulus consists of five distinct components: capillary endothelium, glomerular basement membrane, visceral epithelium (which together make up the filtration barrier), parietal epithelium (Bowman capsule), and mesangium (interstitial cells).[1,2] The glomerular tuft, a highly convoluted series of capillary loops, is fed by the afferent arteriole and drains into the efferent arteriole (Fig. 23-2).

The capillary endothelium synthesizes nitric oxide and endothelin-1, which, by governing vasodilation and vasoconstriction, control renal blood flow. The endothelium has fenestrations about 70 to 100 nm in diameter and lies atop the glomerular basement membrane, which has a total cross section of about 350 nm. The visceral epithelium, which is applied to the underside of the basement membrane, consists of podocytes with filamentous, interdigitating foot processes that contain contractile actin filaments. Filtration slits form 25- to 60-nm gaps between the foot processes and are bridged by a protein membrane slit diaphragm, whose size and permeability are altered by contraction of the foot processes.

The blind parietal epithelial sac of the renal tubule is invaginated around the capillary tuft as Bowman capsule and meets the visceral epithelium at the vascular pole of the glomerulus. Bowman space, between the visceral and parietal layers of the capsule, becomes the lumen of the proximal tubule at the urinary pole of the glomerulus, and the parietal endothelium merges with the cuboidal cells of the proximal tubule.

The central or interstitial mesangial cells are specialized pericytes with numerous functions, including structural support, matrix elaboration, and phagocytosis. They contain myofilament-like threads of actin and myosin. Mesangial contraction in response to vasoactive substances such as angiotensin II restricts blood flow to fewer capillary loops. The mesangial cells thereby regulate the effective glomerular surface area for filtration and, as a consequence, glomerular permeability.[3]

FORMATION OF THE GLOMERULAR ULTRAFILTRATE

To cross the filtration barrier between plasma and tubular fluid, a molecule must pass in succession through the endothelial fenestrations, the glomerular basement membrane, and the epithelial slit diaphragm. The capillary endothelium restricts the passage of cells, but the basement membrane filters plasma proteins. All three layers contain negatively charged glycoproteins, which retard the passage of other negatively charged proteins. Thus, the filtration barrier is both size selective and charge selective.[1] Molecules with an effective radius of less than 1.8 nm (e.g., water, sodium, urea, glucose,

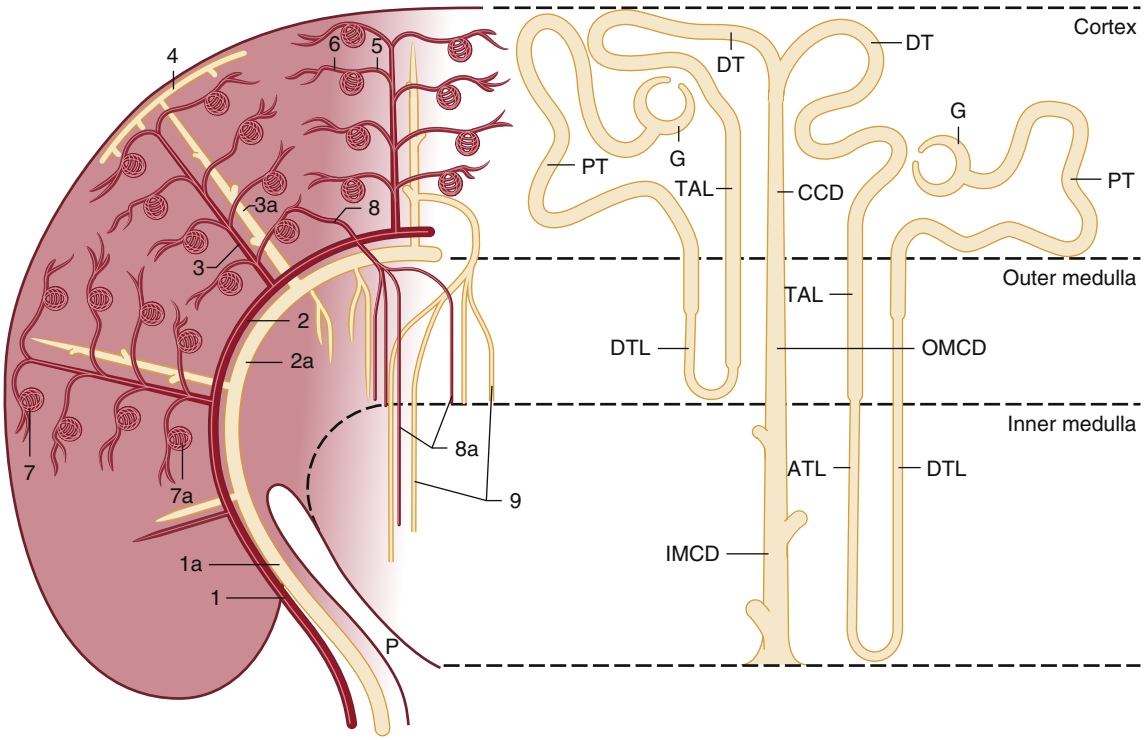

Figure 23-1. Anatomic relationships of the nephron and the renal vasculature. The left side of the diagram represents the renal vasculature as distributed through the inner medulla, outer medulla, and cortex. Arteries are drawn as *solid lines*, veins as hollow tubes. The renal artery divides serially into interlobar arteries (1), arcuate arteries (2), and interlobular arteries (3). The afferent arterioles (5) branch off laterally and provide the capillary tufts of the renal glomeruli in the outer cortex (7a), whose efferent arterioles (6) supply the cortical capillary network (not shown). In the juxtamedullary zone (7b), the efferent arterioles become the vasa recta, which are closely applied to the long loops of Henle (8, 8a, 9). The venous drainage consists of stellate veins (4), interlobular veins (3a), arcuate veins (2a), and interlobar veins (1a). The right side of the diagram represents two nephrons. On the left is the more numerous superficial cortical nephron with a short loop of Henle. On the right is the juxtamedullary nephron with a long loop of Henle, which dives deep into the inner medulla to generate the hyperosmotic interstitium required for tubular urine concentration. *ATL*, Ascending thin loop of Henle; *CCD*, cortical collecting duct; *DT*, distal tubule; *DTL*, descending thin loop of Henle; *G*, glomerulus; *IMCD*, inner medullary collecting duct; *OMCD*, outer medullary collecting duct; *PT*, proximal tubule; *TAL*, thick ascending loop. *(From Kriz W: A standard nomenclature for structures of the kidney,* Kidney Int *33:1-7, 1988.)*

inulin) are freely filtered. Molecules larger than 3.6 nm (e.g. hemoglobin, albumin) are not filtered. Filtration of molecules between 1.8 and 3.6 nm depends on their electrical charge. Cations are filtered, whereas anions are not. In glomerulonephritis the negatively charged glycoproteins are destroyed, polyanionic proteins are filtered, and proteinuria ensues.

Glomerular ultrafiltration is governed by the balance of Starling forces regulating fluid flux across the filtration barrier.[4] Glomerular filtration rate (GFR) depends on the permeability of the filtration barrier and the net difference between the hydrostatic forces pushing fluid into Bowman space and the osmotic forces keeping fluid in the plasma:

$$GFR = K_{uf}\,[(P_{gc} - P_{bs}) - (\pi_{gc} - \pi_{bs})] \qquad [1]$$

where uf = ultrafiltration, gc = glomerular capillary, and bs = Bowman space.

The ultrafiltration coefficient, K_{uf}, reflects capillary permeability and glomerular surface area. Renal arterial pressure determines the hydrostatic pressure in the glomerular capillary, P_{gc}. Afferent arteriolar plasma flow determines the plasma oncotic pressure (π_{gc}): rapid blood flow washes out osmotically effective molecules and lowers π_{gc}, and vice versa.

THE JUXTAGLOMERULAR APPARATUS

The juxtaglomerular apparatus provides a remarkable integration of tubular and glomerular structure and function (Fig. 23-3). A modified portion of the thick ascending limb, the macula densa, is applied to the glomerulus at the vascular pole between the afferent and efferent arterioles.[1] The cells of the macula densa are chemoreceptors and sense the tubular concentration of sodium chloride (NaCl). The juxtaposed segments of the afferent and efferent arterioles contain modified smooth muscle cells (granular cells), which produce renin. The arterioles are innervated by sympathetic nerve fibers and contain baroreceptors that respond to changes in intraluminal blood pressure. Renin catalyzes the formation of angiotensin, which modulates efferent and afferent arteriolar tone and GFR (see next section). The relationship of the juxtaglomerular apparatus to the sympathoadrenal system is discussed later in the section on neurohormonal regulation of renal function.

AFFERENT AND EFFERENT ARTERIOLAR CONTROL MECHANISMS

A primary determinant of GFR is the glomerular filtration pressure, which depends not only on the renal artery

Figure 23-2. Photomicrograph of a cast of a glomerulus without Bowman capsule. At lower left the afferent arteriole (A) originates from an interlobular artery and enters the glomerulus with its many capillary loops. At upper left the efferent arteriole (E) leaves the glomerulus and branches to form the peritubular capillary plexus. Magnification ×300. *(From Tisher CC, Madsen KM: Anatomy of the kidney. In Brenner BM, editor:* Brenner & Rector's The Kidney, *ed 6, Philadelphia, 2000, WB Saunders, pp 3-67.)*

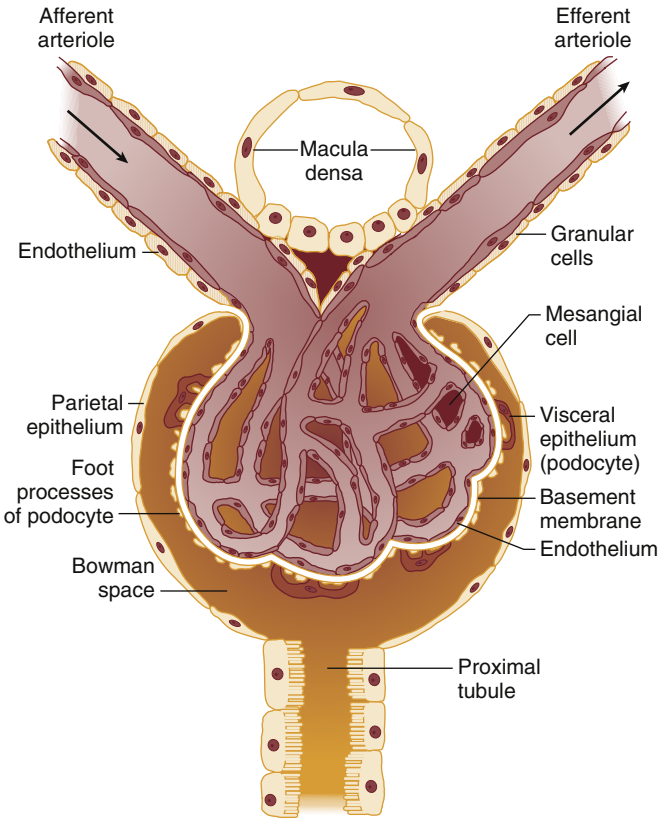

Figure 23-3. The juxtaglomerular apparatus. *(From Stanton BA, Koeppen BM: Elements of renal function. In Berne RM, Levy MN, editors:* Physiology, *ed 4, St Louis, 1998, Mosby, pp 677-698.)*

perfusion pressure but also on the balance between afferent and efferent arteriolar tone. In the face of decreased afferent arteriolar pressure or blood flow, low levels of catecholamines, angiotensin, and arginine vasopressin (AVP) induce preferential efferent arteriolar constriction, which maintains glomerular filtration pressure. This is reflected by an increase in calculated filtration fraction (FF), which is the GFR expressed as a fraction of the renal plasma flow (RPF)—FF = GFR/RPF. High levels of catecholamines and angiotensin (but not AVP) increase afferent arteriolar tone and decrease glomerular filtration pressure (and GFR) out of proportion to renal plasma flow, thus decreasing FF (Fig. 23-4). These mechanisms are described in more detail in the following sections.

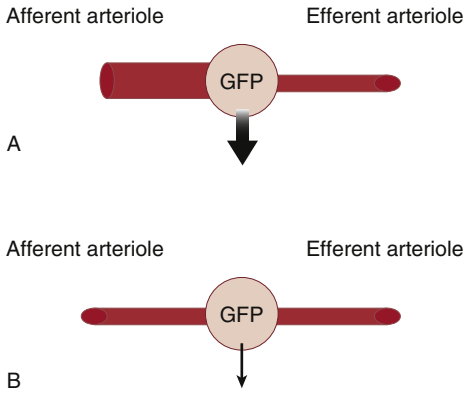

Figure 23-4. Afferent and efferent arteriolar control mechanisms. *(From Sladen RN, Landry D: Renal blood flow regulation, autoregulation, and vasomotor nephropathy,* Anesthesiol Clin North America *18:791-807, ix, 2000.)*

TUBULOGLOMERULAR FEEDBACK

Tubuloglomerular feedback is an important component of renal autoregulation.[3] When GFR is increased, distal tubular NaCl delivery is enhanced. The increase in chloride is sensed by the macula densa, which triggers the release of renin from the adjacent afferent arteriole. Angiotensin is elaborated, and arteriolar constriction ensues, which decreases GFR.

Tubuloglomerular feedback appears to prevent polyuria in acute renal failure. When the thick ascending loop becomes ischemic, reabsorption of NaCl ceases, the ability of the tubule to concentrate urine is lost, and theoretically, intractable polyuria should result. Thurau and Boylan[5] suggested that the increased delivery of NaCl to the macula densa triggers angiotensin-mediated arteriolar constriction, which decreases GFR, induces oliguria, conserves intravascular volume, and protects the organism from dehydration—so-called acute renal success.

RENAL AUTOREGULATION

Autoregulation enables the kidney to maintain solute and water regulation independently of wide fluctuations of arterial blood pressure. In 1951 the classic dog studies of Shipley and Study[6] demonstrated that the kidney

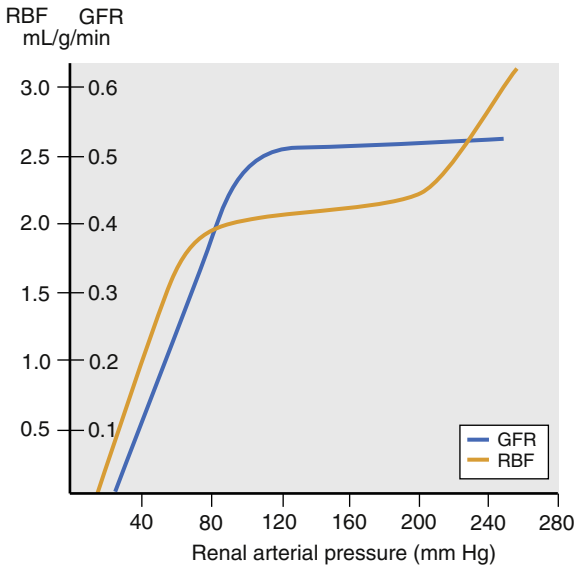

Figure 23-5. Autoregulation of glomerular filtration rate (GFR) and renal blood flow (RBF). Based on the original work of Shipley and Study.[5] GFR and RBF remain constant between renal arterial pressures of 80 and 180 mm Hg. *(From Pitts RF:* Physiology of the kidney and body fluids*, Chicago, 1974, Year Book Medical Publishers.)*

maintains a constant renal blood flow and GFR through an arterial pressure range of 80 to 180 mm Hg (Fig. 23-5). It is noteworthy that urinary flow rate is not subject to autoregulation. Tubular water reabsorption determines urinary flow rate and is closely related to the hydrostatic pressure in the peritubular capillaries. Hypotension, whether induced or inadvertent, results in decreased urinary flow rate that may be correctable only when the arterial blood pressure is restored toward normal.

There is considerable evidence to support two major mechanisms for renal autoregulation.[3] Renal vascular resistance appears to be mediated by variable resistance of the preglomerular afferent arteriole. As mean arterial pressure decreases, renal vascular resistance decreases and renal blood flow (RBF) is maintained. The most plausible explanation is a myogenic response (i.e., the arterioles constrict in response to increased arterial pressure and vice versa). Tubuloglomerular feedback via the juxtaglomerular apparatus also plays a role.[3,4,7] When arterial blood pressure increases through the autoregulatory range, delivery of sodium chloride to the chemosensors of the macula densa is enhanced, which generates ATP and adenosine that stimulate the adenosine A_1 receptor and induces afferent arteriolar constriction (Fig 23-6). This in turn decreases RBF and GFR back to the previous levels. The opposite effect occurs when arterial pressure declines. Local release of nitric oxide attenuates tubuloglomerular feedback, whereas release of angiotensin II enhances it.[4]

Autoregulation is impaired by calcium channel blockade, implying that a calcium-dependent mechanism is involved, but not by most anesthetic agents. It is reset in chronic hypertension and may be lost in the diabetic kidney. Experimental evidence shows that autoregulation is lost in acute renal failure[8]; in part, this may be due to endothelial dysfunction through excessive nitric oxide because inducible nitric oxide synthase is activated by renal ischemia-reperfusion injury.[9] Pressure-dependence of RBF is observed during cardiopulmonary bypass[10] and in severe sepsis,[11] but this may be due to hypotension below the autoregulatory range, rather than abnormal autoregulation per se. In these situations, restoration of renal perfusion pressure to normal levels improves RBF, even if this is achieved by vasoconstrictor therapy.

THE TUBULE

The tubule has four distinct segments: the proximal tubule, the loop of Henle, the distal tubule, and the connecting segment. The loop of Henle itself is divided into the pars recta (the straight portion of the proximal tubule), the descending and ascending thin limb segments, and the thick ascending limb. Each distal tubule drains into a collecting duct, which courses through the cortex, outer medulla, and inner medulla before entering the renal pelvis at the papilla (see Fig. 23-1).

Two populations of nephrons exist. The cortical nephrons, which populate the outer and middle renal cortex, are far more numerous, receive about 85% of the renal blood flow, and have short loops of Henle. Their efferent arterioles drain into a peritubular capillary plexus. The juxtamedullary nephrons populate the inner renal cortex, receive about 10% of the RBF, and have larger glomeruli and long loops of Henle, which dive deeply into the inner medulla.[2] Their efferent arterioles drain into elongated vascular conduits, the vasa recta, which are closely applied to the loops of Henle. Although the vasa recta receive less than 1% of the renal blood flow, they play an important role in generating the countercurrent mechanism for medullary hypertonicity and renal-concentrating ability (see later).

TUBULAR REABSORPTION AND SECRETION

The tubule has an enormous capacity for reabsorption of water and NaCl. Each day, 180 liters of protein-free glomerular ultrafiltrate is formed, of which almost 99% of the water and 99% of the sodium is reabsorbed.

Many other filtered substances are completely reabsorbed, but some, such as glucose, have a maximum rate of tubular reabsorption (tubular maximum). Tubular reabsorption of glucose increases at a rate equal to that of the filtered load. If the GFR is constant, the rate is directly proportional to the plasma glucose concentration. Once this concentration exceeds the tubular maximum (375 mg/dL), no further glucose is reabsorbed, and glycosuria results. Thereafter, the amount of glucose excreted in the urine increases in direct proportion to the filtered load.

Many important endogenous and exogenous solutes are secreted into the tubular lumen from the capillary blood. Some also have a tubular maximum for secretion, such as para-aminohippurate (PAH), which is used to calculate renal plasma flow. This is discussed further in the section on renal function tests.

There is a striking relationship between the structure and function of the different segments of the tubule (Fig. 23-7). The most metabolically active components of the tubule are the proximal tubule, the thick ascending loop of Henle, and the first part of the distal tubule.

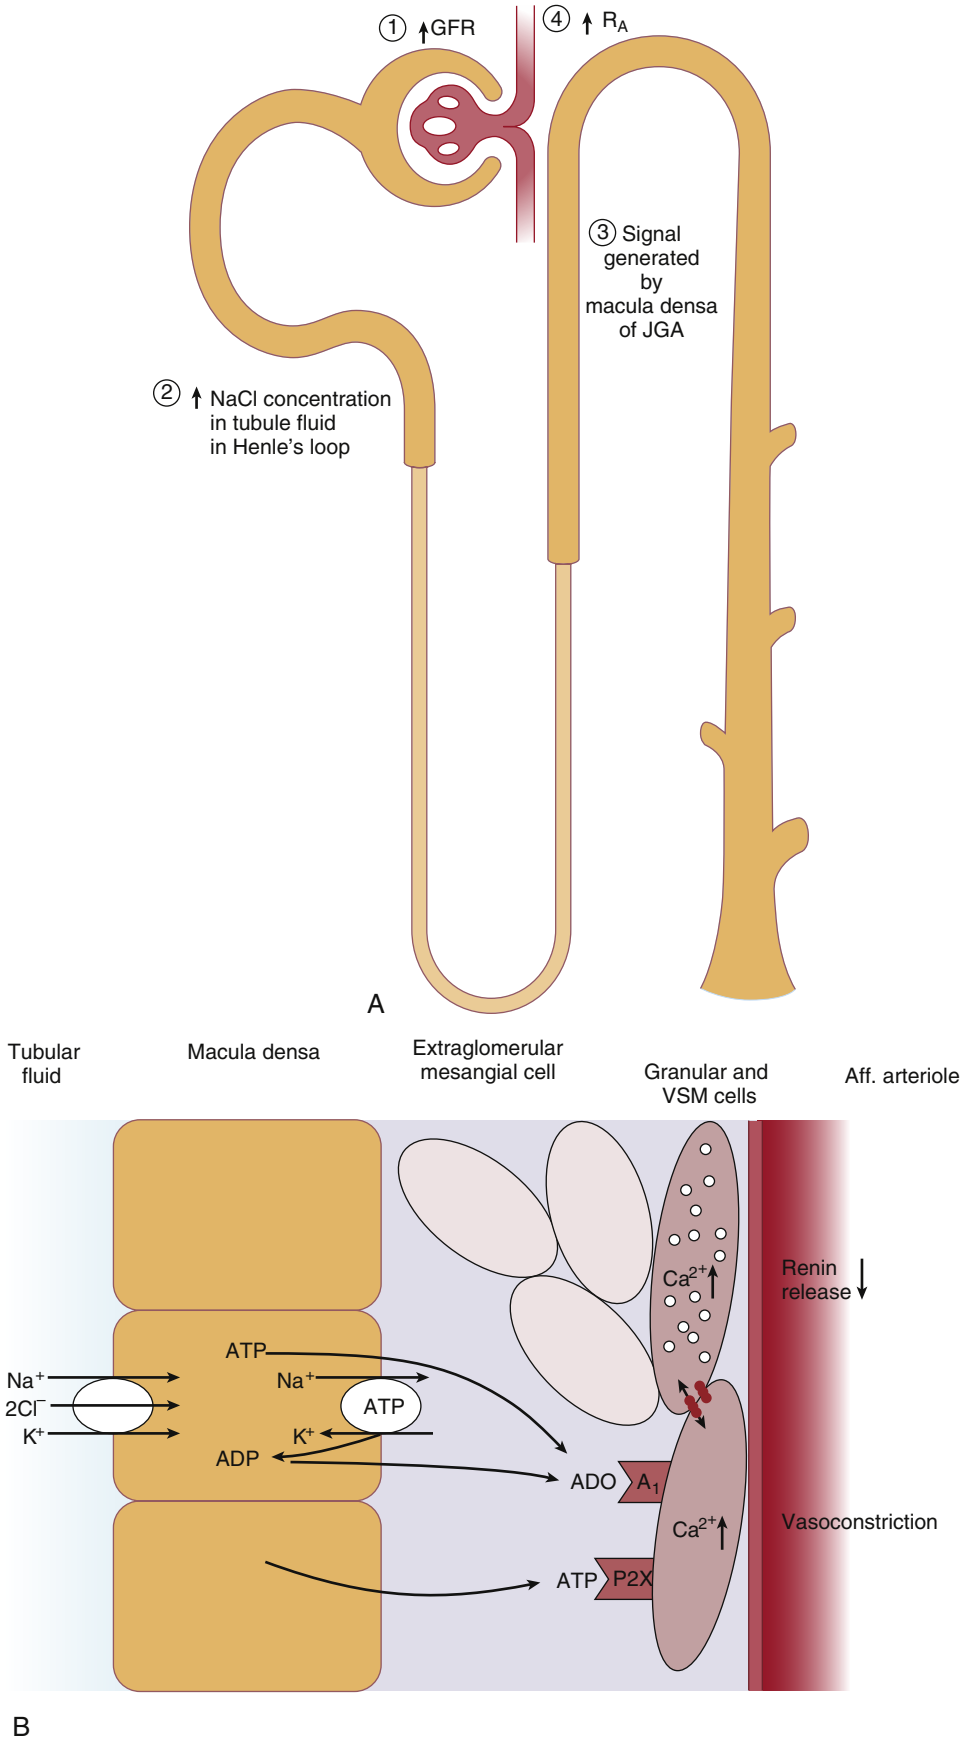

Figure 23-6. A and **B**, Tubuloglomerular feedback. An increase in glomerular filtration rate (GFR) (1) increases sodium chloride (NaCl) concentration in the tubular fluid in the loop of Henle. This is sensed by chemosensors in the modified distal tubular cells of the macula densa in the juxtaglomerular apparatus (JGA) (3). The cells of the macula densa generate adenosine triphosphate (ATP) and adenosine that induces afferent arteriolar constriction and increases its resistance (R_A) (4). This returns the GFR to its former level. A decline in the GFR has the opposite effect. *(From Koeppen BM, Stanton BA: Glomerular filtration and renal blood flow. In Koeppen BM, Stanton BA, editors:* Renal physiology, *ed 4, Philadelphia, 2007, Mosby, pp 31-46.)*

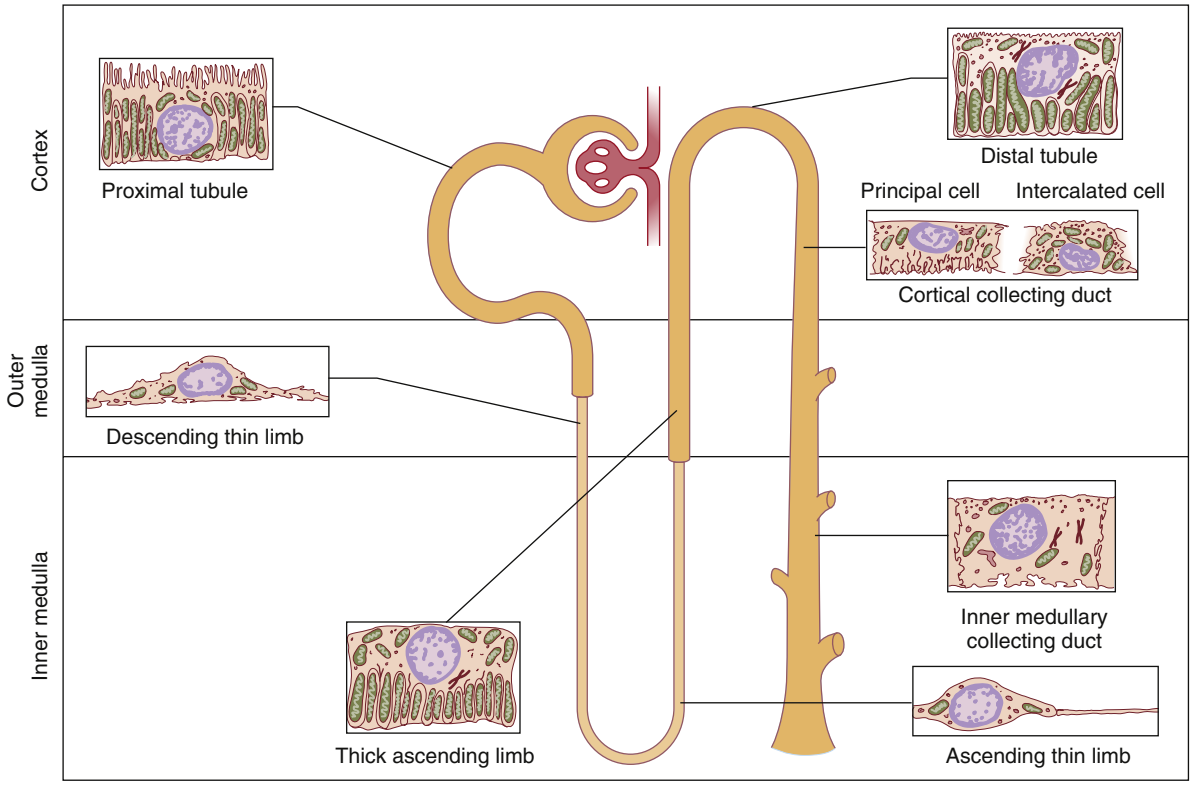

Figure 23-7. Structure-function relationships in the renal tubule. The most metabolically active components of the tubule are the proximal tubule, the thick ascending loop of Henle, and the first part of the distal tubule. Their cells are large, and on the capillary surface (basolateral membrane) there are many invaginations rich in mitochondria. The cells of the proximal tubule have a brush-border on the luminal surface (apical cell membrane), whereas the cells of the descending and thin ascending loops of Henle are flattened with few mitochondria. The second part of the distal tubule and collecting duct are intermediate in nature. The intercalated cells of the distal tubule have many mitochondria; the principal cells have few. *(From Stanton BA, Koeppen BM: Elements of renal function. In Koeppen BM, Stanton BA, editors:* Renal physiology, *ed 4, Philadelphia, 2007, Mosby, pp 677-698.)*

Figure 23-8 illustrates a tubular cell in the thick ascending loop of Henle, which encompasses all the major mechanisms of reabsorption and secretion. The tubular lumen abuts the apical cell membrane, which joins adjacent cells at the tight junctions. From each apical cell membrane protrudes a primary cilium equipped with a flow-sensitive mechanosensor and a chemosensor, both linked to calcium-dependent signaling pathways that control kidney cell function and apoptosis.[1] The remainder of the cell is lined by the basolateral cell membrane, which interfaces with the lateral interstitial spaces on either side and with the peritubular capillary at its base.

A number of protein-based active transport systems exist. The most important one is the sodium-potassium–adenosine triphosphatase (Na-K-ATPase) system, situated in the basolateral membrane. It pumps sodium out of the tubular cell into the interstitial fluid (and capillary blood) against a concentration and an electrical gradient, in exchange for potassium from inside the tubular cell. The consequent decrease in intracellular sodium concentration facilitates passive reabsorption of sodium from the tubular lumen into the cell. The transport of virtually all solutes is coupled to that of sodium.

Active transport systems that move solutes in the same direction into or out of the cell are called symporter systems, whereas those that move solutes in opposite directions are called antiporter systems. Solutes are transported by active and passive mechanisms, but water always diffuses passively along an osmotic gradient.

PROXIMAL TUBULE

The first part of the proximal tubule reabsorbs about 100% of the filtered glucose, lactate, and amino acids, as well as some phosphate by coupling with sodium-symporter systems.[12] Hydrogen ions (H^+) are extruded into the tubule in exchange for bicarbonate by a sodium-H^+ antiporter system. The absorption of organic anions and bicarbonate in the first part of the proximal tubule results in a relatively high chloride concentration downstream, promoting passive ingress of chloride. This leaves the tubular fluid positively charged relative to blood, further promoting the movement of sodium from the tubular fluid into the cell.

Most NaCl is absorbed transcellularly by a sodium-H^+ and chloride-based antiporter system in the apical cell membrane. The Na-K-ATPase system pumps sodium into the interstitial space, and a potassium-chloride symporter system pumps chloride. The resulting increase in osmolality also draws water across. In all, about two thirds of the filtered water, chloride, and potassium are reabsorbed by the proximal tubule, coupled with, and strongly influenced by, sodium absorption.[12]

The proximal tubule is also an important site of secretion of many endogenous anions (bile salts, urate), cations

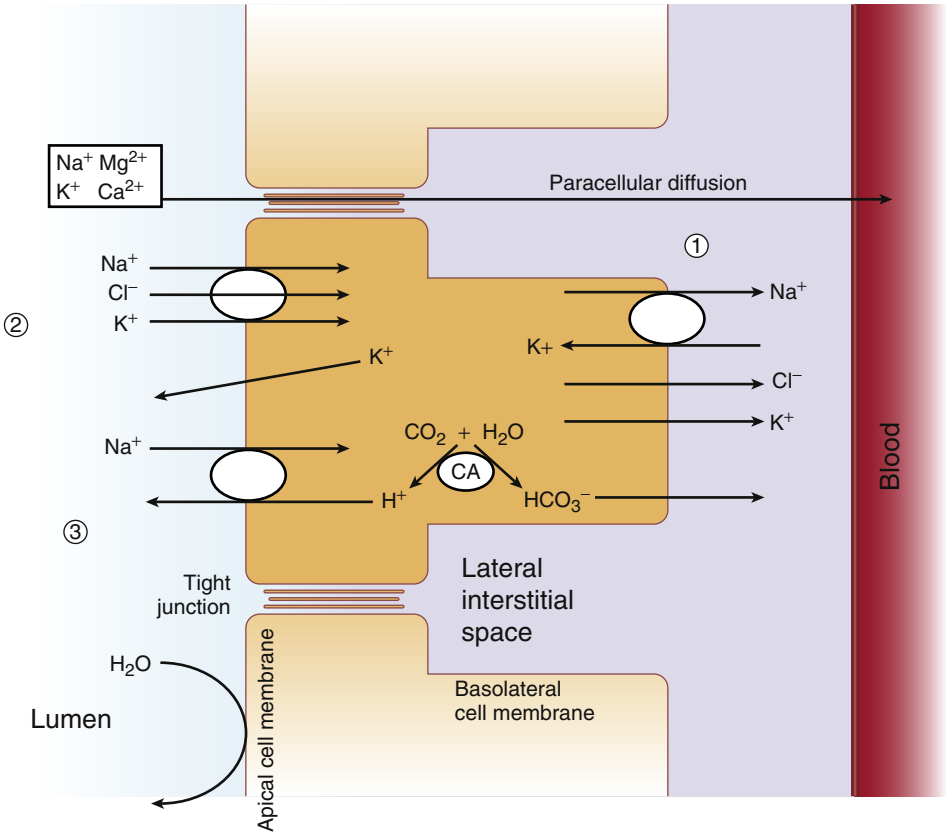

Figure 23-8. Mechanisms of tubular secretion and reabsorption. This tubular cell in the thick ascending loop of Henle encompasses the major mechanisms of secretion and reabsorption, one or more of which is used by various segments of the tubule. The most ubiquitous and important transport mechanism is the energy-requiring Na-K-ATPase pump in the basolateral cell membrane (1), which pumps sodium out into the interstitium against its concentration gradient and maintains a low intracellular concentration. This favors inward movement of sodium from the tubular lumen, facilitated by a sodium chloride symporter system on the apical cell membrane (2), which creates enough potential energy to draw in potassium against its concentration gradient and which is the primary inhibitory site of action of loop diuretics. A sodium-H^+ antiporter system on the apical cell membrane (3) aids sodium reabsorption and extrudes H^+, thereby promoting reaction of water with carbon dioxide to form H^+ and bicarbonate ion under the influence of carbonic anhydrase (CA). Bicarbonate diffuses out into the capillary. Sodium reabsorption is thereby coupled to H^+ loss and bicarbonate reabsorption. The transport proteins create a positive charge in the lumen, which drives ions such as sodium, calcium, potassium, and magnesium passively through the tight junctions by paracellular diffusion. The thick ascending loop of Henle is uniquely highly water-impermeable so that luminal osmolality progressively falls to less than 150 mOsm/kg (the "diluting segment"). *(From Stanton BA, Koeppen BM: Elements of renal function. In Koeppen BM, Stanton BA, editors:* Renal physiology, *ed 4, Philadelphia, 2007, Mosby, pp 677-698.)*

(creatinine, dopamine), and drugs (diuretics, penicillin, probenecid, cimetidine). Organic ions compete with each other for protein transport systems. Thus, administration of probenecid impairs tubular secretion of penicillin and prolongs its action. In chronic renal insufficiency there is an accumulation of organic acids that compete with drugs such as furosemide for secretor proteins, thereby conferring an apparent "resistance" to loop diuretics.

THICK ASCENDING LOOP OF HENLE

The metabolically active component of the loop of Henle is the thick ascending loop, which reabsorbs about 20% of the filtered sodium, chloride, potassium, and bicarbonate. Only the descending loop is permeable to water. In the water-impermeable thick ascending loop, sodium is actively reabsorbed, but water remains. In this so-called diluting segment of the kidney, tubular fluid osmolality decreases to less than 150 mOsm/kg H_2O.

As in the proximal tubule, the Na-K-ATPase pump in the basolateral membrane is the engine that drives the resorptive capacity of the thick ascending loop.[12] Sodium moves from the tubular lumen by passive diffusion along its concentration gradient. A sodium-H^+ antiporter system in the apical cell membrane mediates the net secretion of H^+ and reabsorption of bicarbonate.

An important symporter protein system couples the reabsorption of sodium, chloride, and potassium (the latter against its concentration gradient) across the apical membrane. Blockade of this system is the major site of action of loop diuretics that inhibit NaCl reabsorption in the thick ascending loop of Henle.

OXYGEN BALANCE IN THE MEDULLARY THICK ASCENDING LOOP

The kidneys receive 20% of the total cardiac output but extract relatively little oxygen. The renal arteriovenous oxygen difference (avO_2) is only 1.5 mL/dL. However, there is marked dissimilarity between the renal cortex and medulla with regard to blood flow, oxygen delivery,

and oxygen consumption (Fig. 23-9 and Table 23-1). The medulla receives only 6% of the RBF and has an average oxygen tension (PO_2) of 8 mm Hg. Thus, severe hypoxia could develop in the medulla despite a relatively adequate total RBF; the metabolically active medullary thick ascending loop of Henle (mTAL) is particularly vulnerable.[13]

The mTAL is also a potential site for nephrotoxic injury. Intrarenal blood flow is regulated by endogenous vasoactive compounds. In the outer cortex, at variance to its vasodilator actions elsewhere, adenosine induces vasoconstriction by stimulation of the adenosine A_1 receptor. In the deep juxtamedullary zone, endogenous prostaglandins and nitric oxide promote vasodilation. The net effect is to direct as much available blood flow to the medulla as possible. Drugs that inhibit prostaglandin synthesis, such as nonsteroidal antiinflammatory agents, can upset this compensatory mechanism and result in medullary ischemia.

Stress (e.g., pain, trauma, hemorrhage, hypoperfusion, sepsis, congestive heart failure) activates the sympathoadrenal system and results in renal cortical constriction and potential tubular ischemia. The kidney is relatively devoid of β_2 receptors, so epinephrine release induces predominant vasoconstriction through α receptor or angiotensin activation.

In hemodynamically mediated renal injury, the initial response to renal hypoperfusion is increased active NaCl absorption in the thick ascending limb. This increases oxygen consumption in the face of decreased oxygen delivery. Subsequent sympathoadrenal responses and renal cortical vasoconstriction may be a compensatory attempt to redistribute blood flow to the medulla. Ultimately, ATP stores become depleted and active NaCl reabsorption winds down. This increases the NaCl concentration in tubular fluid reaching the macula densa in the distal tubule, resulting in angiotensin release and afferent arteriolar constriction (i.e., tubuloglomerular feedback). Teleologically, the resultant decrease in GFR benefits renal oxygen balance by decreasing solute reabsorption and oxygen consumption in the medullary thick ascending loop of Henle.[13]

This hypothesis suggests that ischemic or nephrotoxic insults to the renal tubules might be alleviated by the administration of loop diuretics or dopaminergic agents. These drugs inhibit active sodium reabsorption in the thick ascending limb, thereby decreasing oxygen consumption and enhancing tubular oxygen balance. However, clinical trials have thus far been unable to demonstrate that these agents provide significant renoprotection.[14-17]

DISTAL TUBULE AND COLLECTING DUCT

The proximal segment of the distal tubule is structurally and functionally similar to the thick ascending loop. Sodium reabsorption is mediated by an apical cell membrane NaCl symporter system, which is the site of action of thiazide diuretics.[12]

TABLE 23-1 DISTRIBUTION OF RENAL BLOOD FLOW BETWEEN CORTEX AND MEDULLA

	Cortex	Medulla*
Percentage of renal blood flow	94	6
Blood flow (mL/minute/g)	5.0	0.03
PO_2 (mm Hg)	50	8
O_2 extraction ratio (VO_2/DO_2)	0.18	0.79

Data from Brezis M, Rosen S, Epstein F: The pathophysiological implications of medullary hypoxia, Am J Kidney Dis *13:253-258, 1989.*

DO_2, Oxygen delivery; *O_2*, oxygen; *PO_2*, oxygen tension; *VO_2*, oxygen consumption.

*The renal medulla receives only a small fraction of the total renal blood flow, and flow rates are extremely slow. As a result, the tissue oxygen tension is extremely low, and the medulla extracts almost 80% of the oxygen delivered to it. A very mild reduction in total and cortical renal blood flow may therefore induce ischemia and hypoxia in the renal medulla.

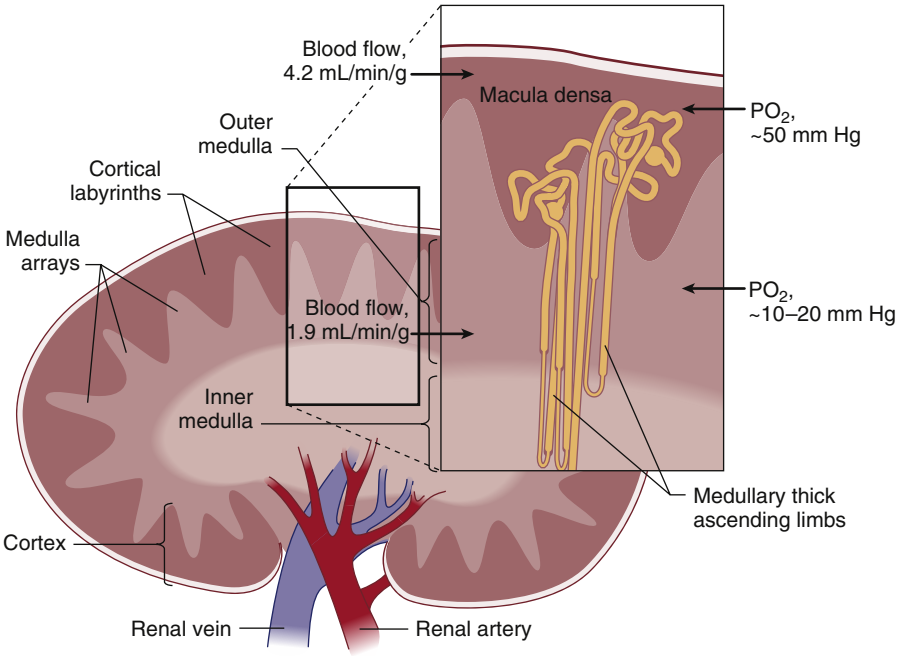

Figure 23-9. Medullary oligemia. To generate and maintain the countercurrent exchange that provides urinary concentrating ability, medullary blood flow must be slow. The juxtamedullary and medullary regions are zones of low blood flow and relative tissue hypoxia. Components of the nephron that have high oxygen consumption such as the medullary thick ascending limb (mTAL) are at high risk of oxygen supply-demand imbalance, and ischemic injury. *(From Brezis M, Rosen S: Hypoxia of the renal medulla—its implications for disease,* N Engl J Med *332:647-655, 1995.)*

The last part of the distal tubule is composed of two types of cells. Principal cells reabsorb sodium and water and secrete potassium via the Na-K-ATPase pump, and intercalated cells secrete H^+ and reabsorb bicarbonate by an H^+-ATPase pump in the apical cell membrane.

REGULATORY MECHANISMS IN SALT AND WATER REABSORPTION

OSMOTIC EQUILIBRIUM

The ability of the kidney to concentrate urine is dependent on the interaction of at least three processes. The first is generation of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling. The second is concentration and then dilution of tubular fluid in the loop of Henle. The third is the action of antidiuretic hormone (now known as arginine vasopressin or AVP) in increasing water permeability in the last part of the distal tubule and collecting ducts.

The medullary interstitium is rendered hypertonic by the countercurrent multiplier effect of the loop of Henle. The primary mechanism is the separation of solute from water (the single effect) by the combination of NaCl reabsorption and water impermeability in the ascending limb. This results in increased NaCl concentration and osmolality in the medullary interstitium. The descending limb is freely permeable to water, which diffuses into the interstitium along the osmotic gradient, and the tubular fluid becomes progressively hyperosmotic at the bend of the loop.

The vasa recta, which are closely applied to the long loops of Henle of juxtamedullary nephrons, maintain this condition by removing water and adding solute as they pass through the medullary interstitium. A standing osmotic gradient is thereby set up among the cortex (300 mOsm/kg), juxtamedullary zone (600 mOsm/kg), and deep medulla (1200 mOsm/kg). This process is enhanced by the passive recycling of urea, which diffuses out of the inner medullary collecting duct into the interstitium and then into the distal loop of Henle. These processes are summarized in Fig. 23-10.

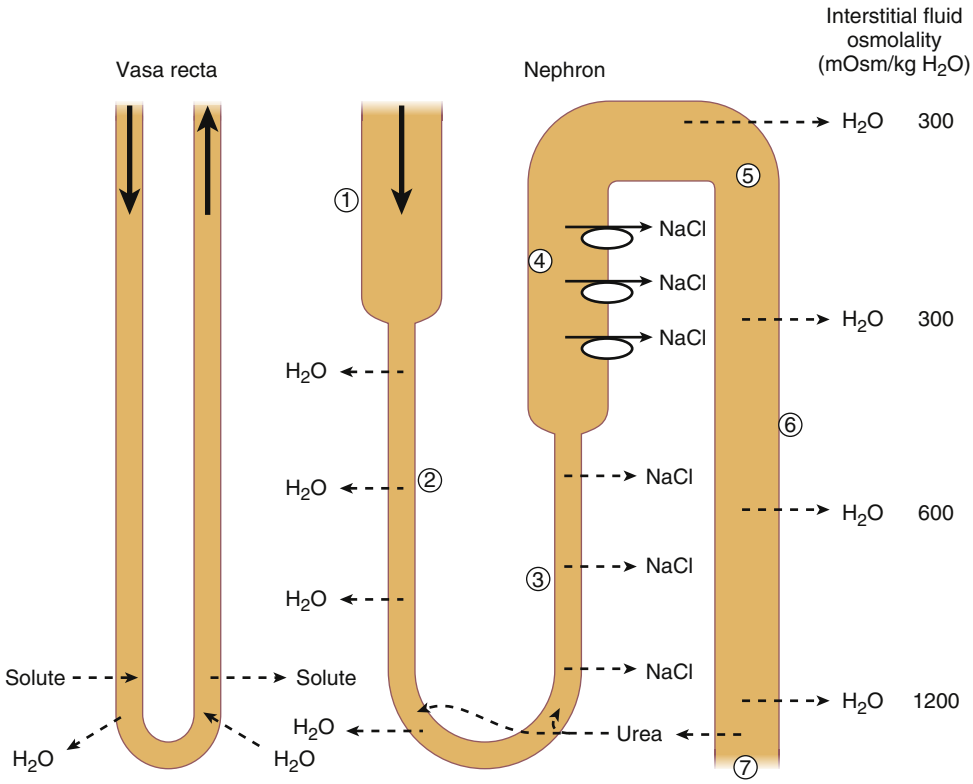

Figure 23-10. Tubular concentration of urine. The juxtamedullary nephrons have long loops of Henle associated with the vasa recta. *Dashed arrows* represent passive movement of fluid or solutes along concentration or osmolar gradients; *solid arrows* represent active transport. (1) Tubular fluid enters the distal proximal tubule iso-osmotic with plasma (300 mOsm/kg). In the descending limb of Henle (2), water rapidly diffuses out into the increasingly hypertonic medulla and is removed by the vasa recta so that the tubular fluid becomes hypertonic, owing largely to concentration of sodium chloride (NaCl). Urea diffuses in from the hypertonic interstitium, further increasing tubular fluid osmolality (1200 mOsm/kg). In the thin ascending loop of Henle (3), NaCl passively diffuses into the interstitium along its concentration gradient, but water is trapped in the water-impermeable tubule, which progressively decreases tubular fluid osmolality. Urea passively diffuses into the tubular fluid (urea recycling). Tubular dilution is accelerated by active reabsorption of NaCl in the thick ascending loop (the diluting segment) and proximal distal tubule (4). The fluid entering the distal tubule is quite hypo-osmotic (100 mOsm/kg). In the collecting segment (5), the osmolality of the tubular fluid returns to that of plasma (300 mOsm/kg), but unlike the contents of the proximal tubule, the solute component consists largely of urea, creatinine, and other excreted compounds. Increased plasma ADH renders the cortical and medullary collecting ducts (6) permeable to water, which passively diffuses into the hypertonic medullary interstitium. Even though some urea diffuses out into the medulla, the maximal osmolality of concentrated urine (7) approaches that of the hypertonic medullary interstitium, about 1200 mOsm/kg. In the absence of ADH, the collecting ducts remain impermeable to water, and the urine is diluted. *(From Stanton BA, Koeppen BM: Control of body fluid osmolality and volume. In Koeppen BM, Stanton BA, editors:* Renal physiology, *ed 4, Philadelphia, 2007, Mosby, pp 715-743.)*

TUBULAR CONCENTRATION AND DILUTION

Hypovolemia

Contraction of the extracellular volume by hypovolemia activates a series of vasoconstrictor, salt-retaining neurohormonal systems: the sympathoadrenal system, the renin-angiotensin-aldosterone axis, and AVP. Initially, the GFR and filtered load of sodium decrease. Sodium reabsorption in the proximal tubule is increased from about 66% to 80% by sympathetic activity and angiotensin II, as well as by the decline in peritubular capillary pressure induced by renal vasoconstriction. Sodium delivery to the thick ascending loop of Henle, distal tubule, and collecting duct is decreased, but aldosterone promotes reabsorption of sodium at these sites. Under the influence of AVP, water is also avidly reabsorbed in the collecting duct so that the urine becomes highly concentrated (osmolality 600 mOsm/kg) but with virtually no sodium (10 mEq/L).

Diuretic drugs abolish the kidney's ability to concentrate urine by washing out the hypertonic medulla. They do this either by an osmotic effect that prevents water reabsorption (e.g., mannitol) or by inhibition of active NaCl transport in the thick ascending loop (e.g., furosemide) or the first part of the distal tubule (e.g., hydrochlorthiazide). An early and important manifestation of acute kidney injury (AKI) is the loss of urinary concentrating ability caused by the breakdown of the energy-requiring Na-K-ATPase pump in the thick ascending loop of Henle.

Hypervolemia

Expansion of the extracellular volume by hypervolemia is countered by a series of vasodilator, salt-excreting neuropeptides, of which atrial, or A-type, natriuretic peptide (ANP) is predominant. The GFR and filtered sodium load increase because of a combination of reflex decreases in sympathetic and angiotensin II activity and the release of ANP. Together with the increase in peritubular capillary hydrostatic pressure, these responses cause sodium reabsorption in the proximal tubule to decrease from 67% to 50%. The decline in plasma aldosterone decreases sodium absorption from the thick ascending loop of Henle to the collecting duct. The presence of ANP and absence of AVP impairs water absorption at the collecting duct so that a dilute urine (osmolality 300 mOsm/kg) with abundant sodium (80 mEq/L) is produced.

It is noteworthy that loop diuretics, which depress tubular resorptive capacity, and acute kidney injury, which may abolish it completely, generate an identical urinary profile (low osmolality, high urinary sodium), even in the presence of hypovolemia.

EVALUATION OF RENAL FUNCTION

CLINICAL MARKERS OF RENAL FUNCTION

Urine Output

The mainstay of the clinical evaluation of renal function remains the measurement of urine output. Oliguria ("little urine") is a relative condition that depends on *expected* urine flow, and it may bear little, if any, relationship to GFR.

Perioperative oliguria is defined as a urine flow rate <0.5 mL/kg/hr, and it is often interpreted as a sign of renal dysfunction. Yet in the perioperative period, oliguria is almost inevitable, whether induced by hypotension, as an appropriate prerenal response to intravascular hypovolemia, or as a manifestation of the physiologic response to surgical stress[18] (see "Neurohormonal Regulation of Renal Function"). When arterial blood pressure and intravascular volume are restored to normal levels, and surgical stress abates postoperatively, the stimulus to the tubules abates and normal urinary flow resumes.

Complete, often abrupt, cessation of urine flow suggests postrenal obstruction. This can occur at the level of the renal pelvis, ureters, bladder, urethra, or urinary catheter. If the obstruction is subtotal, some urine flow may persist, even as AKI progresses.

In the past, acute renal failure was defined on the basis of urinary flow rate—as anuric (zero flow), oliguric (<15 mL/hr), nonoliguric (15 to 80 mL/hr), or polyuric (>80 mL/hr). More recently, urinary flow rate has been combined with changes in serum creatinine to create consensus definitions of AKI known as the RIFLE (risk, injury, failure, loss, end-stage renal disease) criteria[19] and the AKIN (Acute Kidney Injury Network) criteria[20] (Table 23-2). In both definitions, the first three stages of AKI (risk, injury, failure in RIFLE; stages 1, 2, and 3 in AKIN) are categorized on the basis of oliguria (<0.5 or <0.3 mL/kg/hr) of increasing duration.

At the present time, debate continues as to whether prerenal oliguria is an independent, reversible entity, or an early stage (*form fruste*) of AKI. In a study of oliguria as a predictive biomarker of AKI, low urine flow rate was almost inevitably (94% of the time) not a precursor of AKI, and most cases of AKI were not preceded by oliguria[21]. Oliguria was predictive of AKI only when it was associated with hemodynamic instability, which is not included in the RIFLE or AKIN criteria. In contrast, in a prospective observational study of 341 critically ill patients, the incidence of AKI increased from 24% to 52% and was diagnosed earlier when oliguria was added to elevated serum creatinine by the AKIN criteria.[22] The ICU mortality rate was 1.3% for patients without AKI, 8.8% for patients with oliguria without elevated serum creatinine, and 10.4% for patients with oliguria and increased serum

TABLE 23-2 ACUTE KIDNEY INJURY NETWORK (AKIN) DEFINITION

Stage of AKI	Change in SCr	Urine Output
1	>0.3 mg/dL Up to 1.5-2 × baseline	<0.5 mL/kg/hr × 6 hr
2	2-3 × baseline	<0.5 mL/kg/hr × 12 hr
3	>3 × baseline absolute SCr >4.0 mg/dL	<0.3 mL/kg/hr × 12 hr

Data from Mehta RL, Kellum A, Shah SV, et al: Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury, Crit Care *11:R31, 2007.*

AKI, Acute kidney injury; *SCr,* serum creatinine.

creatinine; the mortality rate was higher with increased severity and duration of oliguria.

In sum, perioperative oliguria is a frequent occurrence but almost always is prerenal in nature. On the other hand, the absence of oliguria does not exclude AKI, but its presence implies an increased severity of injury.

Blood Urea Nitrogen

Urea is continuously formed by the metabolism of ammonia in the liver. Hepatic deamination implies the splitting off of amide ($-NH_2$) groups from amino acids and their conversion to ammonia, which enters the arginine cycle and is converted to urea. Urea is a small uncharged molecule that is not protein bound and is rapidly cleared from the blood by glomerular filtration. It subsequently undergoes reabsorption by the tubules so the blood urea nitrogen (BUN) does not correlate directly with GFR.

The normal range of BUN is 5 to 10 mg/dL; given the normal range of serum creatinine (0.5-1.0 mg/dL), the normal ratio of BUN to serum creatinine is about 10:1. An increase in this ratio to 20:1 or higher implies the existence of a prerenal syndrome (prerenal azotemia). However, elevation of BUN out of proportion to decreases in GFR occurs whenever there is increased protein catabolism and formation of urea nitrogen. This scenario occurs with absorption of blood from the GI tract, steroid therapy, major trauma, and sepsis. In contrast, the BUN may be misleadingly low when its production is impaired by severe malnutrition (protein depletion) or severe liver disease (inability to convert ammonia to urea).

Serum Creatinine

Serum creatinine reflects the balance between creatinine production by muscle and creatinine excretion by the kidney, which is dependent on the GFR. Creatinine generation rate varies with muscle mass, physical activity, protein intake, and catabolism. However, when these processes are in equilibrium and renal function is stable, serum creatinine is a useful marker of GFR.

The relationship between serum creatinine and GFR is inverse and exponential. A doubling of the serum creatinine implies a halving of the GFR. An increase in serum creatinine from 0.8 to 1.6 mg/dL may not appear to be serious, but it indicates a 50% decrease in GFR. A much larger increase from 4 to 8 mg/dL also represents a 50% decrease in GFR, but by this time renal insufficiency is well established (Fig. 23-11).

Increases in serum creatinine from baseline are used to define the first three categories of the RIFLE and AKIN criteria for AKI (baseline × 1.5, 2 to 3, and >3 respectively).[19,20] The importance of small increases in serum creatinine are recognized by the AKIN criteria, which define stage 1 AKI by an increase of as little as >0.3 mg/dL. Indeed, there is evidence that this criterion alone predicts outcomes after AKI (hospital length of stay, dialysis, mortality) as accurately as do the full AKIN criteria.[23]

Limitations to Serum Creatinine as a Reflection of GFR. Serum creatinine is usually measured by the Jaffé reaction, a chromogenic assay based on the red color of the creatinine complex with alkaline picrate. It also picks up other normally occurring chromogens, such as glucose, protein, ketones, and ascorbic acid, which represent about 14% of total creatinine when renal function is normal, although substantially less when serum creatinine is elevated. Ketoacidosis, barbiturates, and cephalosporin antibiotics may artifactually increase serum creatinine by as much as 100%, and cimetidine and trimethoprim block its secretion by the tubule. *N*-acetylcysteine, an antioxidant advocated by some as a renoprotective agent in contrast nephropathy,[24] decreases serum creatinine levels, which may in part account for its apparently beneficial effect on renal function.[25]

Because of their nonlinear relationship, serum creatinine does not increase above the normal range until the GFR declines below 50 mL/minute. Large declines in GFR may occur above these levels without a concomitant increase in serum creatinine. The creatinine generation rate is relatively consistent in a given individual, but it varies with muscle mass, rate of catabolism, physical activity, and protein intake.[26] In a cachectic patient with very low muscle mass, creatinine generation may be so feeble that the serum creatinine remains "normal" (<0.9 mg/dL) even in the face of a GFR <25 mL/minute.[27]

The GFR declines progressively and predictably with age, from about 125 mL/minute in a healthy 20-year-old to about 60 mL/minute in an 80-year-old (or a 60-year-old

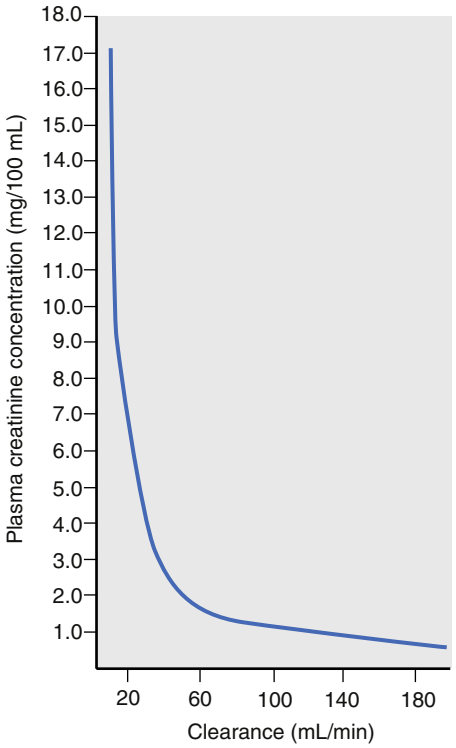

Figure 23-11. Relationship between serum creatinine and GFR. The relationship between serum creatinine and GFR as measured by creatinine clearance is reciprocal and exponential. Doubling of the serum creatinine corresponds to halving of the GFR. Relatively large declines in GFR from normal are associated with small increases in serum creatinine until GFR decreases below 60 mL/minute; further decrements are associated with large increases in serum creatinine. *(From Alfrey AC, Chan L: Chronic renal failure: manifestations and pathogenesis. In Schrier RW, editor:* Renal and electrolyte disorders, *ed 4, Boston, 1992, Little, Brown, p 541.)*

with atherosclerosis[28]) (also see Chapter 80). Because these changes occur at a GFR >50 mL/minute, the impairment induced by aging is not reflected by the serum creatinine. The implication is that a 20-year-old and 80-year-old patient may have an identical serum creatinine within the normal range, but compared with the younger, the older patient has half the GFR and renal reserve.

Creatinine is soluble, freely distributes through the total body water, and is diluted by the 10% to 15% increases in total body water that occur with fluid administration and retention during major surgery. It is not uncommon for serum creatinine to be decreased from baseline on the first postoperative day (e.g. 1.2 to 0.9 mg/dL). Subsequently, when total body water is decreased by fluid mobilization and diuresis, the serum creatinine increases (e.g., from 0.9 to 1.2 mg/dL). This does not necessarily imply AKI, but may simply represent hemoconcentration and a re-equilibration to baseline.

In a steady state the serum creatinine concentration represents an equilibrium between creatinine generation rate, which is dependent on muscle mass and catabolic activity, and creatinine excretion, which is dependent on (and reflective of) the GFR. However, serum creatinine is an unreliable marker of GFR when the GFR is rapidly changing.[26]

This point is lucidly illustrated by an intervention such as suprarenal aortic cross-clamping, which causes instantaneous cessation of renal blood flow, GFR and urinary creatinine excretion. However, measured serum creatinine would still be at baseline and would not detectably increase for several hours. Serum creatinine would then continue to increase as long as creatinine production exceeds creatinine excretion. Because it may take up to 48 hours for the GFR to return to baseline after cross-clamp release, after surgery the serum creatinine may still be increasing, even though the GFR is recovering.[28] In established oliguric acute renal failure, the serum creatinine is directly proportional to the creatinine generation rate, which may vary widely even though the GFR is consistently low.

Cystatin C

There is great interest in defining endogenous plasma markers that provide a more reliable, early indicator of changing GFR, especially in AKI.[29] One that has received prominence is cystatin C, a cysteine-protease inhibitor that is released into the circulation at a constant rate by all nucleated cells. It is completely filtered by the glomerulus and neither secreted nor resorbed by the tubular epithelium, so its serum levels bear a close relationship to serum creatinine and GFR.[30] Unlike creatinine, serum cystatin C is less subject to nonrenal variables such as muscle mass, age, or gender and in certain clinical situations appears to be a more accurate predictor of low GFR than serum creatinine.[31,32] Given the short half-life of cystatin C (approximately 2 hours), it should be anticipated that serum cystatin C will increase more rapidly than serum creatinine after an acute change in GFR. Indeed, evidence suggests that serum cystatin C is superior to creatinine in estimating GFR.[33,34]

However, more recent studies suggest that the relationship between serum cystatin C and GFR is affected by various anthropometric measures, as well as by cigarette smoking, inflammation (elevated C-reactive protein), corticosteroid use, and immunosuppressive therapy.[35,36] As a consequence, cystatin C remains an investigational marker that has not supplemented serum creatinine in clinical practice.

ASSESSMENT OF GLOMERULAR FILTRATION RATE

ESTIMATED GFR

In clinical investigation, serum creatinine-based nomograms derived from population studies are commonly used to calculate estimated GFR (eGFR), thus avoiding the necessity of a timed urine collection.

COCKROFT-GAULT EQUATION

The Cockcroft-Gault Equation utilizes age, weight, serum creatinine, and gender[37]:

$$\text{eGFR in mL/minute} = (140 - \text{age}) \times \text{weight in kg} \div (\text{serum creatinine} \times 72) \quad [2]$$

For females, the result is multiplied by 0.85 to obtain the derived GFR.

In this formula, the body weight that is used may substantially alter the derived GFR. In obese or edematous patients, the total body weight is much greater than the lean body mass from which creatinine is derived, and GFR is overestimated. In cachectic patients with depleted lean body mass, creatinine production is so low that serum creatinine is frequently less than 1.0 mg/dL and overestimates the true GFR. Robert and associates[38] adjusted the Cockroft-Gault Equation to incorporate ideal body weight from a nomogram and serum creatinine corrected to 1.0 mg/dL (if less than 1.0 mg/dL). Using this modification, they found that single measurements in hemodynamically stable patients correlate more closely with inulin clearance than either a 30-minute or a 24-hour creatinine clearance.

MODIFICATION OF DIET IN RENAL DISEASE (MDRD)

This is a complex nomogram based on a study called Modification of Diet in Renal Disease (MDRD)[39] that has the advantage of being independent of body weight:

$$\text{eGFR in mL/minute} = 175 \times \text{serum creatinine}^{-1.154} \times \text{age}^{-0.203} \quad [3]$$

For females, the derived eGFR is multiplied by 0.742, and for black patients, it is multiplied by 1.212.

The MDRD-derived eGFR is the basis of the National Kidney Foundation classification of chronic kidney disease (CKD)[40] (Table 23-3). In a landmark study on 1.2 million adult patients with CKD who did not undergo dialysis or transplantation, there was an exponential increase in

age-standardized rate of death from all causes, cardiovascular events, and hospitalizations with advancing stage of CKD[41] (Table 23-4). In cardiac surgery, the odds ratio for perioperative mortality increases to 1.18, 2.23, and 4.39 for preexisting CKD stages 3, 4, and 5, respectively.[42]

An important caveat is that when renal function is rapidly changing, eGFR based on serum creatinine is subject to the same limitations as serum creatinine itself (see earlier).

RENAL CLEARANCE TECHNIQUES

Clearance is the most commonly used technique to estimate GFR, using compounds that are predominantly filtered by the glomerulus and neither secreted nor reabsorbed by the renal tubules.[43] Based on the Fick principle, the amount of substance *x* excreted by the kidney equals the amount delivered in the arterial supply minus the amount in the venous return:

$$\text{Excretion}_x = \text{delivery}_x - \text{return}_x \quad [4]$$

Therefore,

$$\text{Delivery}_x = \text{return}_x + \text{excretion}_x \quad [5]$$

The amount of substance *x* delivered to the kidney is the product of the arterial plasma concentration (Pa_x) and RBF. The amount returning from the kidney is the product of the venous plasma concentration (Pv_x) and RBF. The urinary excretion rate of substance *x* is the product of its urinary concentration (U_x) and the urine flow rate in milliliters per minute (V). Therefore,

$$(Pa_x \times RBF) = (Pv_x \times RBF) + (U_x \times V) \quad [6]$$

TABLE 23-3 STAGES OF CHRONIC KIDNEY DISEASE

Stage of CKD	eGFR mL/kg/1.73m²	Description
1	>90	Kidney damage with normal GFR
2	60-89	Mildly decreased GFR
3	30-59	Moderately decreased GFR
4	15-29	Severely decreased GFR
5	<15	Kidney failure

Data from Levey AS, Coresh J, Balk E, et al: National Kidney Foundation practice guidelines for chronic kidney disease: evaluation, classification, and stratification, Ann Intern Med *139:137-147, 2003.*

CKD, Chronic kidney disease; *eGFR*, estimated glomerular filtration rate; *GFR*, glomerular filtration rate.

However, in practice, RBF and venous return are not measured. Instead, the removal of substance *x* from the plasma by the kidney is expressed in the concept of clearance. Clearance (C) is defined as the virtual volume of plasma cleared of substance *x* per unit time, in milliliters per minute. This allows the urinary excretion rate of *x* to be equated to its renal arterial plasma concentration:

$$Pa_x \times C = U_x \times V \quad [7]$$

If the assumption is made that the concentration of *x* in renal arterial and venous plasma is identical, the clearance of substance *x* may be calculated using a urine sample, arm venous sample, and measured urinary flow rate:

$$C_x \times = U_x \times Pa_x/V \quad [8]$$

Inulin Clearance

Inulin is an inert polyfructose sugar that is completely filtered by the glomerulus and is neither secreted nor reabsorbed by the renal tubules. The volume in milliliters of plasma cleared of inulin per minute represents the GFR (mL/minute). After an intravenous loading dose of 30 to 50 mg/kg, a continuous infusion of inulin is given to establish a steady-state plasma concentration of 15 to 20 mg/dL. The bladder is usually flushed with air to eliminate any pooled urine. After a carefully timed urine collection (which can be as short as 30 min), urine and plasma inulin concentration (U_{IN}, P_{IN}) are measured, and inulin clearance (C_{IN}) is calculated:

$$GFR = C_{IN} = U_{IN} \times V/P_{IN} \quad [9]$$

Normal values for inulin clearance are 110 to 140 mL/minute/1.73m² (males) and 95 to 125 mL/minute/1.37m² (females).

Although inulin clearance is the gold standard for measurement of GFR, it is seldom used clinically because its accurate measurement is laborious and requires meticulous attention to detail. Large changes in blood glucose during the test may interfere with its measurement. The inulin assay is time consuming, and inulin itself is in short supply because of lack of demand. Thus, although inulin meets all the criteria of an ideal filtration marker, its accuracy in reflecting GFR cannot be directly assessed, only inferred. The predicted variability of inulin clearance is 20% when measurements are compared at two different times in the same individual and 40% when measurements are compared between two individuals.[43]

TABLE 23-4 IMPACT OF STAGE OF CKD ON MORTALITY AND MORBIDITY*

EGFR mL/kg/1.73 m²	Death from All Causes (per 100 person-years)	Cardiovascular Events (per 100 person-years)	Hospitalizations (per 100 person-years)
>60	0.76	2.11	13.54
45-59	1.08	3.65	17.22
30-44	4.76	11.29	45.26
15-29	11.36	21.80	86.75
<15	14.14	36.60	144.61

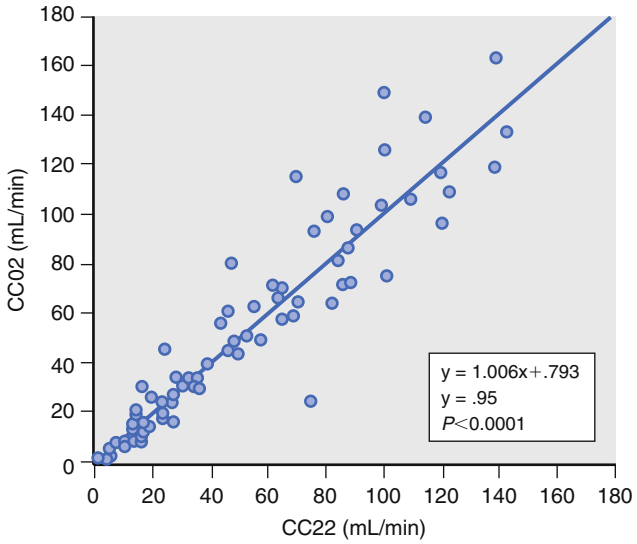

Figure 23-13. Creatinine clearance: 2-hour versus 22-hour values. There is a close and significant correlation in creatinine clearance estimation from a 2-hour and a 22-hour urine collection. *CC02,* 2-hour urine collection; *CC22,* 22-hour urine collection. *(From Sladen RN, Endo E, Harrison T: Two-hour versus 22-hour creatinine clearance in critically ill patients,* Anesthesiology *67:1013-1016, 1987.)*

Sodium iothalamate, a radiocontrast dye, has been substituted for inulin and facilitates accurate assessment of rapid changes in GFR in AKI.[44]

Creatinine Clearance

Creatinine, the endogenous end product of creatine phosphate metabolism, is normally generated from muscle at a very uniform rate and is handled by the kidney in a manner similar to that of inulin (Fig. 23-12). Thus, creatinine clearance (C_{CR}) provides a simple, inexpensive bedside estimate of GFR. A single blood sample is drawn at the midpoint of a carefully timed urine collection, and urine and plasma creatinine (U_{CR}, P_{CR}) and urinary flow rate in mL/minute (V) are used to calculate GFR:

$$GFR = C_{CR} = U_{CR} \times V/P_{CR} \quad [10]$$

The creatinine clearance is far more accurate in tracking rapid alterations in GFR than the serum creatinine alone, because changes in GFR immediately alter the creatinine excretion rate, which is incorporated into the equation above as $U_{CR} \times V$.

Bedside use of creatinine clearance was formerly restricted by the belief that a prolonged (12- to 24-hour) urine collection is necessary to eliminate error induced by residual urine in the bladder neck after spontaneous voiding. This practice is tedious and cumbersome, and it is inaccurate when renal function is rapidly changing. For example, if serum creatinine were to increase from 1 to 2 mg/dL from the beginning to the end of a 24-hour urine collection, clearance calculated on a serum creatinine drawn at the midpoint of the collection would mask the rapid deterioration in true GFR.

The precise timing, not the duration, of the urine collection is the critical issue.[45] If a brisk urine flow is induced by diuresis, and care is taken to empty the bladder, the variability of creatinine clearance is no greater with a 1-hour urine collection than with a 24-hour collection. In catheterized patients with urine flow rates of more than 15 mL/hour, creatinine clearance obtained with a 2-hour urine collection gives values equivalent to those obtained with a 22-hour collection.[46] In the example above, a 2-hour creatinine clearance obtained at the beginning and end of the 24-hour period would truly reflect the halving of GFR represented by a doubling of the serum creatinine from 1 to 2 mg/dL. In critically ill patients, a changing GFR can be closely tracked by serial estimations using a short, carefully timed urine collection (Figs. 23-13 to 23-15). In trauma patients, a 1-hour creatinine clearance of less than 25 mL/minute determined within 6 hours of surgery reliably predicted postoperative acute renal failure, despite the absence of oliguria.[47]

Considerable variation exists in the normal range of creatinine clearance. Tobias and associates[45] reported a variation in creatinine clearance between 88 and 148 mL/minute and in serum creatinine between 0.9 and 1.5 mg/dL in a single healthy individual over 5 years. There is also a diurnal variation, with higher values in the afternoon and a variance of up to 25% around mean values.[48] It is prudent to obtain short-collection creatinine clearance estimations at the same time each day to minimize diurnal variability. "Normal" creatinine clearance is related to body surface area and weight, so values may fluctuate widely in patients with cachexia or edema.

Creatinine clearance has a number of inherent limitations, even if collection error is carefully avoided. First, it is subject to many of the limitations imposed by the

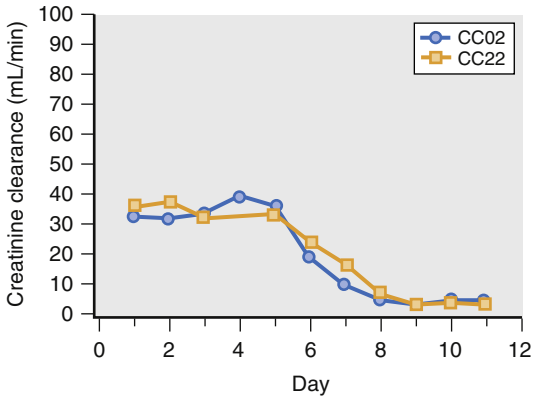

Figure 23-14. New-onset acute renal failure. In a patient developing acute renal failure in the intensive care unit, the exponential decline in creatinine clearance is tracked equally well whether a 2-hour (CC02) or a 22-hour (CC22) urine collection is used. However, data from the 2-hour collection are available well before those from the 22-hour collection.

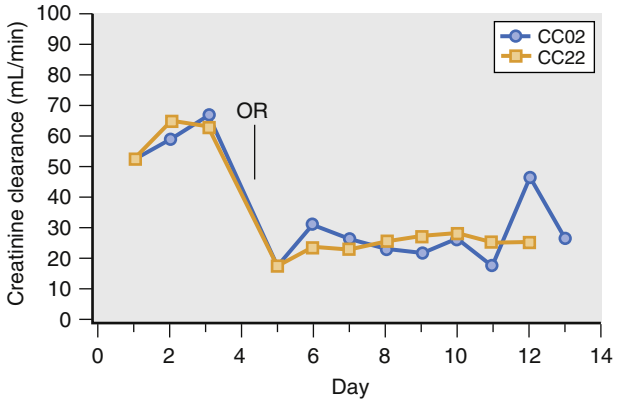

Figure 23-15. Renal revascularization. Patient with renovascular hypertension and renal insufficiency admitted to the intensive care unit for preoperative monitoring and stabilization. Bilateral renal revascularization was performed, and following return from the operating room there was a substantial decline in renal function. These changes were tracked equally well by creatinine clearance derived from a 2-hour (CC02) and a 22-hour (CC22) collection.

measurement of creatinine itself (see earlier). Unlike inulin, about 20% of creatinine is secreted by the proximal tubule, so that creatinine clearance overestimates GFR, and the ratio between the clearance of creatinine and inulin is 1.2:1. As the GFR declines, tubular secretion of creatinine increases. When GFR is less than 40 mL/minute/1.73m^2, a creatinine-to-inulin clearance ratio as high as 1.81 to 2.51 may be achieved.[49] In patients with normal renal function, the underestimate of GFR induced by the Jaffé reaction is balanced by the overestimate of GFR induced by tubular creatinine secretion, and creatinine clearance provides a reasonable representation of GFR. However, widely used drugs such as trimethoprim, H_2-antagonists, and salicylates block tubular secretion of creatinine and may elevate serum creatinine and decrease creatinine clearance. When serum levels of creatinine are very high, it is excreted into the gut and undergoes extrarenal metabolism by intestinal organisms.

Given these constraints, an isolated creatinine clearance estimation may not reveal early renal dysfunction. Nonetheless, serial estimations of creatinine clearance provide a useful clinical guide to alterations in renal function and prognosis. A preoperative creatinine clearance can provide a baseline for comparison with postoperative changes and also give a more accurate measure of effective renal reserve. Postoperatively, daily measurement of creatinine clearance is useful in guiding the dosing of renally excreted, potentially nephrotoxic aminoglycoside antibiotics (gentamicin, tobramycin, amikacin) or calcineurin antagonists (cyclosporine A, tacrolimus). Because the GFR may decline to less than 50% of normal before serum creatinine increases above the normal range, an observed decrease in creatinine clearance may allow down-adjustment of drug dosing before nephrotoxicity becomes established and the drug accumulates even further.

The variability of creatinine clearance diminishes as GFR declines; in fact, loss of variability is a clue to deteriorating renal function. If the GFR is rapidly declining, the creatinine clearance alerts the physician earlier and more compellingly than the serum creatinine because it reflects creatinine excretion rate (i.e., urine creatinine content times urine flow rate [$U_{CR} \times V$]). Directional changes between creatinine clearance and inulin clearance show good agreement.[49] At low levels of GFR a creatinine-to-inulin clearance ratio as high as 2:1 (e.g., 12 versus 6 mL/minute) would induce little actual difference in clinical management.

PLASMA CLEARANCE

Measurement of the rate of disappearance (plasma clearance) of a substance that is completely eliminated by glomerular filtration is an alternate method for measuring GFR without the need for a simultaneous urine collection. It involves an intravenous bolus dose and/or infusion of the marker, followed by measurement of multiple plasma levels to calculate its disappearance rate. The methodology does depend on the achievement of a steady-state plasma concentration of the marker, which is difficult to achieve with rapid changes in GFR.[44]

Numerous markers are used, including nonradioactive inulin and iothalamate, as well as radioisotopes such as Cr^{51}-ethylenediaminetetraacetic acid (EDTA), Tc^{99m}-diethylenetriaminepentaacetic acid (DTPA), and ^{125}I-iothalamate. The radioisotopes, which utilize measurement of decay in radiation, have shown promise in the rapid assessment of GFR.

TUBULAR FUNCTION TESTS

Tests of renal tubular function measure urinary concentrating ability, sodium handling, and urea handling. As such, they can potentially distinguish oliguria due to dehydration (prerenal syndrome) from that due to tubular injury (acute tubular necrosis).

In prerenal oliguria, tubular function is not only preserved but also activated to retain salt and water, resulting in concentrated urine that is low in sodium. With the exception of refractory prerenal states such as severe sepsis and end-stage liver failure (see later), restoration of

a normal hemodynamic status reverses oliguria and tubular activation. The administration of potent diuretics may override tubular conservation, resulting in dilute urine that is high in sodium (natriuresis), a profile that mimics that of acute tubular necrosis (see later). In this situation, analysis of urea handling is a more reliable indicator of a prerenal state. However, if intravascular hypovolemia is sufficiently severe, tubular sodium retention and low urinary sodium may persist despite the administration of diuretics such as small-dose dopamine.[50]

In established acute tubular necrosis, concentrating ability and sodium conservation are lost, resulting in dilute urine with high sodium that is not reversed by restoration of normal renal blood flow. However, in nonoliguric renal failure, which accounts for as much as 75% of cases of acute tubular necrosis encountered clinically,[51] the changes in tubular function are less distinct from those of the prerenal syndrome.

URINARY CONCENTRATING ABILITY

Concentrating ability is a very sensitive barometer of tubular function. In prerenal states, urinary osmolar concentration is markedly increased. In acute tubular necrosis, the ability to concentrate urine may be lost 24 to 48 hours before serum creatinine or BUN starts to increase.

Urine-to-Plasma Osmolar Ratio

The normal tubular response to dehydration or hypovolemia is to concentrate the urine and increase urine osmolality above 450 mOs/kg, compared with a normal serum or plasma osmolality of 280 to 300 mOs/kg. Thus, a prerenal syndrome is indicated by a urine-to-plasma osmolar ratio ($U:P_{OSM}$) of greater than 1.5. Loss of concentrating ability, or isosthenuria ($U:P_{OSM} = 1.0$), in the presence of oliguria implies tubular damage and established acute renal failure. However, isosthenuria can be induced in a prerenal state when diuretics are administered (see earlier).

Free Water Clearance

Free water clearance (C_{H_2O}) is a measure of renal water regulation by tubular dilution or concentration of urine. In essence, free water is cleared by the tubules in response to hypervolemia ("positive free water clearance"), or retained in response to hypovolemia ("negative free water clearance"). The kidney's capacity for water regulation is enormous, and daily C_{H_2O} can vary from 18L positive to 8L negative.[52]

C_{H_2O} is calculated by distinguishing the renal clearance of solute from that of free water. The solute or osmolar clearance (C_{OSM}) is calculated by standard methods, using urine osmolality in mOs/kg (U_{OSM}), plasma osmolality in mOs/kg (P_{OSM}), and urine flow in mL/minute (V):

$$C_{OSM} = (U_{OSM} \bullet V) / P_{OSM} \text{ mL/minute} \quad [11]$$

Then the osmolar clearance is subtracted from the urine flow rate to give free water clearance:

$$CH_2O = V - C_{OSM} \text{ mL/minute} \quad [12]$$

This implies that when urine is dilute and flow is more rapid than osmolar clearance, C_{H_2O} is positive and when urine is concentrated and flow is less than osmolar clearance, C_{H_2O} is negative. Negative free water clearance (i.e., free water retention), also known as tubular conservation of water (TC_{H_2O}), represents the volume of fluid that would have to be added to the urine to make its osmolality equivalent to that of plasma.[52]

With the onset of acute tubular necrosis and loss of concentrating ability, the urine becomes isosmotic and C_{H_2O} approaches zero (±0.25 mL/minute). However, in distinguishing between prerenal and intrarenal oliguria, C_{H_2O} does not really provide any more information about concentrating ability than $U:P_{OSM}$, and in addition, it requires a timed urine collection.

WATER CONSERVATION

Urine-to-Plasma Creatinine Ratio

The urine-to-plasma creatinine ratio ($U:P_{CR}$) represents the proportion of water filtered by the glomerulus that is abstracted by the entire tubule. Normally, about 98% of water is abstracted, and urine creatinine is much greater than plasma creatinine. The ratio can increase 100-fold in severe prerenal states. When tubular function is lost, the ratio declines to less than 20:1.

For example, assume that two patients have oliguria with a serum creatinine elevated to 2.0 mg/dL. In patient A, the urine creatinine is 100 mg/dL, and in patient B, it is 20 mg/dL. Patient A likely has a prerenal state, because tubular water abstraction is high (U:P creatinine = 50:1), whereas patient B likely has acute tubular necrosis, because tubular water abstraction is impaired (U:P creatinine = 10:1).

SODIUM AND UREA CONSERVATION

Urine Sodium

Dehydration or hypovolemia markedly stimulates tubular sodium reabsorption at the mTAL and distal tubule. In the prerenal syndrome, oliguria is characterized by very low urine sodium (U_{Na}), less than 20 mEq/L. Typically, this response is reversed by restoration of intravascular volume. However, in two situations, severe sepsis and the hepatorenal syndrome of liver failure, refractory oliguria with low urine sodium persists despite aggressive fluid resuscitation. The pathogenesis is multifactorial, but common to both syndromes is endotoxemia, which induces renal vasoconstriction and avid tubular sodium reabsorption.

In established acute renal failure, the tubular ability to conserve sodium and protect the intravascular volume is lost, and urine sodium exceeds 60 to 80 mEq/L. Note that after recent diuretic therapy, a high urine sodium cannot be interpreted as tubular injury, but a persistently low urine sodium implies the existence of an intense prerenal state (see earlier).[50]

Fractional Excretion of Sodium

Fractional excretion of sodium (FENa) is an additional means of evaluating tubular responses to hypo- and hypervolemia. FENa expresses sodium clearance as a

percentage of creatinine clearance. The implication is that in hypovolemia, sodium clearance (and thus FENa) declines to reflect tubular sodium conservation; in hypervolemia, the opposite occurs.

FENa is calculated as follows:

$$\text{FENa} = (\text{sodium clearance/creatinine clearance}) \times 100\,\% \quad [13]$$

Based on the relationship expressed earlier in Equation 7:

$$\text{FENa} = (U_{Na} \bullet V/P_{Na}) / (U_{Cr} \bullet V/P_{Cr}) \times 100\,\% \quad [14]$$

Urine flow rate (V) is identical in the numerator and denominator and thus cancels itself out:

$$\text{FENa} = (U_{Na}/P_{Na}) / (U_{Cr}/P_{Cr}) \times 100\,\% \quad [15]$$

Thus, FE_{Na} may be calculated from a spot sample of blood and urine without requiring a timed urine collection.

During dehydration or hypovolemia, sodium clearance and FENa are decreased to less than 1% of creatinine clearance. When tubular ability to conserve sodium is lost in acute renal failure, FENa increases to more than 3%. However, FENa increases with normal tubular function after diuretic therapy and during postoperative sodium mobilization. Sequential increases in FENa associated with a declining creatinine clearance provide a more reliable indicator of deteriorating renal function than does an isolated high FENa.

Fractional Excretion of Urea Nitrogen

Unlike sodium, handling of urea in the ascending loop of Henle and distal tubule is subject to passive forces, and is little influenced by loop diuretic therapy. Fractional excretion of urinary nitrogen (FE_{UN}) is related to water reabsorption in the proximal tubules, which increases to compensate for impaired renal perfusion in a prerenal state. Urea is also reabsorbed, leading to an increased BUN-to-SCr ratio and decreased FE_{UN}. Perhaps the FE_{UN} is more sensitive and more specific than the FENa in differentiating oliguria due to ATN from a prerenal syndrome, especially in the presence of loop diuretic therapy[53].

The FE_{UN} is calculated identically to FENa:

$$FE_{UN} = (U_{UN}/\text{BUN}) / (U_{Cr}/P_{Cr}) \times 100\,\% \quad [16]$$

where U_{UN} is the urinary urea nitrogen, U_{Cr} is urine creatinine, and P_{Cr} is plasma creatinine. In oliguric patients, a FE_{UN} of less than 35% indicates a prerenal syndrome, whereas a FE_{UN} of 50% to 65% suggests established acute renal failure, even in the presence of loop diuretic therapy.[53]

The major limitation to the FE_{UN} is the concomitant administration of proximal tubule diuretics, such as acetazolamide, and osmotic diuretics, such as mannitol. These agents impair water reabsorption in the proximal tubule and help to decrease FE_{UN} in a prerenal state. Excessive urea production in highly catabolic states may itself induce an osmotic diuresis and render the FE_{UN} inaccurate.

In conclusion, accurate diagnosis of a prerenal state should not be based on one test alone. The FE_{UN} reflects proximal tubule activity, the FENa reflects distal tubule activity, and the $U{:}P_{Cr}$ reflects water abstraction throughout the tubule. In difficult situations, a combination of tests is less likely to be subject to error than is a single estimation.[53]

BIOMARKERS OF RENAL INJURY

In contrast to serum creatinine, which is used as an indirect indicator of renal function or dysfunction (i.e., GFR), biomarkers are molecules or compounds that indicate direct tubular injury. Traditional biomarkers include β_2 microglobulin and *N*-acetyl-β-D-glucosaminidase. Their widely acknowledged limitations in the early and accurate detection of evolving renal injury have fostered an increasing interest in a new generation of biomarkers. Functional genomics and proteomics have created the possibility of identifying potential injury biomarkers with a precision and specificity not previously possible, and numerous candidate biomarkers are currently at various stages of clinical investigation. However, to supplant serum creatinine in clinical practice, new biomarkers of renal injury must reliably identify patients at risk for adverse outcomes across a range of clinical populations – a goal that has not yet been achieved.

B_2-MICROGLOBULIN

β_2-microglobulin is a small protein component of the major histocompatibility complex that is present on the surface of almost all cells. It is normally filtered by the glomerulus and then undergoes partial tubular reabsorption. The ratio of β_2-microglobulin between serum and urine may help distinguish glomerular from tubular injury, although the relationship between increased urinary β_2-microglobulin and subsequent ATN has not been characterized.

In glomerular injury, serum β_2-microglobulin levels increase and urine levels decrease. This assessment has been used as an early sign of rejection in renal transplantation.[54] In primary tubular injury, reabsorption of β_2-microglobulin is impaired, so urinary levels increase and serum levels decline. In a study in which cardiopulmonary bypass (CPB) with pulsatile flow was used, a significant decrease occurred in plasma renin activity but urinary β_2-microglobulin increased on CPB with pulsatile or non-pulsatile flow.[55] The implication is that although pulsatile flow maintains better renal perfusion, it does not prevent a subclinical renal tubular injury.

Urinary *N*-acetyl-*β*-D-glucosaminidase

A lysosomal enzyme, *N*-acetyl-β-D-glucosaminidase (NAG) is found abundantly in proximal tubular epithelial cells and increased urinary concentrations of the tubular enzyme NAG is a well-established method of identifying subclinical tubular injury. Urinary NAG levels, or the ratio of its isoenzymes, have been used in the early detection of rejection in transplant patients and to follow the course of chronic renal disease, such as lupus nephritis.[56] NAG was used extensively through the 1990s as a marker of subclinical tubular injury in association with sevoflurane and compound A exposure during anesthesia. However, a relationship between elevations in urinary NAG and histopathologic changes, increasing serum creatinine, or

adverse clinical outcomes has not been established, and the perioperative interpretation and clinical utility of NAG remains uncertain.[35]

Neutrophil Gelatinase–Associated Lipocalin

Neutrophil gelatinase–associated lipocalin (NGAL) is a small 25-kDA polypeptide expressed in distal tubular cells and collecting ducts, whose mRNA undergoes dramatic up-regulation after ischemic tubular injury.[57] Up-regulation can be detected within minutes of ischemia-reperfusion injury; it increases three- to fourfold within 2 to 3 hours and up to 10,000-fold by 24 hours. NGAL is protease resistant and is readily detected in tiny (nanogram/mL) amounts of urine almost immediately after renal injury, preceding the appearance of NAG and β_2-microglobulin.

Urinary NGAL has been demonstrated to increase significantly within 2 hours of CPB in pediatric or adult patients who subsequently went on to develop a 50% increase in postoperative serum creatinine, whose peak was delayed until 1 to 3 days after surgery.[58,59] However, the diagnostic performance of NGAL for AKI has varied widely and dramatically across clinical studies for reasons that remain unclear. Paradoxically, the very limitations of serum creatinine that have driven the search for better diagnostic measures of renal injury, also render creatinine-based measures of injury an unreliable gold standard by which to compare novel biomarkers.[60] Instead, novel biomarkers must demonstrate both validity and clinical utility for identifying individuals at increased risk for adverse clinical outcomes associated with renal injury.[61] Larger studies confirming a relationship between NGAL and adverse outcomes such as mortality, renal replacement therapy, and increased hospital length are beginning to emerge; these findings support a potential role for urinary NGAL as an early, sensitive, and noninvasive urinary biomarker for ischemic and nephrotoxic renal injury.[62,63]

Interleukin-18 (IL-18)

Synthesized as an inactive 23-kDa precursor by several cell types, including proximal tubular epithelial cells, macrophages, and monocytes, IL-18 is a proinflammatory cytokine.[35,64] Multiple studies demonstrate increased urinary IL-18 levels in association with acute kidney injury.[65-67] However, results have been inconsistent with limited data addressing a relationship with adverse clinical outcomes and its potential role as a diagnostic marker in clinical practice remains uncertain.

Other Candidate Biomarkers

Multiple other potential biomarkers of acute kidney injury have been identified. Liver fatty acid–binding protein (L-FABP), a component of the cytoplasm of proximal tubular cells, binds fatty acids for transport to mitochondria. It is released early into the urine following tubular injury, and there is some evidence that it may be more specific than NGAL.[68] In a study on 85 patients undergoing cardiac surgery, AKI was defined by stage 1 of the AKIN criteria. Urinary L-FABP was increased significantly earlier and to a greater extent than urinary NGAL.[69]

Hepcidin is a peptide hormone produced in the liver that regulates iron homeostasis. Its synthesis appears to be up-regulated by CPB and urinary hepcidin increases in patients with normal renal function. In the presence of AKI, 24-hour urinary hepcidin and hepcidin-to-creatinine ratios decrease and provide high sensitivity and specificity for its diagnosis.[70,71]

The true role of the previously mentioned biomarkers, as well as others such as retinol-binding protein and multiple forms of glutathione-S-transferase, awaits larger multicenter studies to characterize their validity and potential clinical utility. It may be practical to consider a panel of biomarkers that together define the course of AKI over time (Fig. 23-16).

At this point in time, an increased serum creatinine concentration, despite all the limitations enumerated earlier, remains the gold standard in the definition of AKI that is consistently and reliably associated with adverse clinical outcomes.[72-75] An emerging approach is the integration of serum creatinine (an indicator of renal function) with biomarkers (evidence of tubular injury). Thus, patients may be classified as having no evidence of injury and intact function (i.e., normal), evidence of injury but intact function (early AKI), loss of function without evidence of injury (CKD), or evidence of injury and loss of function (established AKI).

RENAL HEMODYNAMICS

RENAL PLASMA FLOW AND RENAL BLOOD FLOW

It is impractical to place renal flow probes in patients, so renal plasma flow (RPF) and renal blood flow (RBF) are most often measured indirectly by clearance techniques.

Para-Aminohippurate Clearance

Para-aminohippurate (PAH) is an organic anion filtered by the glomerulus, secreted by the tubule, and almost completely cleared from the plasma in a single pass through the kidney. Thus, clearance of PAH (C_{PAH}) represents RPF.

Like inulin clearance, the test is laborious and requires intravenous and urinary catheters. A PAH infusion is set up to maintain a steady-state PAH concentration of about 2 mg/dL, together with a carefully timed catheter urine collection[43]. Because 10% of the RPF bypasses the peritubular capillaries, C_{PAH} underestimates the true RPF, and is referred to as effective RPF.

$$\text{Effective RPF} = C_{PAH} = U_{PAH} \times V/P_{PAH} \quad [17]$$

In young healthy adults, effective RPF is 660 mL/minute/1.73 m^2.

Effective RBF may be derived if the hematocrit level (Hct) is known and expressed as a decimal (i.e., 35% = 0.35):

$$\text{Effective RBF} = \text{Effective RPF}/1 - \text{Hct} \quad [18]$$

As an example, if effective RPF is 600 mL/minute and Hct is 30% (0.3), effective RBF is 600 ÷ 0.7, or 860 mL/minute.

Unfortunately, C_{PAH} is an unreliable indicator of RPF during surgical stress, because hypovolemia and oliguria induce sequestration of PAH in the kidney. Ironically, the

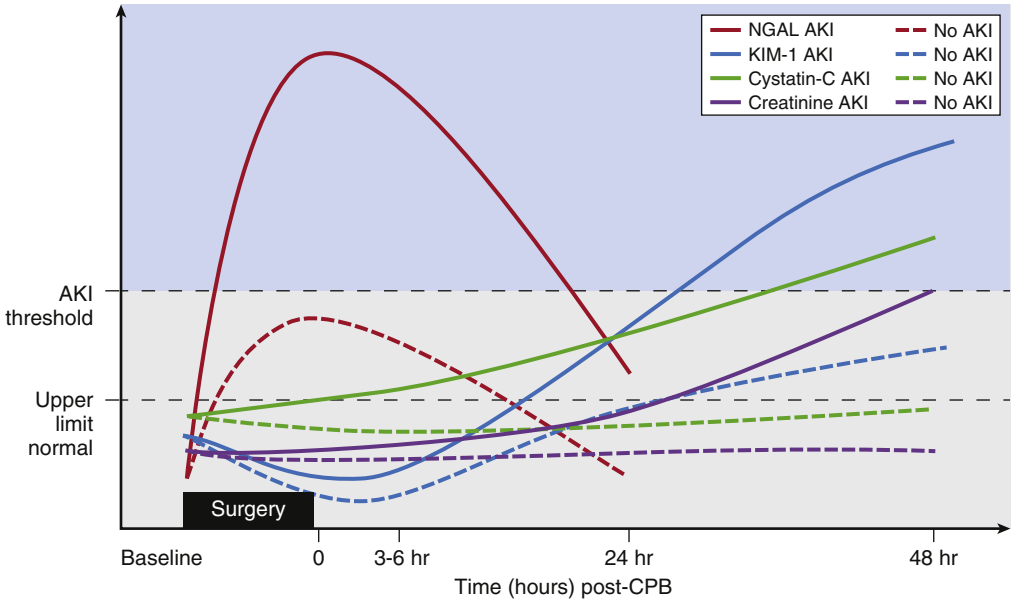

Figure 23-16. Renal biomarkers. Schematic representation of the possible time course of change in biomarker levels for the detection of acute kidney injury (AKI) after cardiac surgery in adults. Patterns of change represent ideal circumstances, which have not been consistently demonstrated in clinical studies. *AKI*, Acute kidney injury; *CPB*, cardiopulmonary bypass; creatinine, serum creatinine; *cystatin-C*, serum cystatin-C; *KIM-1*, urinary kidney injury molecule-1; *NGAL*, urinary neutrophil gelatinase–associated lipocalin. *(Modified from McIlroy D, Wagener G, Lee, HT: Biomarkers of acute kidney injury: an evolving domain,* Anesthesiology *112:998-1004, 2010.)*

most important limitation of C_{PAH} is acute kidney injury, because about 80% of PAH is cleared by tubular secretion. In the presence of proximal tubular injury, PAH secretion declines and C_{PAH} underestimates RPF.[76]

These errors can be overcome if renal vein sampling is accessible (e.g., during major abdominal vascular surgery). Measurement of the difference between arterial and renal vein PAH allows calculation of the renal extraction of PAH (E_{PAH}), an index of proximal tubular function:

$$E_{PAH} = \text{arterial PAH} - \text{renal vein PAH/arterial PAH} \quad [19]$$

When renal function is normal, renal vein PAH is close to zero and E_{PAH} approaches 100% (1.0). With worsening proximal tubular function, renal vein PAH concentration progressively increases and E_{PAH} progressively declines.

True RPF is calculated by dividing PAH clearance by PAH extraction:

$$RPF = C_{PAH}/E_{PAH} \quad [20]$$

In the presence of hypovolemia and oliguria, PAH is sequestered in the kidney. Even with the use of extraction techniques PAH clearance may misrepresent renal plasma flow under these conditions. Despite its relative convenience as an experimental tool, PAH clearance may be an unreliable indicator of RBF during the perturbations induced by anesthesia and surgical stress.

Filtration Fraction

The fraction of the RPF that is filtered by the glomerulus is called the filtration fraction (FF) and can be measured indirectly via the C_{PAH} and C_{IN}:

$$FF = GFR/RPF = C_{IN}/C_{PAH} \quad [21]$$

Normally, GFR is about 125 mL/minute and RPF is about 660 mL/minute, so the filtration fraction approximates 125/660, or about 0.2. Changes in filtration fraction are considered to represent changes in periglomerular arteriolar tone (see "Afferent and Efferent Arteriolar Control Mechanisms"). An increase in filtration fraction indicates that GFR is increased relative to RPF. This could be achieved by efferent arteriolar constriction or afferent arteriolar dilation and maintains glomerular filtration pressure in the face of decreased RPF. Conversely, a decrease in filtration fraction implies that GFR is decreased relative to RPF by afferent arteriolar constriction or efferent arteriolar dilation.

Total Renal Blood Flow

Real-time measurement of RBF is technically challenging and generally confined to the laboratory unless there is direct access to the renal arteries during surgery.

Flow Probes. Electromagnetic flow probes create a magnetic field around the circumference of the vessel that is disrupted by blood flow, and a voltage output proportional to blood velocity is generated.

Ultrasonic flow probes transmit high-frequency sound across the lumen of the vessel. A shift in sound frequency (Doppler effect) is created by the movement of blood and is proportional to blood velocity.

$$\text{Flow (mL/minute)} = \text{Blood velocity (cm/minute)} \times \text{Area of vessel } \left(\text{cm}^2\right) \quad [22]$$

Flow-probe placement is invasive and requires direct surgical exposure of the renal arteries. Probes must be calibrated in vitro before and after measurements. However, they are generally very accurate.

Investigational Methods of Measuring RBF. Numerous investigational methods have been or are being developed

to attempt to measure RBF. Some, such as thermodilution via direct renal vein cannulation, have been confined to animal studies.[77,78] Contrast ultrasonography with sonicated albumin microspheres has been used to measure RBF in animal studies.[79] More recently, this technique, utilizing microbubbles, has successfully measured RBF in healthy volunteers, and may lend itself to studies in patients.[80]

Transesophageal echocardiography (TEE) has been used to quantitate RBF in children and shows a high correlation with transabdominal ultrasonography.[81] Although this is more technically difficult in adults, the left renal artery can be visualized and interrogated by TEE.[82]

Positron emission tomography (PET) has been used to measure acute changes in RBF in patients with chronic renal failure using oxygen 15-radiolabeled water.[83]

Magnetic resonance imaging (MRI) shows some promise in the real-time, noninvasive assessment of RBF. Ungated spiral phase-contrast MRI is able to measure RBF within 6 seconds.[84] Cine phase–contrast magnetic resonance imaging (CPC-MRI) has been successfully used to assess renal blood flow as a fraction of cardiac output in septic patients with established dialysis-dependent AKI.[85] All metallic devices have to be removed before physical transport to an MRI suite, but this noninvasive approach does provide promise in the elucidation of changes in RBF under physiologic or pathologic conditions in patients.

NEUROHORMONAL REGULATION OF RENAL FUNCTION

The role of the kidney in controlling the interior milieu is modulated by a complex set of interactions. Two mutually dependent but opposing neurohormonal systems maintain blood pressure, intravascular volume, and salt and water homeostasis (Fig. 23-17). The sympathoadrenal axis, the renin-angiotensin-aldosterone system, and AVP defend against hypotension and hypovolemia by promoting vasoconstriction and salt and water retention. The prostaglandins and natriuretic peptides defend against hypertension and hypervolemia by promoting vasodilation and salt and water excretion (Fig. 23-18).

Anesthesia does not perturb these systems to any substantial degree. In the intact organism, anesthetics affect renal function through extrarenal circulatory changes, rather than by their direct actions on the kidney.[86] Surgical or traumatic injury, on the other hand, induces profound vasoconstriction and salt and water retention, which may persist for several days. The clinical sequel is postoperative oliguria and edema. Renal vasoconstriction also predisposes the kidney to further perioperative ischemic and nephrotoxic insults. Release of endogenous natriuretic peptides by atrial and ventricular stretch reinforces the notion that renal vasoconstriction can be prevented or modified by maintenance of normal or increased intravascular volume.

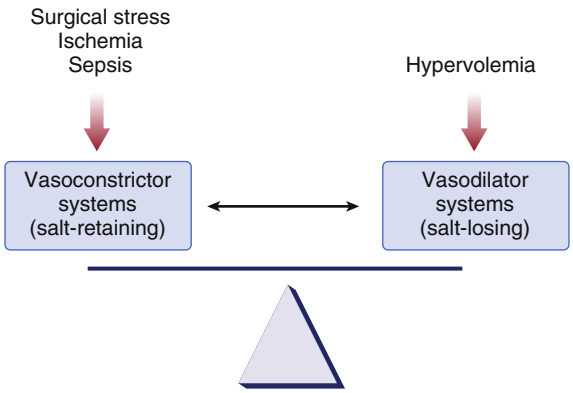

Figure 23-17. Neurohormonal regulation of renal function. Normally, there is a balance between those systems promoting renal vasoconstriction and sodium retention versus those systems promoting renal vasodilation and sodium excretion. Surgical stress, ischemia, and sepsis tip the balance in favor of vasoconstriction and sodium retention. On the other hand, hypervolemia (or the induction of atrial stretch) tips the balance in favor of vasodilation and sodium excretion.

SYSTEMS PROMOTING VASOCONSTRICTION AND SALT RETENTION

THE SYMPATHOADRENAL AXIS

Sympathetic effects on the kidney are mediated by circulating epinephrine and neuronal release of norepinephrine. The renal cortex has a dense plexus of autonomic nerve fibers derived from the T12 to L4 spinal segments via the celiac plexus. The primary stimulus to the sympathetic response is a decrease in arterial blood pressure sensed by baroreceptors in the aortic arch, carotid sinus, and afferent arteriole. Afferent fibers travel via the vagus nerve and decrease impulse transmission rate to the mediating centers in the hypothalamus, which results in increased adrenergic nerve activity. The kidney does not have any parasympathetic innervation.

A G protein–coupled phospholipase C receptor populates vascular smooth muscle and the mesangium, and it responds to α-adrenergic stimulation by epinephrine and norepinephrine. It also mediates vasoconstriction induced by a variety of other hormones and peptides, including angiotensin II, vasopressin, endothelin, platelet-activating factor, and leukotrienes.[3] The receptor subunit in the cell membrane is coupled through G_q protein

Vasoconstrictor Systems	Vasodilator Systems

↓ RBF ↓ GFR ↓ Urine flow ↓ Na excretion	↑ RBF ↑ GFR ↑ Urine flow ↑ Na excretion

Figure 23-18. Neurohormonal renal regulatory systems. *GFR*, Glomerular filtration rate; *Na*, sodium; *RBF*, renal blood flow; *x*, decreased; *y*, increased. *(Modified from Sladen RN: Effect of anesthesia and surgery on renal function,* Crit Care Clin *3:380, 1987.)*

to phospholipase C, which hydrolyzes phosphatidylinositol biphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). In turn, DAG activates protein kinase, opening up a calcium channel in the membrane, and IP_3 triggers the release of calcium from the sarcoplasmic or endoplasmic reticulum. Both mechanisms result in a rapid increase in intracellular calcium, which binds with calmodulin and thereby activates myosin light-chain kinase, resulting in smooth muscle contraction. The calcium-calmodulin complex simultaneously activates phospholipase A_2, resulting in the production of vasodilator prostaglandins (see later).

Mild α-adrenergic stimulation appears to cause preferential efferent arteriolar constriction, which preserves the filtration fraction. Severe α-adrenergic stimulation causes predominant afferent arteriolar constriction and decreases filtration fraction.[87] Thus, the adrenergic response to a moderate decrease in renal perfusion (e.g., general anesthesia) favors the preservation of the GFR. In contrast, the adrenergic response to shock exacerbates the decrease in GFR already induced by renal hypoperfusion (see Fig. 23-4).

Adrenergic nerves also supply the proximal tubule, thick ascending limb of Henle, and collecting duct, and their stimulation enhances NaCl reabsorption at these sites. Gas tracer studies suggested that sympathetic activation caused sodium retention by intrarenal redistribution of RBF from the outer cortex to salt-retaining juxtamedullary nephrons, but this was not confirmed by microsphere studies.[88,89]

A close relationship exists between sympathetic stimulation and activation of the renin-angiotensin system. Adrenergic stimulation releases renin from the juxtaglomerular apparatus, and adrenergically induced vasoconstriction can be blocked by angiotensin-converting enzyme (ACE) inhibitor drugs such as captopril.

The effects of the administration of exogenous adrenergic drugs depend on their agonist activity. Drugs with predominantly α-adrenergic effects, such as norepinephrine, epinephrine, phenylephrine, and high-dose dopamine (>10 μg/kg/minute) exacerbate the endogenous sympathetic responses to hypotension. Drugs with predominantly β_1- and β_2-adrenergic activity, such as dobutamine or isoproterenol, cause marked increases in cardiac output and thus RBF, but it is difficult to ascertain their intrarenal effects. Dopaminergic agonists (Table 23-5) selectively increase RBF and may oppose α-adrenergic renal vasoconstriction.[78]

TABLE 23-5 DOPAMINE AND ITS ANALOGUES

Receptor	DA_1	DA_2	β_1	β_2	α_1
Dopamine	+++	++	++	±	+++

*Dobutamine, dopexamine, and fenoldopam are all pharmacologic analogues of dopamine. However, dobutamine is devoid of dopaminergic activity, dopexamine has about one third the dopaminergic activity of dopamine, and fenoldopam is a pure, selective dopamine$_1$ receptor agonist.

THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Renin and Angiotensin

The juxtaglomerular apparatus consists of three groups of specialized tissues. In the afferent arteriole, modified fenestrated endothelial cells produce renin; in the juxtaposed distal tubule, cells of the macula densa act as chemoreceptors; and in the glomerulus, mesangial cells have contractile properties (see Fig. 23-3). Together these provide an important regulating system for blood pressure, salt, and water homeostasis.[90]

Renin secretion is stimulated by hypovolemia that may be overt (hemorrhage, diuresis, or sodium loss or restriction) or covert (positive pressure ventilation, congestive heart failure, sepsis, or cirrhosis with ascites). Its release is controlled by several mechanisms. A decrease in renal artery perfusion pressure triggers baroreceptors in the afferent arterioles. Sympathetic nerve stimulation and circulating catecholamines act on β-adrenergic receptors in the afferent arterioles. An increase in chloride concentration in the distal tubular fluid activates the cells of the macula densa, which trigger renin release from the afferent arteriole. This tubuloglomerular feedback appears to play a role in modulating GFR during normal and abnormal renal function through a continuous feedback loop.[4,5]

Renin acts on angiotensinogen, a large circulating glycoprotein released from the liver, and cleaves off a decapeptide, angiotensin I. In the kidney and in the lung, angiotensin I is further cleaved by endothelial-based ACE to form an octapeptide, angiotensin II, which is a potent vasoconstrictor (Fig. 23-19). Renin is the rate-limiting enzyme in the production of angiotensin II[91].

Activation of modest amounts of angiotensin II causes renal cortical vasoconstriction predominantly at the level of the efferent arterioles (see Fig 23-4). This acts to maintain glomerular filtration fraction in the face of mild to moderate decreases in RBF or perfusion pressure. The importance of this protective mechanism is emphasized by the deterioration in GFR that occurs when ACE inhibitors are administered to patients with hypotension, renal insufficiency, or unilateral renal artery stenosis.[92,93] Severe stress induces the release of high levels of angiotensin

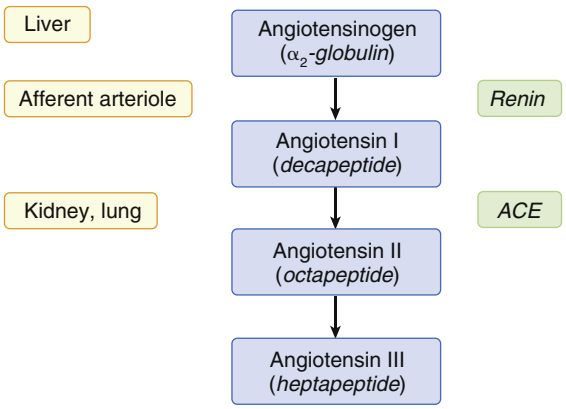

Figure 23-19. Renin-angiotensin system. For explanation, see text. *ACE,* Angiotensin-converting enzyme.

II, which constricts the glomerular mesangial cells and decreases the glomerular filtration fraction. Angiotensin II promotes systemic vasoconstriction at about one tenth of its renal effect. However, systemic arterial pressure and vascular resistance can be markedly decreased by ACE inhibitors (such as captopril, enalapril, or lisinopril) and by angiotensin receptor antagonists such as losartin. The effect of angiotensin II in causing salt and water retention is enhanced by its actions in stimulating aldosterone secretion by the adrenal cortex, AVP secretion by the posterior pituitary, and NaCl reabsorption by the proximal tubule.[90]

Angiotensin II triggers a number of responses that modulate or oppose its own actions. It inhibits renin secretion by a negative feedback mechanism. Blockade of angiotensin formation by ACE inhibitors causes vasodilation but increases plasma renin levels. Angiotensin II activates phospholipase A_2, which triggers the synthesis of intrarenal prostaglandins. Vasodilator prostaglandins modulate the action of angiotensin II and may be responsible for its preferential activity on the efferent arteriole at low plasma levels.[91] Angiotensin-induced vasoconstriction increases atrial pressure and releases ANP, which opposes the renin-angiotensin-aldosterone system.

The consequences of ACE inhibition on renal function depend on the patient's volume status, systemic hemodynamics, and baseline renal perfusion. In the long-term treatment of hypertension and CHF, especially in diabetics, the administration of ACE inhibitors decreases renal vascular resistance and appears to benefit renal function. Short-term pretreatment with captopril may prevent a decrease in RBF and GFR and preserve sodium excretion during cardiopulmonary bypass.[94] However, deterioration in renal function and hyperkalemia have been reported with the use of ACE inhibitors in patients with hypotension, renal insufficiency, or unilateral renal artery stenosis, probably related to the blockade of compensatory angiotensin-mediated efferent arteriolar constriction.[93] It may be prudent to avoid their use when hemodynamics are unstable in the immediate perioperative period.

Aldosterone

Aldosterone is a steroid hormone secreted by the zona glomerulosa of the adrenal cortex in response to hyperkalemia or hyponatremia. Angiotensin II and adrenocorticotropic hormone (ACTH) also trigger its release. It acts at the thick ascending limb of the loop of Henle, the principal cells of the distal tubule, and the collecting duct to increase active absorption of sodium and passive absorption of water, culminating in an expanded blood volume. Sodium retention in vessel walls appears to enhance their response to vasoconstrictor agents.

In contrast to the immediate sympathetic angiotensin II response to hypovolemia, there is a delay of about 1 to 2 hours from the secretion of aldosterone to its action on sodium reabsorption. As illustrated in Fig. 23-20, aldosterone forms a complex with a receptor at the cell membrane in the principal cells of the distal tubule. The aldosterone-receptor complex travels to the cell nucleus, where it induces cytoplasmic transcription of messenger ribonucleic acid (mRNA). This fosters synthesis of proteins that form sodium channels in the apical cell membrane and enhance the Na-K-ATPase pump in the basolateral cell membrane.[95] Sodium is transported from the tubular fluid into the peritubular capillary in exchange for potassium. Long-standing stimulation of aldosterone secretion, characteristically induced by the intravascular volume depletion of chronic ascites, culminates in potassium depletion and hypokalemic alkalosis.

Arginine Vasopressin (AVP)

Arginine vasopressin (AVP), previously known as antidiuretic hormone (ADH), regulates urinary volume and osmolality and controls diuresis and antidiuresis. It is a 9-amino-acid peptide, 8-arginine-vasopressin, which is synthesized in the supraoptic and paraventricular nuclei of the anterior hypothalamus.[95] These nuclei are essentially the cell bodies of neurons whose axons extend down into nerve terminals in the posterior pituitary, together composing the neurohypophysis (Fig. 23-21). When AVP is synthesized, it undergoes neuroaxonal transport to the posterior pituitary gland, where it is stored in granules. Neural stimulation of the cell bodies triggers exocytosis of AVP from the terminal vesicles into the circulation.

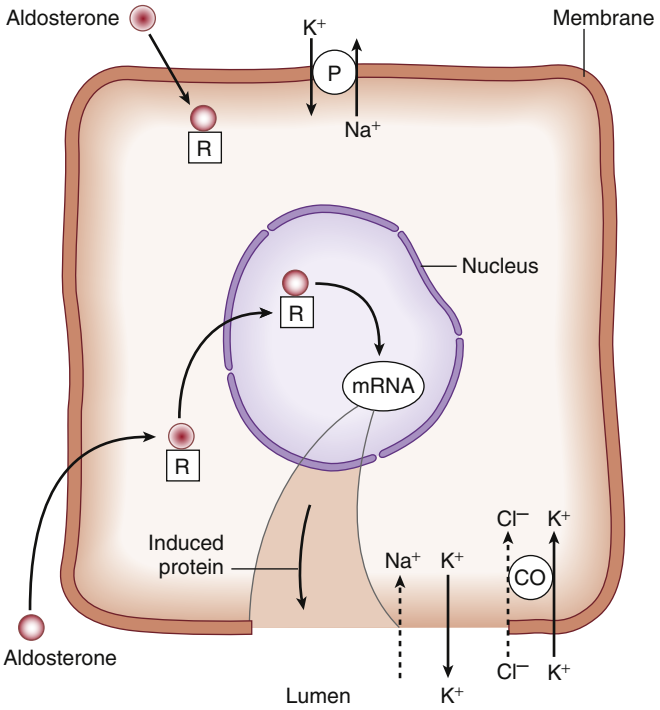

Figure 23-20. Action of aldosterone. Aldosterone enters the distal tubular cytoplasm and attaches to a receptor, then migrates to the nucleus, where it induces the formation of a messenger RNA (mRNA). The mRNA in turn induces the synthesis of a protein that enhances the permeability of the apical (luminal) membrane to sodium and potassium. The reabsorption of sodium stimulates the basolateral membrane Na-K-ATPase pump, the intracellular concentration of potassium rises, and it follows its concentration gradient out into the lumen. The net effect of aldosterone's action is sodium reabsorption and potassium loss. *Cl^-*, Chloride; *CO*, cotransporter (= symporter); *K^+*, potassium; *mRNA*, messenger ribonucleic acid; *Na^+*, sodium; *P*, sodium-potassium ATPase pump; *R*, receptor. *(From Wingard LB, Brody TM, Larner J, Schwartz A: Diuretics: drugs that increase excretion of water and electrolytes. AVP acts on specific V_2 receptors in the collecting ducts to induce water reabsorption and a decreased flow of concentrated urine. It also increases NaCl reabsorption from the thick ascending loop of Henle into the medullary interstitium, which maintains its hypertonicity and facilitates movement of water out of the collecting duct along the osmotic gradient. This results in tubular conservation of water and free water retention (i.e., negative free water clearance). The net effect is that AVP increases urine osmolality and decreases plasma osmolality, without significant alteration in solute excretion.

The V_2 receptor on the basolateral cell membrane of the collecting duct responds to AVP via a receptor mechanism analogous to the β-adrenergic receptor.[95] Through activation of G protein–coupled adenylyl cyclase, ATP is converted to cyclic adenosine monophosphate (cAMP). This in turn activates a protein kinase that causes preformed vesicles containing aquaporin-2 water channels to migrate and fuse with the apical cell membrane. This results in a dramatic increase in membrane permeability to water, which is reabsorbed into the cell and thence into the peritubular capillary. AVP has a short plasma half-life of between 5 and 15 minutes, and this process rapidly reverses as plasma AVP levels decline.

Regulation of AVP Secretion

Hypothalamic osmoreceptors are sensitive to increases in serum osmolality of as little as 1% above normal. As illustrated in Fig. 23-22, *A*, the threshold for AVP secretion (and the sensation of thirst) is between 280 and 290 mOsm/kg. Once this is exceeded, the secretion rate has a very steep gain.[96] Even mild dehydration results in a rapid antidiuresis, and urine osmolality can increase from 300 to 1200 mOs/kg as plasma AVP levels rise from 0 to 5 pg/mL (see Fig. 23-22, *B*).

Decreases in intravascular volume also stimulate AVP secretion, mediated by stretch receptors with vagal afferents in the left atrium and pulmonary veins. Hypovolemia-induced secretion of AVP overrides osmolar responses and contributes to the perioperative syndrome of inappropriate antidiuretic hormone secretion (SIADH): fluid retention, hypo-osmolality, and hyponatremia.[97] The situation is exacerbated by administration of large volumes of hypotonic solutions that decrease serum osmolality. Psychic stress, via cortical input, also induces AVP release and can override osmotic and volume sensors.

By far the most potent trigger for AVP release is systemic arterial hypotension, mediated by aortic and carotid baroreceptors. It overrides all other triggers, and plasma AVP may reach levels 10- to 1000-fold greater than normal (see Fig. 23-22, *C*). At these concentrations AVP acts as a vasoconstrictor, especially in the outer renal cortex. It does so by stimulating the V_{1a} receptor, which exists on vascular smooth muscle, glomerular mesangial cells, and the vasa recta and promotes vasoconstriction via the phosphatidylinositol pathway.[96] AVP maintains effective

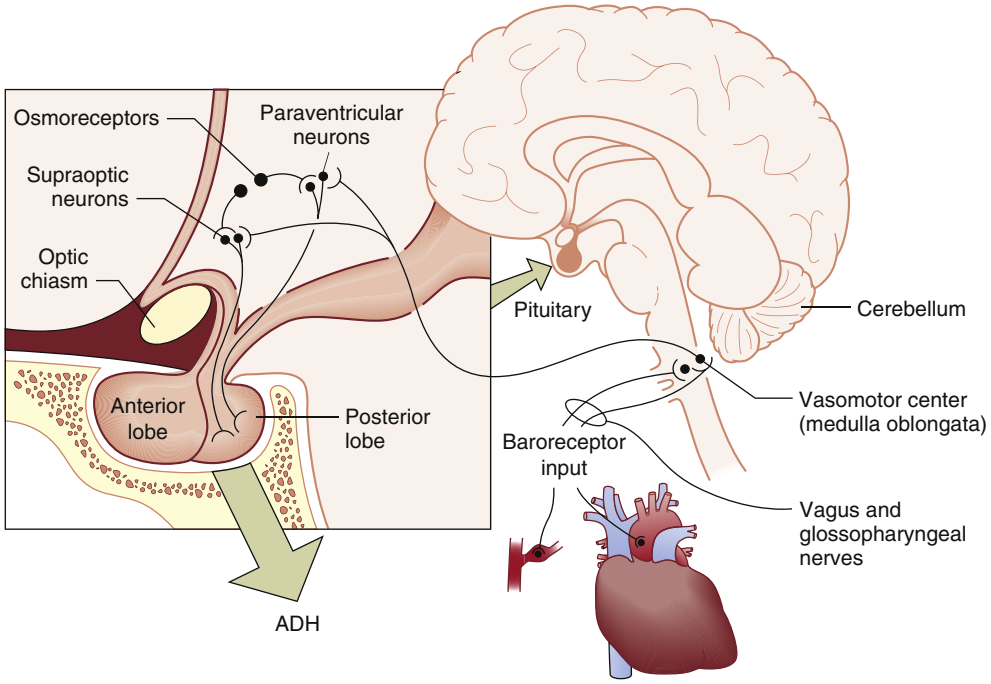

Figure 23-21. Elaboration and synthesis of arginine vasopressin (AVP). *Osmotic control:* An increase in serum osmolality is detected by osmoreceptors in the supraoptic and paraventricular neurons of the hypothalamus. Granules of AVP are elaborated and axonally transported to the posterior lobe of the pituitary gland. From there, they are released into the circulation to reach the V_2 receptors in the distal tubule, where they water retention and restore the serum osmolality. *Hemodynamic control:* Decreases in venous volume are sensed by stretch receptors in the atria and great veins, and decreases in arterial pressure are sensed by baroreceptors in the aortic arch and carotid sinus. The afferent arc is via the vagal and glossopharyngeal nerves to the solitary nucleus in the medulla oblongata (vasomotor center). The efferent arc, from the vasomotor center to the hypothalamic nuclei, induces AVP release. At low levels (<5 pg/mL), AVP stimulation of V_2 receptors may cause inappropriate water retention. At high levels (>20 pg/mL), AVP stimulation of V_{1a} receptors causes vasoconstriction and participates in the baroreceptor reflex. *(From Koeppen BM, Stanton BA: Regulation of body fluid osmolality: regulation of water balance. In Koeppen BM, Stanton BA, editors:* Renal physiology, *ed 4, Philadelphia, 2007, Mosby, pp 71-90.)*

glomerular filtration pressure because it is an extremely potent constrictor of the efferent arteriole, and unlike catecholamines and angiotensin, it has little effect on the afferent arteriole, even at high plasma levels.[98]

Anesthetics have little direct effect on AVP secretion, except via the changes that they induce in arterial blood pressure, venous volume, and serum osmolality. Surgical stimulation is a major stimulus to AVP secretion. This stress response, whether mediated by pain or by intravascular volume changes, is profound and lasts at least 2 to 3 days after the surgical procedure.

SYSTEMS PROMOTING VASODILATION AND SALT EXCRETION

PROSTAGLANDINS AND KININS

Prostaglandins

Intrarenal prostaglandins play an important role in endogenous renal protection, largely by vasodilating juxtamedullary blood vessels and maintaining inner cortical blood flow.[99] Prostaglandins are called autocoids because, unlike true hormones, they are produced in minute amounts and have a local, evanescent action. Because their structure is based on a 20-carbon fatty acid, they are also referred to as eicosanoids, after *eicosa*, the Greek word for the number twenty. The synthesis of intrarenal prostaglandins is summarized in Fig. 23-23.

Phospholipase A_2, which resides in the inner lipid layer of the cell membrane, controls prostaglandin production through its formation of the prime precursor, arachidonic acid. It is stimulated by ischemia and hypotension and also by norepinephrine, angiotensin II, and AVP. Thus, the factors that induce and mediate the stress response simultaneously activate prostaglandins, which defend the kidney against their actions. Cyclooxygenase-1 acts on arachidonic acid to form PGG_2, the precursor of the family of vasodilator prostaglandins that includes PGD_2, PGE_2, and PGI_2 (prostacyclin). They induce vasodilation through activation of cAMP, which blocks distal tubule sodium reabsorption, and they oppose the actions of norepinephrine, angiotensin II, and AVP. Prostaglandins may be particularly important in decreasing the vasoconstrictor activity of angiotensin II on the afferent arteriole and glomerular mesangial cells.[91] Production of prostaglandins promotes renal vasodilation, maintains intrarenal hemodynamics, and enhances sodium and water excretion. The renal vasodilator response to mannitol during hypoperfusion appears to be mediated through prostaglandin activation.[100] At the same time, prostaglandins also stimulate renin secretion so that there is a constant "yin and yang" between the two systems.[101]

Cyclooxygenase-2 forms derivatives of arachidonic acid that induce inflammation and renal vasoconstriction and are important in pathologic states. Thromboxane (TXA_2) is derived from cyclic endoperoxides by the action of thromboxane synthetase. It induces vasoconstriction and platelet aggregation, and in the kidney it causes mesangial cell contraction. This decreases GFR by diminishing the effective glomerular surface area and

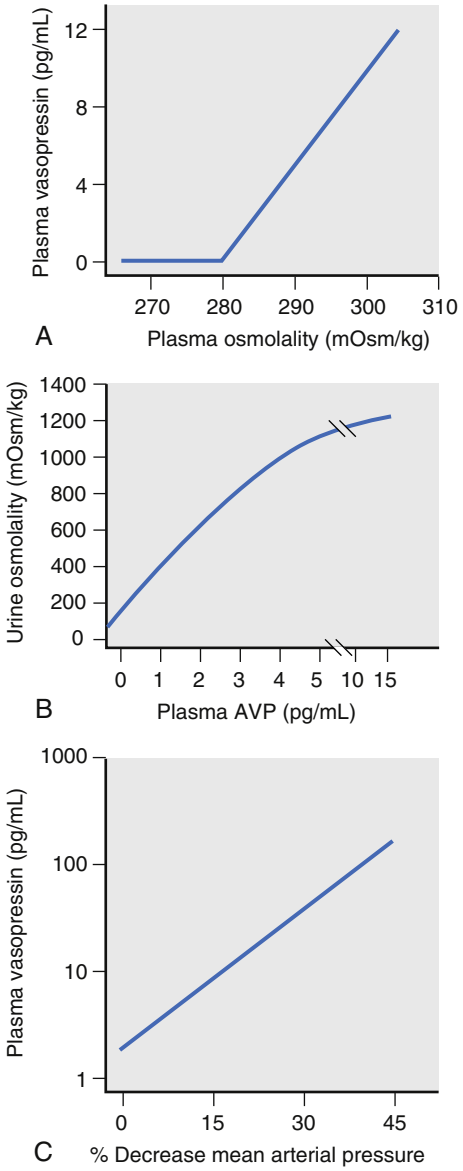

Figure 23-22. A, B, C, Physiologic regulation of arginine vasopressin (AVP). For explanation, see text. *(From Landry DW: Vasopressin deficiency and hypersensitivity in vasodilatory shock: discovery of a new clinical syndrome,* P & S Med Rev *3:3-7, 1996.)*

filtration constant (K_f). Renal levels of thromboxane are increased in experimental acute renal failure and sepsis. In animal experiments, the administration of a specific thromboxane synthetase inhibitor prevents the deterioration in renal function induced by injection of endotoxin.[102] Another vasoconstrictor prostaglandin, PGF_2, which acts on the thromboxane receptor, is formed when arachidonic acid is oxidized by free radicals liberated by leukostasis during acute inflammation. The leukotrienes, arachidonic acid derivatives formed by lipoxygenase, are also released from endotoxin-activated leukocytes. Like thromboxane, leukotrienes C_4 and D_4 induce mesangial cell contraction and decrease GFR.

Kinins

Kinins act as vasodilators that interact with and enhance the actions of prostaglandins, while modulating the

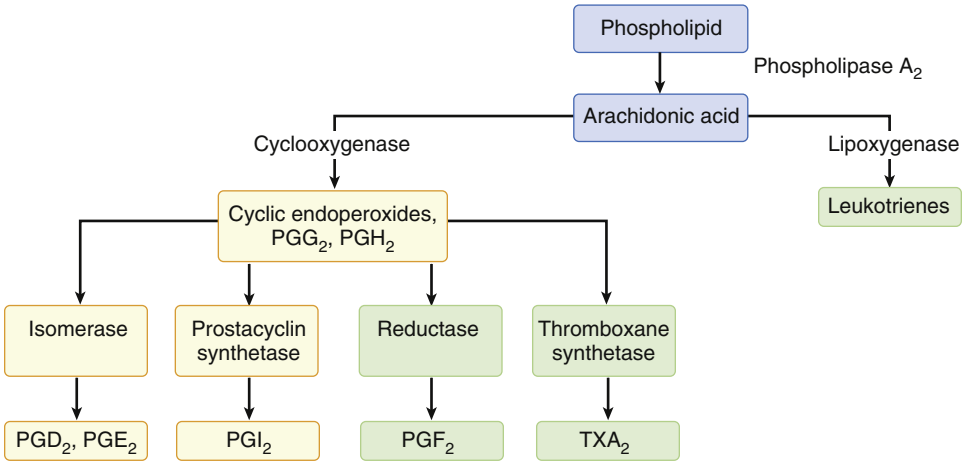

Figure 23-23. Synthesis of renal prostaglandins. Phospholipase A_2 is stimulated by ischemia, norepinephrine, and angiotensin II and cleaves arachidonic acid from its bond with membrane phospholipid. Cyclooxygenase acts on arachidonic acid to form evanescent cyclic endoperoxides (PGG_2 and PGH_2). Actions of isomerase and prostacyclin synthetase culminate in the formation of vasodilator prostaglandins PGD_2, PGE_2, and PGI_2 (prostacyclin), which oppose the actions of the renin-angiotensin system on the kidney and protect against ischemic stress. Inhibition of cyclooxygenase by nonsteroidal antiinflammatory drugs predisposes the kidney to damage. Under hypoxic or ischemic conditions, cyclic endoperoxides undergo reduction to the vasoconstrictor PGF_2, which acts on thromboxane receptors. Endotoxin increases the activity of leukocyte lipoxygenase and thromboxane synthetase. Leukotrienes (especially C_4 and D_4) and thromboxane (TXA_2) induce renal vasoconstriction and contribute to the vasomotor nephropathy of sepsis.

renin-angiotensin system.[103,104] For example, kinins stimulate phospholipase A_2 and prostacyclin formation, as well as endothelial nitric oxide formation. Kininase, which controls intrarenal kinin concentration, is blocked by ACE inhibitors, resulting in increased bradykinin levels. This may be beneficial in diseases such as diabetes and hypertension, because two important intrarenal kinins, bradykinin and kallidin, decrease renal vasoconstriction and sodium retention induced by adrenergic hormones and angiotensin II. On the other hand, it also explains the occasional occurrence of angioedema in patients who take ACE inhibitors.

NATRIURETIC PEPTIDES

The potential role of an endogenous natriuretic hormone was postulated for many years before ANP was identified. In 1972 Gorfinkel and colleagues[105] demonstrated a profound difference in the canine renal response to shock, depending on concomitant atrial pressure. Hypovolemic shock resulted in rapid diminution of RBF to 10% of control, whereas in cardiogenic shock RBF was preserved at 75% of control. The primary difference was that in cardiogenic shock atrial pressures were elevated, suggesting that atrial distention caused the release of a renal protective hormone. In 1981 de Bold and colleagues[106] confirmed the existence of ANP by demonstrating that an extract of atrial tissues caused natriuresis in rats, and the important actions of ANP on renal hemodynamics and sodium excretion were characterized.[107,108]

Subsequently, an entire series of peptides with a similar precursor was identified, with a common 25 to 32 amino acid core. These include ANP (atrial or A-type natriuretic peptide), released from electron-dense granules in atrial myocytes in response to local wall stretch and increased atrial volume; BNP (brain or B-type natriuretic peptide), released from the ventricles when they are distended; CNP (C-type natriuretic peptide) released from the endothelium of major vessels; and urodilatin, a natriuretic peptide produced in the lower urinary tract.[109] Human recombinant analogs have been developed for exogenous administration, including anaritide, derived from ANP, and nesiritide, derived from BNP. All these compounds induce arterial and venous dilation, increase RBF and GFR, and suppress the actions of norepinephrine, angiotensin, and endothelin.[110]

Natriuretic peptides dilate vascular smooth muscle through activation of guanylate cyclase and formation of cyclic guanosine monophosphate (GMP). At the phospholipase C–linked receptor, natriuretic peptides competitively block norepinephrine and noncompetitively block angiotensin II, thus reversing vascular smooth muscle constriction. They cause a prompt, sustained increase in GFR and glomerular filtration fraction, even when RBF is not increased or when arterial pressure is decreased. This suggests that natriuretic peptides promote afferent arteriolar dilation with or without efferent arteriolar constriction. The increased GFR increases the filtered load of sodium, but natriuresis may be due to increased medullary blood flow, which washes out the concentration gradient.

Natriuretic peptides have a mutually antagonistic interaction with endothelin, the endogenous vasoconstrictor peptide produced by vascular endothelium.[91] They oppose the renin-angiotensin-aldosterone system on several fronts (Fig. 23-24). Natriuretic peptides inhibit renin secretion and decrease angiotensin-stimulated aldosterone release. They also inhibit aldosterone release directly at the zona glomerulosa of the adrenal cortex and block the salt-retaining action of aldosterone at the distal tubule and collecting duct. Through cyclic GMP activation, they inhibit NaCl reabsorption at the medullary portion of the collecting duct.[12] Natriuretic peptides also promote diuresis by inhibiting AVP secretion from

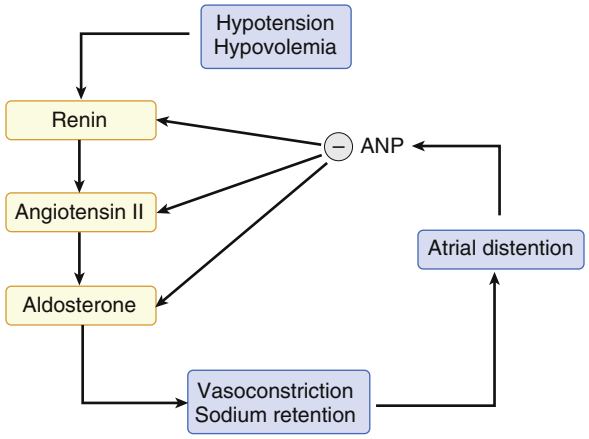

Figure 23-24. Interactions between ANP and the renin-angiotensin-aldosterone system. Hypotension or hypovolemia triggers release of renin from the afferent arteriole, causing the formation of angiotensin II, which stimulates release of aldosterone from the adrenal cortex. Angiotensin II and aldosterone cause vasoconstriction and sodium retention, ultimately resulting in reexpansion of the intravascular volume; this causes atrial distention, which triggers release of ANP. ANP inhibits release of renin, renin's action on angiotensinogen to form angiotensin II, angiotensin-induced vasoconstriction, stimulation of aldosterone secretion by angiotensin II, and the actions of aldosterone on the collecting duct. Thus, the actions of ANP promote vasodilation and sodium excretion. Therapeutic administration of fluids to distend the atrium and release ANP is an important intervention to curtail renal vasoconstriction and sodium retention.

the posterior pituitary and antagonizing its effect on the antidiuretic V_2 receptor in the collecting duct.

The renal protective role of endogenous ANP was elucidated by Shannon and colleagues,[111] who noticed that patients undergoing mitral valve replacement had lower urine output after cardiac surgery than those undergoing aortic valve replacement or coronary revascularization. They discovered that patients whose postoperative mean left atrial pressure declined by more than 7 mm Hg from preoperative values (which commonly occurs with correction of mitral valve disease) had significantly decreased postoperative urine sodium excretion and flow rate. Furthermore, a direct correlation was seen between the quantitative decrease in left atrial pressure and a postoperative decline in circulating ANP levels (Fig. 23-25). In other words, patients with mitral valve disease and high left atrial pressure have a constant stimulus to ANP release. Valve replacement or repair results in decreased left atrial pressure, decreased ANP, and thereby, decreased sodium excretion and urinary flow rate.

The advent of the total artificial heart (TAH), in which the ventricles are resected and replaced by prosthetic pumps, has highlighted the role of BNP in normal urine production. In TAH patients, urine flow declines despite stable hemodynamic status and responds to exogenous infusion of nesiritide.[112] After about 8 weeks, nesiritide can be weaned, suggesting that extraventricular sources of BNP become up-regulated.

THE DOPAMINERGIC SYSTEM

There are at least two subtypes of dopaminergic (DA) receptors.[113] At the end-organ, DA_1 receptors occur not

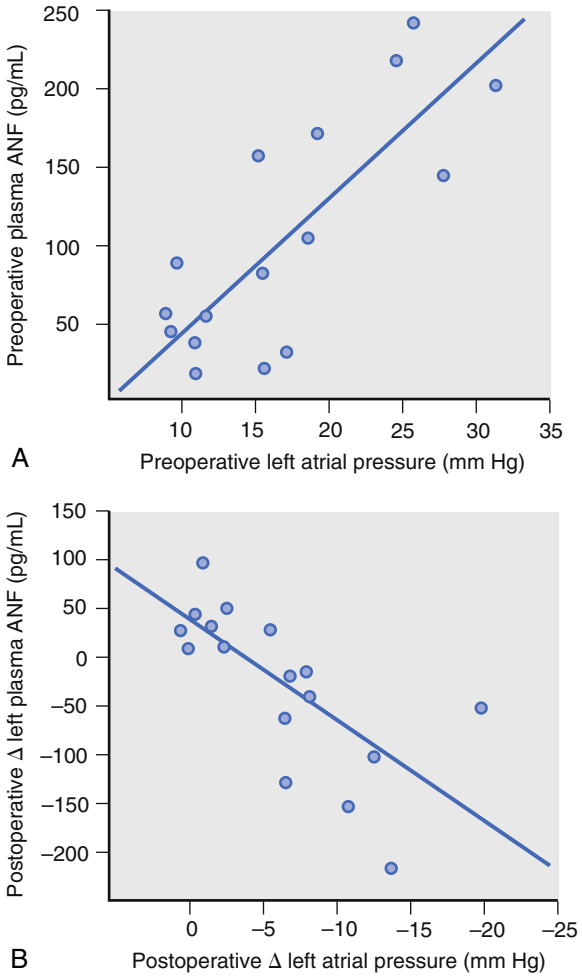

Figure 23-25. Correlation between left atrial pressure and plasma ANP in a group of patients undergoing cardiac surgery. **A,** Significant correlation ($r = 0.8$, $P < .001$) exists between absolute preoperative left atrial pressure and plasma ANP. **B,** Significant correlation ($r = 0.72$, $P < .002$) exists between the postoperative decrease in left atrial pressure and postoperative decrease in plasma ANP, ANF, and atrial natriuretic factor, synonymous with ANP. Δ, Change. *(From Shannon RP, Libby E, Elahi D, et al: Impact of acute reduction in chronically elevated left atrial pressure on sodium and water excretion,* Ann Thorac Surg *46: 430-437, 1988)*

only on the renal and splanchnic vasculature but also on the proximal tubule itself.[114] Stimulation of the DA_1 receptor activates cyclic AMP and induces renal vasodilation, increased RBF and GFR, natriuresis, and diuresis. However, natriuresis can occur independently of increases in RBF and GFR and is abolished by specific D_1 receptor antagonists.[115] In the proximal tubule, dopamine inhibits the sodium-hydrogen antiporter system at the brush-border membrane. In the mTAL, it also inhibits the Na-K-ATPase pump at the basolateral membrane.[115]

Neuronal DA_2 receptors exist on the presynaptic terminal of postganglionic sympathetic nerves. Stimulation inhibits the release of norepinephrine from presynaptic vesicles, a mechanism analogous to stimulation of the presynaptic α_2 receptor. Through inhibition of norepinephrine, DA_2-receptor activation facilitates vasodilation.

The dopaminergic system plays an integral role in the endogenous vasodilator-natriuresis system and the

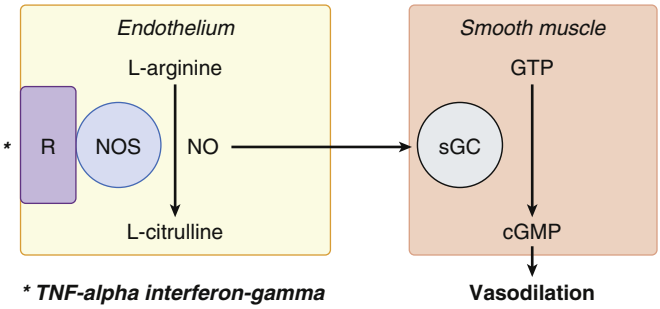

Figure 23-26. Synthesis of endogenous nitric oxide.

maintenance of normal blood pressure. Endogenous dopamine constitutively activates the DA_2 receptor, which synergistically enhances the activation of the DA_1 receptor.[116] It acts as an autocrine and paracrine natriuretic factor by inhibiting tubular Na^+-K^+-ATPase activity, especially when sodium intake is increased.[117] It also opposes the antinatriuretic effects of norepinephrine, angiotensin II, and aldosterone. Some evidence suggests that endogenous ANP acts via the renal dopamine system by recruiting "silent" DA_1 receptors from the interior of the cell toward the plasma membrane[117] and also enhances dopamine accumulation.[118]

Urinary dopamine excretion is increased with salt loading; decreased dopaminergic activity may contribute to the pathogenesis of idiopathic edema, which manifests as retention of salt and water in the upright position.[119] There is evidence that the endogenous dopamine system is activated in compensated cirrhosis and helps to maintain renal sodium excretion.[120]

NITRIC OXIDE

Endogenous formation of nitric oxide is controlled by the enzyme nitric oxide synthase (NOS), which catalyzes the hydroxylation of the nonessential amino acid L-arginine to L-citrulline.[121] Most actions of nitric oxide are mediated through its activation of soluble guanylate cyclase, which catalyzes the conversion of guanidine triphosphate (GTP) to cyclic GMP (Fig. 23-26). Cyclic GMP has two major actions: relaxation of vascular smooth muscle and suppression of the inflammatory response. It inhibits leukocyte adhesion, platelet activation and aggregation, and cellular proliferation. Cyclic GMP is converted to GMP by phosphodiesterase I and V. Thus, the local action of nitric oxide can be enhanced by the administration of a selective phosphodiesterase V inhibitor, such as sildenafil. Nitric oxide itself is rapidly inactivated by binding to intracellular heme and heme proteins (oxyhemoglobin, oxymyoglobin, guanylate cyclase, cyclooxygenase, cytochrome P_{450}).

Nitric Oxide Synthase (NOS)

There are several distinct subtypes of NOS, which determine the site and function of nitric oxide synthesis (also see Chapter 104). Constitutive NOS is calcium and calmodulin dependent and releases small amounts of nitric oxide for short periods of time ("tonic" release). Constitutive NOS has two subtypes: neuronal NOS, which acts as a peripheral neurotransmitter and induces cerebral vasodilation, and endothelial NOS, which exists in the vascular endothelium and mediates the activity previously ascribed to endothelium-derived relaxing factor (EDRF). The latter is an important modulator of systemic and pulmonary vascular resistance. In the kidney, endogenous nitric oxide preserves blood flow to the oligemic juxtamedullary cortex and medulla and may also provide endogenous protection against ischemic and nephrotoxic medullary injury.[122-124]

Inducible NOS is calcium and calmodulin independent and is induced by cytokines predominantly in inflammatory cells (macrophages, granulocytes) but also in vascular smooth muscle. At low levels of activation, inducible NOS enhances the response to infection and promotes inflammation and wound healing. In severe sepsis, inducible NOS produces huge amounts of nitric oxide for protracted periods of time (phasic release) and is largely responsible for its characteristically profound systemic vasodilation that is refractory to norepinephrine.[125] High levels of nitric oxide, as well as its reactive products nitrogen dioxide and peroxynitrite, induce lipid peroxidation and denaturation of proteins that drive the systemic inflammatory response syndrome (SIRS) and its attendant acute renal injury.

Duality of Nitric Oxide in Renal Function and Injury

Goligorsky and associates[126] have framed the hypothesis that an imbalance between the expression and activity of constitutive and inducible NOS plays an important role in the pathophysiology of acute renal failure. In experimental models of sepsis, nonselective inhibitors of both constitutive and inducible NOS improve blood pressure but worsen overall perfusion, including renal perfusion. Selective inhibitors of inducible NOS show promise in suppressing severe inflammation and vasodilation, while maintaining tonic perfusion to vital organs, including the kidneys.[127]

THE RENAL ADENOSINE SYSTEM

Adenosine Receptors

Adenosine, the endogenous degradation product of ATP, is produced by every mammalian cell type and is normally thought of as a potent vasodilator. However, in the kidney, it plays an essential role in regulating intrarenal blood flow by inducing outer cortical vasoconstriction and preserving juxtamedullary perfusion. This variance in function is explained by the identification of at least four subtypes of adenosine receptor: A_1, A_{2a}, A_{2b}, and A_3 (Table 23-6). Activation of the A_1 adenosine receptor induces outer cortical vasoconstriction; it also decreases renin release and inhibits diuresis and natriuresis. In contrast, A_{2a} adenosine receptors increase medullary renal blood flow and enhance renin release, diuresis, and natriuresis.

Ischemic Preconditioning and Adenosine

In a series of studies in an in vivo rat model of ischemic acute renal failure, Lee and Emala[128] characterized the role of adenosine and its receptor subtypes in ischemic

TABLE 23-6 ADENOSINE RECEPTOR SUBTYPES AND FUNCTIONS

Receptor	Agonist Function	Ischemic Injury
A_1	Outer cortical vasoconstriction Decreased renin release Inhibition of diuresis and natriuresis	Highly protective
A_{2a}	Juxtamedullary vasodilation Increased renin release Promotion of diuresis and natriuresis	Highly protective
A_{2b}	Unknown	
A_3	Unknown	Potentiates injury

From Fozard JR, Hannon JP: Adenosine receptor ligands: potential as therapeutic agents in asthma and COPD, Pulm Pharmacol Ther *12:111-114, 1999.*

preconditioning. Preischemic administration of adenosine and a selective A_1 adenosine receptor agonist protected the kidney against global renal ischemic reperfusion injury. The A_3 receptor appears to have polymorphic effects. In murine models of ischemic injury, pretreatment with a selective A_3 receptor activation potentiates renal injury; however, in murine septic peritonitis, activation of the A_3 receptor appears to protect the kidney by attenuating the hyperacute inflammatory response.[129] A selective A_{2a} adenosine receptor agonist had the greatest renal protective effects, even if its administration was delayed until the early reperfusion period after termination of renal ischemia.[130]

It is conceivable that A_1 adenosine receptor stimulation decreases renal oxygen consumption through a decrease in cortical blood flow, GFR and sympathetic tone, mediated by induction of cytoprotective sphingosine kinase and the synthesis of sphingosine-1-phosphate.[131] Adenosine has cytoprotective properties and promotes synthesis of protective heat shock proteins.[132] It is the key mediator of ischemic preconditioning in the heart and brain and is known to increase cellular resistance to ischemia in these organ systems. Pharmacologic development of a safe, specific A_{2a} adenosine receptor agonist might provide specific protection against renal ischemic injury.

PERIOPERATIVE ISCHEMIC AND NEPHROTOXIC INJURY

This section will review perioperative agents and events that may disrupt normal renal physiology. If the disruption is severe enough or occurs in susceptible individuals, it may induce ischemic or nephrotoxic acute tubular necrosis (ATN), a severe form of perioperative AKI. However, multiple studies indicate that even mild AKI (AKIN stage 1 or the R in RIFLE criteria) is associated with increases in hospital mortality, hospital lengths of stay, and resource utilization, as well as an increased risk of subsequent chronic kidney disease and long-term mortality.[72,73,75,133-137]

PATHOGENESIS

Ischemia-Reperfusion Injury

In many clinical situations (e.g., hypovolemic shock, suprarenal aortic cross-clamping), the kidney is subject to a classic ischemia-reperfusion injury that involves several distinct phases.[138] Acute injury to the tubular epithelium and vascular endothelium initiates a rapid decline in GFR. The injury is extended by epithelial and endothelial cell apoptosis and necrosis. The injury becomes stabilized during the maintenance phase, with the beginning of cellular reorganization that culminates in the recovery phase. The initiation phase is often transient, so the extension phase is the most important "window of opportunity" for therapeutic intervention that might reverse AKI. However, the timing of renal ischemia-reperfusion may be more subtle than in the above examples, emphasizing the importance of early, sensitive detection of rapid declines in GFR.[44]

Nephrotoxic Injury

The putative mechanisms of nephrotoxic tubular injury have been previously discussed (see "Oxygen Balance in the Medullary Thick Ascending Loop"). The risk of nephrotoxic AKI is exponentially related to the number of nephrotoxic insults.[13] An isolated nephrotoxin (e.g., radiocontrast dye) is unlikely to cause AKI when the kidney is well perfused. In animal models of nephrotoxic ATN, injection of radiocontrast dye predictably injures more than 50% of the renal mTAL only when the kidney is previously "primed" by a sequence of three other insults: dehydration, LMMA (a nitric oxide synthase inhibitor), and indomethacin (a prostaglandin synthesis inhibitor).[139]

ANESTHETIC DRUGS

The choice of an anesthetic technique to preserve renal function during and after surgery is predicated on the preservation of RBF and perfusion pressure, the suppression of vasoconstrictor, salt-retaining stress responses to surgical stimulation and postoperative pain, and the avoidance or curtailment of nephrotoxic insults. No single anesthetic drug alone meets these criteria (also see Chapters 69 and 74).

REGIONAL ANESTHESIA

Spinal or epidural anesthesia that achieves sympathetic blockade of the fourth through tenth thoracic segments is extremely effective in suppressing the sympathoadrenal stress response and release of catecholamines, renin, and AVP (also see Chapter 56). During major surgery, RBF and GFR are preserved as long as adequate renal perfusion pressure is maintained.[140-142] This implies careful titration of the block, especially in older adult patients with cardiovascular disease, and may necessitate a 25% to 50% increase in intraoperative intravenous fluid administration.[143] However, Gamulin and colleagues[144] found that renal sympathetic blockade obtained by epidural anesthesia did not block increases in renal vascular resistance induced by infrarenal aortic cross-clamping, nor

did it prevent postoperative decreases in creatinine clearance. Combined spinal-epidural anesthesia for nephrectomy in living related donors appeared to promote graft renal blood flow more than general anesthesia, but there was no difference in renal function or outcome in recipients[145] (also see Chapter 75). A large randomized controlled trial on patients undergoing major abdominal surgery compared general anesthesia plus perioperative epidural analgesia with general anesthesia and opiate-based postoperative analgesia; this study also revealed no difference in renal outcomes.[146]

GENERAL ANESTHESIA

All general anesthetics tend to decrease GFR and intraoperative urine flow as a consequence of decreased cardiac output and arterial blood pressure.[86] Some drugs also decrease RBF, but filtration fraction is usually increased, which implies that angiotensin-induced efferent arteriolar constriction limits the decrease in GFR. However, these effects are much less significant than those caused by surgical stress or aortic cross-clamping, and after emergence from anesthesia they usually resolve promptly. Any anesthetic technique that induces hypotension will result in decreased urine flow because of altered peritubular capillary hydrostatic gradients, even if renal autoregulation is preserved (as it usually is during anesthesia). Permanent injury seldom results, unless the kidneys are abnormal to begin with or the hypovolemic insult is prolonged and exacerbated by nephrotoxic injury.

Volatile anesthetics with nitrous oxide induce mild to moderate reductions in RBF and GFR, primarily because of their effects on the central circulation (myocardial depression, peripheral pooling).[147] These effects can be attenuated by prior intravenous hydration.

High-dose opioid techniques using fentanyl or sufentanil do not depress myocardial contractility and have minimal effect on RBF and GFR. They are also considerably more effective in suppressing the release of catecholamines, angiotensin II, aldosterone, and AVP during surgery than are volatile anesthetics. However, during cardiopulmonary bypass both AVP and catecholamine levels increase markedly despite high-dose opioid anesthesia[148] (also see Chapter 67). Intravenously administered anesthetics, such as thiopental and diazepam, cause minor changes in renal function, about 10% to 15% deviation from control. Ketamine increases RBF but decreases urine flow rate, possibly through sympathetic activation; it preserves RBF during hemorrhagic hypovolemia.[149]

Nephrotoxicity of Volatile Anesthetics

The potential nephrotoxicity of volatile anesthetics (also see Chapter 26) is due to their metabolic breakdown to free fluoride ions, which cause a tubular lesion that results in loss of concentrating ability and polyuric acute renal failure.[150] Toxicity is exacerbated by aminoglycosides or prior renal dysfunction. Peak fluoride levels less than 50 μm/L seldom induce injury, whereas levels >150 μm/L are associated with a frequent incidence of polyuric acute renal failure.[151] Administration of methoxyflurane at more than one (minimal alveolar concentration of anesthetic) (MAC) for more than 2 hours is capable of generating a peak fluoride level greater than 100 μm/L, and for this reason, this anesthetic is no longer used. Enflurane is metabolized more rapidly, and most studies indicated that peak fluoride levels seldom rose above 25 μm/L. The antituberculotic drug isoniazid enhances fluoride production, but only isolated reports of fluoride-induced nephrotoxicity due to enflurane ever appeared. Isoflurane produces peak fluoride levels less than 4 μm/L, and halothane is not metabolized to fluoride at all.[152]

The potential nephrotoxicity of sevoflurane remains controversial. Although its metabolism generates more fluoride than enflurane, clinically significant fluoride-induced nephrotoxicity has not been detected. Compound A, a vinyl ether formed by degradation of sevoflurane at low flow through carbon dioxide absorbents, is capable of inducing renal injury in rats. Although acute renal failure has not been reported in humans, Eger and associates reported evidence of transient renal injury (albuminuria, tubular enzymuria) in volunteers subjected to 8 hours of 1.25 MAC sevoflurane at 2 L/minute gas flow.[153] There were no changes in urinary concentrating ability, serum creatinine, or blood urea nitrogen (BUN). Subsequently, Eger and associates[154] described a dose-response relationship between biochemical markers of glomerular and tubular injury (urinary albumin, alpha-glutathione-S-transferase) and compound A exposure expressed as parts per million-hours (ppm/h). They suggested that the threshold of renal injury is 80 to 168 ppm/h based on their observation of altered biochemical markers with 1.25 MAC sevoflurane at 2 L/minute for 4 hours, which was not seen after 2 hours, and not at all with desflurane.

Other laboratories have disputed Eger's findings. Bito and colleagues compared 6-hour patient exposure to low- and high-flow sevoflurane with low-flow isoflurane and found no differences in BUN, creatinine, or tubular enzymes for 3 days postoperatively.[155] Kharasch and colleagues[156] had similar results with the use of sevoflurane or isoflurane at 1 L/minute in 73 patients undergoing procedures lasting longer than 2 hours. They concluded that moderate duration of low-flow sevoflurane anesthesia, even with the formation of compound A, is as safe as low-flow isoflurane anesthesia. Ebert and associates[157] attempted to duplicate the original 8-hour Eger sevoflurane study in volunteers at two sites with blinded laboratory analyses. Biochemical derangements were minimal and transient, and there were no significant changes in BUN, creatinine, or creatinine clearance. Despite the similarity in experimental design, the mean level of compound A was about 25% lower, and the mean arterial pressure about 10% higher than in the Eger study and may have accounted for the difference in results.

In summary, clinically significant renal injury with the use of low-flow sevoflurane anesthesia has not been reported in patients, even with moderate preexisting renal dysfunction. The relationship between compound A formation, biochemical injury, and clinically relevant renal dysfunction remains unclear and unproven. Nonetheless it appears prudent to follow current FDA guidelines, which recommend a fresh gas flow of at least 2 L/minute to inhibit compound A formation and its rebreathing and to enhance its washout.

Volatile Anesthetics and Ischemia-Reperfusion Injury

In direct contrast to the debate just described, experimental evidence suggests that volatile anesthetics can ameliorate ischemia-reperfusion injury in the kidney and beyond. In a murine model, Lee and Emala demonstrated that anesthesia with desflurane, sevoflurane, isoflurane, and halothane significantly attenuated the increase in serum creatinine compared with pentobarbital or ketamine.[158] The mechanism is independent of potassium-ATP channels but related to induction of cytoprotective factors and suppression of proinflammatory cytokine and chemokine activation in response to ischemia-reperfusion. In cultured renal tubule cells, sevoflurane induces the phosphorylation of cytoprotective kinases, up-regulates heat shock protein, and attenuates the proinflammatory transcription factor NF-κB, partly because of the release of transforming growth factor-β_1 (TGF-β_1).[159]

Isoflurane has similar protective effects, and in a murine model, it is able to protect against liver and intestinal injury associated with ischemia-reperfusion AKI.[160] As with adenosine receptor agonism described earlier, a major protective mechanism appears to be isoflurane-induced activation of sphingosine kinase-1 and production of sphingosine-1-phosphate.

These observations are consistent with the concept that volatile anesthetics confer protection only when administered during ischemia and reperfusion and do not appear to have a preconditioning effect.[161]

MECHANICAL VENTILATION

Mechanical ventilation and positive end-expiratory pressure (PEEP) may cause decreases in RBF, GFR, sodium excretion, and urine flow rate, or even acute renal injury.[162] There are several mechanisms for these effects (also see Chapter 103).

Hemodynamically mediated changes are the most common. Transmission of increased airway and intrapleural pressures to the intravascular space leads to decreases in venous return, transmural (i.e., effective) cardiac filling pressures, and cardiac output. Transmission may actually be attenuated in acute lung injury because of poor lung compliance. High levels of mean airway pressure may compress the pulmonary arterial circulation, increase right ventricular afterload, and induce the intraventricular septum to shift into the left ventricle and decrease its filling and cardiac output.[163] Positive pressure ventilation increases inferior vena caval pressure and renal venous pressure and may increase tubular sodium reabsorption by increases in peritubular capillary pressure.

The decrease in cardiac output and systemic arterial pressure results in a carotid and aortic baroreceptor-mediated increase in sympathetic nerve tone to the kidney, with renal vasoconstriction, antidiuresis, and antinatriuresis. Volume receptors in the atria respond to decreased filling by decreased ANP secretion, resulting in increased sympathetic tone, renin activation, and AVP activity.

Salt and water retention during airway pressure therapy was originally thought to be due to an AVP effect,[164] but it is now considered that sympathetic responses are more important and that sodium retention is largely the result of decreased sodium delivery to the tubules. The renin-angiotensin-aldosterone system undoubtedly augments the renal responses to positive pressure ventilation. Annat and colleagues[165] found that 15-cm H_2O PEEP depressed cardiac output, RBF, GFR, and urine volume by 20% to 30% and was associated with increases in renin and aldosterone but not AVP. The impairment in renal function induced by airway pressure therapy can be prevented or reversed by preserving normal circulatory status, either by hydration[166] or by use of dopamine.[167]

Although, theoretically, the extent of depression of renal function depends on the mean airway pressure, there is no difference in creatinine clearance and FENa, whether volume controlled- or pressure-support ventilation is used.[168] Therapeutic maneuvers used in severe acute lung injury, such as permissive hypercapnia or permissive hypoxemia, may promote renal vasoconstriction.[162]

Finally, in experimental lung injury there is evidence that an injurious ventilatory mode induces acute inflammation associated with renal epithelial cell apoptosis and dysfunction.[169] These findings appear to be in keeping with the clinical observation of multiorgan dysfunction in patients with acute respiratory distress syndrome and its amelioration when a lung protective strategy of mechanical ventilation is used.[162]

INDUCED HYPOTENSION

During anesthesia with induced hypotension, substantial reduction of GFR and urine flow rate is common. However, when the duration of hypotension is less than 2 hours, no permanent impairment of renal function occurs, even in older adult patients.[170] Vasodilators used to induce hypotension differ in their effect on RBF. Administration of sodium nitroprusside decreases renal vascular resistance but tends to shunt blood flow away from the kidney. Moreover, its administration is associated with marked renin-angiotensin activation and catecholamine release, which results in rebound hypertension if the infusion is suddenly discontinued. Nitroglycerin decreases RBF less than sodium nitroprusside.[171] The selective DA_1-dopaminergic agonist fenoldopam is capable of providing induced hypotension without any significant decrease in RBF.[172]

AORTIC CROSS-CLAMPING

The relative effects of suprarenal and infrarenal aortic cross-clamping on renal function in patients undergoing major vascular surgery have been studied (also see Chapter 69).[28] Regardless of the position of the aortic cross-clamp, RBF is decreased to 50% of normal during surgical preparation of the aorta, presumably due to direct compression or reflex spasm of the renal arteries. After release of the suprarenal cross-clamp, RBF increases above normal (reflex hyperemia), but GFR remains depressed to one third of control for up to 2 hours. After 24 hours GFR is still only two thirds of control. Tubular functions

(concentrating ability, sodium and water conservation) are markedly impaired, but urine flow is maintained. Myers and Moran[173] observed that these changes resemble an attenuated form of acute tubular necrosis. In this study all patients received mannitol pretreatment, which probably limited the tubular insult, because oliguria was uncommon and recovery was relatively rapid. Cross-clamp times longer than 50 minutes are associated with prolonged depression of GFR and transient azotemia.[28,174]

In animal models, suprarenal aortic cross-clamping induces a decrease in renal endothelial nitric oxide; nitric oxide synthesis and cortical blood flow is enhanced by the administration of its substrate, arginine.[175] Whether this intervention might attenuate the renal consequences of cross-clamping awaits further investigation.

Infrarenal aortic cross-clamping may also impair RBF and GFR by inducing decreases in cardiac output in response to increased systemic vascular resistance.[176] Atheromatous embolism of the renal arteries may be induced by cross-clamping or manipulation in areas of dense aortic plaque. Partial or complete cortical necrosis may occur, which is usually irreversible.

RENAL PROTECTION DURING AORTIC CROSS-CLAMPING

Mannitol has been used for more than 40 years to provide renal protection during aortic cross-clamping (also see Chapter 69).[177] Its protective effects have been clearly demonstrated in animal models of ischemic acute tubular necrosis (ATN),[178] but few prospective controlled human studies exist. Low-dose dopamine has commonly been used during major vascular surgery. In a canine study of thoracic aortic cross-clamping, RBF, GFR and urine flow remained impaired for a considerable time after cross-clamp release. This delay was not prevented by prophylactic dopamine.[179] In a human study of infrarenal cross-clamping, Paul and associates[180] compared diuretic therapy with a combination of mannitol and dopamine versus fluid loading with saline to a pulmonary artery occlusion pressure (PAOP) of 12 to 15 mm Hg. Although mannitol and dopamine substantially increased urine flow and sodium excretion during cross-clamping, they were no better than saline in attenuating residual GFR depression after cross-clamp release.

Fenoldopam, a synthetic phenolated dopamine analog that is a selective agonist of the dopamine-1 receptor, increases renal blood flow in a dose-dependent manner.[181] Infusion of fenoldopam has demonstrated a renoprotective effect in experimental suprarenal aortic cross-clamping.[182] In a controlled, randomized, blinded study in 28 patients undergoing infrarenal aortic cross-clamping, fenoldopam 0.1 mcg/kg/minute or placebo was infused intravenously before surgical skin incision and continued until release of the aortic cross-clamp.[183] Fenoldopam significantly attenuated the decrease in creatinine clearance and increase in serum creatinine observed in patients who received placebo.

However, in a different model of intraoperative renal ischemia, a randomized, double-blind study in 77 patients with a solitary functioning kidney undergoing partial nephrectomy, a 24-hour infusion of fenoldopam at 0.1 mcg/kg/minute did not attenuate the postoperative increase in serum creatinine.[184] Larger studies with this agent appear warranted.

CARDIAC SURGERY AND CARDIOPULMONARY BYPASS

The incidence of acute renal failure requiring renal replacement therapy after uncomplicated cardiac surgery in patients with previously normal renal function is infrequent (<2%).[185] However, the incidence of AKI defined by consensus definitions is about 20% to 30%.[186,187] Multiple risk factors have been identified, including preoperative renal dysfunction, hypertension, diabetes, impaired cardiac function, preoperative anemia, perioperative erythrocyte transfusion, combined surgical procedures, prolonged cardiopulmonary bypass, and advanced age (also see Chapter 67).[188,189]

Regardless of pathogenesis, AKI requiring renal replacement therapy after cardiac surgery has a profound impact on mortality, and even milder forms of AKI are consistently associated with increased mortality, length of stay, and hospital costs.[73,75,134,186] The potential mechanisms of cardiac surgery–associated renal injury are complex and multifactorial.

Preoperative hypertension is a major risk factor for AKI after cardiac surgery. This risk is increased by preexisting systolic (wide pulse pressure) hypertension. The risk of AKI increases by nearly 50% for every 20 mm Hg increase in pulse pressure above 40 mm Hg.[190] Increased variability of intraoperative blood pressure control also appears to be a risk factor.[191]

Most patients undergoing cardiac surgery will have undergone contrast angiography in preparation for surgery, and the time interval between this established nephrotoxin and surgery has been suggested as a potential contributory factor to perioperative AKI.[192]

Acute anemia (hemoglobin <9 g/dL) during cardiopulmonary bypass is associated with an increased risk of AKI, but so is red cell transfusion when hemoglobin is >8 g/dL[193] (also see Chapter 61). Decreased mean arterial pressure appears to be well tolerated, unless it is associated with anemia. On the other hand, a combination of patient factors and procedural factors result in a cumulative particulate, gaseous, micro- or macroscopic embolic load that may contribute to AKI.

During CPB, hypotension with nonpulsatile flow promote renal vasoconstriction and decreased RBF. Norepinephrine concentrations increase progressively during bypass, and the renin-angiotensin system is activated. Acute renal failure has been associated with persistent elevation of plasma renin levels.[173] Thromboxane, released from activated platelets, and vascular elaboration of endothelin could add to renal vasoconstriction during extracorporeal circulation.

Tubular enzymuria and microalbuminuria, an index of subclinical injury to the nephron, is consistently observed during cardiopulmonary bypass.[194] Inflammatory cascades initiated by surgery may be further amplified in response to CPB while the trauma of the CPB system causes hemolysis with release of free hemoglobin,

an established nephrotoxin, into the plasma.[195] Another consequence of hemolysis is the release of labile free iron that contributes to activation of reactive oxygen species, inflammation, and AKI.[196] A number of the tubular biomarkers released in AKI are associated with iron metabolism: NGAL participates in iron transport, L-FABP is a high-affinity heme binding protein, and hepcidin (which appears to be protective) sequesters free iron.[197] In a study specifically examining hemolysis during CPB for repair of thoracoabdominal aortic aneurysms, there was a direct association among peak plasma free hemoglobin, NAG, and perioperative AKI.[198]

Unfortunately, despite all the putative mechanisms described earlier, it still remains unclear exactly how much CPB itself contributes to AKI during cardiac surgery. The individual response to CPB varies greatly and may be the consequence of variable genetic polymorphisms that regulate the response to inflammatory and vasomotor processes.[199]

RENAL PROTECTION DURING CARDIOPULMONARY BYPASS

Pulsatile Perfusion During CPB

In animal and human studies, pulsatile perfusion during CPB enhances renal cortical blood flow and decreases circulating catecholamines, endothelin, and cytokine activation (also see Chapter 67).[200,201] Plasma renin activity is suppressed by pulsatile perfusion; however, evidence of glomerular injury (in this case, microalbuminuria) persists.[55] In a randomized prospective study on 215 pediatric patients undergoing repair of congenital heart disease, the use of pulsatile flow during CPB was associated with decreased inotropic drug requirement, shorter ICU and hospital lengths of stay, and increased urine output. Yet no difference was seen in serum creatinine.[202] Intraaortic balloon counterpulsation was used to provide pulsatile flow during CPB in a randomized, prospective study on 100 adult patients undergoing cardiac surgery.[203] Pulsatile flow attenuated the decline in GFR, but there was no difference in urine flow or renal outcome. In a large nonrandomized observational study, pulsatile flow was provided during CPB in 915 of 1820 patients but did not provide increased protection against perioperative renal injury.[204] Overall, results of clinical studies of pulsatile perfusion on CPB are inconsistent and further complicated by the absence of a precise and widely accepted definition of what constitutes pulsatile flow on CPB. Current evidence appears to be insufficient to allow recommendations either for or against the routine use of pulsatile perfusion on CPB to decrease the risk of renal injury.[205]

Avoidance of CPB

The benefit to renal function of off-pump coronary artery bypass (OPCAB, also known as beating heart surgery) also remains equivocal. In patients with a small risk, little difference has been observed in the incidence of acute kidney injury, regardless of whether CPB is used.[206] Most published studies to date have been small (< 60 patients), Although OPCAB is associated with less evidence of acute kidney injury, as manifested by lower levels of serum creatinine, cystatin C, microalbuminuria, and NAG, a clear benefit to renal outcome, morbidity, or mortality has not resulted.[207,208] A recent meta-analysis of randomized trials, found evidence to support a reduction in AKI with off-pump surgery but with no demonstrated reduction in dialysis or mortality.[209] However, the quality of included studies is variable, there is large interstudy variation in the definition of AKI, and the results and conclusions may have been skewed by one study. We need additional high-quality evidence that addresses clinically relevant end points to clarify the potential renal benefit of off-pump cardiac surgery.

Perfusion Pressure during CPB

Animal studies of cardiopulmonary bypass have shown that RBF is dependent on renal perfusion pressure, and infusion of dopamine does not increase RBF during low pressure states.[10] This suggests that autoregulation may be impaired during cardiopulmonary bypass. However, Hilberman and associates[210] found no relationship between low flow (<50 mL/kg/minute) and low mean arterial pressure (<50 mm Hg) and postoperative acute renal failure. Instead, the severity of postoperative renal dysfunction and its outcome correlated with the severity of cardiac dysfunction after cardiopulmonary bypass.[211]

These observations are supported by more recent ones that found no correlation between mean arterial pressure during cardiopulmonary bypass and AKI, unless hypotension was associated with severe anemia.[193] Perhaps the hemodilution of mild anemia preserves RBF at low perfusion pressure, but in severe anemia this is overcome by the deficit in oxygen delivery (also see Chapter 61 regarding anemia and the indications for blood transfusions).

Dopaminergic and Diuretic Drugs

In a study comparing equi-inotropic doses of dopamine and dobutamine after cardiac surgery, the two agents had similar effects on GFR, RBF, renal vascular resistance, and filtration fraction, but dopamine caused greater urine flow rate, natriuresis, fractional excretion of sodium, and potassium excretion, indicating a diuretic effect independent of changes in RBF and GFR.[212] However, there is no evidence that the prophylactic administration of low-dose dopamine has a protective role during CPB in patients with previously normal[213,214] or impaired renal function.[206,215]

In part, the lack of benefit may be due to the variable pharmacokinetic effect of dopamine. In a study on normal volunteers, McGregor and colleagues found a 30-fold intersubject variability in plasma dopamine levels.[216] Some subjects given an infusion of low-dose dopamine had plasma levels consistent with those associated with doses in the high, α-adrenergic range. Even at small doses it can cause unwanted tachycardia, and its postoperative infusion is associated with a more frequent incidence of supraventricular and ventricular arrhythmias.[217]

In contrast to dopamine, a renoprotective effect may occur from an infusion of low-dose fenoldopam infusion (0.1-0.3 mcg/kg/minute) during cardiac surgery[218] (also see Chapter 67). Echocardiographic studies using the Doppler technique have demonstrated a dose-dependent

increase in renal blood flow, especially in the cortical zones, when fenoldopam is administered in this dose range.[219] A meta-analysis of 13 randomized and case-matched studies on 1059 patients found that fenoldopam infusion is associated with a significant decrease in dialysis requirement, ICU length of stay, and in-hospital mortality.[16] However, most studies with fenoldopam have been relatively small and have identified improved serum creatinine and creatinine clearance rather than renal outcome.[220,221] The most convincing evidence thus far comes from a randomized, double-blinded study in 193 high-risk patients by Cogliati and colleagues.[222] Risk factors included increased preoperative serum creatinine concentrations (>1.5 mg/dL), age >70 years, diabetes, or previous cardiac surgery. Patients who received fenoldopam had a decreased incidence of acute kidney injury (12.6 versus 27.6%, $P = 0.02$) and requirement for dialysis (0 versus 8.2%, $P = 0.004$).

Prophylactic administration of diuretics during CPB may actually be harmful: in a study on 126 patients undergoing elective cardiac surgery, perioperative infusion of furosemide (0.5 mcg/kg/minute) worsened serum creatinine compared with low-dose dopamine and placebo.[213]

Natriuretic Peptides

Exogenous administration of anaritide (human recombinant ANP) decreases systemic arterial blood pressure through arterial and venous dilation. There has been considerable interest in the ability of infused anaritide to reverse established acute renal failure ("renal rescue"). Animal studies of ischemic and nephrotoxic acute tubular necrosis,[223,224] as well as preliminary clinical studies,[225] offer promise. A large prospective study demonstrated significantly increased dialysis-free survival with anaritide infusion in oliguric acute renal failure, but in nonoliguric acute renal failure, survival actually worsened.[51] Subsequently, a randomized, double-blind, placebo-controlled trial in 222 patients with oliguric acute renal failure found no differences in dialysis requirement, dialysis-free survival, or 60-day mortality between anaritide and placebo.[226] However, patients receiving anaritide had significantly more frequent incidence of hypotension during infusion of the study drug.

Infusion of anaritide has been studied during CPB.[227] Compared with controls, patients who received anaritide had significantly lower plasma levels of renin, angiotensin II, and aldosterone and higher GFR and urine output. A recent Cochrane review of ANP therapy concluded that although there was some evidence supporting a beneficial effect of low-dose ANP as a preventive strategy to reduce the risk of AKI requiring dialysis, the evidence is insufficient to make any strong recommendations.[228]

Nesiritide (human recombinant BNP) is approved by the FDA for the parenteral treatment of advanced decompensated congestive heart failure. It decreases increased cardiac preload and afterload, enhances cardiac function, and promotes diuresis and relieves symptoms related to pulmonary congestion and edema.[229] The major adverse effect is dose-related hypotension, which if excessive, can impair renal function.[230] A meta-analysis of studies of nesiritide infusion in patients with advanced decompensated heart failure indicated increasing serum creatinine levels.[231] However, a large prospective placebo-controlled study demonstrated no worsening of renal function in patients with advanced decompensated heart failure,[232] and similar results have been found when comparing nesiritide to nitroglycerin[233] or nitroprusside.[234]

Perioperative infusion of low-dose (0.01 mcg/kg/minute) nesiritide infusion in high-risk patients undergoing cardiac surgery may have a renoprotective effect.[235] In a prospective, randomized, blinded study of 279 patients with left ventricular dysfunction (EF <40%) undergoing coronary revascularization or mitral valve surgery, patients who received nesiritide had increased urine output, an attenuated postoperative increase in serum creatinine, and improved survival 6 months after surgery.

A meta-analysis of 15 trials of infusions of ANP or BNP in cardiovascular surgery found consistent benefits, including increased urine output and GFR, decreased diuretic use, decreased peak postoperative serum creatinine and requirement for dialysis, and decreased ICU and hospital length of stay.[236] These findings have yet to be confirmed by a large, multicenter, prospective randomized controlled trial.

N-Acetylcysteine

N-acetylcysteine is an antioxidant that directly scavenges reactive oxygen species, and it has been widely used to prevent radiocontrast nephropathy (see later discussion). On the other hand, no evidence exists that perioperative administration of *N*-acetylcysteine has any efficacy in the prevention of AKI during cardiac surgery. In two prospective, blinded, randomized studies neither intermittent injection[237] or continuous infusion[238] of *N*-acetylcysteine had any impact on renal function or outcome after cardiac surgery. A study on 254 patients with chronic renal insufficiency (GFR <60 mL/minute) was similarly unable to demonstrate any significant benefit from intermittent injection of *N*-acetylcysteine.[239] Most recently, a randomized controlled study on more than 2300 patients undergoing coronary or peripheral vascular angiography failed to show any benefit associated with *N*-acetylcysteine administration.[240]

Urinary Alkalinization

As described earlier, hemolysis is a common occurrence during CPB, the release of labile free iron may play a role in inducing activation of reactive oxidation species, and AKI in this situation could be considered a form of pigment nephropathy.[195] Under these circumstances, urinary alkalinization could prevent formation of methemoglobin and tubular casts, decrease endocytic hemoglobin uptake, and attenuate proximal tubular necrosis; bicarbonate may scavenge free iron-mediated reactive oxygen species such as hydroxyl ions and peroxynitrite.[196] Indeed, in a small, randomized, double-blind trial of in 100 patients undergoing cardiac surgery who were at increased risk of perioperative AKI, urinary alkalinization by a 24-hour infusion of sodium bicarbonate decreased the incidence of a 25% postoperative increase in SCr from 52% to 32%, with decreased urine NGAL.[241] These preliminary observations—and their impact on outcome—remain to be confirmed by larger prospective studies.

NEPHROTOXIC INSULTS

DRUG-INDUCED NEPHROTOXICITY

Nephrotoxic injury by drugs or contrast dyes seldom occurs without the presence of coexisting risk factors.[13] These may be acute (shock, hypovolemia, congestive heart failure) or chronic (advanced age, diabetes, chronic renal insufficiency). The risk of nephrotoxicity increases exponentially with the number of risk factors and nephrotoxic combinations.

Nephrotoxic acute renal failure is usually nonoliguric, with loss of concentrating ability and slowly progressive azotemia. As GFR declines, accumulation of renally excreted drugs exacerbates nephrotoxicity unless drug levels are carefully monitored and dosage repeatedly adjusted. However, the prognosis for recovery is good if these agents are discontinued in time and no coexistent organ failure exists.[242]

Aminoglycosides

Aminoglycosides (gentamicin, tobramycin, amikacin) are polycationic compounds that are filtered into the proximal tubule, where they bind to anionic brush-border membrane phospholipids. Their nephrotoxicity is directly related to their polycationic status, so that neomycin (six cationic sites) is more destructive than gentamicin (five sites) or streptomycin (three sites).[243] They are absorbed into intracellular lysosomes by endocytosis and thence released into the cytosol. Within the cell they induce the formation of reactive oxygen metabolites that injure lysosomes, plasma membranes, and mitochondria and, in particular, inhibit oxidative phosphorylation and the synthesis of high-energy phosphate compounds such as ATP. In animal studies, administration of antioxidants such as melatonin ameliorates nephrotoxicity.[244]

Aminoglycoside-induced nephrotoxicity is directly related to sustained high-trough serum levels, especially when associated with advanced age, preexisting renal disease, renal vasoconstrictive states (sepsis, hypovolemia, liver disease, congestive heart failure), adjuvant drug therapy (loop diuretics, vancomycin, cephalosporins, NSAIDs, cyclosporine A, amphotericin B), and electrolyte disorders (hypokalemia, hypomagnesemia, hypercalcemia, and metabolic acidosis).[245]

Prevention of aminoglycoside nephrotoxicity depends on maintenance of adequate hydration, avoidance or removal of the risk factors enumerated above, and careful monitoring of serum aminoglycoside levels. A daily 2-hour creatinine clearance can also be helpful in the early detection of aminoglycoside-induced nephrotoxicity and appropriate dose adjustment for GFR. Once-daily administration of aminoglycosides to achieve a high therapeutic level with an adequate trough period for renal recovery may limit the occurrence of nephrotoxicity.[246] Low-dose dopamine increases renal clearance of aminoglycosides, but it is not known whether this protects against tubular injury.

Nonsteroidal Antiinflammatory Drugs

Cyclooxygenase-1 is inhibited by nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin, meclofenamate, and ketorolac for about 8 to 24 hours (also see Chapter 32). A single dose of aspirin causes its irreversible acetylation. In platelets, the impact lasts for the lifetime of these cells (7 to 10 days), but the kidney resynthesizes cyclooxygenase within 24 to 48 hours. The renal protective function of prostaglandins is "switched on" by injury, illustrated by the fact that NSAIDs cause nephrotoxicity in ischemic but not in normal kidneys. During conditions of stress, impaired prostaglandin activity results in decreased RBF and GFR, increased renal vascular resistance, attenuated diuretic responsiveness, and hyperkalemia.

Adverse effects of NSAIDs and aspirin (e.g., hemorrhage, endotoxemia, increased venous pressure, and low cardiac output) have occurred in animals and in humans with mild underlying renal dysfunction who also have congestive heart failure, ascites, or systemic lupus erythematosus.[247] However, in an individual patient, the risk of NSAID-induced nephrotoxicity is very much dependent on the milieu. Short-term postoperative analgesia with a single analgesic such as ketorolac is extremely unlikely to cause injury in a relatively young, healthy, well-hydrated patient. The risk of nephrotoxic injury increases exponentially with the addition of concomitant nephrotoxins (e.g., contrast dye, aminoglycosides) and in the presence of acute or chronic cardiovascular instability.

NSAIDs selective for cyclooxygenase-2 (celecoxib, rofecoxib, valdecoxib) are less likely to cause gastric irritation and erosion. However, the proposed decreased risk of nephrotoxic injury compared with nonselective cyclooxygenase inhibitors has not been shown.[248] Their use has been severely curtailed after reports of increased adverse cardiovascular events in clinical trials.

Calcineurin Antagonists (Cyclosporine A, Tacrolimus)

Cyclosporine A is a remarkably potent immunosuppressive drug; together with steroids and azathioprine, it is routinely used to prevent rejection after organ transplantation. Indeed, heart, lung, and liver transplantation increased exponentially after the release of cyclosporine A in 1981. It causes renal injury in part because it induces sympathetic hyperreactivity, hypertension, and renal vasoconstriction. Preexisting renal dysfunction, hypovolemia, and other nephrotoxic insults exacerbate its nephrotoxic effects. Many transplant patients must tolerate a moderately elevated serum creatinine (1.5-2 mg/dL) in order to sustain adequate immunosuppression.

A related calcineurin immunosuppressive agent, tacrolimus (FK506), has been considered somewhat less nephrotoxic than cyclosporine and has largely replaced it. However, renal biopsy studies in pancreas transplant patients indicate that the risk of nephrotoxicity does not differ between tacrolimus and cyclosporine A.[249] There is considerable genetic variability in the metabolism of tacrolimus by the hepatic CP450 enzyme system and its pharmacodynamic effects on immunosuppression; thus, the risk of nephrotoxicity also varies significantly.[250] For example, patients who express the CYP3A5*1 allele require higher tacrolimus doses to achieve therapeutic levels and have an increased risk of nephrotoxicity.[251]

Coadministration of calcium channel blockers competes for CP450 metabolism and results in higher levels

of cyclosporine A and tacrolimus. Most transplant immunologists will avoid this drug interaction, but it may actually be beneficial. In patients undergoing cadaveric renal transplantation, the calcium channel blocker diltiazem was added to the graft preservative solution, infused into the donor for 48 hours, and then given orally.[252] The incidence of transplant acute tubular necrosis decreased from 41% to 10%, and when AKI did occur, hemodialysis requirement was significantly less. Diltiazem impairs cyclosporine metabolism so that plasma cyclosporine levels are higher, but this results in fewer episodes of early acute rejection, and calcium channel blockade protects against cyclosporine nephrotoxicity.[253] Cyclosporine dosage may be reduced by 30% to achieve the same drug levels, representing a substantial cost savings to patients.

An alternative approach that is gaining some traction is to replace cyclosporine A or tacrolimus with a noncalcineurin agent, sirolimus, which appears to have similar immunosuppressive effects with considerable less potential to induced renal injury.[254]

CONTRAST-INDUCED NEPHROTOXICITY

The nephrotoxicity of contrast dye is likely mediated through intense renal vasoconstriction leading to medullary hypoxia, combined with oxidative stress (also see Chapter 90). Direct cytotoxicity almost certainly plays a role as well, because contrast agents are water soluble and readily gain access to the urinary space of the glomerulus and renal tubules.[255] Its likelihood is increased by intraarterial administration and use of large volumes of contrast. The risk of contrast-induced nephrotoxicity (CIN) is exacerbated in the setting of diabetic renal insufficiency, hypovolemia, congestive heart failure, and myeloma.[256]

Radiocontrast dyes are hypertonic and cause an osmotic diuresis, which induces a false sense of security but may actually exacerbate hypovolemia and renal damage. The potential toxicity of radiocontrast media was thought to be directly related to their osmolality. However, meta-analysis has failed to disclose a renoprotective benefit of iso-osmolar contrast compared with a pooled group of low-osmolar contrast agents.[257] The further finding that nephrotoxicity may vary among low-osmolar agents suggests that contrast-induced nephrotoxicity is mediated by other factors in addition to simply osmolality.

When CIN occurs, azotemia commences 24 to 48 hours after exposure and peaks at 3 to 5 days. This provides a clear warning to defer elective surgery to ameliorate the risk of perioperative acute renal failure. On the other hand, the impact of CIN may be missed when surgery immediately follows radiologic studies or when studies are performed during surgery.

The cornerstone of prophylaxis against CIN is adequate hydration—for instance, 1 mL/kg normal saline initiated at least 4 hours before and continued for 12 hours after radiocontrast administration.[258]

A number of pharmacologic agents have raised and then dashed hopes of their role in preventing or attenuating contrast-induced AKI, and nothing has replaced hydration as first-line protection. Intravenous mannitol has been used for many years but may exacerbate injury if it induces dehydration though excessive osmotic diuresis. In the last decade, most interest has focused on antioxidants and dopaminergic agonists.

N-Acetylcysteine

Tepel and associates reported that prophylactic administration of the antioxidant *N*-acetylcysteine (600 mg orally twice daily) attenuated CIN in a study on 83 patients with chronic renal insufficiency (mean serum creatinine 2.4 mg/dL) undergoing contrast radiography.[259] Only 2% of patients receiving *N*-acetylcysteine had an increase in serum creatinine of >0.5 mg/dL, compared with 21% of patients receiving saline placebo, and mean serum creatinine concentrations actually decreased.

Subsequent studies either did not confirm these results[260] or found that *N*-acetylcysteine provided better protection than saline alone only when a low dose of contrast dye was used.[261] *N*-acetylcysteine may itself decrease serum creatinine levels independent of changes in GFR.[25] The protective role of *N*-acetylcysteine clarified by a randomized controlled trial on more than 2300 patients with at least one risk factor for contrast-induced AKI (age >70 years, CKD, diabetes mellitus, heart failure, or hypotension).[240] The incidence of CIN was the same (about 13%), whether a standard *N*-acetylcysteine regimen or placebo was used before and after administration of radiocontrast.

Fenoldopam

An intravenous fenoldopam infusion prevented the decrease in RPF induced by radiocontrast media.[262] However, a large, multicenter RCT on 315 patients with preexisting renal insufficiency (creatinine clearance <60 mL/minute) showed that it had no benefit on renal function compared with placebo.[263] A more recent retrospective evaluation of a direct infusion of fenoldopam into the renal arteries in high-risk patients undergoing coronary angiography and percutaneous revascularization indicated a decrease in incidence of CIN from 31% to 12%.[264] As with many others, this intervention needs to be tested in a formal prospective, randomized, blinded study.

PIGMENT NEPHROPATHY

Pigment nephropathy implies AKI as a consequence of the nephrotoxic effects of the heme pigments myoglobin, hemoglobin, and bilirubin.

Rhabdomyolysis and Myoglobinemia

Muscle necrosis (rhabdomyolysis) occurs most commonly with direct trauma involving major crush or thermal injury. However, it also occurs with acute muscle ischemia induced by vascular disease or injury, or by prolonged immobilization. Compartment syndromes exacerbate rhabdomyolysis. They are particularly likely to occur with major hemorrhage in an extremity or when vascular insufficiency coexists with tissue edema (e.g., femoral placement of an intraaortic balloon after vein harvesting). Dramatic increases in metabolic rate (severe exercise, prolonged fever, status epilepticus, or myoclonus), severe hypophosphatemia, or direct proteolysis (acute pancreatitis) can all precipitate rhabdomyolysis.[265]

Myoglobin, the oxygen-carrying heme pigment of muscle, is released into the bloodstream (myoglobinemia)

and rapidly excreted by the glomerulus at a plasma threshold of 0.03 mg/dL. Delivery of myoglobin to the proximal tubule is greater in a well-muscled individual with normal GFR than in a cachectic patient with low GFR. At a urine pH less than 5.6, myoglobin is transformed into ferrihematin, which precipitates in the proximal tubule.[266] Renal damage is facilitated by hypovolemia (i.e., low tubular flow) and acidic urine. Because of the associated hypercatabolic state, oliguria is associated with acute hyperkalemia, hypocalcemia, anion-gap metabolic acidosis, and rapid azotemia. Serum creatinine and BUN increase very rapidly (1.0-1.5 mg/dL/day and 20-30 mg/dL/day, respectively).

The most important aid to the diagnosis of rhabdomyolysis is a high index of suspicion. The affected muscle may be obviously ischemic or swollen, painful, and edematous. Urine myoglobin often tests positive without reddish urine. The serum is clear because of the low renal threshold for myoglobin excretion, whereas in hemoglobinemia the larger hemoglobin molecule is poorly filtered and accumulates in serum, coloring it pink. Serial total creatinine phosphokinase (CPK) is a helpful guide to the severity of rhabdomyolysis (e.g., CPK-MM release).[267] AKI is much more likely when total CPK exceeds 10,000 U/L.

Prevention of myoglobin-induced AKI is dependent on the maintenance of high RBF and tubular flow. Urine flow should be kept between 100 to 150 mL/hour by osmotic diuresis with intravenous mannitol, 6.25 to 12.5 g every 6 hours, with or without intravenous furosemide, 10 to 20 mg as required.[268] Urine pH should be kept above pH 5.6 with intravenous sodium bicarbonate, 50 mEq intravenously, as required, and/or acetazolamide, 250 mg every 6 hours. However, because there are no prospective data that confirm the beneficial effect of urinary alkalinization, urine pH should not be increased at the expense of causing significant acid-base imbalance. Calcium should be given to treat hyperkalemia only.

Hemolysis and Hemoglobinemia

Hemolysis is induced by CPB, resulting in the release of free hemoglobin into the plasma, where it subsequently forms a complex with haptoglobin. This complex is too large to be filtered by the kidney and undergoes metabolism in the liver. When free hemoglobin production is excessive, it overwhelms the haptoglobin system and accumulates in the plasma. The hemoglobin molecule is small enough to be filtered by the glomerulus and enters the tubule, where it scavenges endothelium derived nitric oxide, subsequently releasing iron and causing tubular occlusion with hemoglobin cast formation. The released free iron is nephrotoxic, through the generation of reactive oxygen species.[195]

Preliminary evidence suggests that urinary alkalinization may attenuate AKI during CPB (see earlier).[241] Acute intravascular hemolysis due to mismatched blood transfusion (ABO incompatibility) represents a direct and devastating renal insult. However, renal damage is thought to be predominantly due to red blood cell stroma rather than to free hemoglobin. Protective renal management is essentially the same as for rhabdomyolysis (i.e., aggressive and sustained hydration, with or without osmotic diuresis, and urinary alkalinization).

Jaundice and Bilrubinemia

There is a direct correlation between the degree of preoperative obstructive jaundice and postoperative renal dysfunction.[269] When cholestasis causes the conjugated bilirubin to increase above 8 mg/dL, bile salt excretion effectively ceases, resulting in portal septicemia and renal damage. This situation is analogous to hepatorenal syndrome and sepsis, in which circulating endotoxins induce renal vasoconstriction and damage (vasomotor nephropathy).

Administration of preoperative oral bile salts (e.g., sodium taurocholate) or intravenous mannitol may provide perioperative renal protection in patients with severe obstructive jaundice. However, in a prospective, randomized study in patients with obstructive jaundice undergoing surgery, Plusa and Clark[270] found no difference in renal outcome between these two regimens. Nevertheless, mannitol provokes a brisk osmotic diuresis, and it is important to replace urinary losses appropriately. Diuresis-induced hypovolemia negates the protective effect of mannitol.[271]

SEPSIS

Sepsis is the most common cause of new-onset AKI in the postoperative period (also see Chapter 101). It may induce renal damage by altered hypotension and vasomotor nephropathy and through the direct and indirect effects of endotoxin, and renal function may deteriorate progressively without defined episodes of hypotension. In addition, sepsis predisposes the kidney to further ischemic and nephrotoxic insults (e.g., from concomitant aminoglycoside usage).[272] Acute renal failure itself and hemodialysis may both perpetuate sepsis by activating leukocytes.

Renal autoregulation may be impaired in sepsis, and RBF and GFR decrease pari passu with systemic vascular resistance and mean arterial pressure. Hypotension, in turn, sets off a cascade of neurohormonal responses (sympathoadrenal activity; renin-angiotensin, vasopressin, and thromboxane activation) that result in decreased RBF, GFR, sodium excretion, and urine flow. The severity of renal dysfunction is directly related to the severity of sepsis and the degree of plasma renin activation.[273]

Renal dysfunction in sepsis is characterized as a vasomotor nephropathy, which implies renal vasoconstriction in the face of increased total cardiac index. Renal vasoconstriction, mesangial cell contraction, decreased ultrafiltration coefficient, and decreased GFR are induced by endotoxin and by compounds activated in sepsis.[274] These include endothelin and eicosanoids, such as thromboxane, prostaglandin F_2, and the leukotrienes C4 and D4. Prostaglandin F_2, which mimics the action of thromboxane, is formed during leukostasis when arachidonic acid is oxidized by free oxygen radicals.

Endotoxin causes leukocyte arachidonic acid to undergo lipoxygenation to form leukotrienes; it also impairs their biliary elimination. In addition, experimental infusion of lipopolysaccharide (endotoxin) directly decreases RBF, GFR, and tubular concentrating ability and

increases urinary loss of tubular enzymes. It causes sequestration of leukocytes in peritubular capillaries, induces endothelial lesions by releasing neutrophil-derived elastase (enhanced by reperfusion injury), and potentiates renal ischemia such that brief hemodynamic instability causes rapid loss of renal function. It also potentiates nephrotoxicity. The changes caused by endotoxin are mimicked by the cytokine, tumor necrosis factor-α.

It has been estimated that about 10% to 26% of septic patients receiving aminoglycoside antibiotics will develop nephrotoxic renal insufficiency.[245] Aminoglycoside nephrotoxicity is enhanced by the interaction of fever, renal vasoconstriction, hypovolemia, and endotoxin. In the presence of these and other risk factors (see earlier), alternative nonnephrotoxic antibiotics should be considered to cover gram-negative infections, including penicillins (ticarcillin), cephalosporins (ceftazidime), carbapenems (imipenem), or monobactams (aztreonam).

RENAL PROTECTION IN SEPTIC SHOCK

Antiinflammatory Drugs

Cumming and associates[275] demonstrated a marked renal protective effect of a selective thromboxane synthetase inhibitor (U63557A) in laparotomy on a intravascularly volume-loaded sheep peritonitis model. Administration of the selective inhibitor either before or 30 minutes after surgery prevented deterioration in creatinine clearance, urinary sodium excretion, and urine flow rate. Beneficial effects have also been observed with aprotonin, perhaps through its antiinflammatory action.[102] In contrast, nonselective cyclooxygenase inhibition by NSAIDs worsens renal function in sepsis by decreasing the synthesis of the renal vasodilator prostacyclin.[276]

The use of pharmacologic doses of methylprednisolone in septic shock was discredited by two large multicenter studies showing no beneficial effect on outcome.[277,278] Moreover, patients who received steroids had significant increases in BUN but not in serum creatinine, suggesting a prerenal state induced by increased protein catabolism.[279] Other potentially adverse effects of large-dose steroids include impaired mitochondrial function, impaired leukocyte function, and inhibition of phospholipase A_2, resulting in decreased synthesis of intrarenal vasodilator prostaglandins.

Supranormal Oxygen Delivery

Over the last decade there has been considerable controversy in the concept of supranormal oxygen delivery to the tissues to overcome the defect that exists in oxygen utilization by septic tissues.[280] This approach uses inotropic support and blood transfusion to drive global oxygen delivery (DO_2) to one of three end points: (1) a DO_2 level consistently found in survivors (600 mL/minute/m^2), (2) a level at which global oxygen consumption (VO_2) no longer increases with increasing DO_2 (consumption independence), or (3) the point at which blood lactate levels start to decline. The benefits of supranormal oxygen delivery on outcome have been disputed, and high-dose inotropic and vasopressor support may themselves have adverse consequences. Moreover, renal DO_2 and VO_2 differ markedly from systemic indices. Renal VO_2 is largely determined by tubular metabolic function, which is regulated by fluid and electrolyte changes. In a volume-loaded septic porcine model, inotropic support with dobutamine increased systemic DO_2 and VO_2 but did not increase renal indices.[77] Furthermore, decreased global renal DO_2 does not appear to cause tubular damage, possibly because tubular work and VO_2 are decreased when GFR declines.[281]

Dopaminergic Agents

Low-dose dopamine (1 to 3 μg/kg/minute) is frequently administered to septic patients in the belief that it confers renal protection through renal vasodilation or perhaps by inhibition of the Na^+-K^+-ATPase pump and decreases in renal tubular VO_2.

In cases of sepsis, low-dose dopamine is also administered in combination with more potent pressors (dobutamine, epinephrine, and norepinephrine) in the hope of enhancing hepatic, renal, and mesenteric perfusion. There are limited animal data to support this practice. In a nonseptic dog study in which RBF was measured by thermodilution, the addition of low-dose dopamine to a norepinephrine infusion of 0.2-1.6 μg/kg/minute increased RBF by 40% to 50%.[78] However, a subsequent study demonstrated that although low-dose dopamine increased RBF when added to an epinephrine infusion in healthy sheep, this benefit could not be found in an intraperitoneal sepsis model.[282] Low-dose dopamine can increase hepatic DO_2, but possibly at the expense of splanchnic oxygenation.

In patients with sepsis syndrome (signs of sepsis without hypotension), low-dose dopamine infusion doubled urine flow rate and increased creatinine clearance by 60% without any change in systemic hemodynamics.[283] However, the renal response to dopamine decreased significantly after 48 hours of dopamine infusion, possibly due to down-regulation of the renal dopaminergic receptors or diuresis-induced contraction of the intravascular volume. In patients with established septic shock who required catecholamines for blood pressure support, low-dose dopamine did not alter systemic hemodynamics or renal function.

The prophylactic administration of low-dose dopamine in sepsis has been resolved by a large prospective controlled study conducted by the Australian and New Zealand Intensive Care Society (ANZICS). They randomized 328 patients with signs of the systemic inflammatory response syndrome (SIRS) and early renal dysfunction (oliguria or increasing serum creatinine) to dopamine 2 mcg/kg/minute or placebo. They found no differences in serum creatinine, dialysis requirement, ICU or hospital length of stay, or overall mortality.[284]

The potential role of dopexamine in septic shock remains speculative. Most studies have examined its role in splanchnic and hepatic perfusion rather than in renal protection. In animal models of sepsis, dopexamine improves splanchnic and hepatic DO_2, but its β_2-adrenergic activity in causing tachycardia and hypotension may limit its application in clinical sepsis. Smithies and colleagues[285] administered dopexamine to patients with sepsis syndrome, acute respiratory failure,

and at least one other organ system failure. Cardiac index increased and gastric intramucosal pH (an index of splanchnic perfusion) improved significantly.

In contrast, there is at least preliminary evidence that infusion of low-dose fenoldopam may have a renoprotective effect in sepsis. A pilot randomized, double-blind, placebo-controlled trial on 300 septic patients found that fenoldopam infusion (0.09 mcg/kg/minute) resulted in a significant decrease in AKI (defined as an increase in SCr >150 mM/L) and ICU length of stay, but not mortality.[286] These encouraging results await confirmation by a large multicenter study.

Norepinephrine

In the setting of severe vasodilatory shock, concern that infusions of norepinephrine may impair renal blood flow through α-adrenergic–induced vasoconstriction appears to be unfounded. In patients with septic shock, profound hypotension, and oliguria, vasopressor therapy with norepinephrine may actually improve renal function by enhancing renal perfusion pressure. Desjars and associates[11] evaluated a group of septic patients who remained oliguric despite volume resuscitation and the use of dopamine up to doses of 15 μg/kg/minute. The addition of norepinephrine and reduction of dopamine to a low-dose level resulted in an improvement in mean arterial pressure from 50 to 70 mm Hg, a tripling of urine flow, and a doubling of creatinine clearance. Norepinephrine increased the systemic vascular resistance (SVR) with little change in cardiac index or DO_2. Subsequent studies confirm that the use of norepinephrine to keep mean arterial pressure greater than 60 mm Hg results in improved cardiac function (increase in stroke volume and decrease in heart rate) and GFR without deleterious effects on cardiac index (CI), VO_2, or oxygen extraction.[287]

Large doses of norepinephrine may be required to achieve these goals, because in septic shock the peripheral vasculature is notoriously refractory to norepinephrine-induced vasoconstriction. This occurs because of massive inducible nitric oxide release and vasopressin deficiency (see later). Nonetheless, these findings strongly support the concept that renal autoregulation is impaired in sepsis and that maintenance of adequate renal perfusion pressure is an important component of renal protection.

Arginine Vasopressin

Patients in vasodilatory shock have inappropriately low plasma levels of arginine vasopressin (AVP) and marked vascular sensitivity to its exogenous administration at low doses.[288] Vasodilatory shock is defined as hypotension, increased cardiac index, and low systemic vascular resistance refractory to pressors such as norepinephrine. Septic shock is its most common manifestation, but it is also characteristic of the contact activation syndrome induced by cardiopulmonary bypass or ventricular assist devices.[289]

Landry and colleagues[290] observed unusual sensitivity to the vasoconstrictor effects of infused AVP in patients with septic shock and profound hypotension despite catecholamine infusion. Infusion of AVP at doses of 2.4 U/hour, less than one tenth of those used in the treatment of bleeding esophageal varices, resulted in a dramatic

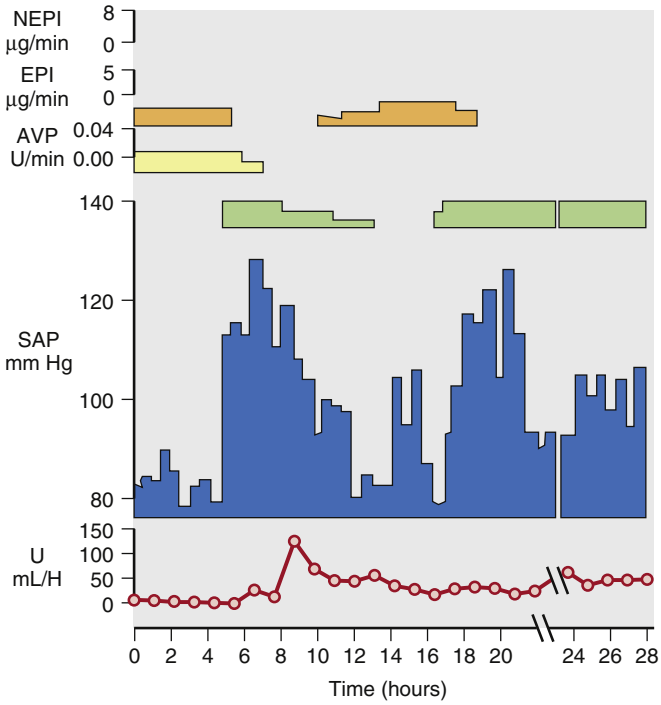

Figure 23-27. Effects of an infusion of AVP in vasodilatory shock.

increase in systolic blood pressure from 92 ± 4 mm Hg to 146 ± 4 mm Hg (mean ± SEM, $P < .001$), and catecholamine infusions were able to be discontinued (Fig. 23-27). In an associated report[291] the authors observed that urine flow increased concomitantly in three of five patients, from an average of 30 mL/hour to 110 mL/hour.

Plasma AVP levels were remarkably low (3.1 ± 1.0 pg/mL) and significantly lower than in a cohort of patients in cardiogenic shock also receiving catecholamines (22.7 ± 2.2 pg/mL, $P < 0.001$).[290] It has been postulated that this AVP deficiency may be the result of excessive baroreceptor-mediated AVP release from sustained hypotension. This is strongly supported by a canine study demonstrating almost complete depletion of radiolabeled AVP in the posterior pituitary following 1 hour of hemorrhagic shock.[288] In a human study in patients in vasodilatory shock we confirmed very low levels of endogenous plasma AVP (<2 pg/mL) that were corrected to the 20- to 30-pg/mL range by an infusion of AVP at 1 to 4 U/hour (Table 23-7).

A second mechanism for sensitivity to AVP in septic patients is explained by its effect on the potassium-ATP (K_{ATP}) channel.[288] Intracellular acidosis, lactic acid accumulation, and ATP depletion close K_{ATP} channels in the sarcolemma of vascular smooth muscle. This traps potassium outside the cell and hyperpolarizes the membrane, which in turn closes calcium channels essential for norepinephrine-induced vasoconstriction. AVP binds at the K_{ATP} channel and opens it, reversing membrane hyperpolarization and restoring sensitivity to norepinephrine.

The beneficial effect of AVP on renal function in sepsis may be due in part to its ability to increase low renal perfusion pressure back into the autoregulatory range. Another important factor is that, unlike norepinephrine, even at high local concentrations, AVP preferentially

TABLE 23-7 PLASMA VASOPRESSIN LEVELS IN VASODILATORY SEPTIC SHOCK

	Vasopressin Levels in pg/mL	
	T0*	T1
AVP (n = 12)	1.84 ± 0.59	32.3 ± 7.69
Placebo (n = 11)	1.72 ± 0.72	1.5 ± 0.5

From Kinster C, Germann P, Ullrich R, Landry D, Sladen RN: Infusion of arginine vasopressin (AVP) enhances blood pressure and renal function while preserving cerebral and splanchnic perfusion in patients in septic shock. Presented at Annual Meeting of American Society of Anesthesiologists (ASA), Orlando, FL, 2002.

AVP, Arginine vasopressin

*T0 represents mean baseline levels of plasma vasopressin in 23 patients in vasodilatory septic shock (hypotension requiring norepinephrine infusion to maintain mean arterial pressure [MAP] > 65 mm Hg, elevated cardiac index, decreased systemic vascular resistance, and three or more criteria of systemic inflammatory response syndrome). Mean plasma vasopressin levels are uniformly low, <2 pg/mL.

Patients were randomized in a blinded fashion to an infusion containing AVP (1-6 units/hr) or placebo, until norepinephrine infusion was no longer required to keep MAP >65 mm Hg, or the maximum infusion rate (6 mL/hr) was achieved, or the infusion had been administered for 2 hours.

Patients randomized to AVP infusion had a significant, 65% decrease in norepinephrine requirement, whereas it was unchanged in the placebo group. As indicated at T1—the point at which study end points were achieved—the mean plasma vasopressin that reflected a therapeutic effect of AVP infusion was about 32 pg/mL, which is in the range of the effective physiologic human vasopressin response to hypotension.

These observations support the concept that exogenous AVP infusion in vasodilatory septic shock restores the normal response to hypotension that is attenuated by posterior pituitary vasopressin depletion.

constricts the efferent arteriole, thereby improving filtration fraction and GFR.[292] In a large, prospective, randomized, blinded trial in 778 patients with severe septic shock, low-dose AVP (0.01-0.03 units/minute) did not provide an overall mortality benefit or decrease the requirement for dialysis, when compared with an infusion of norepinephrine (5-15 mcg/minute).[293] However, a post hoc analysis of the data found that in patients who entered the study with the R (risk) criterion of RIFLE-defined AKI, significantly fewer (21% versus 40%) progressed to the F (failure) or L (loss) categories or needed dialysis (17% versus 38%) when they were randomized to AVP rather than norepinephrine.[294]

RENAL CROSSTALK

Awareness and concern have increased that AKI may lead to acute injury in other, multiple organ systems, including the lung, brain, liver, and heart, through the phenomenon of organ "crosstalk."[295] The organ crosstalk that is initiated by AKI is mediated by acute inflammation, oxidative stress, and reactive oxygen species, resulting in activation of leukocytes and cytokines and induction of apoptosis and necrosis in distant organs. Multisystem organ dysfunction is common in patients developing AKI in the ICU, and it may account for a morbidity and mortality rate out of proportion to that anticipated by isolated AKI alone.

Crosstalk works both ways. For example, not only may AKI lead to acute lung injury, but the inflammatory processes induced by acute lung injury may themselves initiate or exacerbate AKI. Kidney-heart interactions involve much more than inflammatory pathways alone; they involve numerous neurohormonal interactions, resulting in a series of entities known as cardiorenal syndromes (CRS).[296] The most obvious kidney-brain interaction is uremic encephalopathy, but there also appear to be structural neuronal injuries caused by uremic toxins, especially NOS-modulating guanidine compounds, that are proexcitatory at the NMDA receptor.[297] Acute liver injury and transaminitis may be observed with severe AKI,[298] and in reverse, severe liver failure and vasoactive compound dysregulation may result in impaired kidney function (i.e., hepatorenal syndrome).

Chapter 24

Basic Principles of Pharmacology

TAE KYUN KIM • SHINJU OBARA • KEN B. JOHNSON

Acknowledgment: The editors and publisher would like to thank Drs. Steven L. Shafer, Pamela Flood, and Debra A. Schwinn for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Pharmacokinetics describes the relationship between drug dose and drug concentration in plasma or at the site of drug effect over time. For anesthetic drugs, the processes of distribution and elimination (metabolism and excretion) govern this relationship.
- The time course of intravenously administered drugs is a function of distribution volume and clearance. Estimates of distribution volumes and clearances are described by pharmacokinetic parameters. These parameters are derived from mathematical formulas fit to measured blood or plasma concentrations over time following a known drug dose.
- Alterations in cardiac output substantially influence the pharmacokinetic behavior of anesthetic drugs in terms of onset and duration of effect.
- Biophase refers to the time delay between changes in plasma concentration and drug effect. Biophase accounts for the time required for drug to diffuse from the plasma to the site of action plus the time required, once drug is at the site of action, to illicit a drug effect.
- Pharmacodynamics describes what the drug does to the body. In particular, pharmacodynamics describes the relationship between drug concentration and pharmacologic effect.
- The effect-site concentration describes a mathematically derived virtual location where an anesthetic drug exerts its effect. This approach cannot describe a mechanism of drug action (e.g., drug-receptor interaction)
- A single anesthetic drug has multiple effects (i.e., analgesia, ventilatory depression, loss of response to laryngoscopy, and changes in the electroencephalogram) that typically occur at various effect-site concentrations.
- The concentration range where changes in drug effect occur is known as the dynamic range. Concentrations outside the dynamic range do not yield much change in drug effect. Levels below the dynamic range are ineffective and those above the dynamic range do not provide additional effect.
- Anesthesia is the practice of applied drug interactions. Anesthetics rarely consist of one drug, but rather a combination of drugs to achieve desired levels of hypnosis, analgesia, and muscle relaxation. Hypnotics, analgesics, and muscle relaxants all interact with one another such that rarely does one drug, when administered in the presence of other drugs, behave as if it were administered alone.
- Pharmacokinetic and pharmacodynamic principles characterize the magnitude and time course of drug effect, but because of complex mathematics, they have limited clinical utility. Advances in computer simulation have brought this capability to the point of real-time patient care in the form of drug displays.
- Special populations: Many aspects of a patient's demographics and medical history are considered in finding the correct dose. Some of these include age; body habitus; gender; chronic exposure to opioids, benzodiazepines, or alcohol; presence of heart, lung, kidney, or liver disease; and the extent of blood loss or dehydration.
- Some patient characteristics (e.g., obesity and age) influence anesthetic drug behavior, whereas other patient characteristics (chronic opioid use, hepatic and renal failure) remain poorly described.

The basic principles of pharmacology are fundamental to an anesthesia provider's knowledge base. The aim of this chapter is to provide an overview of key principles in clinical pharmacology used to describe anesthetic drug behavior. This chapter is divided into three major sections: pharmacokinetic principles, pharmacodynamic principles, and the importance of patient characteristics. Pharmacokinetics is the relationship between drug administration and drug concentration at the site of action. Core concepts include volumes of distribution, drug clearance, transfer of drugs between plasma and tissues, and binding of drugs to circulating plasma proteins. The section on pharmacokinetics introduces both the physiologic processes that determine pharmacokinetics and the mathematical models used to relate dose to concentration.

Pharmacodynamics is the relationship between drug concentration and pharmacologic effect. An anesthetic rarely consists of only one drug. In fact, most anesthetics are a combination of several drugs with specific goals in analgesia, sedation, and muscle relaxation. This section reviews common pharmacodynamic interactions and how they influence anesthetic effect.

The last section briefly addresses patient demographics and how they influence anesthetic behavior. When formulating an anesthetic, the following factors need to be considered in determining the correct dose: age; body habitus; gender; chronic exposure to opioids, benzodiazepines, or alcohol; the presence of heart, lung, kidney, or liver disease; and the extent of blood loss or dehydration. This section focuses on body habitus and age, both known to influence the pharmacology of many anesthetic drugs and both of which serve as excellent examples of altered pharmacokinetics and pharmacodynamics.

PHARMACOKINETICS PRINCIPLES

Pharmacokinetics describes the relationship between drug dose and drug concentration in plasma or at the site of drug effect over time. The processes of absorption, distribution, and elimination (metabolism and excretion) govern this relationship. Absorption is not relevant to intravenously administered drugs but is relevant to all other routes of drug delivery. The time course of intravenously administered drugs is a function of distribution volume and clearance. Estimates of distribution volumes and clearances are described by pharmacokinetic parameters. Pharmacokinetic parameters are derived from mathematical formulas fit to measured blood or plasma concentrations over time following a known drug dose.

FUNDAMENTAL PHARMACOKINETIC CONCEPTS

Volume of Distribution

An oversimplified model of drug distribution throughout plasma and tissues is the dilution of a drug dose into a tank of water. The volume of distribution (Vd) is the apparent size of the tank required to explain a measured drug concentration from the tank water once the drug has had enough time to thoroughly mix within the tank (Fig. 24-1). The distribution volume is estimated using the simple relationship between dose (e.g., mg) and measured concentration (e.g., mg/L) as presented in Equation 1.

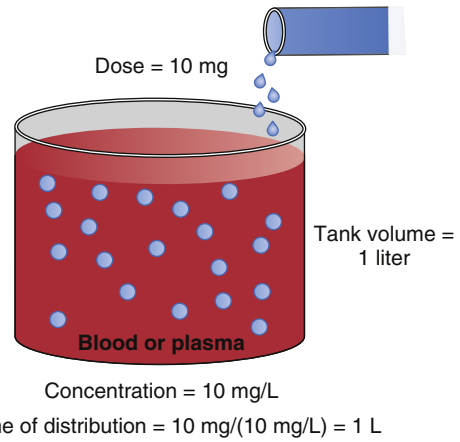

Figure 24-1. Schematic of a single-tank model of distribution volume. The group of blue dots at the top right represents a bolus dose that, when administered to the tank of water, evenly distributes within the tank.

$$\text{Volume of Distribution} = \frac{\text{Amount of dose}}{\text{Concentration}} \quad [1]$$

With an estimate of tank volume, drug concentration after any bolus dose can be calculated. Just as the tank has a volume regardless of whether there is drug in it, distribution volumes in people are an intrinsic property regardless of whether any drug has been given.

Human bodies are not water tanks. As soon as a drug is injected, it begins to be cleared from the body. To account for this in the schematic presented in Figure 24-1, a faucet is added to the tank to mimic drug elimination from the body (Fig. 24-2). Using Equation 1, to estimate the volume of distribution without accounting for elimination leads to volume of distribution estimates that become larger than initial volume. To refine the definition of distribution volume, the amount of drug that is present at a given time t is divided by the concentrations at the same time:

$$Vd = \frac{\text{Amount (t)}}{\text{Concentration (t)}} \quad [2]$$

If elimination occurs as a first-order process (i.e., elimination is proportional to the concentration at that time), the volume of distribution calculated by Equation 2 will be constant (Fig. 24-3; also see Fig. 24-2).

When a drug is administered intravenously, some drug stays in the vascular volume, but most of the drug distributes to peripheral tissues. This distribution is often represented as additional volumes of distribution (tanks) connected to a central tank (blood or plasma volume). Peripheral distribution volumes increase the total volume of distribution (Fig. 24-4).

The schematic in Figure 24-4 presents a plasma volume and tissue volume. The peripheral tank represents distribution of drug in peripheral tissues. There may be more than one peripheral tank (volume) to best describe the entire drug disposition in the body. The size of the peripheral volumes represents a drug's solubility in tissue

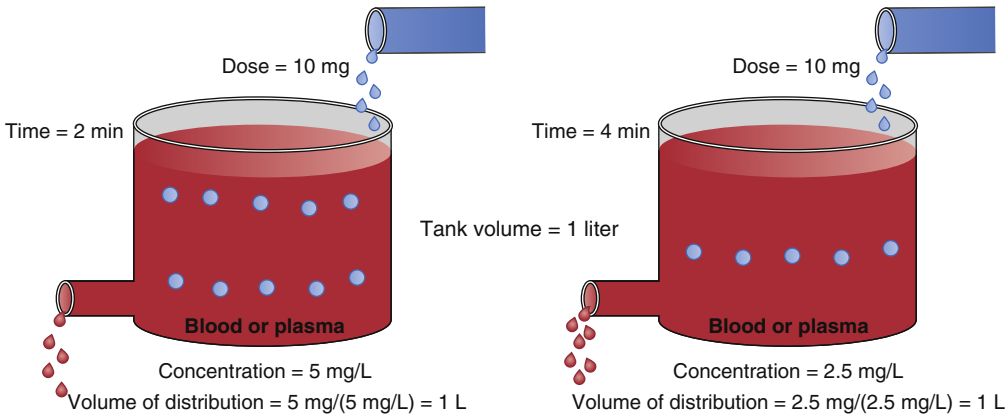

Figure 24-2. Schematic of a single-tank model of elimination as a first order process. At 2 minutes (*left panel*) and 4 minutes (*right panel*) following a 10-mg drug bolus, tank concentrations are decreasing from 5 to 2.5 mg/mL. Accounting for elimination, estimates of the distribution volume at each time point are both 1 liter.

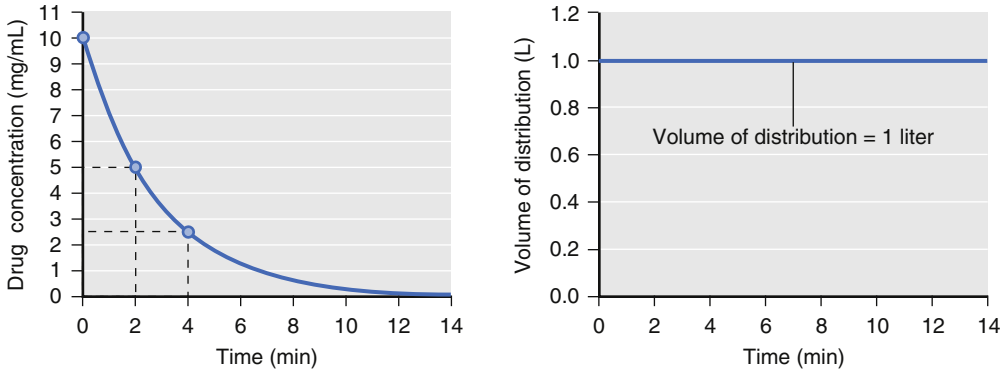

Figure 24-3. Simulation of concentration (*left panel*) and distribution volume (*right panel*) changes over time following a bolus dose for a single-tank (one-compartment) model. The distribution volume remains constant throughout.

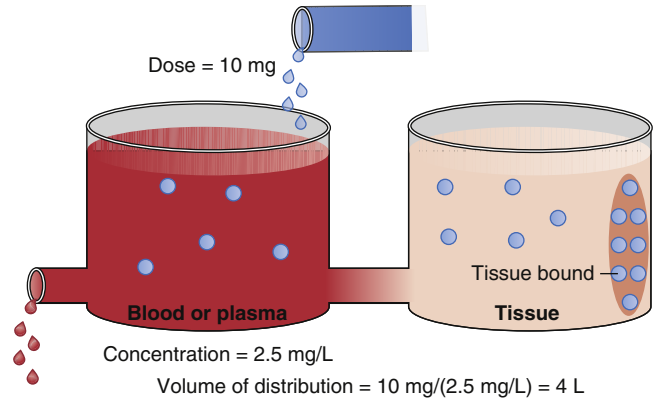

Figure 24-4. Schematic of a two-tank model. The total volume of distribution consists of the sum of the two tanks. The brown ellipse in the peripheral volume represents tissue that binds up drugs. The measured concentration in the blood or plasma is 2.5 mg/mL just after a bolus dose of 10 mg. Using Figure 24-1, this leads to a distribution volume of 4 liters.

relative to blood or plasma. The more soluble a drug is in peripheral tissue relative to blood or plasma, the larger the peripheral volumes of distribution.

An important point illustrated in Figure 24-4 is that drug not only distributes to the peripheral tank and thus increases the volume of distribution, but it also binds to tissue in that tank. This process further lowers the measureable concentration in the central tank. Thus, the total volume of distribution may even be larger than the two tanks added together. In fact some anesthetics have huge distribution volumes (e.g., fentanyl has an apparent distribution volume of 4 L/kg) that are substantially larger than an individual's vascular volume (0.07 L/kg) or extracellular volume (0.2 L/kg).

With an additional tank, the volume of distribution no longer remains constant over time. As illustrated in Figure 24-5, at time = 0, the volume of distribution is estimated as 4.3 L, the same as that of the model presented in Figure 24-3, which has only one tank. The volume of distribution then increases to 48 liters over the next 10 minutes. The increase is due to the distribution of drug to the peripheral volume and elimination once drug is in the body. The amount of drug that moves to the peripheral tissue commonly surpasses the amount that is eliminated during the first few minutes after drug administration. As an example, consider a simulation of a propofol bolus that plots the accumulation of propofol in peripheral tissues and the amount eliminated over time (Fig. 24-6). During the first 4 minutes, the amount distributed to the peripheral tissue is larger than the amount eliminated out of the body. Following 4 minutes, the amounts reverse.

Front-End Kinetics

Front-end kinetics refers to the description of intravenous drug behavior immediately following administration. How a drug rapidly moves from the blood into peripheral tissues directly influences the peak plasma drug concentration. With compartmental models, an important assumption is that an intravenous bolus instantly mixes in the central volume, with the peak concentration occurring at the moment of injection without elimination or

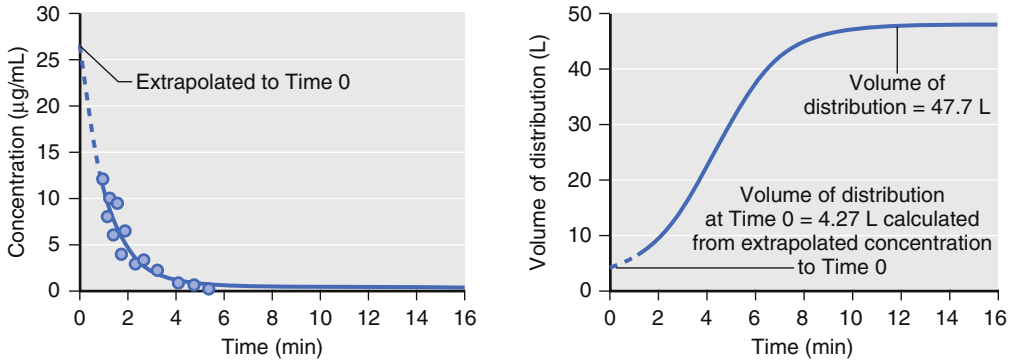

Figure 24-5. Simulation of concentration and apparent distribution volume changes over time following a bolus dose for a two-tank (two-compartment) model. *Left panel:* The dots represent measured drug concentrations. The *solid line* represents a mathematical equation fit to the measured concentrations. The *dotted line* represents an extrapolation of the mathematical equation (i.e., pharmacokinetic model) to time 0. *Right panel:* The apparent distribution volume is time dependent with the initial volume of distribution much small than the distribution volume at near steady state. The apparent distribution volume of time 0 is not true reflection of the actual volume of distribution.

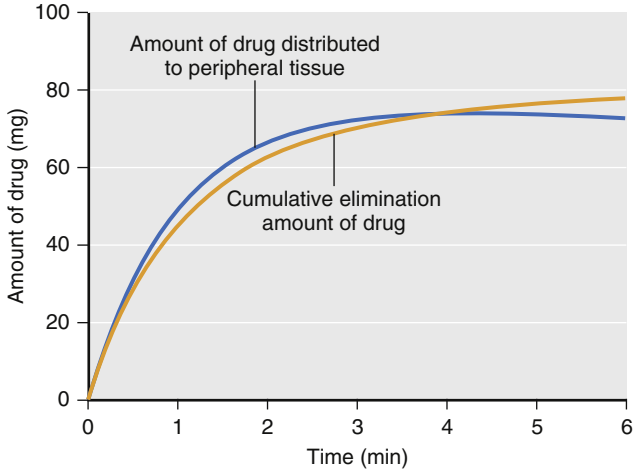

Figure 24-6. Simulation of propofol accumulation in the peripheral tissues (*blue line*) and the cumulative amount of propofol eliminated (*gold line*) following a 2-mg/kg propofol bolus to a 77-kg (170-lb), 53-year-old male who is 177 cm (5 ft 10 in) tall, using published pharmacokinetic model parameters.[1] *Drug* indicates propofol.

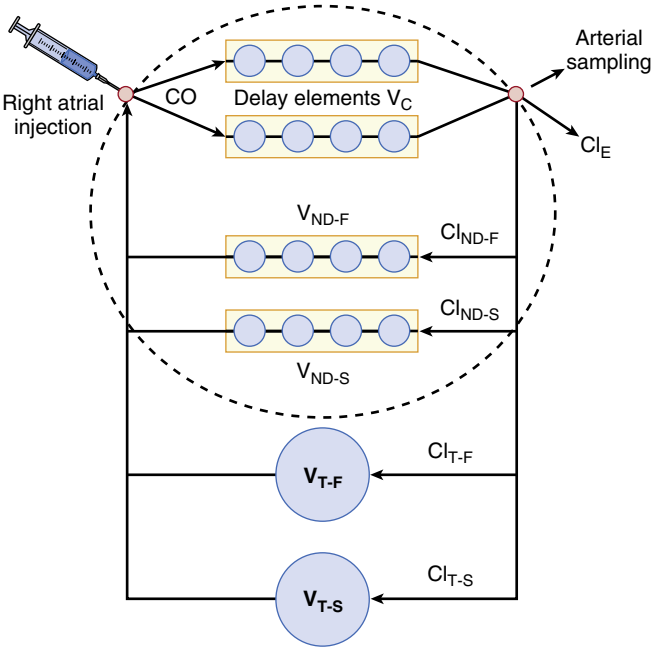

Figure 24-7. A recirculatory model accounting for cardiac output (CO), transit delays, pulmonary uptake (delay elements V and C), and nondistributive mixing pathways (V_{ND} and Cl_{ND}). All the components within the *dashed circle* are required to accurately model the central volume of distribution. In most situations, this complexity is not required, and the simpler approach of assuming instantaneous mixing within the central volume is an adequate approximation. Cl_{ND-F}, Fast nondistributive clearance; Cl_{ND-S}, slow nondistributive clearance; Cl_{T-F}, fast tissue clearance; Cl_{T-S}, slow tissue clearance; V_{ND-F}, fast nondistributive volume; V_{ND-S}, slow nondistributive volume; V_{T-F}, fast tissue volume; V_{T-S}, slow tissue volume.[2]

distribution to peripheral tissues. For simulation purposes, the initial concentration and volume of distribution at time = 0 are extrapolated as if the circulation had been infinitely fast. This, of course, is not real. If drug is injected into an arm vein and that the initial concentration is measured in a radial artery, drug appears in the arterial circulation 30 to 40 seconds after injection. The delay likely represents the time required for drug to pass through the venous volume of the upper part of the arm, heart, great vessels, and peripheral arterial circulation. More sophisticated models (e.g., a recirculatory model)[1] account for this delay and are useful when characterizing the behavior of a drug immediately following bolus administration, such as with induction agents where the speed of onset and duration of action are of interest (Fig. 24-7).

Clearance

Clearance describes the rate of drug removal from the plasma/blood. Two processes contribute to drug clearance: systemic (out of the tank) and intercompartmental (between the tanks) clearance (Fig. 24-8). Systemic clearance permanently removes drug from the body, either by eliminating the parent molecule or by transforming it into metabolites. Intercompartmental clearance moves drug between plasma and peripheral tissue tanks. By way of clarification, in this chapter, the words *compartment* and *tank* are interchangeable.

Clearance is defined in units of flow, that is, the volume completely cleared of drug per unit of time (e.g., liters/minute). Clearance is not to be confused with elimination rate (e.g., mg/minute). To explain why elimination rates

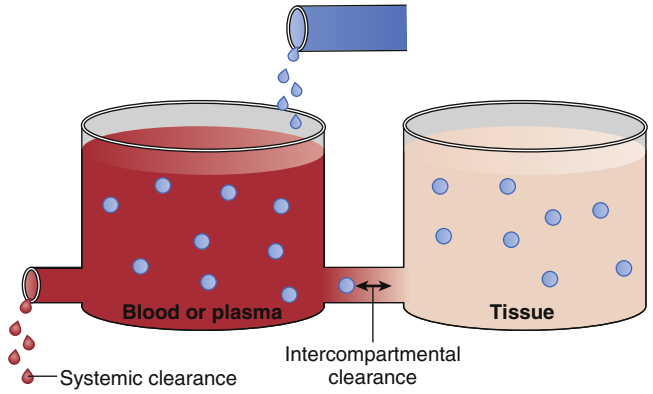

Figure 24-8. Schematic of a two-tank model illustrating two sources of drug removal from the central tank (blood or plasma): systemic and intercompartmental clearance.

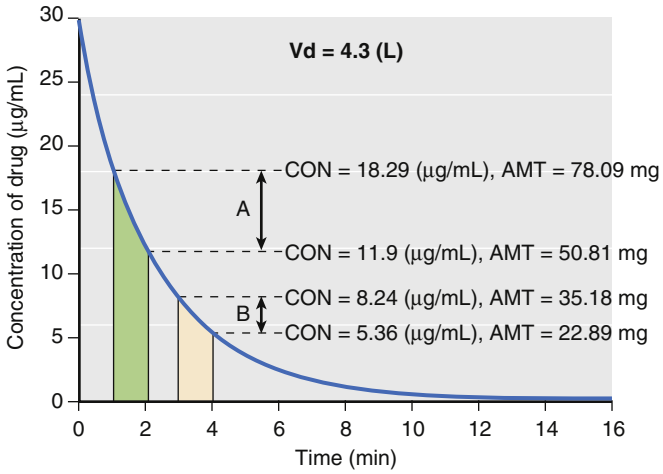

Figure 24-9. Simulation of drug concentration changes when a drug is administered to a single-tank model with linear elimination (see Fig. 24-2). The concentration changes for two time windows are labeled with diagonal lines from 1 to 2 minutes (*time window A*) and from 3 to 4 minutes (*time window B*), respectively. The concentrations (*CON*) at the beginning and end of each time window are used to calculate the amount (*AMT*) of drug that is eliminated (see text). *s* Volume of distribution.

do not accurately characterize clearance, consider the simulation presented in Figure 24-9. Using the volume of distribution, the total amount of drug can be calculated at every measured concentration. The concentration change in time window A is larger than in time window B even though they are both 1 minute in duration. The elimination rates are 27 and 12 mg/minute for time windows A and B, respectively. They are different and neither can be used as a parameter to predict drug concentrations when another dose of drug is administered. Because of this limitation with elimination rate, clearance was developed to provide a single number to describe the decay in drug concentration presented in Figure 24-9.

For discussion purposes, assume that concentration is the power necessary to push drug out of the water tank. The higher the concentration, the larger the amount of drug eliminated. To standardize the elimination rate, the eliminated amount of drug is scaled to concentration. For example, the elimination rate in time window A (27 mg/minute) scaled to the mean concentration during that time window (15 µg/mL) is 0.001807 mg/minute/mg/L. Reducing the units gives 0.002 L/minute. Normalizing the elimination rate in time window B to concentration gives the same as result as A. If the time interval is narrowed so that the time window approaches zero, the definition of clearance becomes:

$$\text{Clearance} = \frac{\frac{dA}{dt}}{C(t)} \qquad [3]$$

where dA/dt is the rate of drug elimination at given time and C(t) is the corresponding concentration at time. Rearranging Equation 3 and integrating both numerator and denominator, the following relationship holds:

$$\text{Clearance} = \frac{\int_0^\infty dA}{\int_0^\infty C(t)dt} \qquad [4]$$

because the term $\int_0^\infty dA$ is equal to the total amount of drug eliminated and $\int_0^\infty C(t)\,dt$ is the area under curve (AUC), then the following equation can be derived:

$$\text{Clearance} = \frac{\text{Dose}}{\text{AUC}} \qquad [5]$$

With long infusions, drug concentrations reach a steady-state condition where the rate of drug elimination (dA/dt) is in equilibrium with the rate of drug administration. Clearance in a steady-state condition can be obtained using Equation 3 as follows:

$$\text{Clearance} = \frac{\text{Infusion Rate}}{C_{ss}} \qquad [6]$$

where C_{ss} is the plasma concentration at steady state.

Physiologic Model for Clearance

Drug extraction by metabolic organs is illustrated in Figure 24-10. This model contains a metabolic organ system responsible for drug elimination. According to mass balance, the rate at which drug flows *out* of metabolic organs is the rate at which drug flows *into* them minus the metabolic rate. The elimination rate (dA/dt) can be expressed as $Q(C_{in} - C_{out})$. Rearranging C(t) in Equation 3 with C_{in}, clearance in Equation 3 can be expressed as

$$\text{Clearance} = \frac{Q(C_{in} - C_{out})}{C_{in}} \qquad [7]$$

where Q is the blood flow to metabolic organs, C_{in} is the concentration of drug delivered to metabolic organs, and C_{out} is the concentration of drug leaving metabolic organs. The fraction of inflowing drug extracted by the organ is $\frac{C_{in} - C_{out}}{C_{in}}$. This is called the extraction ratio (ER). Clearance can be estimated as organ blood flow multiplied by the ER. Equation 7 can be simplified to

$$\text{Clearance} = \frac{Q(C_{in} - C_{out})}{C_{in}} = Q \times \frac{C_{in} - C_{out}}{C_{in}} = Q \times ER \qquad [8]$$

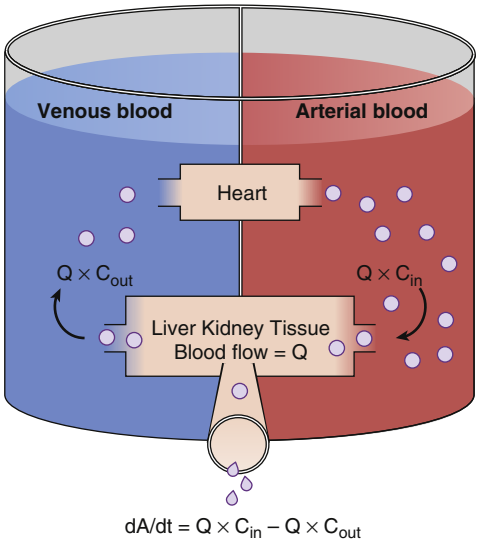

Figure 24-10. Schematic of drug extraction. *Q* indicates blood flow. C_{in} and C_{out} indicate drug concentrations presented to and leaving metabolic organs. *A* indicates the amount of drug, and *dA/dt* is the drug elimination rate.

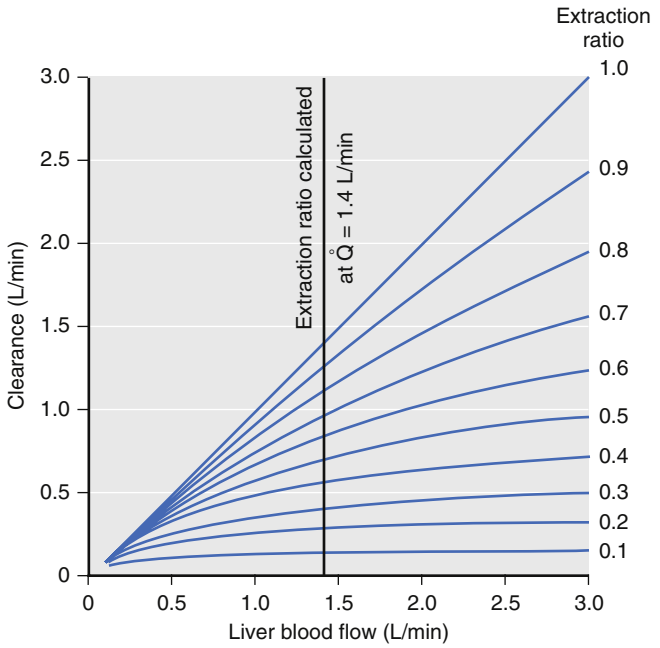

Figure 24-11. Relationship among liver blood flow (*Q*), clearance, and extraction ratio. For drugs with a high extraction ratio, clearance is nearly identical to liver blood flow. For drugs with a low extraction ratio, changes in liver blood flow have almost no effect on clearance.[3]

The total clearance is the sum of each clearance by metabolic organs such as the liver, kidney and other tissues.

Hepatic clearance has been well characterized. For example, the relationship among clearance, liver blood flow, and the extraction ratio is presented in Figure 24-11.[3] For drugs with an extraction ratio of nearly 1 (e.g., propofol), a change in liver blood flow produces a nearly proportional change in clearance. For drugs with a low extraction ratio (e.g., alfentanil), clearance is nearly independent of the rate of liver blood flow. If nearly 100% of the drug is extracted by the liver, this implies that the liver has a very large metabolic capacity for the drug. In this case, the rate-limiting step in metabolism is the flow of drug to the liver, and such drugs are said to be "flow limited." As a consequence, any reduction in liver blood flow due to circulatory effects of anesthetic agents or changes in circulatory volumes in cases of perioperative bleeding or other situations of excessive fluid loss can be expected to reduce liver-dependent drug clearance. However, moderate changes in hepatic metabolic function per se will have little impact on clearance because hepatic metabolic capacity is overwhelmingly in excess of demand.

For many drugs (e.g., alfentanil), the extraction ratio is considerably less than 1. For these drugs, clearance is limited by the capacity of the liver to take up and metabolize drug. These drugs are said to be "capacity limited." Clearance will change in response to any change in the capacity of the liver to metabolize such drugs, as might be caused by liver disease or enzymatic induction. However, changes in liver blood flow caused by the anesthetic regimen or other changes in splanchnic circulation usually have little influence on clearance because the liver handles only a fraction of the drug that it sees.

Hepatic Biotransformation

Most anesthetic drugs are cleared by hepatic biotransformation. The synthetic pathways for biotransformation are covered in detail in many biochemistry texts. Briefly, the liver metabolizes drugs through oxidation, reduction, hydrolysis, or conjugation. Oxidation and reduction occur in the cytochrome P450 system. These enzymes can be induced by exposure to certain drugs (e.g., the herbal remedy St. John's wort) and increase the liver's intrinsic metabolic capacity. Other drugs or hepatic disease can inhibit these enzymes (e.g., selected calcium channel blockers and selected antibiotics). Routes of oxidative metabolism include hydroxylation, dealkylation, deamination, desulfuration, epoxidation, and dehalogenation. Conjugation and hydrolysis often occur outside the P450 system, although glucuronidation involves the P450 system as well. The effect of conjugation is to transform hydrophobic molecules into water-soluble molecules through the addition of polar groups and thus render the metabolites easier to excrete via the kidneys. The metabolites generated by the liver are generally inactive, although some drugs (e.g., morphine, midazolam) have metabolites that are as potent as the parent drug. Genetic polymorphism can occur in all of these pathways, and this accounts for part of the variability in clearance in the population.

Extrahepatic Metabolism

Although most anesthetic drugs are cleared by hepatic metabolism, remifentanil, succinylcholine, and esmolol are cleared in the plasma and tissues by ester hydrolysis, and pancuronium is cleared via the kidney. The relationship between metabolism and clearance is complex. The following exploration of this relationship will assume hepatic metabolism, although the principles apply to the metabolism of drug in any tissue. The rate of metabolism for most anesthetic drugs is proportional

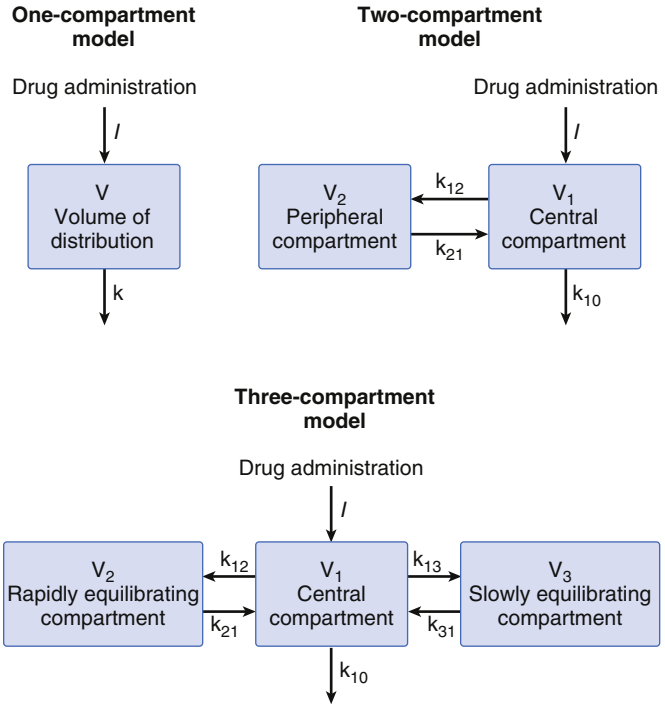

Figure 24-12. One-, two-, and three-compartment mammillary models.

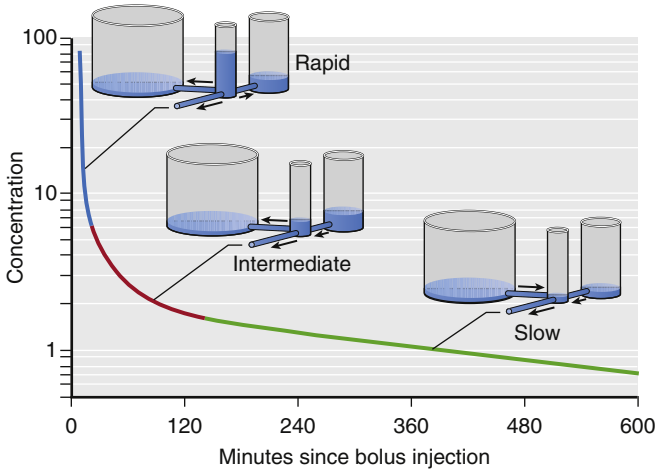

Figure 24-13. Hydraulic model of fentanyl pharmacokinetics. Drug is administered into the central tank, from which it can distribute into two peripheral tanks, or it may be eliminated. The volume of the tanks is proportional to the volumes of distribution. The cross-sectional area of the pipes is proportional to clearance.[5]

to the concentration of drug distributed via circulation to the liver. As was shown earlier, this means that metabolic clearance is usually constant and independent of dose.

Physiologic Pharmacokinetic Models

It is possible to analyze volumes and clearances for each organ in the body and construct models of pharmacokinetics by assembling the organ models into physiologically and anatomically accurate models of the entire animal.[4] Models that work with individual tissues are mathematically cumbersome and do not offer a better prediction of plasma drug concentration than models that lump the tissues into a few compartments. If the goal is to determine how to give drugs to obtain therapeutic plasma drug concentrations, all that is needed is to mathematically relate dose to plasma concentration. For this purpose, conventional compartmental models are usually adequate.

Compartmental Pharmacokinetic Models

Compartmental models are built on the same basic concepts as physiologic models, but with gross simplifications. The one-compartment model seen in Figure 24-12 contains a single volume and a single clearance, as though humans were built like tanks. For anesthetic drugs, human bodies resemble several tanks connected by pipes. These are usually modeled by two- or three-compartment models, also shown in Figure 24-12. The volume to the right in the two-compartment model—and in the center of the three-compartment model—is the central volume. The other volumes are peripheral volumes. The sum of all volumes is the volume of distribution at steady state, Vd_{ss}. Clearance in which the central compartment is left for the outside is the central, or metabolic, clearance. Clearances between the central compartment and the peripheral compartments are the intercompartmental clearances.

Multicompartment Models

Plasma concentrations over time after an intravenous bolus resemble the curve in Figure 24-13. This curve has the characteristics common to most drugs when given by intravenous bolus. First, the concentrations continuously decrease over time. Second, the rate of decline is initially steep but continuously becomes less steep, until we get to a portion that is log-linear.

For many drugs, three distinct phases can be distinguished, as illustrated in Figure 24-13. A rapid-distribution phase (blue line) begins immediately after injection of the bolus. Very rapid movement of the drug from plasma to the rapidly equilibrating tissues characterizes this phase. Frequently, there is a second, slow-distribution, phase (red line), which is characterized by movement of drug into more slowly equilibrating tissues and return of drug to plasma from the most rapidly equilibrating tissues. The terminal phase (green line) is a straight line when plotted on a semilogarithmic graph. The terminal phase is often called the elimination phase because the primary mechanism for decreasing drug concentration during the terminal phase is elimination of drug from the body. The distinguishing characteristic of the terminal elimination phase is that the plasma concentration is lower than tissue concentrations and the relative proportion of drug in plasma and peripheral volumes of distribution remains constant. During this terminal phase, drug returns from the rapid- and slow-distribution volumes to plasma and is permanently removed from plasma by metabolism or excretion.

The presence of three distinct phases after bolus injection is a defining characteristic of a mammillary model

with three compartments.[5] In this model, there are three tanks, corresponding (from left to right) to the slowly equilibrating peripheral compartment, the central compartment (the plasma, into which drug is injected), and the rapidly equilibrating peripheral compartment. The horizontal pipes represent intercompartmental clearance or (for the pipe draining onto the page) metabolic clearance. The volumes of each tank correspond to the volumes of the compartments for fentanyl. The cross-sectional areas of the pipes correlate with fentanyl systemic and intercompartmental clearance. The height of water in each tank corresponds to drug concentration. By using this hydraulic model, we can follow the processes that decrease drug concentration over time after bolus injection. Initially, drug flows from the central compartment to both peripheral compartments via intercompartmental clearance and completely out of the model via metabolic clearance. Because there are three places for drug to go, the concentration in the central compartment decreases very rapidly. At the transition between the blue line and the red line, a change occurs in the role of the most rapidly equilibrating compartment. At this transition, the concentration in the central compartment falls below the concentration in the rapidly equilibrating compartment, and the direction of flow between them is reversed. After this transition (red line), drug in plasma has only two places to go: into the slowly equilibrating compartment or out the drain pipe. These processes are partly offset by the return of drug to plasma from the rapidly equilibrating compartment. The net effect is that once the rapidly equilibrating compartment has come to equilibration, the concentration in the central compartment falls far more slowly than before.

Once the concentration in the central compartment falls below both the rapidly and slowly equilibrating compartments (green line), the only method of decreasing the plasma concentration is metabolic clearance, the drain pipe. Return of drug from both peripheral compartments to the central compartment greatly slows the rate of decrease in plasma drug concentration.

Curves that continuously decrease over time, with a continuously increasing slope (i.e., curves that look like Fig. 24-13), can be described by a sum of negative exponentials. In pharmacokinetics, one way of denoting this sum of exponentials is to say that the plasma concentration over time is

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t} \quad [9]$$

where t is the time since the bolus, C(t) is the drug concentration after a bolus dose, and A, α, B, β, C, and γ are parameters of a pharmacokinetic model. A, B, and C are called coefficients, whereas α, β, and γ are called exponents. After a bolus injection, all six of the parameters in Equation 9 will be greater than 0. The main reason that polyexponential equations are used is that they describe the plasma concentrations observed after bolus injection, except for the misspecification in the first few minutes mentioned previously. Compartmental pharmacokinetic models are strictly empirical. The models have no anatomic correlates. They are solely based on fitting equations to measured plasma concentrations following a known dose. Kinetic models are transformed into models that characterize concentration changes over time in terms of volumes and clearances. Although more intuitive, these models have no physiologic correlates.

Special significance is often ascribed to the smallest exponent. This exponent determines the slope of the final log-linear portion of the curve. When the medical literature refers to the half-life of a drug, unless otherwise stated, the half-life will be the terminal half-life. However, the terminal half-life for drugs with more than one exponential term is nearly uninterpretable. The terminal half-life sets an upper limit on the time required for the concentrations to decrease by 50% after drug administration. Usually, the time needed for a 50% decrease will be much faster than that upper limit.

Part of the continuing popularity of pharmacokinetic compartmental models is that they can be transformed from an unintuitive exponential form to a more intuitive compartmental form, as shown in Figure 24-12. Micro rate constants, expressed as k_{ij}, define the rate of drug transfer from compartment i to compartment j. Compartment 0 is the compartment outside the model, so k_{10} is the micro rate constant for processes acting through metabolism or elimination that irreversibly remove drug from the central compartment (analogous to k for a one-compartment model). The intercompartmental micro rate constants (k_{12}, k_{21}, etc.) describe movement of drug between the central and peripheral compartments. Each peripheral compartment has at least two micro rate constants, one for drug entry and one for drug exit. The micro rate constants for the two- and three-compartment models can be seen in Figure 24-12.

Back-End Kinetics

Using estimates of distribution volume and clearance, back-end kinetics is a useful tool to describe the behavior of intravenous agents when administered as continuous infusions. Back-end kinetics provides descriptors of how plasma drug concentrations decrease once a continuous infusion is terminated. An example is decrement time, which predicts the time required to reach a certain plasma concentration once an infusion is terminated. Decrement times are a function of infusion duration. Consider the example of decrement times for a set of continuous target controlled infusions (Fig. 24-14). In this simulation, target-controlled infusion of propofol is set to maintain a concentration of 4 μg/mL for 30, 60, and 120 minutes. Once the infusion is stopped, the time to reach 0.5 μg/mL is estimated. As illustrated, the longer the infusion, the longer the time required to reach 0.5 μg/mL. This example demonstrates how drugs accumulate in peripheral tissues with prolonged infusions. This accumulation prolongs the decrement time.

Another use of decrement times is as a tool to compare drugs within a drug class (e.g., opioids). As a comparator, plots of decrement times are presented as a function of infusion duration. When used this way, decrement times are determined as the time required to reach a target

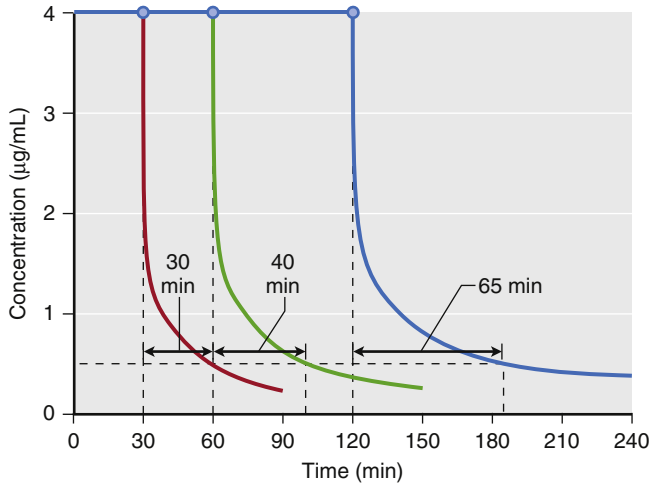

Figure 24-14. Simulation of decrement times for a target-controlled infusion set to maintain a target propofol concentration of 4 µg/mL for 30, 60, and 120 minutes. Once terminated, the time required to reach 0.5 µg/mL was 30, 40, and 65 minutes for each infusion, respectively. Simulations of the decrement times used a published pharmacokinetic model.[1]

percentage of the concentration just before the termination of a continuous infusion. Examples of 50% and 80% decrement times for selected opioids and sedatives are presented in Figure 24-15. Of note, for shorter infusions, the decrement times are similar for both classes of anesthetic drugs. Once infusion duration exceeds two hours, the decrement times vary substantially. A popular decrement time is the 50% decrement time, also known as the context-sensitive half-time.[6] The term *context-sensitive* refers to infusion duration. The term *half-time* refers to the 50% decrement time.

Biophase

Biophase refers to the time delay between changes in plasma concentration and drug effect. Biophase accounts for the time required for drug to diffuse from the plasma to the site of action plus the time required (once drug is at the site of action) to illicit a drug effect. A simulation of various propofol bolus doses and their predicted effect on bispectral index are presented in Figure 24-16. Of note, the time to peak effect for each dose is identical (approximately 1.5 minutes following the peak plasma concentration). The difference between each dose is the

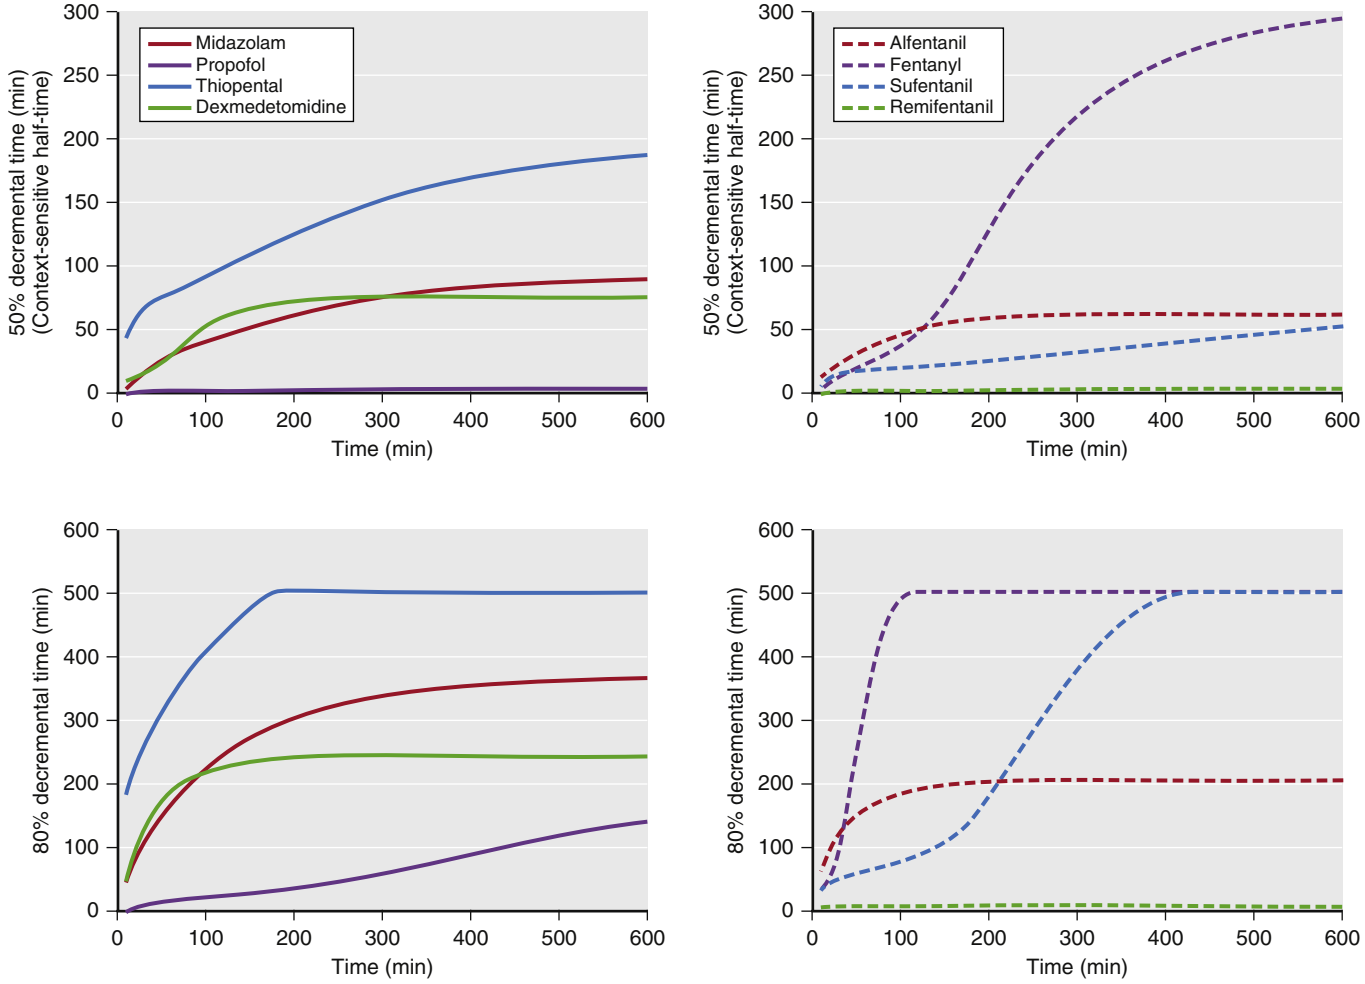

Figure 24-15. 50% and 80% decrement times for selected sedatives (*left side*) and opioids (*right side*). The vertical axis refers to the time required to reach the desired decrement time. The horizontal axes refer to infusion duration. Simulations of the decrement times used published pharmacokinetic models for each sedative and analgesic.[1,6-10]

magnitude and duration of effect. A key principle here is that when drug concentrations are in flux (e.g., during induction and emergence), changes in drug effect will lag behind changes in drug concentration. This lag between the plasma concentration and effect usually result in the phenomenon called hysteresis, in which two different plasma concentrations correspond to one drug effect or one plasma concentrations correspond to two drug effect. Figure 24-16 shows that different concentrations, C and c, correspond to the same bispectral image scale (BIS) score.

To collapse the hysteresis between plasma concentration and effect and to match one plasma concentration to one drug effect, this lag is often modeled with an effect-site compartment added to the central compartment. Kinetic micro rate constants used to describe biophase include k_{1e} and k_{e0}. The k_{1e} describes drug movement from the central compartment to the effect site, and k_{e0} describes the elimination of drug from the effect-site compartment. Two important assumptions must be understood with the effect-site compartment: (1) the amount of drug that moves from the central compartment to the effect-site compartment is negligible and vice versa, and (2) there is no volume estimate to the effect-site compartment.

Typically, the relationship between plasma and the site of drug effect is modeled with an effect-site model, as shown in Figure 24-17. The site of drug effect is connected to plasma by a first-order process. The equation that relates effect-site concentration to plasma concentration is

$$\frac{dCe}{dt} = k_{e0} \times (Cp - Ce) \qquad [10]$$

where Ce is the effect-site concentration, Cp is the plasma drug concentration, and k_{e0} is the rate constant for elimination of drug. The constant k_{e0} describes the rate of rise and off set of drug effect (Fig. 24-18).

In summary, although of interest to many clinicians, the conventional pharmacokinetic term *half-life* has limited meaning to anesthetic practice since the clinical behavior of drugs used in anesthesia is not well described by half-life. Instead, the pharmacokinetic principles discussed in this section (such as volume of distribution, clearance, elimination, front-end kinetics, back-end kinetics, context-sensitive half-time, and biophase) describe how drugs used in anesthesia will behave.

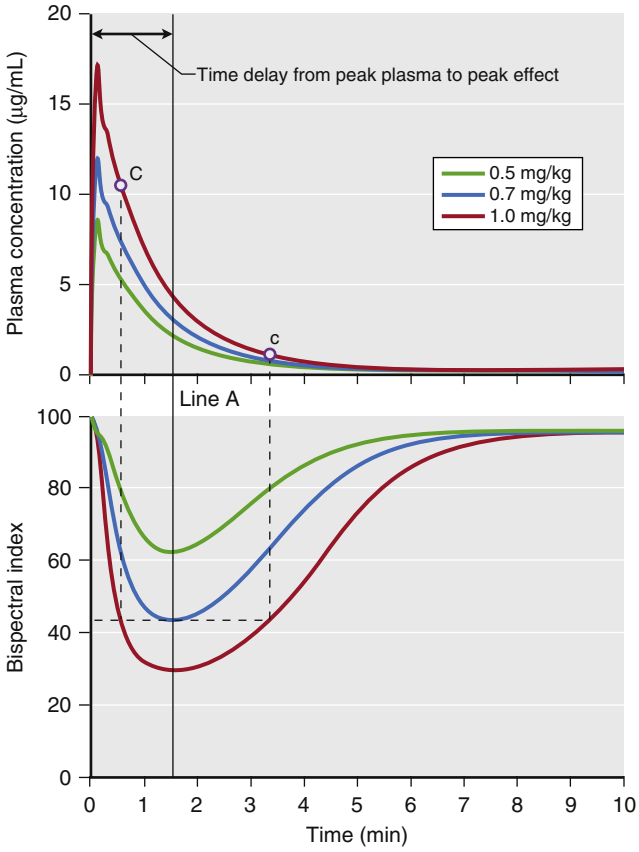

Figure 24-16. Illustration of biophase. The *top plot* presents a simulation of three propofol doses and the resultant plasma concentrations. The *bottom plot* presents a simulation of the predicted effect on the bispectral index scale (BIS). These simulations assume linear kinetics: regardless of the dose, effects peak at the same time (*line A*), as do the plasma concentration. The time to peak effect is 1.5 minutes. Even the plasma concentrations of points C and c are different; the BIS of those two points are same. It shows the hysteresis between plasma concentration and BIS. Simulations used published pharmacokinetic and pharmacodynamic models.[1,11]

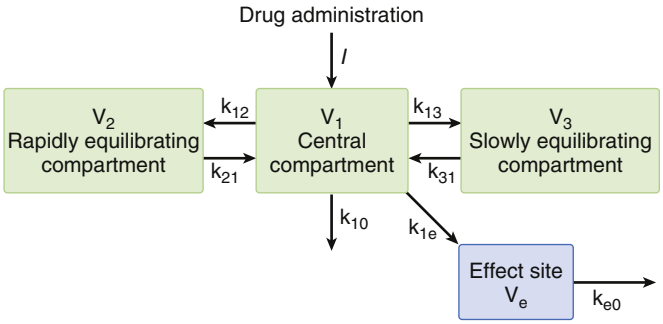

Figure 24-17. A three-compartment model with an added effect site to account for the delay in equilibration between the rise and fall in arterial drug concentrations and the onset and offset of drug effect. The effect site is assumed to have a negligible volume.

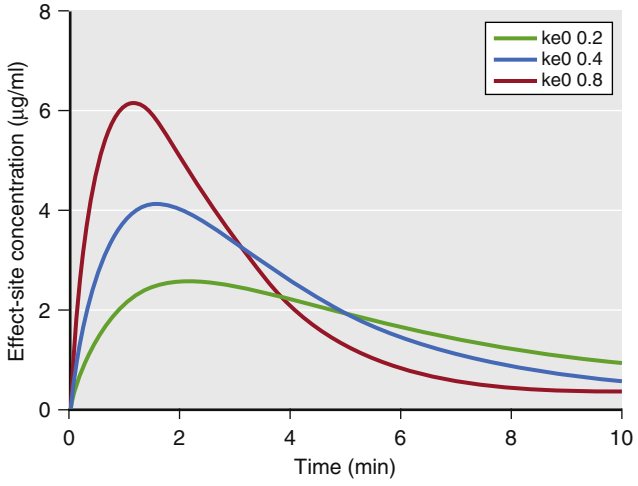

Figure 24-18. Effect of the k_{e0} changes. As the k_{e0} decreases, the time to peak effect is prolonged.[1,11-12]

PHARMACODYNAMIC PRINCIPLES

Simply stated, pharmacokinetics describes what the body does to the drug, whereas pharmacodynamics describes what the drug does to the body. In particular, pharmacodynamics describes the relationship between drug concentration and pharmacologic effect.

Models used to describe the concentration-effect relationships are created in much the same way as pharmacokinetic models; they are based on observations and used to create a mathematical model. To create a pharmacodynamic model, plasma drug levels and a selected drug effect are measured simultaneously. For example, consider the measured plasma concentrations of a drug following a bolus dose and the associated changes in the spectral edge from one individual presented in Figure 24-19. Spectral edge is an easily captured metric used to quantify the electroencephalogram (EEG). Shortly after the plasma concentration peaks, the spectral edge starts to drop, reaches a nadir, and then returns back to baseline as the plasma concentrations drop to near 0.

Combining data from several individuals and plotting the measured concentrations versus the observed effect (modified to be a percentage of the maximal effect across all individuals), the data create a hysteresis loop (Fig. 24-20). The ascending portion of the loop represents rising drug concentrations (see arrow). While rising, the increase in drug effect lags behind the increase in drug concentration. For the descending loop, the decrease in drug effect lags behind the decrease in drug concentration.

To create a pharmacodynamic model, the hysteresis loop is collapsed using modeling techniques that account for the lag time between plasma concentrations and the observed effect.[13] These modeling techniques provide an estimate of the lag time, known as the t1/2ke0, and an estimate of the effect-site concentration (Ce) associated with a 50% probability of drug effect (C_{50}). Most concentration effect relationships in anesthesia are described with a sigmoid curve. The standard equation for this relationship is the "Hill equation" also known as the sigmoid E_{max} relationship:

$$\text{Effect} = E_0 + \left(E_{max} - E_0\right) * \left(C^{\gamma} / \left(C_{50}{}^{\gamma} + C^{\gamma}\right)\right) \qquad [11]$$

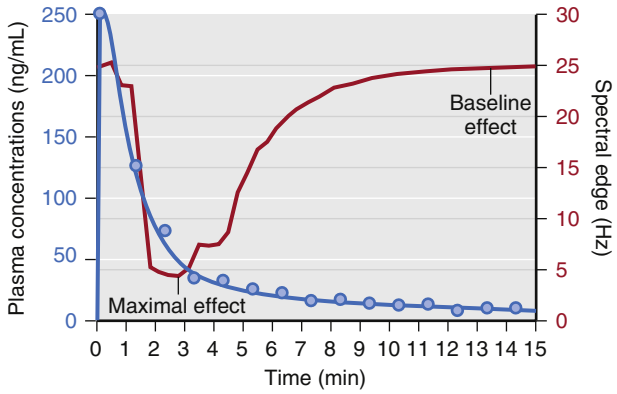

Figure 24-19. Schematic representation of drug plasma concentrations (*blue circles*) following a bolus and the associated changes in the electroencephalogram's spectral edge (*red line*) measured in one individual. Note that changes in spectral edge lag behind changes in plasma concentrations.

where E_0 is the baseline effect, E_{max} is the maximal effect, C is the drug concentration, and γ represents the slope of the concentration-effect relationship. Gamma (γ) is also known as the "Hill coefficient." For values of γ <1, the curve is hyperbolic; for values of γ >1, the curve is sigmoid. Figure 24-21 presents an example of this relationship: a fentanyl effect-site concentration-effect curve for analgesia. This example illustrates how C_{50} and γ characterize the concentration-effect relationship.

Potency and Efficacy

Two important concepts are relevant to this relationship: potency and efficacy. Potency describes the amount of drug required to elicit an effect. The C_{50} is a common

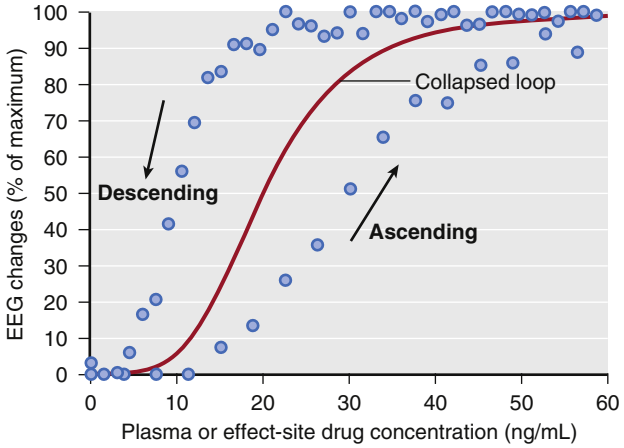

Figure 24-20. Schematic representation of plasma concentrations versus normalized spectral edge measurements (presented as a percentage of maximal effect) from several individuals (*blue circles*). The *black arrows* indicate the ascending and descending arms of a hysteresis loop that coincide with increasing and decreasing drug concentrations. The *red line* represents the pharmacodynamic model developed from collapsing the hysteresis loop.

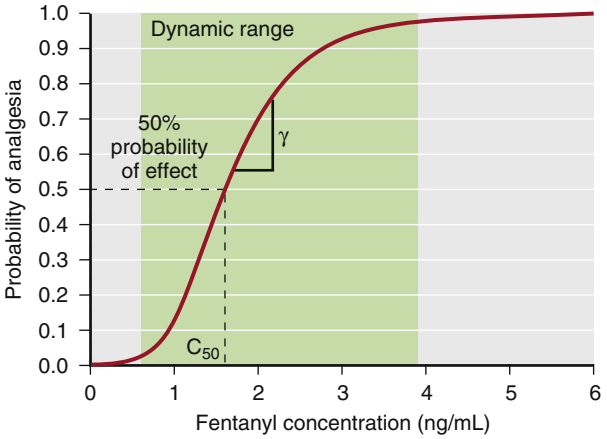

Figure 24-21. A pharmacodynamic model for the analgesic effect of fentanyl. The gray area represents the dynamic range, the concentration range where changes in concentration lead to a change in effect. Concentrations above or below the dynamic range do lead to changes in drug effect. The C_{50} represents the concentration associate with 50% probability of analgesia. Gamma (γ) represents the slop of the curve in the dynamic range.

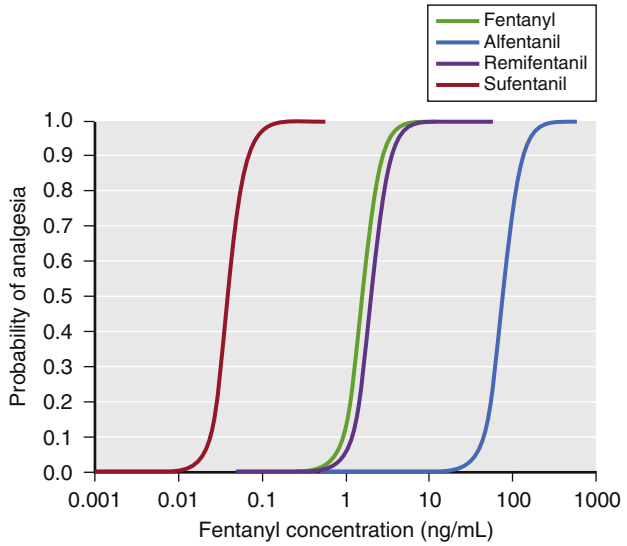

Figure 24-22. Pharmacodynamic models for fentanyl congeners. The C_{50} for each drug is different, but the slope and maximal effect are similar.[14]

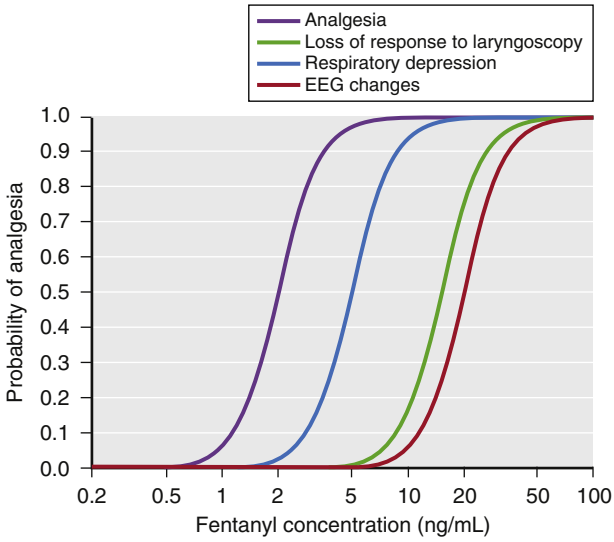

Figure 24-23. Pharmacodynamic models for various fentanyl effects.[14]

parameter used to describe potency. For drugs that have a concentration-versus-effect relationship that is shifted to the left (small C_{50}), the drug is considered to be more potent; the reverse is true for drugs that have a concentration-versus-effect relationship shifted to the right. For example, as illustrated in Figure 24-22, the analgesia C_{50} for some of the fentanyl congeners ranges from small for sufentanil (0.04 ng/mL) to large for alfentanil (75 ng/mL). Thus, sufentanil is more potent that alfentanil.

Efficacy is a measure of drug effectiveness at producing an effect once it occupies a receptor. Similar drugs that work through the same receptor may have varying degrees of effect despite having the same receptor occupancy. For example, with G-protein coupled receptors, some drugs may bind the receptor in such a way as to produce a more pronounced activation of second messengers causing more of an effect than others. Drugs that achieve maximal effect are known as full agonists, and those that have an effect less than maximal are known as partial agonists.

Effective Versus Lethal Doses

A single drug can have multiple effects. The C_{50} concept is used to compare various drug effects for a single drug. For example, as illustrated in Figure 24-23, fentanyl has a different C_{50} for analgesia (2 ng/mL), ventilatory depression (4 ng/mL), loss of response to laryngoscopy (15 ng/mL), and changes in the electroencephalogram (20 ng/mL).[14]

The concentration range where changes in drug effect occur is known at the dynamic range. In Figure 24-21, the dynamic range is from 0.6 to 3.9 ng/mL to cover a probability of analgesia ranging from 2% to 97%. Concentrations outside the dynamic range do not yield much change in drug effect. Levels below the dynamic range are ineffective, and those above the dynamic range do not provide additional effect.

Like other effects, the concentration-relationship for death is also described with a sigmoid E_{max} curve. The relationship between drug and effect is expressed differently in that the horizontal axis uses dose in place of concentration. Similar to the C_{50}, the ED50 is the dose at which there is a 50% probability of effect, and the LD50 is the dose with a 50% probability of death. The therapeutic index of a drug is defined as the ratio between the LD50 and the ED50 (Fig. 24-24). The larger the ratio, the safer the drug is for clinical use.

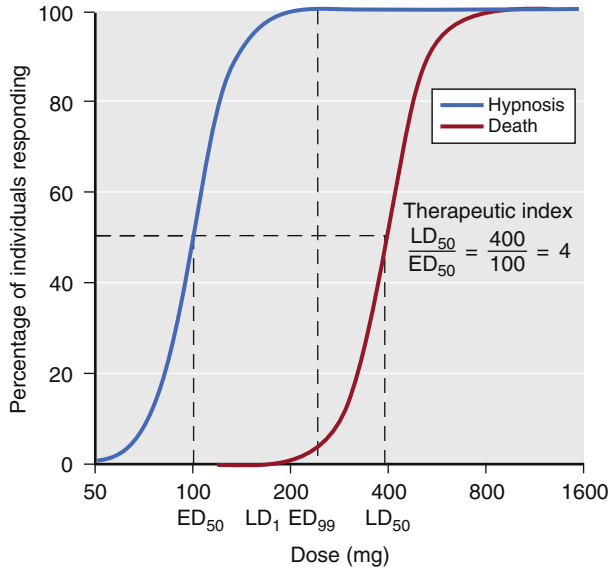

Figure 24-24. Median effective dose (ED_{50}), median lethal dose (LD_{50}), and the therapeutic index. The *blue curve* represents the dose-effect relationship for a sedative hypnotic to achieve unresponsiveness. The *red curve* represents the dose-effect relationship for the same sedative hypnotic to achieve death. The therapeutic index is the ratio of the LD50/ED50, which in this example is 400. Also of interest are the ED_{99} and LD_1. The ED_{99} is the dose with a 99% probability of unresponsiveness, and the LD_1 is the dose with a 1% probability of death. In this example, the LD_1 is less than the ED_{99}, which is clinically unacceptable.

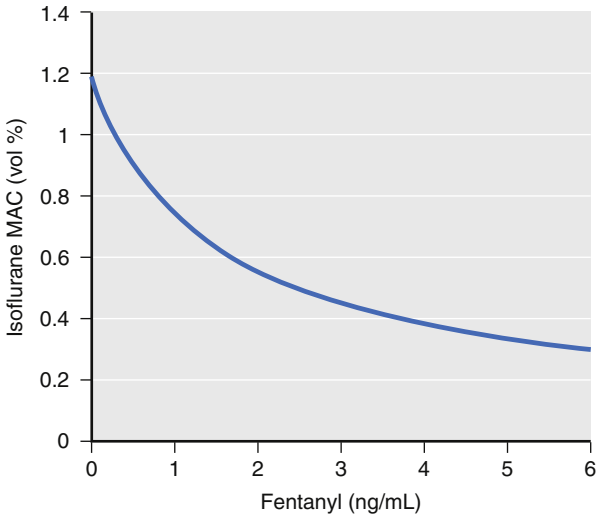

Figure 24-25. The influence of fentanyl on the isoflurane minimum alveolar concentration (*MAC*) associated with a 50% probability of movement with skin incision. *(Modified from McEwan AI, Smith C, Dyar O, et al: Isoflurane minimum alveolar concentration reduction by fentanyl,* Anesthesiology *78:864-869, 1993.)*

Anesthetic Drug Interactions

Anesthetics rarely consist of only one drug, but rather a combination of drugs to achieve desired levels of hypnosis, analgesia, and muscle relaxation. Hypnotics, analgesics, and muscle relaxants all interact with one another such that rarely does one drug, when administered in the presence of other drugs, behave as if it were administered alone. For example, when administering an analgesic in the presence of a hypnotic, analgesia is more profound with the hypnotic than by itself and hypnosis is more profound with the analgesic than by itself. Thus, anesthesia is the practice of applied drug interactions. This phenomenon is likely a function of each class of drug exerting an effect on different receptors.

Early work by McEwan and associates described interactions between two drugs and is illustrated in Figure 24-25.[15] It presents the interaction between isoflurane, a likely GABA agonist, and fentanyl, an opioid receptor agonist. This plot illustrates two key points: First, with a relatively low fentanyl concentration (<2 ng/mL), there is a substantial decrease (>50%) in the end tidal isoflurane concentration necessary to achieve minimum alveolar concentration (MAC) necessary to avoid movement with skin incision. Second, with fentanyl concentrations above 3 ng/mL, the end tidal concentration of isoflurane to maintain the MAC, although low, does not change much. Thus, a ceiling effect exists, indicating that some isoflurane is necessary regardless of the fentanyl concentration to maintain a MAC of anesthesia.

Work has been done to explore how anesthetic drugs interact with one another. As illustrated in Figure 24-26, interactions have been characterized as antagonistic, additive, and synergistic. When drugs that have an additive interaction are coadministered, their overall effect is the sum of the two individual effects. With antagonistic interactions, the overall effect is less than if the drug combination were additive; with synergistic interactions, the overall effect is greater than if the drug combination were additive.

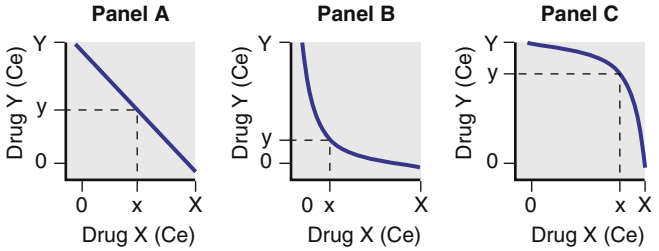

Figure 24-26. Drug interactions. For two drugs, X and Y, *Panel A* represents additive, *Panel B* represents synergistic, and *Panel C* represents antagonistic interactions.

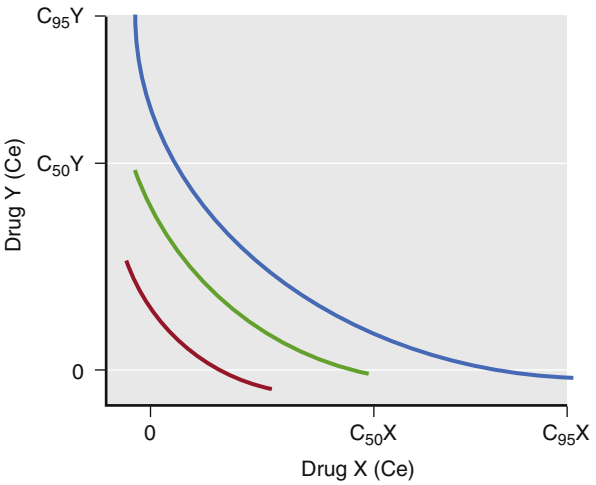

Figure 24-27. Schematic illustration of isoeffect (isobole) lines. The *red, green,* and *blue lines* represent the 50% and 95% isoboles for a synergistic interaction between drugs X and Y. Isoboles represent concentration pairs with an equivalent effect. A set of 5%, 50%, and 95% isoboles can be used to describe the dynamic range of the concentrations for drugs X and Y for a given effect. As with single concentration effect curves, the ideal dosing leads to concentration pairs that are near the 95% isobole.

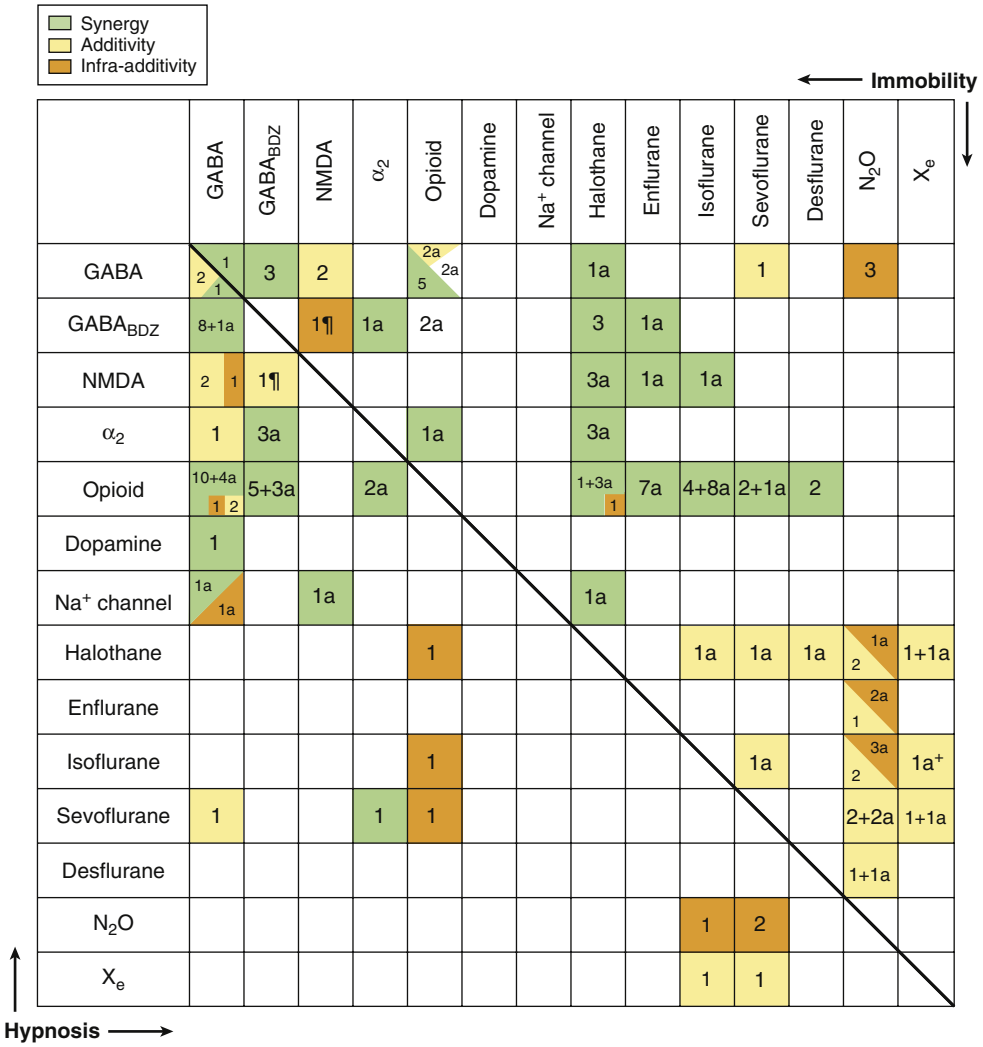
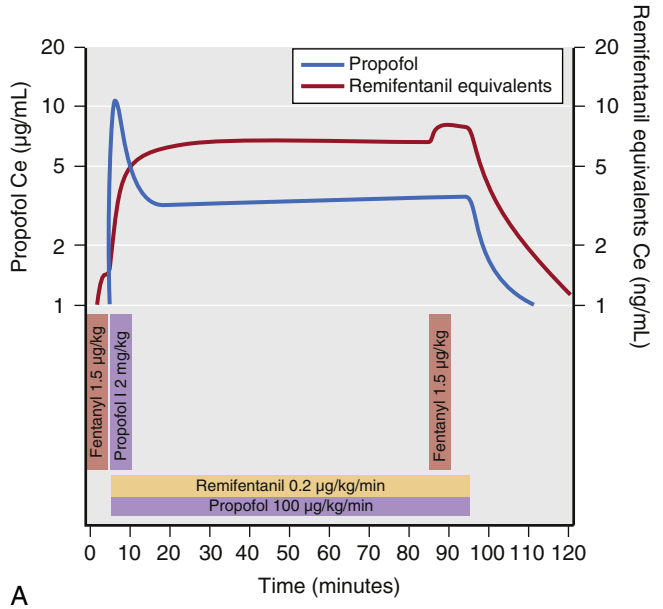
A term used to characterize the continuum of drug concentrations across various combinations of drug pairs (X in combination with Y) is the *isobole*. The isobole is an isoeffect line for a selected probability of effect. A common isobole is the 50% isobole line. It represents all possible combinations of two-drug effect-site concentrations that would lead to a 50% probability of a given effect. Other isoboles are of more clinical interest. For example, the 95% isobole for loss of responsiveness represents the concentration pairs necessary to ensure a 95% probability of unresponsiveness. Similarly, the 5% isobole represents the concentration pairs in which the likelihood of that effect is low (i.e., most patients would be responsive). When formulating an anesthetic dosing regimen, dosing an anesthetic to achieve a probability of effect just above, but not far beyond, the 95% isobole is ideal (Fig. 24-27).

Work in both humans and animal models have described anesthetic drug interactions for opioids, sedative hypnotics, and inhalation agents for two anesthetic effects: (1) loss of responsiveness (humans) and loss of the righting reflex (animals) and (2) immobility defied as loss of movement response to noxious stimulus in a nonparalyzed subject.[16] First, based on these findings, inhalation





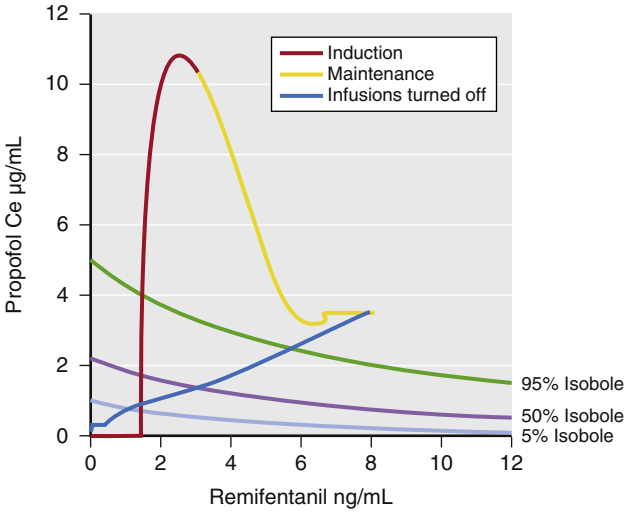


Figure 24-28. Summary of drug interactions in humans and animals for hypnosis (loss of responsiveness in humans, loss of righting reflex in animals) and immobility (loss of movement in response to a noxious stimulus). The numbers in each cell refer to the number of papers supporting the finding. α_2 Agonists include dexmedetomidine and clonidine. Opioid agonists include morphine, remifentanil, fentanyl, sufentanil, and alfentanil. Dopamine agonists include droperidol and metoclopramide. Na$^+$ (sodium) channel antagonists include lidocaine and bupivacaine. The letter *a* indicates the interaction was characterized in an animal model. The *thick diagonal line* separates studies characterizing drug-drug interactions of hypnosis (bottom half) and immobility (top half). *GABA,* Gamma aminobutyric acid (GABA agonist drugs include propofol, thiopental, methohexital, and etomidate; GABA$_{BDZ}$, agonist drugs that work via benzodiazepine binding site include midazolam and diazepam); *NMDA, N*-methyl-D-aspartate (NMDA receptor antagonists include ketamine). *(From Hendrickx JFA, Eger EI, Sonner JM, et al: Is synergy the rule? A review of anesthetic interactions producing hypnosis and immobility,* Anesth Analg *107:494-506, 2008.)*

agents, when combined, are strictly additive, suggesting a common mechanism of action—except for nitrous oxide, which has an infra-additive interaction with other inhalation agents. Second, interactions between various intravenous drugs and inhalation agents are synergistic, except for nitrous oxide and GABA sedative hypnotics. Third, interactions between different classes of intravenous agents (e.g., opioids and sedative hypnotics) are also primarily synergistic, except for ketamine and benzodiazepines (Fig. 24-28).

Several researchers have developed mathematical models that characterize anesthetic drug interactions in three dimensions. These models are known as response surface models and include effect-site concentrations for each drug, as well as a probability estimate of the overall effect. As an example, Figure 24-29 presents the propofol-remifentanil interaction for loss of responsiveness as published by Bouillon and associates.[17] The response surface presents the full range of remifentanil-propofol isoboles (0% to 100%) for loss of responsiveness. There are two common representations of the response surface model: the three-dimensional plot and the topographical plot. The topographic plot represents a top-down view of the response surface with drug concentrations on the vertical and horizontal axes. Drug effect is represented with selected isobole lines (i.e., 5%, 50%, and 95%).

Response surface models have been developed for a variety of anesthetic effects to include responses to verbal and tactile stimuli, painful stimuli, hemodynamic or respiratory effects, and changes in electrical brain activity. For example, with airway instrumentation, response surface models have been developed for loss of response

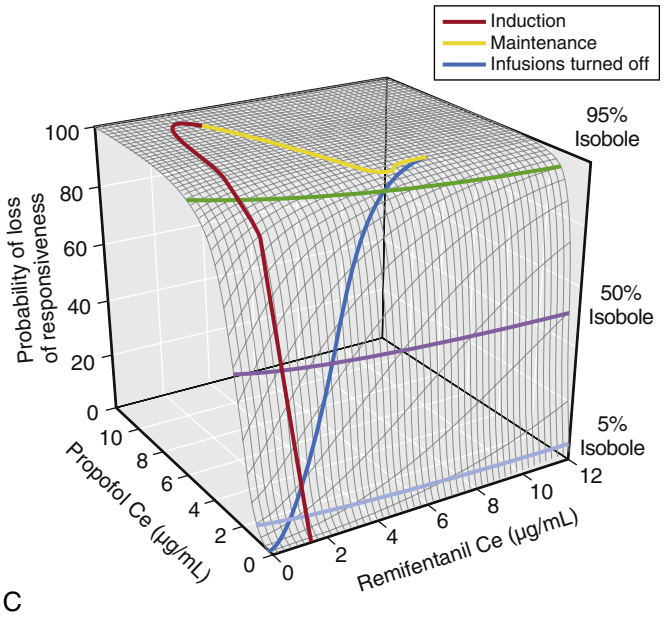

Figure 24-29. Simulation of a 90-minute total intravenous anesthetic consisting of propofol bolus (2 mg/kg) and infusion (100 µg/kg/minute), remifentanil (0.2 µg/kg/minute) and intermittent fentanyl boluses (1.5 µg/kg). **A,** Resultant effect-site concentrations (*Ce*) are presented. **B,** Predictions of loss of responsiveness are presented on a topographical (top-down) view. **C,** A three-dimensional response surface plot is shown. The *light blue, purple,* and *green lines* represent the 5%, 50%, and 95% isoboles. Each isobole presents the propofol-remifentanil pairs that yield the same effect. The inward bow of the isoboles indicates that the interaction is synergistic. The isoboles are in close proximity to one another, indicating a steep transition from responsive to unresponsive.

to placing a laryngeal mask airway,[18] laryngoscopy,[19,20] tracheal intubation,[21] and esophageal instrumentation[22] in selected combinations of anesthetic drugs. Although many response surface models exist, several gaps exist in available models, covering all common combinations of anesthetic drugs and various forms of stimuli encountered in the perioperative environment.

The interaction between sevoflurane and remifentanil has been characterized for a variety of drug effects, including loss of responsiveness, loss of response to several surrogates of surgical pain such as electrical tetany (up to 50 mA), pressure algometry (50 PSI pressure on the anterior tibial), loss of response to laryngoscopy, and temperature.[20] End tidal measurement of sevoflurane were inaccurate under non–steady-state conditions (i.e., with a change in vaporizer settings) End tidal concentrations did not account for the hysteresis (or time lag) between end tidal and effect-site concentrations. Improved model predictions were achieved when using estimated effect-site concentrations Overall, for sevoflurane-opioid interactions, analgesic effects are markedly synergistic, whereas sedative effects are somewhat synergistic.

Preliminary work has explored the adaptability of the sevoflurane-remifentanil interactions to other potent inhaled agent opioid combinations using MAC and opioid equivalencies.[23] Predictions from sevoflurane-remifentanil models adapted to isoflurane-fentanyl correlated well with observed effects in patients undergoing elective general surgery procedures. Also, models have been constructed that characterize the interactions between three or more drugs,[24] such as a model that accounts for nitrous oxide, sevoflurane, and remifentanil.[25] This is of clinical relevance because most anesthetics consist of more than two anesthetic drugs. In line with this, works has explored interactions between sedative hypnotics and opioids, primarily propofol with alfentanil[26] or remifentanil[17,19,22,27,28] for a variety of effects. As with potent inhaled anesthetics and opioids, the interactions between sedative hypnotics and opioids for analgesic effects are markedly synergistic, whereas sedative hypnotic effects are somewhat synergistic.

Interaction studies of different types of sedative hypnotics such as midazolam combined with propofol[29,30] and propofol combined with a volatile anesthetic[31-33] reveal that the interactions are primarily additive.

Drug Displays

The major disadvantage of response surface models is that they are complex and difficult to use in a clinical setting. These models have been adapted to drug displays that allow clinicians to use them in real-time patient care settings.

These displays provide estimates of not only drug concentrations (both plasma and effect site) but also various drug effects over time, such as loss of responsiveness, analgesia, and reduction in response to peripheral "train of four" stimulation (i.e., monitoring of muscle relaxant action), among others. With manual entry of patient demographics (age, gender, height, and weight) and drugs administered by syringe, either by bolus or continuous infusion along automated data collection from an anesthesia machine (end tidal potent inhaled anesthetic concentrations and, in some instances, infusion pump information), drug displays provide predictions of drug concentration and effects. Drug displays are currently available from several anesthesia machine manufactures (Navigator Suite from GE Healthcare, Wauwatosa, Wis, and SmartPilot View from Dräger, Lübeck, Germany). An example of a drug display is presented in Figure 24-30. All drug display examples are based on response surface interaction models.

A unique feature of the displays is that a given dosing regimen can be simulated before administration, which may be useful in identifying the optimal dose in challenging patients, especially when more than one drug is used. The drug displays use population models that, although generalizable, may not provide a good "fit" for every patient. For some drug display systems, observed patient responses are used to calibrate predictions of drug effect (see Fig. 24-30). For example, with older adults or debilitated patients, smaller doses are often required to achieve a desired effect (also see Chapter 80). Drug displays allow clinicians to identify concentrations that produce a desired response and can be used to titrate additional anesthetic.

Use of drug displays provides several other advantages. When titrating an anesthetic, it is often difficult to appreciate when effect-site concentrations are near steady state. Clinicians may be tempted to administer additional drug, assuming that drug concentrations have peaked (with bolus dosing) or are near steady-state conditions (with continuous infusions of potent inhaled agents). Clinicians may also be impatient, assuming that drug concentrations are near zero when in fact they are still increased, even after terminating delivery (e.g., the end tidal potent inhaled agent concentration is 0 mm Hg but there is persistent unresponsiveness).

A second advantage is that drug displays provide a means of delivering passive target-controlled infusions (TCI). Although widely used throughout the rest of the world, TCI is not used in the United States because of regulatory barriers.[34] TCI uses population pharmacokinetic models to drive infusion pumps. After entering the target plasma or effect-site concentration, a computer identifies the optimal infusion rate to achieve that concentration. With passive TCI, population models are used to display predicted effect-site concentrations and associated effects over time, but the models do not deliver information to drive infusion pumps as with TCI. With this approach, clinicians can test out dosing regimens (bolus doses and infusion rates) before administering them, thus allowing confirmation that they will achieve a desired effect. These features provide for a more consistent approach to drug delivery.

A third advantage of using drug displays is that they provide a better approach to dosing anesthetics. Instead of considering an anesthetic in terms of MAC, where 50% of patients may respond to surgical stimulus, drug displays provide a more refined characterization of anesthetic effect. Clinicians do not titrate an anesthetic to achieve a 50% probability of effect but rather aim for a 95% to 99% probability of effect. With response surfaces, anesthetic dosing regimens necessary to achieve this level of effect are easily visualized. Second, the concept of MAC does not fully embody the three elements of an anesthetic: analgesia, sedation and hypnosis, and muscle relaxation. Drug displays provide a means of visualizing all three effects simultaneously over a full 0% to 100% probability range.

SPECIAL POPULATIONS

When formulating an anesthetic, many aspects of patient demographics and medical history need to be considered to find the correct dose: age; body habitus; gender; chronic exposure to opioids, benzodiazepines, or alcohol; the presence of heart, lung, kidney, or liver disease; and the extent of blood loss or dehydration. Any of these factors can dramatically affect anesthetic drug kinetics and dynamics. Unfortunately, most studies characterizing anesthetic drug behavior have been conducted in healthy volunteers that rarely represent the general population presenting for surgery. Extensive work has explored how some patient characteristics (e.g., obesity) influence anesthetic drug behavior, whereas other patient characteristics remain difficult to assess (chronic opioid exposure). In addition, not all anesthetics have been studied. Most work has primarily focused on newer anesthetic drugs, such as propofol and remifentanil, whereas minimal work

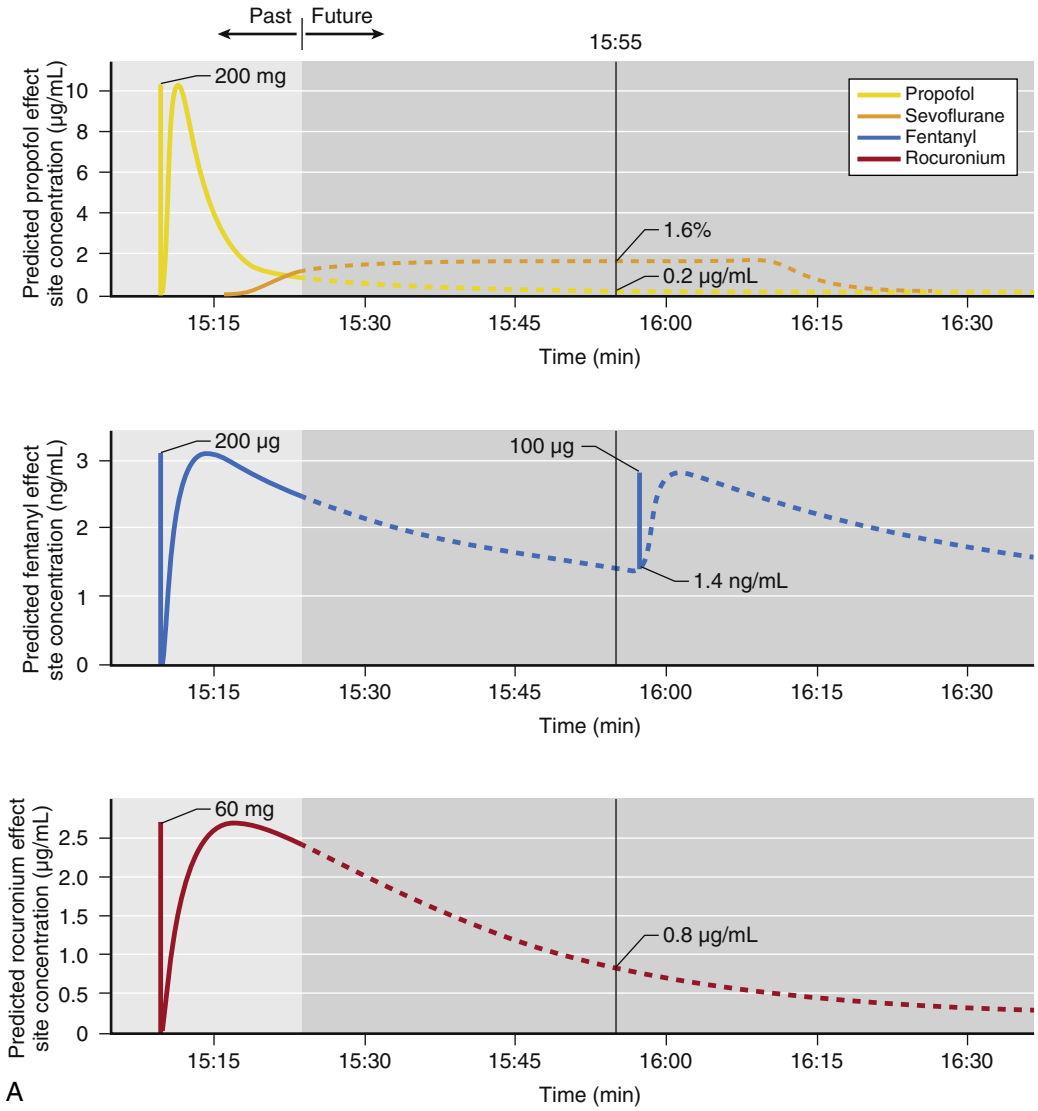

Figure 24-30. Example of a drug display. This example presents predictions of effect site concentrations (**A**) and drug effects (**B**) for a combined technique using fentanyl (2 µg/kg), propofol (2 mg/kg), and rocuronium (0.6 mg/kg) boluses and maintenance with sevoflurane (2%) and fentanyl bolus (1 µg/kg). This simulation assumes a 30-year-old, 100-kg male, 183 cm tall, with normal cardiac output and lung ventilation. **A,** Predicted effect site concentrations for propofol *(bright yellow line),* sevoflurane *(dark yellow line),* fentanyl *(blue line),* and rocuronium *(red line).* Bolus doses are represented as *vertical lines,* with the dose labeled adjacent to the line. Past predictions are *solid lines* and future predictions are dashed lines. The *vertical black line* represents a future prediction of effect-site concentrations at 15:55 PM. Concentrations are reported. (From Applied Medical Visualizations, Salt Lake City, Utah.)

has focused on many older, commonly used drugs, such as morphine. This section will briefly summarize work that has been done to characterize the pharmacokinetics and pharmacodynamics in a few unique special populations.

INFLUENCE OF OBESITY ON ANESTHETIC DRUGS

Obesity is a worldwide epidemic, and overweight patients frequently undergo anesthesia and surgery (also see Chapter 71). Furthermore, pharmacologic alterations of anesthetics occur in obese individuals. In general, manufacturer dosing recommendations are on a per-kg basis according to the actual total body weight (TBW). Anesthesia providers rarely use mg/kg dosing in obese patients for fear or administering an excessive dose (e.g., a 136-kg patient does not require twice as much drug as a patient of the same height who weighs 68 kg). To resolve this problem, several weight scalars have been developed in attempt to avoid excessive dosing or underdosing in this patient population. Some of these include lean body mass (LBM), ideal body weight (IBW), and fat-free mass (FFM). Table 24-1 presents the formulas used to estimate these weight scalars. Table 24-2 shows samples of the resultant scaled weight for a lean and obese individual. In general, the aim of weight scalars is to match dosing regimens for obese patients with what is required for normal-size patients. These scaled weights are usually smaller than TBW in obese patients and thus help prevent excessive drug dosing (Fig. 24-31). Scaled weights have been used in place of TBW for both bolus (mg/kg) and infusion (mg/kg/hr) dosing and also for TCI.

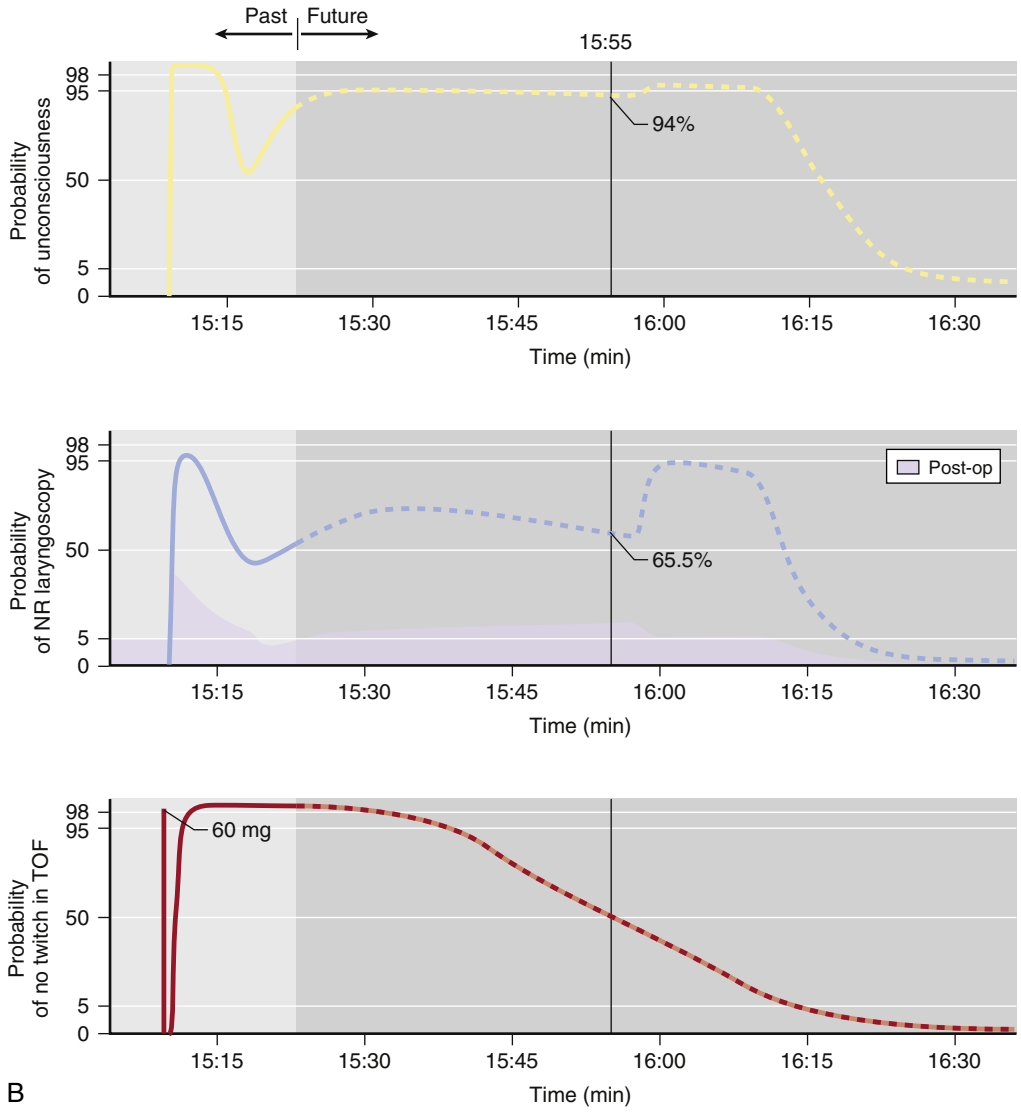

Figure 24-30, cont'd. B, Predicted drug effects. Probability of unresponsiveness *(yellow line),* probability of no response to laryngoscopy *(blue line),* and probability of loss of train of four *(red line)* from this combined technique. The *white horizontal lines* represent the 5%, 50%, 95%, and 98% probability of effect. The *vertical black line* represents a future prediction of drug effects at 15:55 PM. *NR laryngoscopy,* No response to laryngoscopy; *TOF,* train-of-four.

This section will discuss the pharmacologic (primarily pharmacokinetic) alterations of select intravenous anesthetic drugs (propofol, remifentanil, and fentanyl) in obese patients, review examples of weight scalars and their shortcomings when used in bolus and continuous infusion dosing, and when data are available, briefly describe pharmacologic models used to drive TCI.

Propofol

Dosing propofol in obese patients can be a challenge (also see Chapter 71). For bolus dosing and continuous infusions, the choice of weight scalar is specific to the dosing technique being used (i.e., one is best for bolus dosing and another for continuous infusions). Furthermore, of the available propofol pharmacokinetic models, the one built from observations in obese patients may be best for TCI.

The influence of obesity on propofol pharmacokinetics is not entirely clear. Generally, in obese patients, the blood distributes more to nonadipose than to adipose tissues. This may result in higher plasma drug concentrations in obese patients with mg/kg dosing than in normal patients with less adipose mass. Furthermore, propofol clearance increases because of the increased liver volume and/or liver blood flow associated with obesity (and increased cardiac output). Distribution likely influences concentration peaks with bolus dosing, and clearance likely influences concentrations during and following infusions

Dosing Scalars for Propofol. Simulations of an infusion using various weight scalars are presented in Figure 24-32. The simulations predict propofol effect-site concentrations from a 60-minute infusion (167 μg/kg/minute) in 176-cm (6-ft) males, obese (185 kg) and lean (68 kg).

TABLE 24-1 COMMON WEIGHT SCALARS

Name	Equations
Ideal body weight	Male: 50 kg + 2.3 kg for each 2.54 cm (1 in) over 152 cm (5 ft) Female: 45.5 kg + 2.3 kg for each 2.54 cm (1 in) over 152 cm (5 ft)
Lean body mass	Male: $1.1 \times TBW - 128 \times (TBW \div Ht)^2$ Female: $1.07 \times TBW - 148 \times (TBW \div Ht)^2$
Fat free mass[35]	Male: $(9.27 \times 10^3 \times TBW) \div (6.68 \times 10^3 + 216 \times BMI)$ Female: $(9.27 \times 10^3 \times TBW) \div (8.78 \times 10^3 + 244 \times BMI)$
Pharmacokinetic mass[36,37]	$52 \div [1 + (196.4 \times e^{-0.025\ TBW} - 53.66) \div 100]$ (fentanyl only)
Corrected body weight[38,39]	IBW + 0.4* (IBW – FFM)

BMI, Body mass index; *FFM,* fat-free mass; *Ht,* height in centimeters; *IBW,* ideal body weight; *LBM,* lean body mass; *MFFM,* modified fat-free mass; *TBW,* total body weight in kg.
*The dose/kg using IBW, TBW, or FFM in an obese person are all less than the dose/kg using TBW in a nonobese patient.

TABLE 24-2 DOSING WEIGHTS BASED ON VARIOUS DOSING SCALARS

	176-cm (6-ft) Male	
	68 kg (BMI = 22)	185 kg (BMI = 66)
Dosing Scalar	Dosing Weight (kg)	Dosing Weight (kg)
Total body weight (TBW)	68	185
Ideal body weight (IBW)	71	71
Lean body mass (LBM)	55	62
Fat-free mass (FFM)	55	87
Corrrected body weight (CBW)	68	115

BMI, Body mass index (kg/m^2).

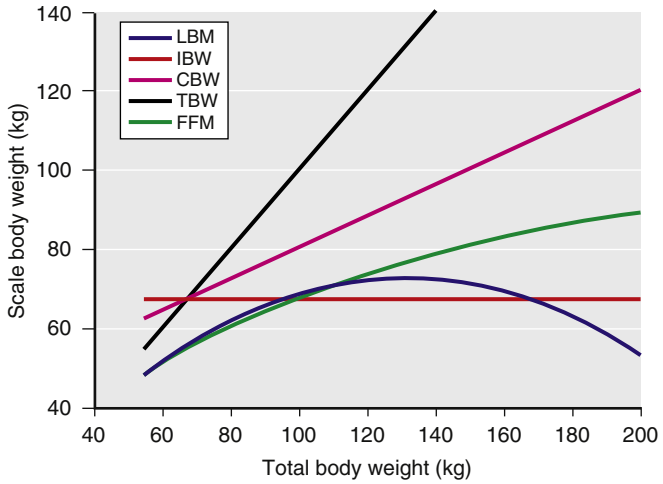

Figure 24-31. Scaled weights as a function of total body weight (TBW). Key points in this plot: IBW remains the same regardless of the TBW, and LBM starts to decline for weight increases above 127 kg. *CBW,* Corrected body weight; *FFM,* fat-free mass; *IBW,* ideal body weight; *LBM,* lean body mass (for a 40-year-old male, 176 cm tall).

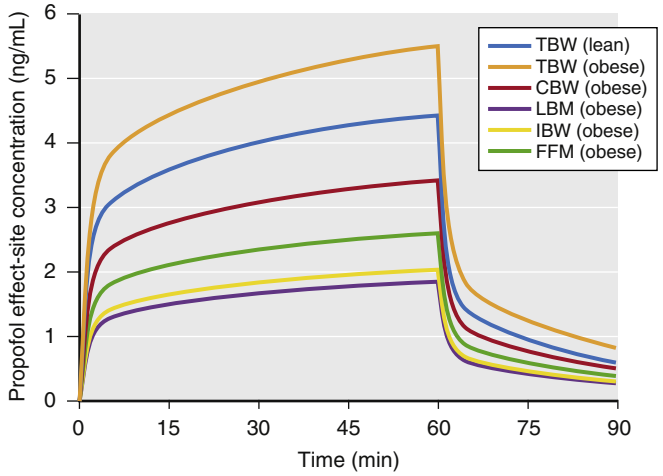

Figure 24-32. Simulations of propofol effect site concentrations that result from a 60-minute infusion (10 mg/kg/hour—167 μg/kg/minute) to a 40-year-old male who is 176 cm tall. Simulations include the following dosing weights: total body weights (TBW) of 68 kg and 185 kg (body mass indices of 22 and 60, respectively) and scaled weights for the 185 kg weight to include Servin's corrected body weight (CBW), lean body mass (LBM), ideal body weight (IBW), and fat-free mass (FFM). Key points: At the 185-kg weight, when dosed to TBW, the infusion leads to high propofol concentrations, whereas when dosed to IBW or LBM, the infusion leads to low propofol concentrations. When the 185-kg individual is dosed using CBW, it best approximates the propofol concentrations that result from TBW in a lean individual. Predictions of propofol effect site concentrations were made using the Cortinez model.

If dosed according to TBW, peak plasma concentrations in a lean and obese individual are different; their respective peak propofol concentrations are approximately 4.4 and 5.4 μg/mL, respectively. If the obese individual is dosed to CBW, the peak concentration is near 3.4 μg/mL. The other weight scalars lead to much lower concentrations with the infusion.

Of the many available dosing scalars, authors recommend LBM for bolus dosing (i.e., during induction) and TBW or corrected body weight (CBW) for infusions.[38,39] For continuous infusions, other weight scalars are likely inadequate (the most worrisome is LBM). When dosing to CBW, plasma concentrations may be lower than concentrations when dosed to TBW.

One concern with using TBW to dose continuous infusions is drug accumulation. Prior work, however, does not support this assumption. Servin and colleagues[38] performed pharmacokinetic analyses of propofol administration to normal and obese patients using TBW and CBW. The CBW was defined as IBW + 0.4 × (TBW – IBW).[40] They found similar concentrations at eye opening in both groups and absence of propofol accumulation in obese patients; in fact, obese patients showed earlier awareness after the termination of propofol infusions than did the normal subjects. Data suggest that dosing infusions according to Servin's CBW may markedly underdose obese patients.[41]

Propofol Kinetic Models for Target-Controlled Infusions. Of the many available models available, the two most widely used propofol kinetic models for TCI are those published by Marsh and associates[42] and Schnider and colleagues[1] In addition to model selection, as with bolus and continuous infusion dosing, identifying the ideal weight scalar to use is important.

The Marsh model, although useful in general, was built from data collected in a pediatric population. Researchers have explored different dosing weights using this model in morbidly obese patients when coadministered with remifentanil with varied results. Albertin and colleagues[40] used CBW to dose a propofol TCI using the Marsh model. They found predicted substantially overestimated measured propofol concentrations and expressed concern for intraoperative awareness when using CBW with the Marsh TCI model. The same group[43] compared the predictive performance of the TCI using CBW versus TBW and found that CBW performed worse than TBW. They concluded that TBW, not CBW, should be used to administer propofol via TCI to morbidly obese patients and then carefully titrate to targeted processed electroencephalographic values.

The Schnider model, although built from data collected in adults over a range of weights, heights, and age, does not specifically include obese patients. This model uses the weight scalar LBM, which has limited application in morbidly obese patients.[1] For comparison, the Marsh or the Schnider model has been applied on morbidly obese patients. Echevarria and colleagues[44] reported differences in effect-site propofol concentrations with a BIS of <60 between the two pharmacokinetic models when used for induction in morbidly obese patients. To achieve a 95% probability of effect, target concentrations of 4.2 and 5.5 μg/mL were required for the Marsh and Schnider models, respectively. This difference occurred because of the potential prediction errors in each pharmacokinetic model used (the actual drug concentrations in each patient are unknown).

Cortinez and colleagues used an international data repository called Open TCI (www.opentci.org) to build a model using propofol concentrations from a wide range of body weights.[39] They built a propofol kinetic model that scales normal-size to obese individuals using an empirically derived formula. In this formula, TBW accounts for differences in distribution and clearances in obese patients. TBW is divided by a standard patient size (70 kg) and raised to the power of 1 for distribution volumes and by the power of 0.75 for clearances. Van Kralingen and colleagues[45] further modified this approach and reported better model performance with exponents of 0.72 for clearance.

Figure 24-33 presents a simulation of propofol infusion rates and associated plasma concentrations using the Marsh, Schnider, and Cortinez models to drive a TCI to achieve a concentration of 3 μg/mL. Key points from this simulation include the following: TCI infusions based on the Marsh model are linear to TBW such that the infusion rates and plasma concentrations are identical across weights. With an increase in body weights, the degree of increase in total propofol amounts for TCI administrations is smaller with the Cortinez model than with the Marsh and Schnider models.

For propofol, the Cortinez model may be best suited for TCI in obese and morbidly obese patients. Unfortunately, this model is not yet available in many commercial TCI pumps. One caveat that is important to consider is that model differences are likely overshadowed by interindividual variability. In sum, any one of the three models will likely yield similar clinical results if titrated to effect in conjunction with processed EEG monitoring. Prospective external validation is warranted to explore how these new models will behave when used in TCIs.

Other Sedative-Hypnotics

Only limited information is available on the behavior of other sedatives (i.e. midazolam, ketamine, etomidate, and barbiturates) in obese patients.[46] In this study by Greenblatt and associates, the volume of distribution, even when normalized to weight (e.g., L/kg) was larger in obese patients, suggesting that lean tissue may take up less midazolam than adipose tissue. Thus, midazolam's distribution volume follows the TBW: as patient size increases, so does the distribution volume. In addition, midazolam elimination was the same in all study subjects (lean or obese). This suggests that regardless of dose, hepatic metabolism of midazolam is fixed and elimination will require more time in obese patients. Another interesting finding was that time to peak concentration and peak plasma drug concentrations were the same when administered in a weight-normalized fashion regardless of body habitus (also see Chapter 30).

Although not clinically validated in obese patients, bolus doses probably should be scaled to TBW and other dosing scalars may lead to inadequate effect. On the other hand, with a fixed elimination, continuous infusion rates should dosed to IBW.[46]

Opioids

With the exception of remifentanil, minimal work has explored the implication of obesity on the kinetic and dynamic behavior of opioids.

Remifentanil. In obese patients, largely because of its rapid metabolism by nonspecific esterases, the distribution volume and clearance of remifentanil are similar in lean and obese patients.[47] As with propofol, researchers have explored several scaled weights in an effort to optimize bolus dosing, continuous infusions, and TCIs.

Dosing Scalars. As above with propofol, simulation is used to present the predicted remifentanil effect-site concentrations and analgesic effect for a variety of scaled weights in individuals 176 cm in height, some obese (185 kg, BMI of 60) and some lean (68 kg, BMI of 22) (Fig. 24-34). Several key points are illustrated in these simulations:

1. For an obese patient, dosing scaled to FFM or IBW resulted in almost identical remifentanil effect-site concentrations as in the lean patient dosed according to TBW. Unlike propofol, dosing remifentanil to CBW (red line) leads to higher plasma concentrations compared with levels achieved when doing to TBW in a lean individual.

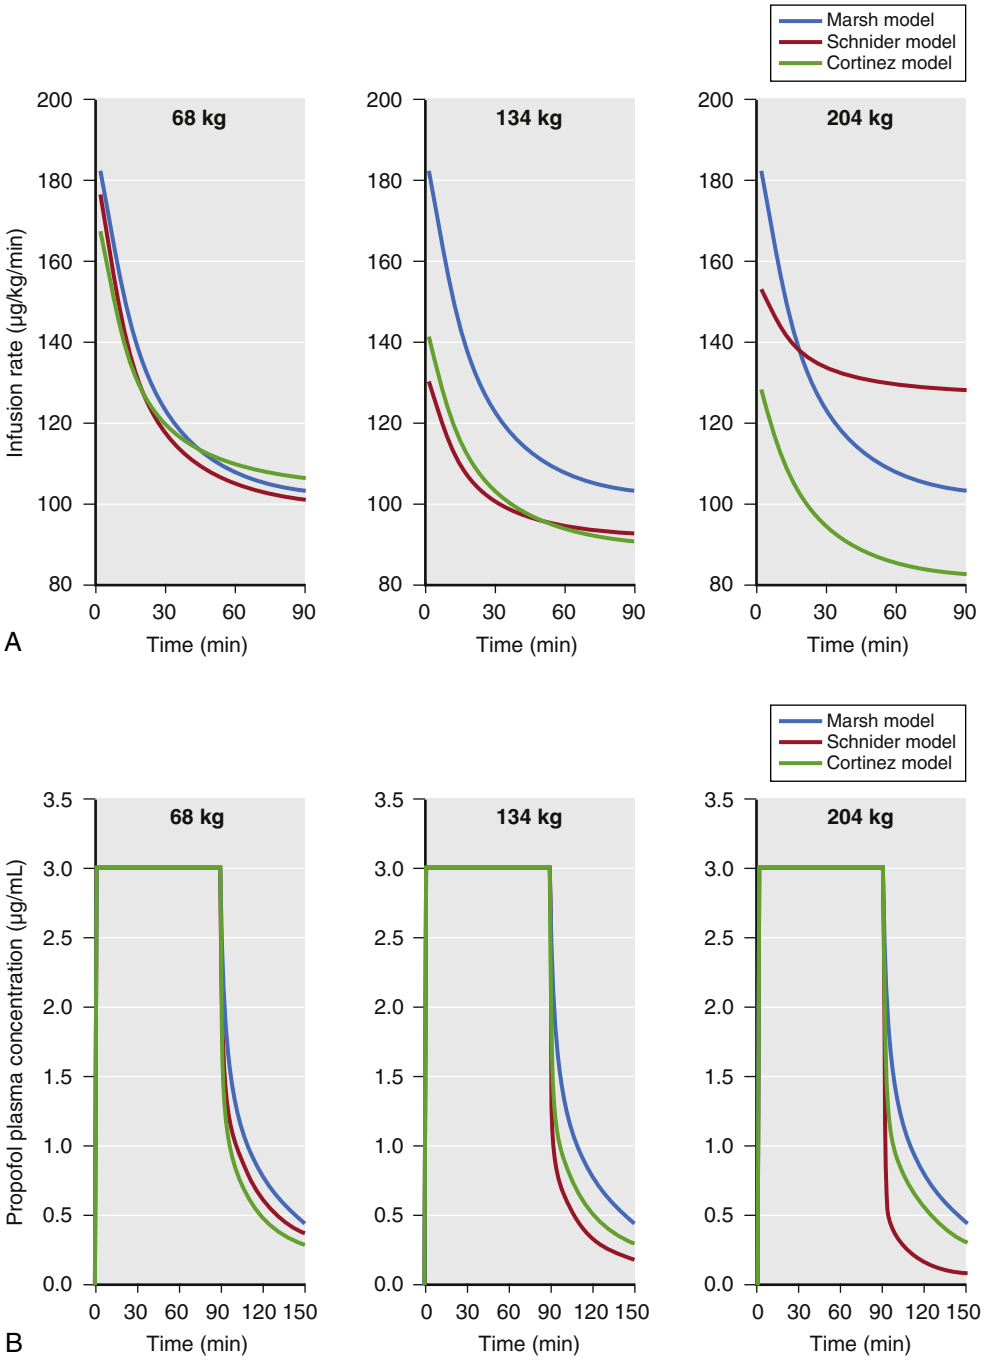

Figure 24-33. Simulations of a 90-minute propofol target-controlled infusion set to achieve and maintain a plasma concentration (*Cp*) of 3 µg/mL using three different published propofol pharmacokinetic models: Marsh and colleagues,[42] Schnider and associates,[1] and Cortinez and colleagues.[39] Simulations assumed 40-year-old males who are 176 cm tall and weigh 68, 136, or 204 kg. **A,** Propofol infusion rates for each model at each weight. **B,** Propofol plasma concentrations predicted by each model for each weight.

2. Dosing scaled to LBM in the obese individual resulted in lower effect-site concentrations than those in a lean individual dosed according to TBW.
3. Dosing the obese individual to TBW was excessive.
4. All dosing scalars, except LBM, provided effect-site concentrations associated with a high probability of analgesia.

As can be appreciated in Figure 24-34, LBM has substantial shortcomings in morbidly obese patients.[43] First, dosing remifentanil to LBM leads to plasma concentrations with a low probability of effect compared with the other dosing scalars. Second, with excessive weight (BMI over 40), LBM actually becomes smaller, with increasing TBW making it impractical to use (see Fig. 24-31). A modified LBM,[40] FFM eliminates the extremely small-dosing weight problem.[48] In this simulation, IBW also provides suitable effect-site concentrations, but this may not always be the case when using a weight scalar that is based only on patient height and not on body habitus, such as the FFM).

Remifentanil Kinetic Models for Target-Controlled Infusions. For remifentanil TCI, one pharmacokinetic model is currently available, published by Minto and

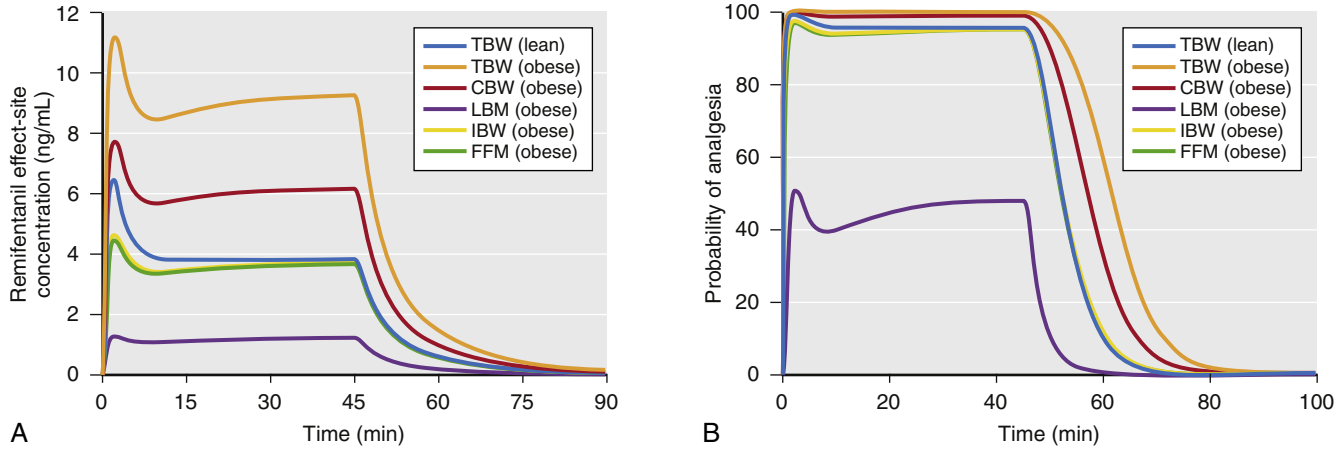

Figure 24-34. Simulations of remifentanil effect-site concentrations (**A**) and analgesic effect (**B**) that result from a 1 μg/kg bolus and a 60-minute infusion at a rate of 0.15 μg/kg/minute to a 40-year-old male who is 176 cm tall. Simulations include the following dosing weights: total body weights (TBW) of 68 kg and 185 kg (body mass indices of 22 and 60, respectively) and scaled weights for the 185-kg weight to include Servin's corrected body weight (CBW), lean body mass (LBM), ideal body weight (IBW), and fat-free mass (FFM). Remifentanil effect-site concentrations and estimates of analgesic effect were estimated using published pharmacokinetic models.[27,48] Analgesia was defined as loss of response to 30 PSI of pressure on the anterior tibia.

associates.[50] Although built from data collected in adults over a range of weights, heights, and age, obese and morbidly obese patients were not included. Many of the model parameters are scaled to LBM. As previously discussed, this may limit the application of this model in the morbidly obese. La Colla and colleagues propose using a weight-adjusted height to enter when programming a TCI pump for delivery of remifentanil to morbidly obese.[48] This adjusted height, based on FFM,[51] is designed to offset the inaccurate influence of LBM on model predictions used to drive the infusion pump. The fictitious weight-adjusted height uses actual height and weight to estimate a new (taller) height that will modify the Minto model to provide more remifentanil via TCI in overweight patients. For example, with a 176-cm 185-kg 40-51 year-old male, the adjusted fictitious height is 254 cm.

To illustrate the impact of the La Colla modification, Figure 24-35 presents a simulation of the predicted remifentanil plasma concentrations based on the Minto model and La Colla correction of the Minto model. The Minto model overestimates remifentanil concentrations with increasing weight. This is likely due to the use of LBM when estimating pharmacokinetic parameters.

A more reasonable approach would be to construct a new pharmacokinetic model based on data measured in obese patients rather than modifying an existing model that did not specifically include this patient population when it was built. A possible approach to constructing a new model is to use allometric body mass scaling as was described for propofol.[44,46]

In summary, available models (Minto or the La Colla modified Minto model) are appropriate for TCI in this patient group but will administer different amounts of remifentanil and require titration to achieve desired yet avoid adverse clinical effects.

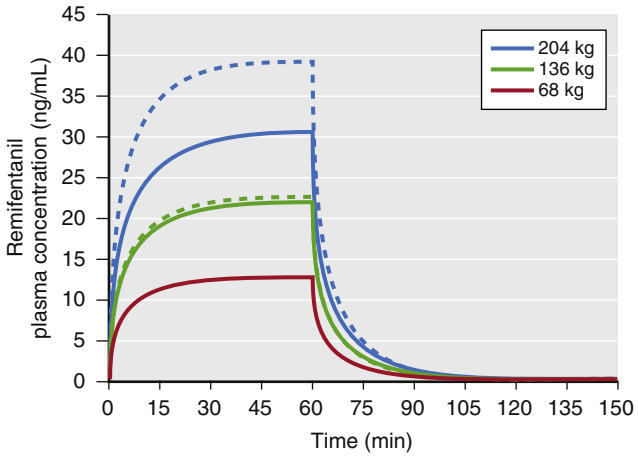

Figure 24-35. Simulations of remifentanil plasma concentrations that result from a 60-minute infusion (0.5 μg/kg/minute) in a 40-year-old male, 176 cm tall. The simulations include three total body weights: 68, 136, and 204 kg with body mass indices of 22, 44, and 66, respectively. Simulations were performed using pharmacokinetic parameters published by Minto and associates[39] (*dashed lines*) and with the La Colla's modification of Minto's model[38] (*solid lines*). In an extremely obese (204-kg) individual, Minto's model predicts very high remifentanil concentrations.

Fentanyl

Despite widespread use in the clinical arena, relatively little work has explored how obesity impacts fentanyl pharmacokinetics (also see Chapter 31). Published fentanyl pharmacokinetic models[52] tend to overestimate fentanyl concentrations as TBW increases. A fentanyl kinetic model based on data collected in obese subjects has not (yet) been published. As with La Colla and associates' work with remifentanil, Shibutani and colleagues[36,37] explored ways to improve predictions using published models by modifying demographic data (e.g., either height or weight). They characterized a nonlinear relationship between fentanyl clearance and TBW and recommended the use of a modified weight, called the pharmacokinetic mass, to improve the predictive performance of one of the many available fentanyl kinetic models, a model published by Shafer and colleagues. Shibutani and associates then explored the use of pharmacokinetic mass when

dosing obese patients with fentanyl in a postoperative setting. They found that dosing based on TBW may be excessive.[39]

Other Opioids

Even less information regarding the impact of obesity on drug behavior is available for opioids other than remifentanil and fentanyl. Sufentanil has been studied in obese patients, where its volume of distribution increases linearly with TBW[53] and clearance was similar between lean and obese individuals. It was recommended that bolus dosing use TBW and "prudently reduced" dosing for continuous infusions. For TCI, Slepchenko and colleagues found model estimates of sufentanil concentrations accurately predicted measured concentrations in morbidly obese patients[54] using a previously published mode of sufentanil kinetics by Gepts and associates.[55] This is likely due to the fact that the kinetic model was built from measured concentrations in patients with a weight range of 47 to 94 kg.

Inhaled Anesthetics

The perception of volatile anesthetics is that they accumulate more in obese than in lean patients and that this leads to prolonged emergence. Studies on inhaled anesthetics in obese individuals, however, has not confirmed this perception.[56] Two phenomena contribute to this observation: first, blood flow to adipose tissue *decreases* with increasing obesity,[57] and second, the time required to fill adipose tissue with volatile anesthetics is long. The times required to achieve 63% of the final equilibrium within adipose tissue for desflurane and isoflurane are longer than 22 and 35 hours, respectively.[58,59]

INFLUENCE OF INCREASING AGE ON ANESTHETIC DRUG PHARMACOLOGY

Clinicians are often faced with anesthetizing older adult patients adults and have long recognized that these patients usually require a smaller dosage of most anesthetics to produce the desired therapeutic effect while minimizing adverse effects. Age is one of the most valuable covariates to consider when developing an anesthetic plan (also see Chapter 80). The influence of age on pharmacokinetics and pharmacodynamics of many anesthetics has been well described. As with obesity, both remifentanil and propofol can serve as prototypes to understand how age influences anesthetic drug behavior. Studies specifically designed to assess the influence of age on remifentanil and propofol have characterized the influence of age in quantitative terms.[1,11,49,50]

With remifentanil, older patients require less drug to produce an opioid effect. Reduced doses are primarily a function of changes in pharmacodynamics but may also involve pharmacokinetic changes.[50] The concentration required to produce electroencephalographic changes is decreased. Based on previously published pharmacokinetic and pharmacodynamic models built from measurements over a wide age range,[1,11,49,50] simulations can be performed to explore how age may influence dosing. For example, to achieve equipotent doses in 20- and 80-year-olds, the dose for the 80-year-old should be reduced by 55%. A similar analysis for propofol recommends that the dose for an 80-year-old be reduced by 65% compared with that of a 20-year-old.

The mechanisms for these changes are not clear, especially for pharmacodynamic changes. One possible source of change in pharmacokinetic behavior may be decreased cardiac output. Lower cardiac output in older adults[60] results in slower circulation with subsequent changes in drug distribution and redistribution. This may lead to high peak concentrations[60,61] and decreased drug delivery to metabolic organs and reduced clearance. This is consistent with what has been described for many intravenous anesthetics (propofol, thiopental, and etomidate), which have slower clearance and a smaller volume of distribution.[1,62-64] Beyond age-related changes in cardiac output, other comorbidities may also reduce cardiovascular function.[65] Taking this into account, anesthesiologists often consider a patient's "physiologic" age instead of solely relying on actual age.[60,67] For some older adult patients, such as those with no significant coexisting disease, normal body habitus, and good exercise tolerance, a substantial reduction in dose may not be warranted.

SUMMARY

This chapter has reviewed the basic principles of clinical pharmacology used to describe anesthetic drug behavior: pharmacokinetics, pharmacodynamics, and anesthetic drug interactions. These principles provide the information needed to make rational decisions about the selection and administration of anesthetics. From a practical aspect, these principles characterize the magnitude and time course of drug effect, but because of complex math requirements, they have had limited clinical use in everyday practice. Advances in computer simulation, however, have brought this capability to the point of real-time patient care. Perhaps one of the most important advances in our understanding of clinical pharmacology is the development of interaction models that describe how different classes of anesthetic drugs influence one another. This is especially relevant to anesthesiologists, given that they rarely use just one drug when providing anesthesia.

Chapter 25

Inhaled Anesthetics: Mechanisms of Action

MISHA PEROUANSKY • ROBERT A. PEARCE • HUGH C. HEMMINGS, JR.

Key Points

- Anesthesia consists of separable and independent components or physiologic substates, each of which involves distinct, but possibly overlapping, mechanisms at different sites in the central nervous system.
- The potency of general anesthetics correlates with their solubility in oil, indicating the importance of interactions with hydrophobic targets.
- General anesthetics act by binding directly to amphiphilic cavities in proteins. Binding sites can be identified by a combination of site-directed mutagenesis and high-resolution structural analysis of anesthetic binding. Mutations rendering putative effector proteins insensitive to inhaled anesthetics have been constructed and expressed in mice but have not generated breakthroughs analogous to the success of this strategy with intravenous anesthetics.
- The effects of inhaled anesthetics cannot be explained by a single molecular mechanism. Rather, multiple targets contribute to the component actions comprising the anesthetic effects of each anesthetic. However, these effects do converge on a limited number of states underlying the behavioral effects.
- The immobilizing effect of inhaled anesthetics involves actions in the spinal cord, whereas sedation/hypnosis and amnesia involve supraspinal mechanisms that interact with endogenous memory, sleep, and consciousness pathways and networks.
- Volatile inhaled anesthetics enhance inhibitory synaptic transmission postsynaptically by potentiating ligand-gated ion channels activated by γ-aminobutyric acid (GABA) and glycine, extrasynaptically by enhancing GABA receptors and leak currents, and presynaptically by enhancing basal GABA release.
- Inhaled anesthetics suppress excitatory synaptic transmission presynaptically by reducing glutamate release (volatile anesthetics) and postsynaptically by inhibiting excitatory ionotropic receptors activated by glutamate (gaseous, and to some extent volatile, anesthetics).
- No comprehensive theory of anesthesia yet describes the sequence of events leading from the interaction between an anesthetic molecule and its targets to the behavioral effects.

Despite the widespread clinical use of general anesthetics, our current understanding of their molecular, cellular, and network mechanisms is incomplete. This critical gap in the pharmacology of one of medicine's most important drug classes not only impedes rational use of available anesthetics but also hinders the development of newer anesthetics that might selectively achieve the desirable end points of anesthesia with fewer adverse cardiovascular, respiratory, and possibly neuropathologic side effects. Although major progress has been made in understanding the pharmacology of the intravenous anesthetics by molecular genetic approaches (see Chapter 30), the actions of the inhaled anesthetics at the molecular and cellular levels are more enigmatic. It is still not possible to trace precisely the sequence of events that leads from inhaled anesthetic–target interactions, through ascending levels of biologic complexity, to the various behavioral effects that characterize the composite state of clinical anesthesia in humans. Nevertheless, investigations continue to reveal fundamental principles of action and have led to a framework for understanding anesthetic effects at different organizational levels. The focus of this chapter is on the mechanisms involved in the principal therapeutic effects (anesthesia) and on the side effects of the inhaled anesthetics (Fig. 25-1), a chemically and pharmacologically diverse group that includes the potent halogenated

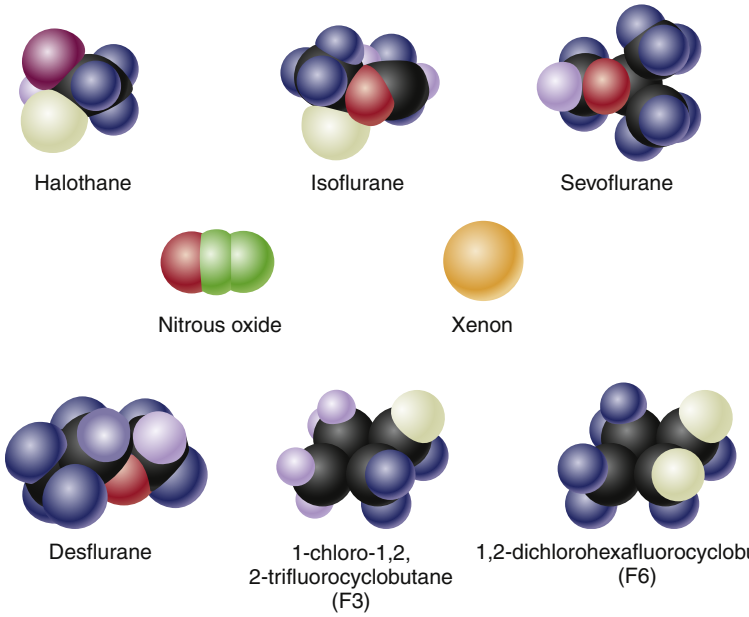

Figure 25-1. Structure of representative general anesthetics and a nonimmobilizer (F6) shown as space-filling models.

TABLE 25-1 **OVERVIEW OF CANDIDATE SITES OF ANESTHETIC ACTION**

	Site	Effect	Targets
Proteins	Amphiphilic binding sites	Conformational flexibility, ligand binding	Ion channels, receptors, signaling proteins
Action potential	Nervous system	Small reduction in amplitude	Na^+ channels
	Cardiovascular system	Reduced amplitude, duration	Ca^{2+} channels, K^+ channels
Synaptic transmission			
Inhibitory	Presynaptic terminal	Enhanced transmitter release	?
	Postsynaptic receptors	Enhanced transmitter effects	Glycine, $GABA_A$ receptors
Excitatory	Presynaptic terminal	Reduced transmitter release	Na^+ channels, K_{2P} channels
	Postsynaptic receptors	Reduced transmitter effects	NMDA receptors, nicotinic acetylcholine receptors
Neuronal networks	Neuronal circuit	Altered long-term potentiation (LTP)/ long-term depression (LTD)	Synaptic plasticity
	Neuronal integration	Altered rhythmicity, coherence	HCN channels, K_{2P} channels, extrasynaptic $GABA_A$ receptors, etc.
Central nervous system	Neocortex, hippocampus, amygdala	Sedation, amnesia	Slow 1-Slow 4, δ-, α-, θ-, γ-rhythms, cross-frequency coupling
	Diencephalon (thalamus), brainstem (reticular formation)	Unconsciousness	γ-band transfer entropy?, cross-frequency coupling? cortical integration capability?
	Spinal cord	Immobility	Thalamic deafferentation? Nocifensive reflex
Cardiovascular system	Myocardium	Negative inotropy	Excitation-contraction coupling
	Conduction system	Dysrhythmias	Action potential
	Vasculature	Vasodilation	Direct and indirect vasoregulation

HCN, Hyperpolarization-activated cyclic nucleotide; *NMDA, N*-methyl-D-aspartate.

ether (isoflurane, sevoflurane, desflurane, enflurane) and alkane (halothane) volatile anesthetics and the gaseous anesthetics (nitrous oxide and xenon). This critical summary of the current state of knowledge begins with an historical overview and a review of the behavioral end points of anesthesia. We then trace, where possible, inhaled anesthetic effects through ascending levels of organization from molecules, cells, circuits, networks, and organs to mammalian behavior; an overview is provided in Table 25-1. We also briefly address studies of anesthetic effects in model organisms, with anesthetic end points being identified that bear unclear relationships to those in mammals.[1]

HISTORY

THE UNIFIED PARADIGM OF ANESTHETIC THEORIES

The first monograph reporting experimental work on anesthetic mechanisms, proposing a soon-to-be

discredited lipid-elution theory of anesthetic action, was published only 6 months after Morton's Ether Dome demonstration. For decades thereafter, the phenomenon of anesthesia puzzled, inspired, and awed those who tried to understand it. A most influential paradigm of anesthetic action formulated by Claude Bernard in the 1870s posited that anesthesia was a "unified" phenomenon: a unitary mechanism applicable to all forms of life. Although the anesthetized state could be brought about by a variety of agents, its essence was the same in all living creatures. In fact, Bernard thought that life itself was defined by susceptibility to anesthesia. Bernard also proposed a more specific theory of anesthesia, coagulation of protoplasm, which competed with a number of coexisting theories entertained by the scientific community. In a major work published in 1919, Hans Winterstein summarized the perplexing diversity of anesthetic theories by listing more than 600 references, the majority to original laboratory work—a convincing testimony to the interest of the scientific world in this phenomenon. Of note, the work of Meyer and Overton at the end of the nineteenth century had only a limited effect on the trajectory of research until the 1960s.[1] Only then was the striking simplicity of the Meyer-Overton correlation (Fig. 25-2, *A*) of anesthetic potency with solubility in olive oil interpreted by the majority of researchers as an indicator that lipids are likely the anesthetic target. This interpretation focused attention on anesthetic effects on the bulk physical properties of cell membranes, which were known at that time to consist primarily of lipid molecules. Such nonspecific or "lipoid-based" anesthetic theories dominated the field from the 1960s to the 1980s.

MINIMUM ALVEOLAR CONCENTRATION: A BRIDGE BETWEEN PAST AND PRESENT

The potencies of inhaled anesthetics for immobilization were established in the classic studies in the 1960s of Eger and colleagues,[2,3] who defined the *minimum alveolar concentration* (MAC) as the inhaled anesthetic atmospheric pressure required to prevent movement in response to a defined noxious stimulus in 50% of subjects. The concept of MAC evolved within a unitary paradigm of anesthetic action and reflected the priorities of clinical practice. As a result, prevention of movement (immobility) became a universal yardstick for anesthetic effects, presumed to occur in the brain. Moreover, the simple elegance of the relationship between MAC and lipid solubility (see Fig. 25-2, *A*) graphically illustrated Meyer and Overton's conclusion that "All chemically indifferent substances that are soluble in fat are anesthetics … their relative potency as anesthetics will depend on their affinity to fat on the one hand and water on the other hand, that is, on the fat/water partition coefficient."[1] This was interpreted as favoring lipids as the primary targets of anesthetics and a single nonspecific theory to explain anesthesia. The appeal of a single unified mechanism to explain anesthesia was (and remains) intellectually appealing. This focused the bulk of research efforts on delineating how anesthetic interactions with lipid membranes might lead to the behavioral changes observed under anesthesia, the nonspecific lipoid theory.

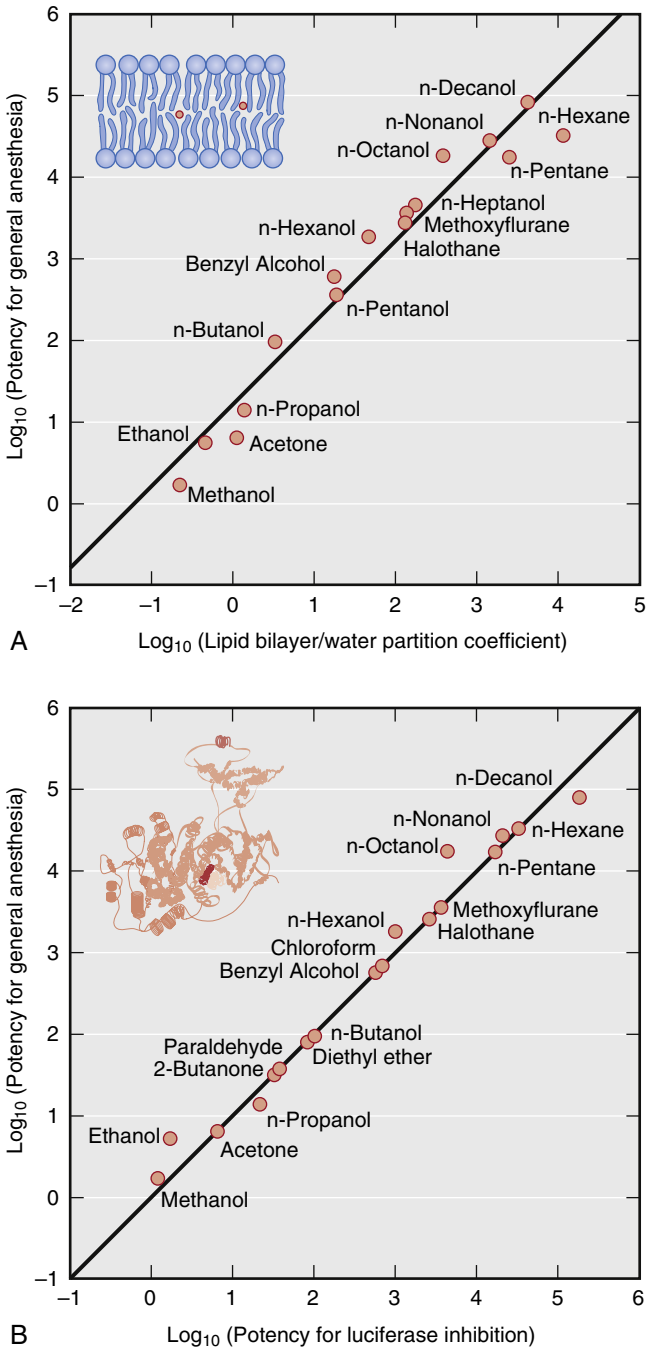

Figure 25-2. General anesthetics act by binding directly to proteins. **A,** The iconic Meyer-Overton correlation (ca. 1900) between anesthetic potency and the lipid-water partition coefficient was initially interpreted as evidence that lipids of nerve membranes were the principal anesthetic target sites. **B,** Progress in the twentieth century showed that general anesthetic potencies correlate equally well with their ability to inhibit activity of the soluble firefly enzyme luciferase, which is not a physiologically relevant anesthetic target itself but serves as a lipid-free model protein for anesthetic binding. *Inset,* The crystal structure of luciferase with bound anesthetic *(red). (Reprinted with permission from Franks NP, Lieb WR: Molecular and cellular mechanisms of general anesthesia,* Nature *367:607-614, 1994.)*

Because inhaled anesthetic concentrations reflect concentrations in the tissues after equilibration, which is most rapidly achieved for well-perfused organs such as the brain and heart, MAC is analogous to the plasma concentration for 50% effect (EC_{50}) for intravenous anesthetics. In clinical applications, MAC is usually expressed as volume percent (vol%), which varies considerably with temperature and atmospheric pressure caused by changes in aqueous solubility, whereas the equivalent liquid-phase molar concentration is temperature- and pressure-independent.[4] The MAC concept provided researchers and clinicians with a universal standard to measure a defined anesthetic end point (immobility), making meaningful comparisons of experimental results possible and accelerating clinical and laboratory research into anesthetic mechanisms. Today, a more nuanced understanding of MAC takes into account the structural and functional diversity of the physiologic targets for the different components of the anesthetic state.

SHIFT FROM LIPID- TO PROTEIN-CENTERED MECHANISMS

Lipid-centered mechanisms of anesthesia prevailed in the 2 decades after definition of the MAC concept. Alternative targets were repeatedly proposed but largely neglected by the scientific mainstream. Experimental inconsistencies of lipid targets,[5,6] as well as evidence compatible with proteins as primary sites of action,[7,8] remained largely unnoticed. A shift from lipid- to protein-centered mechanisms occurred in the 1980s, owing largely to the landmark discoveries by Franks and Lieb,[9,10] who in a classic series of publications demonstrated that protein targets were also compatible with the Meyer-Overton correlation (see Fig. 25-2, *B*)—a proof of concept that, within a couple of years, redirected the bulk of research efforts toward proteins. As a corollary of this reorientation, evidence against lipid-based theories was recognized. Examples include the cutoff in anesthetic potency in homologous series of long-chain anesthetic alcohols, and the identification of hydrophobic drugs that do not obey the Meyer-Overton correlation.[1,11] The enantiomeric selectivity of several anesthetics further strengthened the case for specific binding sites on proteins because stereoselectivity is difficult to reconcile with lipid targets.[12] Today, there is widespread (but not universal) acceptance of the notion that critical signaling proteins (e.g., ion channels or ligand-gated receptors) are the relevant molecular targets of anesthetic action, even though the submolecular mechanisms of their modulation by anesthetics are debated. The exact identity of proteins contributing to specific anesthetic end points continues to be sought, with research addressing not only the "where" (target) but also the "how" (process) of anesthetic mechanisms.

DIVERSITY OF POTENTIAL ANESTHETIC TARGETS

At high concentrations in vitro, most inhaled anesthetics affect the functions of multiple proteins, many of which can be plausibly connected to the components of the anesthetic state or anesthetic side effects. However, when considering a specific anesthetic end point, anesthetics are effective in vivo over quite a narrow concentration range. This makes the concentration at which a relevant anesthetic effect is observed a critical consideration for deciding potential relevance. The mechanistic relevance of small effects observed in vitro at relevant concentrations is less clear; that is, what effect is too small to be considered relevant to anesthesia?[13-15] Whether anesthesia results from the sum of minor perturbations at multiple sites that are amplified in cascades across multiple levels of integration to produce the macroscopic effect, or from strong effects on a small number of targets should be resolved as results of reductionist molecular studies are integrated into more complex molecular and cellular networks, and as genetic studies are extended to encompass inhaled anesthetics. The picture that is emerging includes multiple cellular and molecular targets in distinct brain regions that are involved in both the desired and adverse effects of general anesthetics.

ANESTHESIA: A COMPOSITE NEUROPHARMACOLOGIC STATE

Along with progress in identifying the molecular mechanisms of anesthesia, our understanding of the nature of the anesthetic state has evolved. Whereas a drug-induced comalike state of general anesthesia can be induced by inhaled anesthetics administered at appropriate concentrations (approximately 1.3 times MAC, equivalent to the EC_{95} of a volatile anesthetic), the use of such high concentrations can lead to short-, and possibly long-term, side effects. It is now clear that anesthesia consists of separable and at least partially independent components or substates, each of which involves distinct, but possibly overlapping, mechanisms in different regions of the central nervous system (CNS) and with variations in relative potencies between specific agents.[16] Immobilization, the core measure of MAC, is mediated largely at the level of the spinal cord by inhaled anesthetics[17,18] but not by barbiturates.[19] On the other hand, the spinal cord is unlikely to be the major site of such phenomena as amnesia, sedation, and unconsciousness, which rather are produced by anesthetic effects on cerebral cortical function (Fig. 25-3). A functional separation between amnesia and sedation has been demonstrated for intravenous anesthetics,[20] and it seems likely that this will apply to inhaled anesthetics as well. The state commonly referred to as "unconsciousness" is in itself heterogeneous, with evidence for distinct states of unresponsiveness and unconsciousness.[21] These and similar findings have led to the concept that general anesthesia consists of multiple independent components that can be resolved experimentally and clinically.

In principle, each component of anesthesia can be preferentially induced in a concentration- and agent-specific manner using individual cellular/molecular pathways in various regions of the CNS. For example, injections of pentobarbital into discrete sites in the mesopontine tegmentum induce a comatose state,[22] whereas sedation induced by systemic administration of propofol can be reversed by microinjections of γ-aminobutyric acid $(GABA)_A$ receptor antagonists into the tuberomammillary

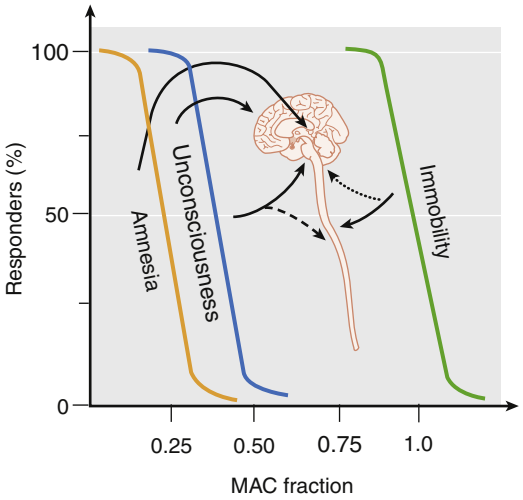

Figure 25-3. Multiple behavioral end points and sites of action underlie inhaled anesthetic action. Amnesia, the most sensitive anesthetic end point, probably involves the hippocampus, amygdala, mediotemporal lobe, and other cortical structures. Unconsciousness likely involves the cerebral cortex, thalamus, and reticular formation. Sedation and hypnosis (loss of responsiveness) are part of the consciousness-unconsciousness continuum and are not shown. Immobility occurs by anesthetic action in the spinal cord, although supraspinal effects *(dotted arrow)* are likely important for some anesthetics. Anesthetic action in the spinal cord blunts ascending impulses arising from noxious stimulation and might indirectly contribute to anesthetic-induced unconsciousness and amnesia *(dashed arrow)*. Cardiovascular responses occur at even greater MAC fractions (not shown). *(Courtesy Joseph Antognini, University of California, Davis.)*

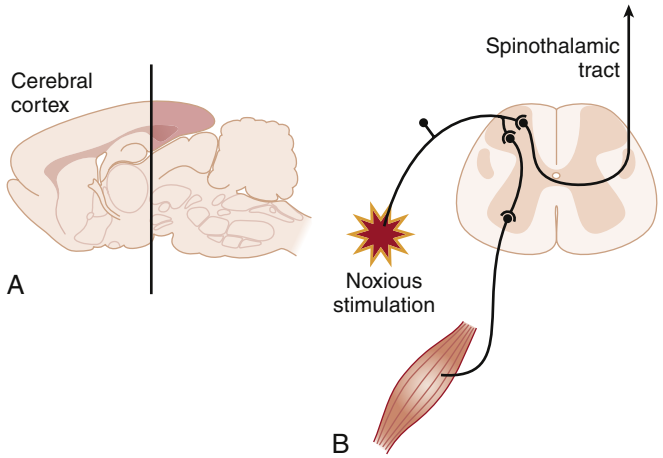

Figure 25-4. Inhaled anesthetics produce immobility at the spinal level. **A,** Decerebration by removal of the forebrain rostral to the *black line* does not alter the MAC of isoflurane in rats, indicating that volatile anesthetic immobilization does not depend on the cerebral cortex.[17,18] **B,** Anesthetics suppress the nocifensive withdrawal reflex response to noxious stimulation transmitted to the dorsal horn by sensory nerves at the spinal level. Current efforts are focused on identifying the molecular, cellular, and anatomic substrates for this effect.

nucleus, a sleep-regulating nucleus in the hypothalamus.[23] Thus, general anesthetics produce separate identifiable anesthetic substates via agent-specific actions at discrete anatomic sites in the CNS through different molecular targets. An important consequence of this complexity is that MAC, which is based exclusively on a motor response, might not proportionately reflect other components of anesthesia. Although this heterogeneity of anesthetic actions complicates a mechanistic understanding, it does open the possibility of developing substate-specific drugs.

INTEGRATED EFFECTS ON CENTRAL NERVOUS SYSTEM FUNCTION

IMMOBILITY

Electroencephalography as a monitor of brain activity has been applied both to the study of anesthetic mechanisms and as a monitor of the anesthetic state (also see Chapter 44). Failure to find a correlation between quantitative electroencephalographic activity and immobility in response to noxious stimulation led to the somewhat radical (at the time) hypothesis that immobility was not a cerebral cortex–mediated phenomenon.[24] Experimental demonstration that volatile anesthetics act on the spinal cord to suppress movement[17,18] supported this hypothesis and was a major factor leading to the contemporary separation of anesthetic substates, of which immobility requires the highest drug concentrations (see Fig. 25-3). Taking advantage of the unusual blood supply of goat CNS, which allows separate perfusion of brain and spinal cord, Antognini and associates[17,25] showed that immobility involves anesthetic effects at the spinal level because selective delivery of isoflurane or halothane only to the brain required 2.5-fold to 4-fold higher concentrations. At the same time, experiments by Rampil and co-workers[18] that used surgical separation of the forebrain and midbrain from the spinal cord in rats led to the conclusion that immobilization involves primarily suppression of the nocifensive withdrawal reflex arc at the level of the spinal cord (Fig. 25-4).

In the 20 years since the identification of the spinal cord as the site of anesthetic-induced immobility, research has centered on pharmacologic, genetic, and complex network approaches. The pharmacologic approach to identify receptor-level contributions to isoflurane-induced immobility (isoflurane being the standard potent ether for experimental purposes) yielded the surprising insight that actions at $GABA_A$ receptors appear to be unimportant.[26] Perhaps less surprisingly, inhibition of central nicotinic acetylcholine receptors also plays no role in immobilization.[27] A role for voltage-gated sodium (Na^+) channels was suggested by the finding that intrathecal administration of a selective inhibitor of Na^+ channels potentiates anesthetic immobility (reduces MAC), whereas a Na^+ channel activator does the opposite.[28] Anesthetic-resistant transgenic mice confirmed that $GABA_A$ receptors containing α1- or α3-subunits do not contribute to the immobilizing action of isoflurane.[29,30] In contrast, mutant mice lacking the TASK-1, TASK-3, or TREK-1 K_{2P} channels have higher MAC values for volatile anesthetics but not intravenous anesthetics,[31-33] indicating a role for these channels, possibly by a presynaptic mechanism.[34]

Work with physiologic preparations that attempt to preserve parts of the complex spinal cord circuitry suggests that anesthetic inhibition of afferent (noxious sensory) input to the dorsal horn plays a subordinate role to the suppression of the efferent (motor) output from the ventral horn, although this may vary by specific agent. This motor output is coordinated by neuronal networks organized in so-called central pattern generators that control the activity of cholinergic motoneurons.[35] Not unlike understanding the anesthetic effects on higher cognitive function, the key to understanding immobility will likely lie in resolving the effect of anesthetics on integrated spinal network activity.

UNCONSCIOUSNESS

Consciousness, as a quality of the mind, is easy to recognize but difficult to define (see Chapters 13 and 14). It has been described as "what abandons us every night when we fall into dreamless sleep and returns the next morning when we wake up or when we dream." This intuitive description applies equally as well to general anesthesia as it does to sleep; however, it does not provide a concrete definition that is useful for scientific studies. Consciousness consists of inner qualitative subjective states of sentience or awareness.[36] A recent suggestion that seeks to provide a quantitative measure of consciousness, and that may serve as a definition, is that consciousness is the capacity of a system to integrate information.[37] Loss of consciousness (or hypnosis) is a hallmark of the onset of anesthesia, and anesthetic drugs are being used as tools for understanding the neural correlates of consciousness (NCC).[38] However, what is commonly referred to as *unconsciousness* under anesthesia might be better described as *unresponsiveness*, which could obscure states of self- and environmental awareness lacking explicit memory traces.[21]

Although it is a relatively new field, particularly within the field of anesthesiology, the "science of consciousness" has generated considerable interest and has led to a number of specific hypotheses that are experimentally tractable. The "thalamic theory" of anesthesia proposes a somatosensory deafferentation by anesthetic action in the thalamus as a mechanism of unconsciousness.[39] In support of this hypothesis, isoflurane hyperpolarizes and shunts thalamic neurons,[40] an action consistent with impaired thalamic transfer of sensory information.[41] Functional human brain imaging shows preferential suppression of thalamic activity by some, but not all, anesthetics, and this has led to the "thalamic switch" hypothesis.[39] However, loss of consciousness occurs within a very narrow range of anesthetic concentrations,[42] typically up to 0.5 MAC,[43,44] whereas quantifiable effects in the thalamus occur above this concentration range and are typically incremental (dimmerlike) rather than sudden (switchlike). A comprehensive theory of anesthetic-induced unconsciousness must be more inclusive than a simple block of information transfer through the thalamus to be compatible with existing evidence[45,46] and must also explain the suppression of endogenous cortical activity that is generated without external stimulation.

Contemporary neuroscience has replaced the Cartesian view of an anatomically discrete brain structure as the center of consciousness with the concept that consciousness requires integration of information between multiple brain regions across large-scale cerebral networks.[45,47] The rich connectivity of the cerebral cortex and its hierarchical organization are especially suited to enable high levels of information integration in the human brain. Some brain areas present a "rich-club" organization (i.e., highly connected nodes tend to be preferentially connected to other highly connected nodes), which has been suggested to be optimal for information integration.[48,49] These hubs might be promising targets for the hypnotic action of general anesthetic drugs.

Anesthetics might act by interfering with the operational synchronicity and coherence of these networks. Consequent disruption of cortical functional and effective connectivity has been observed during natural slow wave sleep[50] and midazolam-induced loss of responsiveness.[51] This breakdown of cortical connectivity, rather than pharmacologic deafferentation from the environment, could underlie loss of consciousness.[45] Unconsciousness would then be characterized not by the absence but by the fragmentation of cortical processing. Although the mechanism of "binding" (i.e., creating the unity of perception) is uncertain, synchronicity of neuronal activity in the 40- to 90-Hz range across functionally connected cortical areas (commonly referred to as 40 Hz- or γ-rhythm) is a viable candidate. Animal[52,53] and human[42] data implicate activity in the γ-band throughout the cortex as a network-level target of general anesthetics. Anesthetic actions on cortical information processing probably consist not merely of suppression of responses but of reduced complexity and variability reflected counterintuitively in increased reliability and precision of evoked responses.[54,55]

LEARNING AND MEMORY

Anterograde amnesia, one of the core desirable anesthetic end points, is achieved at lower anesthetic concentrations (~0.25 MAC) than those required for unconsciousness (~0.5 MAC). Perhaps the closest analogue in rodents to explicit memory in humans is medial temporal lobe–dependent learning of temporal and spatial sequences known as *hippocampus-dependent spatial learning*. This can be tested by a variety of experimental paradigms, including fear conditioning to context (Fig. 25-5). Other learning paradigms, such as fear conditioning to tone, are by contrast independent of the hippocampus. Isoflurane and the nonimmobilizer F6 both inhibit hippocampus-dependent learning at about one-half the concentration necessary for disrupting hippocampus-independent learning.[56] Similarly, anesthetic concentrations that inhibit explicit memory in humans (memory that can be explicitly recalled as opposed to motor learning, classical conditioning, and so on) are similarly lower than concentrations that impair implicit memory (not subject to willful recollection).[46] Taken together, these findings implicate effects on function of the medial temporal lobe, including the hippocampus, in the suppression of explicit

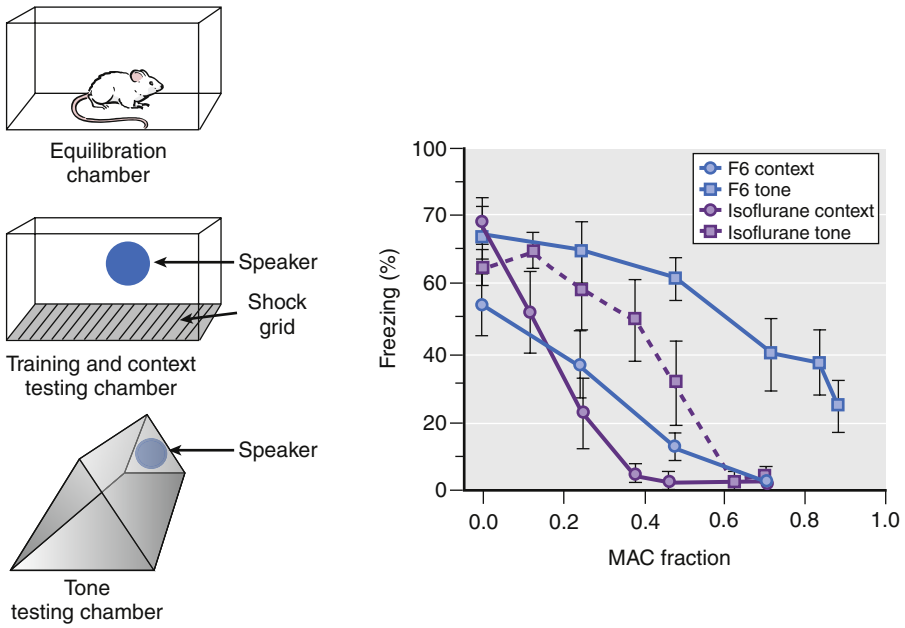

Figure 25-5. Differential sensitivity of different types of learning to anesthetics and nonimmobilizers. Freezing in anticipation of a noxious stimulus is a measure of learning in rats; less freezing indicates less learning. *Left,* The learning protocol involves pre-equilibration of rats in the equilibration chamber to isoflurane or the nonimmobilizer F6 at the desired concentration before placement into the training chamber. For testing of memory to context, the training and test chamber are identical. For testing of memory to tone, training and testing take place in different chambers. *Right,* Hippocampus-dependent learning (fear conditioning to context, *closed symbols*) is inhibited by isoflurane *(circles)* at lower concentrations than hippocampus-independent learning (fear conditioning to tone, *purple squares*). This differential sensitivity is mirrored by the nonimmobilizer F6 (*blue circles* and *blue squares* for context and tone, respectively). *(Left panel adapted with permission from Eger EI 2nd, et al: Isoflurane antagonizes the capacity of flurothyl or 1,2-dichlorohexafluorocyclobutane to impair fear conditioning to context and tone,* Anesth Analg *96: 1010-1018, 2003; right panel data points reconstructed from Dutton RC, et al: Short-term memory resists the depressant effect of the nonimmobilizer 1-2-dichlorohexafluorocyclobutane (2N) more than long-term memory,* Anesth Analg *94:631-639, 2002, and Dutton RC, et al: The concentration of isoflurane required to suppress learning depends on the type of learning,* Anesthesiology *94:514-519, 2001.)*

memory by anesthetics. Effects on other structures, such as the amygdala, may be relevant to anesthetic impairment of implicit or other types of memory.[57]

Comparison of the amnesic potency of five inhaled anesthetics using an inhibitory avoidance paradigm revealed that nitrous oxide was the most and halothane the least potent amnestic (expressed in MAC fractions), with the halogenated ethers of intermediate potency.[58] Because inhaled anesthetics affect multiple cellular targets at amnesic concentrations, it is difficult to attribute amnesia to specific cellular mechanisms. It is also unclear whether inhibition of learning and memory by drugs known to have different receptor affinities shares common mechanisms at some level of integration. Comparison with more selective drugs provides some insight. Yet, θ-rhythms (4-12/Hz) are clearly important for hippocampus-dependent learning and memory.[59] Benzodiazepines[60] and cannabinoids[61] slow and suppress hippocampal θ-rhythms in proportion to their ability to impair hippocampus-dependent learning (also see Chapters 13 and 30). Isoflurane and the nonimmobilizer F6 have comparable effects on θ-rhythms at amnesic concentrations while having different receptor-level profiles and opposite effects on sedation.[62] Thus alterations in neuronal synchrony provide a common network-level substrate for memory impairment. The synchronization between amygdalar and hippocampal θ-rhythms that occurs during fear memory retrieval indicates that this principle might also apply to other forms of memory and their impairment by anesthetics.[63] As with other components of the anesthetic state, the precise mechanisms of memory impairment by anesthetics, and of memory itself, remain to be fully elucidated.

SEDATION

Sedation (defined as a decrease in activity, alertness, arousal, and/or vigilance), which is on a behavioral continuum leading to hypnosis, is achieved at anesthetic doses similar to those that produce amnesia (<0.5 MAC). There is no clear mechanistic or clinical separation between sedation and hypnosis. By contrast, even though sedation can be difficult to separate from amnesia, for intravenous anesthetics (see Chapter 30) there may be separate but overlapping substrates for these two end points.[20,64] The mechanisms involved in these behavioral effects are likely to resemble those of less promiscuous drugs, for which genetic approaches have been informative. An amino acid knock-in mutation (H101R) in mice that renders the α_1 $GABA_A$ receptor subunit insensitive to modulation by benzodiazepines produces resistance to the sedative and amnesic effects of benzodiazepines while maintaining other behavioral effects, among them anxiolysis.[65] The α_1 subunit is abundantly expressed in the CNS, mainly in the cortical areas and thalamus. Volatile anesthetics have qualitatively similar

effects on α_1-containing $GABA_A$ receptors (but also those containing other subunits) at low concentrations. The observation that the nonimmobilizer F6, which is devoid of sedative properties,[62] is amnesic[66] but does not modulate benzodiazepine-sensitive α_1-containing $GABA_A$ receptors,[67,68] is compatible with a role for α_1-containing receptors in volatile anesthetic-induced sedation, because few other targets are affected at purely sedative concentrations. Possible targets for the sedative effects of the gaseous anesthetics nitrous oxide and xenon, which do not affect $GABA_A$ receptors, include *N*-methyl-D-aspartate (NMDA) receptor antagonism[69] and K_{2P} channel activation.[70] Consistent with this distinct pharmacologic profile, nitrous oxide has strikingly different effects from benzodiazepines in behavioral tests aimed at evaluating sedation in mice.[71]

Recognizing that there may be more than a superficial similarity between natural sleep and anesthetic-induced sedation and hypnosis, the effects of some anesthetics apparently share natural sleep mechanisms by directly activating discrete sleep-promoting nuclei in the hypothalamus.[23] Electroencephalographic patterns during natural slow-wave sleep and anesthesia show similarities,[72] and recovery from sleep deprivation can occur under propofol[73] and inhalational anesthesia,[74] supporting this concept (also see Chapter 14). Anesthetic effects on other cortical[75] and subcortical structures[21] may also contribute to anesthetic-induced sedation and hypnosis.

ANESTHETIC NEUROTOXICITY AND NEUROPROTECTION

Early Postnatal Neurotoxicity

General anesthetics can cause persistent neurologic effects beyond their classic reversible production of anesthesia. Yet its clinical significance remains unknown.[76-78] Since the discovery that postnatal exposure of the developing rodent brain to high doses of commonly used anesthetic drugs, in isolation or in combination, for a period of several hours, can induce apoptotic cell death with potentially long-term functional consequences,[78] the neonate rodent model has been extensively studied and discussed. Similar effects have been reproduced with all commonly used general anesthetic drugs. How the results translate quantitatively and qualitatively from short-lived altricial (such as rodents) to long-lived, more precocial (such as *Homo sapiens*) species remains to be defined. Interestingly, postexposure environmental factors appear to play a substantial role in the expression of neurotoxicity.[79]

Ischemic Neuroprotection

Pharmacologic neuroprotection from cerebral ischemia and reperfusion is a rapidly evolving area of research that is characterized by great potential, but comparable disappointments, because results from promising animal studies have failed to translate into clinical benefits. Despite considerable research, clinical evidence for ischemic brain protection by inhaled anesthetics remains controversial.[80] Ischemic neuronal injury results from early excitotoxic cell death mediated by excessive release of excitatory amino acid transmitters such as glutamate and oxidative stress caused by reperfusion injury together with delayed cell death as a result of apoptosis.[81,82] Volatile anesthetics (e.g., isoflurane) and xenon exhibit early neuroprotection in animal models that is sustained only for mild insults. This is consistent with a beneficial effect on excitotoxicity but minimal effects on delayed cell death caused by apoptosis. A therapeutic strategy to extend this early neuroprotection is suggested by the finding that isoflurane combined with caspase inhibitors to prevent apoptosis results in more sustained neuroprotection.[83] In contrast, xenon appears to have an intrinsic antiapoptotic action that contributes to its neuroprotective properties, consistent with its distinct molecular mechanisms.[84] Interestingly, "preconditioning" with ketamine appears to protect against ketamine-induced neurotoxicity.[85] In addition, volatile anesthetics probably protect by suppression of brain energy requirements owing to inhibition of excitatory transmission and potentiation of inhibitory receptors and ion channels.[81] The potential for beneficial effects from anesthetic-induced preconditioning has also received considerable recent attention. Similar to the protective effects of anesthetics administered before cardiac ischemia (anesthetic preconditioning; see later), protective effects have also been observed in animal models of focal cerebral ischemia (see also Chapters 67, 69, and 70).[86]

Postoperative Cognitive Effects

Adverse postoperative cognitive effects persisting beyond a duration explainable by pharmacokinetic factors have been attributed to anesthetics since the nineteenth century. Three clinical entities must be distinguished: delirium, dementia, and postoperative cognitive dysfunction (POCD). Contrary to delirium and dementia, POCD is not a clinical diagnosis but a result of comparison of pre- and postoperative scores on neuropsychological test batteries among patients undergoing surgery and matched control populations that did not undergo surgery. This is a highly complex experimental paradigm that is prone to artifacts. For example, as a result of these analyses, postoperative cognitive improvement coexists with POCD,[87] and whether either or both of these entities exists as pathologic entities and are clinically relevant remains an open question. The situation is fundamentally different with respect to delirium and neurodegeneration, which can be diagnosed by established criteria and standardized tools.

Although direct effects of inhalational anesthetics have been linked to memory deficits persisting for days in young adult mice, specifically via interaction with the α_5 subunit of the $GABA_A$ receptor,[88] postanesthesia changes in exploratory behaviour are dependent on interaction with central cholinergic signaling pathways.[89] Accumulating evidence, however, points to immune- and/or inflammation-mediated changes triggered by surgical trauma and anesthesia as potential mechanisms for delirium-like, short- or intermediate-term postoperative cognitive dysfunction (also see Chapter 99).[90,91]

Experimental evidence obtained using mice rendered genetically susceptible to Alzheimer disease–like neurodegeneration does not support a role of anesthetic agents per se in promoting neurodegenerative disease.[92] It provides experimental support for observational studies in humans that cognitive decline after surgery is caused by neither accelerated neurodegeneration nor anesthetic agents.[93]

Rather than an anesthetic-mediated effect, a determining role for the underlying disease trajectory (as opposed to the surgical/anesthetic intervention) in determining the long-term cognitive course of most patients is likely.[94] Short-term effects on cognition appear to be related to physiologic perturbations resulting from invasive interventions with either aggravating and/or mitigating roles of anesthetics.

INTEGRATED EFFECTS ON THE CARDIOVASCULAR AND RESPIRATORY SYSTEMS

Mechanisms of Cardiovascular Effects

The classic cardiovascular effects of the volatile anesthetics are usually undesired deleterious side effects that limit their safe use in the critically ill, but recent studies have shown that there are also direct cardioprotective effects.[95] All volatile anesthetics produce agent- and dose-dependent reductions in myocardial contractility, systemic vascular resistance, and cardiac preload, with consequent reduction in mean arterial pressure. However, significant differences do exist in the relative potencies of these effects between anesthetics (see Chapter 28).[96] Volatile anesthetics depress contractility by reducing Ca^{2+} availability and/or Ca^{2+} sensitivity of the contractile apparatus.[97] The major targets responsible for the negative inotropic effects of volatile anesthetics are cardiac Ca^{2+} channels, sarcoplasmic Ca^{2+} handling, and the contractile apparatus. Inhibition of depolarization-induced increases in myoplasmic Ca^{2+} concentration occur primarily via inhibition of cardiac L-type voltage-gated Ca^{2+} currents and shortening of action potential duration.[98] Volatile anesthetics also inhibit the sarcoendoplasmic Ca^{2+} adenosine triphosphatase (SERCA), whereas halothane, but not isoflurane or sevoflurane, opens sarcoplasmic reticulum (SR) Ca^{2+} release channels (ryanodine receptors), depleting SR Ca^{2+} content and reducing excitation-evoked SR Ca^{2+} release.[97] The resulting negative inotropic effect of this reduced Ca^{2+} availability is enhanced by reductions in the Ca^{2+} sensitivity of myofibrils. In contrast, xenon has no effect on ventricular contractility, conduction, or major cation currents.[98,99] consistent with its lack of significant cardiovascular effects. Nitrous oxide causes mild reductions in ventricular function[99] by poorly characterized effects on Ca^{2+} availability. This is usually accompanied by sympathetic nervous system stimulation that increases vascular resistance and counteracts the myocardial depression.[100,101]

Volatile anesthetics can produce vasodilation at clinical concentrations.[102] (Also see Chapter 28.) The vascular effects of volatile anesthetics are multifactorial and tissue specific, and the precise cellular mechanisms are poorly understood.[103,104] Peripheral vasodilation is mediated by both direct endothelium-independent vasodilating effects on vascular smooth muscle cells and indirect effects involving the sympathetic nervous system and the vascular endothelium. The mechanisms of these effects involve agent-specific effects on presynaptic norepinephrine release, inhibition of smooth muscle Ca^{2+} influx via L-type Ca^{2+} channels, activation of hyperpolarizing adenosine triphosphate (ATP)-sensitive K^+ (K_{ATP}) and K-Ca channels, and endothelium-dependent factors, including nitric oxide production.[105] As with the CNS, cardiovascular function depends on the integrated function of multiple ion channels, many of which are expressed in both of these excitable tissues. Volatile anesthetics have agent-specific effects on heart rate and induction of arrhythmias caused by actions on cardiac ion channels. Because multiple cardiac ion channels are sensitive to volatile anesthetics at clinical concentrations, and because most manipulations of cardiac ion channel function are potentially proarrhythmic, it is difficult to link anesthetic arrhythmogenicity to actions on specific channels.[106] Electrophysiologic studies indicate that cardiac L-type Ca^{2+} channels, which are critical to the plateau phase of the cardiac action potential and electromechanical coupling, are inhibited by volatile anesthetics, leading to shortening of the refractory period. Multiple voltage-gated K^+ channels are also inhibited and might predispose to arrhythmias by delaying repolarization. Alternatively, inhaled anesthetics can protect the heart against ischemia and reperfusion injury, possibly involving antioxidant, antiinflammatory, and/or preconditioning mechanisms.[107,108] Volatile anesthetics[109] and xenon[110] can mimic the strong cardioprotective effects produced by ischemic preconditioning (termed anesthetic preconditioning by analogy) through activation of various cytoprotective G-protein–coupled receptors and protein kinases, including protein kinase C (PKC), mitogen-activated protein kinases (MAP kinases), extracellular signal–regulated kinases (ERK), Akt (protein kinase B), and tyrosine kinases.[95,111] Although not entirely clarified, sarcolemmal and putative mitochondrial K_{ATP} channel activation, involving PKC activation and increased formation of free radicals and nitric oxide, are the likely end effectors of anesthetic preconditioning in the heart.

Mechanisms of Respiratory Effects

Inhaled anesthetics also have important effects on the respiratory system. All volatile anesthetics cause significant respiratory depression at concentrations necessary for surgical anesthesia. The peripheral chemo-reflexes and upper airway patency are particularly sensitive to subanesthetic concentrations of volatile anesthetics.[112] The mechanisms involved in these potentially serious effects involve depression of central respiratory networks mediated by depression of excitatory and facilitation of inhibitory transmission. The precise molecular targets responsible for the exquisite sensitivity of these networks to low concentrations of volatile anesthetics remain to be elucidated (see Chapters 19 and 27).

IDENTIFICATION OF MOLECULAR SITES OF ANESTHETIC ACTION

CRITERIA FOR IDENTIFYING SITES RELEVANT TO ANESTHESIA

Specific criteria have been proposed to evaluate the relevance of the many potential molecular targets of anesthetics.[113] These criteria include:

1. *Reversible alteration of target function at clinically relevant concentrations*. This criterion requires comparable in vivo and in vitro sensitivity and depends on the anesthetic end point under consideration. For example, targets involved in immobility must be sensitive to anesthetics near MAC, whereas targets mediating amnesia must be affected at a fraction of MAC. Recent evidence for persistent effects of inhaled anesthetics demonstrable in the absence of continued anesthetic exposure is challenging the notion of reversibility for certain effects.
2. *Expression of the target in appropriate anatomic locations to mediate the specific anesthetic end point*. For example, immobilization by inhaled agents appears to involve primarily actions in the spinal cord independent of actions in the brain.
3. *Concordant stereoselectivity of anesthetic effects in vivo and on the target in vitro*. Without a specific pharmacologic antagonist of anesthesia, correlation between the stereoselective actions of general anesthetics in vivo and in vitro is a useful test of pharmacologic relevance of putative molecular targets. Stereoselectivity data correlating in vivo potency and in vitro receptor actions implicate $GABA_A$ receptors as a target for the anesthetic actions of etomidate, pentobarbital, neurosteroid anesthetics, and possibly isoflurane.
4. Appropriate sensitivity or insensitivity to model anesthetic and nonanesthetic compounds. Anesthetic halogenated cyclobutanes together with structural analogs that do not produce anesthesia at concentrations predicted to be anesthetic by the Meyer-Overton correlation (nonimmobilizers) can be used to discriminate relevant volatile anesthetic targets in vitro. For example, the anesthetic F3 (1-chloro-1,2,2-trifluorocyclobutane), but not the structurally similar nonanesthetic F6 (1,2-dichlorohexafluorocyclobutane), affect $GABA_A$, glycine, AMPA, kainite, and 5-HT3 receptors, and Na^+ channels, consistent with possible roles in immobility, whereas both F3 and F6 affect neuronal nicotinic, M1 muscarinic, 5-HT2C, and mGluR5 receptors, indicating that these targets are not involved in immobility. F6 is interesting in that it lacks sedative and immobilizing effects but does possess amnesic effects, hence the more accurate term *nonimmobilizer*, making it a useful pharmacologic tool for discriminating targets for these actions.
5. *Predictable effects of genetic manipulations targeted to putative molecular targets*. The effects of targeted deletion of specific molecules implicated as anesthetic targets (knockout mutations) or genetic engineering to introduce specific mutations that modify anesthetic sensitivity (knock-in mutations) in model organisms provide powerful approaches to test the roles of putative molecular targets of anesthetic action. This approach has been particularly successful in implicating specific $GABA_A$ receptor subtypes in the effects of the GABAergic intravenous anesthetics propofol and etomidate, where single amino acid substitutions in specific receptor subtypes eliminates anesthetic effects both in vitro and in vivo.[114] Targeted mutations of putative anesthetic targets provide a bridge between in vitro observations and whole-animal experiments essential for demonstrating anesthetic end points. The existence of multiple targets and redundancy among ion channel subtypes make this a more challenging experimental approach for inhaled anesthetics compared with intravenous anesthetics (discussed later).

PHYSICOCHEMICAL PROPERTIES OF ANESTHETIC BINDING SITES

A convergence of x-ray crystallography, molecular modeling, and structure-function studies indicate that inhaled anesthetics bind in hydrophobic cavities formed within proteins.[14,115] The lipophilic (or hydrophobic) nature of these binding sites explains their adherence to the Meyer-Overton correlation. An element of amphiphilicity (possessing both polar and nonpolar characteristics) is also required for effective interaction with these cavities, as indicated by improvements in the Meyer-Overton correlation with more amphipathic solvents (possessing both hydrophobic and hydrophilic properties).

FROM MODEL PROTEINS TO RECEPTORS
