Chapter 40

Anesthetic Implications of Complementary and Alternative Medications

CHONG-ZHI WANG • CHUN-SU YUAN • JONATHAN MOSS

Acknowledgment: The editors and publisher would like to thank Dr. Michael Ang-Lee, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Herbal medication use has increased dramatically in the overall population and particularly in preoperative patients.
- Patients might not volunteer information unless they are queried specifically about herbal medication use.
- Although many commonly used herbs have side effects that affect drug metabolism, bleeding, and neuronal function, they are not subject to regulations on purity, safety, and efficacy.
- Although discontinuing herbal medications up to 2 weeks preoperatively can eliminate many of these problems, patients often arrive for surgery without having had a preoperative visit 2 weeks before surgery. Knowledge of specific interactions and metabolism of herbs can provide practical guidelines to facilitate perioperative management.
- Other complementary therapies, including acupuncture and music therapy, have become increasingly popular, although less is known about their effectiveness.

Complementary and alternative medicine (CAM) has implications for physicians in general, but has particular importance for perioperative physicians because of specific complications associated with certain therapies often used as anesthesia adjuvants. Complementary medicine is defined as the addition of nonconventional therapies to accepted treatments; alternative medicine describes the use of nonconventional therapies in lieu of accepted treatments. They have become an important part of contemporary health care. In 2007, 38% of Americans used CAM therapies in the preceding year.[1] Visits to CAM practitioners exceed those to American primary care physicians,[2] and CAM is even more widely used in Europe, where herbal medicines are prescribed more frequently than conventional drugs are. Furthermore, patients undergoing surgery appear to use CAM more than the general population does.[3] Aside from the widespread use of CAM, perioperative physicians have a special interest in CAM therapies for several reasons. First, several commonly used herbal medications exhibit direct effects on the cardiovascular and coagulation systems. Second, some CAMs can interfere with conventional medications that are commonly given in the postoperative period. Finally, the therapeutic potential of CAM in the perioperative period is increasingly being described in the literature.

Despite the public enthusiasm for CAM, scientific knowledge in this area is still incomplete and often confusing for practitioners and patients. One recent study confirmed poor knowledge of this subject among physicians.[4] Recommendations for clinicians are often based on small clinical trials, case reports, animal studies, predictions derived from known pharmacology, and expert opinion. Research is essential because CAM therapies are often widely adopted by the public before adequate data are available to support their safety and efficacy. In 1991, Congress established the Office of Alternative Medicine, which became the National Center for Complementary and Alternative Medicine within the National Institutes of Health in 1998. In 2006, more than twice as many CAM-related English-language research articles were published compared with 1996.

Practices encompassed by CAM are heterogeneous and evolving. The most commonly used CAM were natural products (17.7%), deep breathing exercises (12.7%), meditation (9.4%), chiropractic or osteopathic manipulation

BOX 40-1 ***Five Major Categories of Complementary and Alternative Medicine***

1. Alternative medical systems (e.g., homeopathic medicine, naturopathic medicine, traditional Chinese medicine, ayurveda)
2. Mind-body interventions (e.g., meditation; prayer; art, music, or dance therapy)
3. Biologically based treatments (e.g., herbal medicines, dietary supplements)
4. Manipulative and body-based methods (e.g., chiropractic manipulation, osteopathic manipulation, massage)
5. Energy therapies (e.g., acupuncture, electromagnetic fields, reiki, qi gong)

Adapted from the National Center for Complementary and Alternative Medicine. <http://nccam.nih.gov/health/whatiscam>. (Accessed 02.06.12.)

(8.6%), massage (8.3%), and yoga (6.1%). CAM practices can be classified into five general categories (Box 40-1).[5] This chapter is not intended as a comprehensive review of CAM. Specific therapies relevant to anesthesia are discussed, and we focus primarily on herbal medicines. Nonherbal dietary supplements, acupuncture, and music are also considered because they are relevant to anesthesia practice.

HERBAL MEDICINES

Preoperative use of herbal medicines has been associated with adverse perioperative events.[6] Surveys estimate that 22% to 32% of patients undergoing surgery use herbal medications.[7-9] In a recent retrospective review, 23% of surgery patients indicated the use of natural products, and older patients preferred dietary supplements.[10]

Herbal medicines can affect the perioperative period through several classic mechanisms: direct effects (i.e., intrinsic pharmacologic effects), pharmacodynamic interactions (i.e., alteration of the action of conventional drugs at effector sites), and pharmacokinetic interactions (e.g., alteration of the absorption, distribution, metabolism, and elimination of conventional drugs). Because approximately 50% of herbal medicine users take multiple herbs concomitantly[7] and 25% of herbal medicine users take prescription drugs,[11] adverse effects are difficult to predict and attribute.

Herbal medicines are associated with unique problems not usually found with conventional drugs.[12] Many of the issues complicating the understanding of herbal medications derive from the fact that they are classified as dietary supplements under the Dietary Supplement Health and Education Act of 1994. As such, the introduction of herbal medications does not require animal studies, clinical trials, or postmarketing surveillance. Under current law, the burden is shifted to the U.S. Food and Drug Administration (FDA) to prove products unsafe before they can be withdrawn from the market. In one well-publicized action, more than 130 reports of persistent anosmia (thought to be zinc related) led to the withdrawal of intranasal Zicam (Matrixx Initiatives, Inc., Bridgewater, New Jersey), which is widely used for colds.[13] Commercial herbal medicine preparations can have unpredictable pharmacologic effects resulting from inaccurate labeling, misidentified plants, adulterants, variations in natural potency, and unstandardized processing methods. Two of the major problems confronting herbal medicine research involve quality control and added adulterants.

In a recent clinical trial to treat human H1N1 influenza, an herbal formulation containing 12 different Chinese herbal medicines including licorice (genus *Glycyrrhiza*) was used.[14] Some of the other botanicals in the formula were not accurately identified. There are three *Glycyrrhiza* species on the market, and the author did not identify the species used in the trial. The content of glycyrrhizin, a major marker compound of licorice, showed a twofold difference when the three species were compared, suggesting that the chemical composition of different *Glycyrrhiza* species varies.[15] Labeled active ingredients can vary tenfold in different commercial preparations.[16] In June 2007, the FDA issued regulations for current good manufacturing practices (GMPs) for dietary supplements.[17] This rule requires that proper controls be in place so that dietary supplements are processed in a consistent manner and meet quality standards. Especially emphasized are the identity, purity, strength, and composition of the products. Dietary product GMPs undoubtedly reduce the potential risk in the use of herbal medicines. Because this rule is somewhat similar to that for prescription drug GMPs, many supplement manufacturers believe that it is not practical for botanicals.[18]

Beyond quality control is the inclusion of biologically active pharmacologic adulterants in herbal medications and supplements. There are clinical consequences when quality control is lacking or herbal preparations are adulterated. In one popular weight-loss remedy, a manufacturing error resulted in the substitution of one herb (*Stephania tetranda*) by another with the carcinogen aristolochic acid. The substitution led to an outbreak of nephropathy and urothelial carcinoma, first noted when a renal transplant patient developed an unusual form of this cancer.[19] The effect of misidentified ingredients or adulterants can be acute. In another well-publicized event, more than 14 million capsules of Zotrex (TSN Labs, Inc., Salt Lake City, Utah), a sexual enhancement supplement, were recalled because the compound on the label did not actually exist. However, the supplement did contain an analogue of sildenafil, which has not been tested in humans.[20] In July 2011, the FDA drafted a guidance because of the popularity of dietary supplements and several egregious cases of pharmacologic adulterants in supplements.[21] The FDA's new guidance proposes to evaluate the safety of supplements on their history of use, formulation, proposed daily dose, and recommended duration of use. Although the proposal represents only a fraction of what is necessary for a new drug application, it requires some testing for tolerability in animals when products are marketed for consumption at doses substantively greater than those historically ingested. Any ingredient formulated or prepared in a novel manner is considered a new ingredient. Under the guidance, a tolerability study of even a single dose in humans is not required for approval.[21]

In this section, we discuss the preoperative assessment and management of patients who use herbal medicines

TABLE 40-1 CLINICALLY IMPORTANT EFFECTS, PERIOPERATIVE CONCERNS, AND RECOMMENDATIONS FOR PERIOPERATIVE DISCONTINUATION OF 11 COMMONLY USED HERBAL MEDICINES

Herbs (Common Names)	Pharmacologic Effects	Perioperative Concerns	Discontinue Before Surgery
Echinacea (purple coneflower root)	Activation of cell-mediated immunity	Allergic reactions Decreases effectiveness of immunosuppressants Potential for immunosuppression with long-term use	No data
Ephedra (ma huang)	Increases heart rate and blood pressure through direct and indirect sympathomimetic effects	Risk of myocardial ischemia and stroke from tachycardia and hypertension Ventricular arrhythmias with halothane Long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability Life-threatening interaction with MAO inhibitors	24 hours
Garlic (ajo)	Inhibits platelet aggregation (may be irreversible) Increases fibrinolysis Equivocal antihypertensive activity	May increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	7 days
Ginger	Anti-emetic Antiplatelet aggregation	May increase risk of bleeding	No data
Ginkgo (duck-foot tree, maidenhair tree, silver apricot)	Inhibits platelet-activating factor	May increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	36 hours
Ginseng (American ginseng, Asian ginseng, Chinese ginseng, Korean ginseng)	Lowers blood glucose Inhibits platelet aggregation (may be irreversible) Increased PT/PTT in animals	Hypoglycemia May increase risk of bleeding May decrease anticoagulant effect of warfarin	7 days
Green tea	Inhibits platelet aggregation Inhibits thromboxane A2 formation	May increase risk of bleeding May decrease anticoagulant effect of warfarin	7 days
Kava (awa, intoxicating pepper, kawa)	Sedation Anxiolysis	May increase sedative effect of anesthetics Increase in anesthetic requirements with long-term use unstudied	24 hours
Saw palmetto (dwarf palm, *Sabal*)	Inhibits 5α-reductase Inhibits cyclooxygenase	May increase risk of bleeding	No data
St. John's wort (amber, goat weed, hardhay, hypericum, Klamath weed)	Inhibits neurotransmitter reuptake MAO inhibition unlikely	Induction of cytochrome P450 enzymes; affects cyclosporine, warfarin, steroids, and protease inhibitors; may affect benzodiazepines, calcium channel blockers, and many other drugs Decreased serum digoxin levels Delayed emergence	5 days
Valerian (all heal, garden heliotrope, vandal root)	Sedation	May increase sedative effect of anesthetics Benzodiazepine-like acute withdrawal May increase anesthetic requirements with long-term use	No data

MAO, Monoamine oxidase; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

and examine 11 herbal medicines that have the greatest effect on perioperative patient care: *Echinacea*, ephedra, garlic, ginger, *Ginkgo biloba*, ginseng, green tea, kava, saw palmetto, St. John's wort, and valerian (Table 40-1). These 11 medicines account for 30% of the dietary supplements sold in the United States.[22]

PREOPERATIVE ASSESSMENT AND MANAGEMENT

Preoperative assessment should address the use of herbal medicines (see Chapter 38). One study found that 90% of anesthesia providers do not routinely ask about herbal

medicine use.[23] Moreover, more than 70% of patients are not forthcoming about their herbal medicine use during routine preoperative assessment.[7] When a positive history of herbal medicine use is elicited, one in five patients is unable to properly identify the preparation being taken.[24] Asking patients to bring their herbal medicines and other dietary supplements with them at the time of the preoperative evaluation would be helpful. A positive history of herbal medicine use should alert one to the presence of undiagnosed disorders causing symptoms leading to self-medication. Patients who use herbal medicines may be more likely to avoid conventional diagnosis and therapy.[25]

In general, herbal medicines should be discontinued preoperatively. In clinical practice, patients who require nonelective surgery are not evaluated until the day of surgery or are noncompliant with instructions to discontinue herbal medications preoperatively. They may take herbal medicines until the day of surgery. In this situation, anesthesia can usually proceed safely at the discretion of the anesthesia provider, who should be familiar with commonly used herbal medicines. For example, recent use of herbal medicines that inhibit platelet function (e.g., garlic, ginseng, *Ginkgo biloba*) may warrant specific strategies for procedures with substantial intraoperative blood loss (e.g., platelet transfusion) and those that alter the risk/benefit ratio of using certain anesthetic techniques (e.g., neuraxial blockade).

Preoperative discontinuation of all herbal medicines might not eliminate complications related to their use. Withdrawal of regular medications can increase morbidity and mortality after surgery.[26] Alcoholics who abstain from drinking alcohol preoperatively may have poorer postoperative outcomes than those who continue drinking preoperatively.[27] The danger of abstinence after long-term use may be similar with herbal medicines such as valerian, which can produce acute withdrawal after long-term use.

Although the American Society of Anesthesiologists has no official standards or guidelines for the preoperative use of herbal medications, public and professional educational information released by this organization suggests that herbals be discontinued at least 2 weeks before surgery.[26] Our review of the literature favors a more targeted approach, because evaluating patients 2 to 3 weeks before elective surgery may be impossible. Moreover, some patients require nonelective surgery or are noncompliant with instructions to discontinue herbal medications preoperatively. These factors and the extensive use of herbal medicines could mean that herbal medications are taken until the time of surgery. Pharmacokinetic data on selected active constituents indicate that some herbal medications are eliminated quickly and may be discontinued closer to the time of surgery. When pharmacokinetic data for the active constituents in an herbal medication are available, the timeframe for preoperative discontinuation can be tailored. For other herbal medicines, 2 weeks is recommended.[28]

Evidence-based estimates of herbal safety in the perioperative period are limited. One study of 601 patients who used traditional Chinese herbal medications suggested an infrequent rate of potential serious complications.[29] Clinicians should be familiar with commonly used herbal medications to recognize and treat any complications that might arise. Table 40-1 summarizes the clinically important effects, perioperative concerns, and recommendations for preoperative discontinuation of the 11 herbal medications discussed in this chapter. The type of surgery and potential perioperative course should be considered in these clinical recommendations.

ECHINACEA

Three species of *Echinacea*, a member of the daisy family, are used for the prophylaxis and treatment of viral, bacterial, and fungal infections, particularly those of upper respiratory origin, although its efficacy in the latter is doubtful.[30] A recent meta-analysis showed the benefit of *Echinacea* in decreasing the incidence and duration of the common cold.[31] Its pharmacologic activity cannot be attributed to a single compound, although the lipophilic fraction, which contains alkylamides, polyacetylene, and essential oils, appears to be more active than the hydrophilic fraction. The biological activity of *Echinacea* could be immunostimulatory, immunosuppressive, or antiinflammatory depending on the portion of the plant and extraction method.[32] Although no studies have specifically addressed interactions between *Echinacea* and immunosuppressive drugs, expert opinion generally warns against the concomitant use of *Echinacea* and these drugs because of the probability of diminished effectiveness.[33,34] Therefore, patients who might require perioperative immunosuppression, such as those awaiting organ transplantation, should be counseled to avoid *Echinacea*. In contrast to its immunostimulatory effects with short-term use, long-term use of more than 8 weeks is accompanied by the potential for immunosuppression[34] and a theoretically increased risk for certain postsurgical complications, such as poor wound healing and opportunistic infections. A recent phytochemical study identified a potential immunosuppressant compound from *Echinacea*—cynarine.[35]

Echinacea can cause allergic reactions, including one reported case of anaphylaxis.[36] Therefore, *Echinacea* should be used with caution in patients with asthma, atopy, or allergic rhinitis. Concern for potential hepatoxicity has also been raised, but documented cases are lacking.[37] Although several in vitro and in vivo pharmacokinetics studies of *Echinacea* have been reported, information about its pharmacokinetics is still limited.[38] *Echinacea* significantly reduced plasma concentrations of S-warfarin, but did not significantly affect warfarin pharmacodynamics and platelet aggregation in healthy subjects.[39] However, this herb should be discontinued as far in advance of surgery as possible when compromises in hepatic function or blood flow are anticipated.[40] In the absence of definitive information, patients with preexisting liver dysfunction should be cautious in using *Echinacea*.

EPHEDRA

Ephedra, known as *ma huang* in Chinese medicine, is a shrub native to central Asia. It is used to promote weight loss, increase energy, and treat respiratory conditions

such as asthma and bronchitis. Ephedra contains alkaloids, including ephedrine, pseudoephedrine, norephedrine, methylephedrine, and norpseudoephedrine.[26] Commercial preparations can be standardized to a fixed ephedrine content. Publicity about adverse reactions to this herb prompted the FDA to bar its sale in 2004, but ephedra is still widely available via the Internet.

Ephedra causes dose-dependent increases in arterial blood pressure and heart rate. Ephedrine, the predominant active compound, is a noncatecholamine sympathomimetic that exhibits α_1, β_1, and β_2 activity directly at adrenergic receptors and indirectly by releasing endogenous norepinephrine (noradrenaline). These sympathomimetic effects have been associated with more than 1070 reported adverse events, including fatal cardiac and central nervous system complications.[41]

Although ephedrine is widely used as first-line therapy for intraoperative hypotension and bradycardia, the unsupervised preoperative use of ephedra raises certain concerns. Vasoconstriction and, in some cases, vasospasm of coronary and cerebral arteries can cause myocardial infarction and thrombotic stroke.[42] Ephedra can also affect cardiovascular function by causing hypersensitivity myocarditis, characterized by cardiomyopathy with myocardial lymphocyte and eosinophil infiltration.[43] Long-term use results in tachyphylaxis from depletion of endogenous catecholamine stores and can contribute to perioperative hemodynamic instability. In these situations, direct-acting sympathomimetics may be preferred as first-line therapy for intraoperative hypotension and bradycardia. Concomitant use of ephedra and monoamine oxidase inhibitors can result in life-threatening hyperpyrexia, hypertension, and coma. Finally, continuous ephedra is a rare cause of radiolucent kidney stones.[44]

The pharmacokinetics of ephedrine have been studied in humans.[45,46] Ephedrine has an elimination half-life of 5.2 hours, with 70% to 80% of the compound excreted unchanged in urine. Based on the pharmacokinetic data and the known cardiovascular risks associated with ephedra, including myocardial infarction, stroke, and cardiovascular collapse from catecholamine depletion, this herb should be discontinued at least 24 hours before surgery.

GARLIC

Garlic is one of the most extensively researched medicinal plants. It has the potential to modify the risk for atherosclerosis by reducing arterial blood pressure, thrombus formation, and serum lipid and cholesterol concentrations.[47] These effects are primarily attributed to its sulfur-containing compounds, particularly allicin and its transformation products. Commercial garlic preparations can be standardized to a fixed alliin and allicin content.

Garlic inhibits platelet aggregation in vivo in a concentration-dependent fashion. The effect of one of its constituents, ajoene, is irreversible and can enhance the effect of other platelet inhibitors such as prostacyclin, forskolin, indomethacin, and dipyridamole.[48] Although the effects are not consistently demonstrated in volunteers, there is one case described in an 80 year old who had a spontaneous epidural hematoma develop that was attributed to continuous garlic use.[49] Garlic has interacted with warfarin, resulting in an increased international normalized ratio (INR).[50]

In addition to bleeding concerns, garlic can decrease systemic and pulmonary vascular resistance in laboratory animals, but this effect is marginal in humans.[51] Although there are insufficient pharmacokinetic data on garlic's constituents, the potential for irreversible inhibition of platelet function may warrant discontinuation of garlic at least 7 days before surgery, especially if postoperative bleeding is a particular concern or other anticoagulants are given.

GINGER

Ginger (*Zingiber officinale*) is a popular spice with a long history of use in Chinese, Indian, Arabic, and Greco-Roman herbal medicines. Ginger has a wide range of reported health benefits for those with arthritis, rheumatism, sprains, muscular aches, pains, sore throats, cramps, constipation, indigestion, nausea, vomiting, hypertension, dementia, fever, infectious diseases, and helminthiasis.[52] Ginger contains up to 3% volatile oil, mostly monoterpenoids and sesquiterpenoids.[53] Gingerols are representative compounds in ginger.[54]

Ginger is an antiemetic and has been used to treat motion sickness and to prevent nausea after laparoscopy.[55] The number of postoperative antiemetic medications was significantly reduced after aromatherapy with essential oil of ginger.[56] In another recent trial, ginger supplementation reduced the severity of acute chemotherapy-induced nausea in adult cancer patients.[57] This response compared favorably to conventional antiemetics (see Chapter 97).

In an in vitro study, gingerols and related analogues inhibited arachidonic acid–induced human platelet serotonin release and aggregation, with a potency similar to that of aspirin.[54] In another in vitro study, the antiplatelet effects of 20 ginger constituents were evaluated. Five constituents showed antiplatelet activities at relatively low concentrations. One of the ginger compounds (8-paradol) was the most potent COX-1 inhibitor and antiplatelet aggregation drug.[58] In a case report, a ginger-phenprocoumon combination resulted in an increased INR and epistaxis.[59]

Although the sample size was relatively small, the platelet inhibition potential of ginger has been suggested in a pilot clinical study.[60] This result may warrant the discontinuation of ginger at least 2 weeks before surgery,

GINKGO

Ginkgo is derived from the leaf of *Ginkgo biloba* and has been used for cognitive disorders, peripheral vascular disease, age-related macular degeneration, vertigo, tinnitus, erectile dysfunction, and altitude sickness. Studies have suggested that ginkgo can stabilize or improve cognitive performance in patients with Alzheimer disease and multi-infarct dementia,[61] but not in healthy geriatric patients.[62] The compounds that might be responsible for its pharmacologic effects are the terpenoids and flavonoids. The two

ginkgo extracts used in clinical trials are standardized to ginkgo-flavone glycosides and terpenoids.

Ginkgo alters vasoregulation, acts as an antioxidant, modulates neurotransmitter and receptor activity, and inhibits platelet-activating factor. Of these effects, inhibition of platelet-activating factor is of primary concern for the perioperative period. Although bleeding complications have not occurred in clinical trials, four cases of spontaneous intracranial bleeding,[63-65] one case of spontaneous hyphema,[66] and one case of postoperative bleeding after laparoscopic cholecystectomy[67] have been described when ginkgo was being taken.

Terpene trilactones are highly bioavailable when administered orally. The elimination half-lives of the terpene trilactones after oral administration are between 3 and 10 hours. For ginkgolide B, a dosage of 40 mg twice daily resulted in a higher area under the curve, and a longer half-life and residence time, than after a single 80-mg dose. A once daily dose of 80 mg guaranteed a larger maximum concentration peak (T_{max}) that was reached 2 to 3 hours after administration.[68] The pharmacokinetics of terpene trilactones in three different ginkgo preparations in human plasma[69] indicate that ginkgo should be discontinued at least 2 weeks before surgery to avoid bleeding.[40]

GINSENG

Among the several species of ginseng used for their pharmacologic effects, Asian ginseng (*Panax ginseng*) and American ginseng (*Panax quinquefolius*) are the most commonly described.[70] Ginseng has been labeled an "adaptogen" because it reputedly protects the body against stress and restores homeostasis.[71] Because its pharmacologic actions are attributed to the ginsenosides, a group of compounds known as *steroidal saponins,* many commercially available ginseng preparations have been standardized to ginsenoside content.[70,72]

The many heterogeneous and sometimes opposing effects of different ginsenosides[73,74] give ginseng a broad but incompletely understood pharmacologic profile including general health, fatigue, immune function, cancer, cardiovascular disease, diabetes mellitus, cognitive function, viral infections, sexual function, and athletic performance.[71] The underlying mechanism is similar to that classically described for steroid hormones. This herb decreases postprandial blood glucose in healthy patients and those with type 2 diabetes,[75] an effect that can create unintended hypoglycemia in patients who have fasted before surgery.

Ginseng can alter coagulation pathways. The antiplatelet activity of panaxynol, a constituent of ginseng, may be irreversible in humans.[76] Ginseng extract and ginsenosides inhibit platelet aggregation in vitro[77,78] and prolong thrombin time and activated partial thromboplastin time in in vivo animal models.[79,80]

The clinical evidence implicating ginseng as a cause of bleeding is weak and based on only a few case reports.[81] Although ginseng may inhibit the coagulation cascade, in one case its use was associated with a significant decrease in warfarin anticoagulation.[82] Subsequently, a study in volunteers showed that American ginseng interfered with warfarin-induced anticoagulation,[83] reducing its anticoagulant effect. When prescribing warfarin, clinicians should specifically ask about ginseng use. In another clinical trial, warfarin's clearance was moderately increased with Asian ginseng.[84] Because warfarin is often used after orthopedic or vascular procedures, this herbal drug interaction can affect perioperative management in many patients.

In rats, after an intravenous infusion of ginseng, ginsenosides Re and Rg1 were eliminated quickly from the body with elimination half-lives between 0.7 and 4 hours; ginsenosides Rb1 and Rd were eliminated slowly from the body with half-lives between 19 and 22 hours.[85] After oral administration of ginseng, ginsenoside Rb1 reached the maximum plasma concentration at approximately 4 hours with a prolonged half-life.[86,87] These data suggest that ginseng should be discontinued at least 48 hours before surgery. Because platelet inhibition by ginseng may be irreversible, ginseng use should be stopped at least 2 weeks before surgery.[40]

GREEN TEA

Tea from the *Camellia sinensis* is one of the most ancient and the second most widely consumed beverage in the world.[88,89] Tea can be classified into three types: green, oolong, and black. Green tea, which is not fermented and is derived directly from drying and steaming fresh tea leaves, contains polyphenolic compounds. Catechins in green tea account for 16% to 30% of its dry weight. Epigallocatechin-3-gallate (EGCG), the most predominant catechin in green tea, is responsible for much of the biological activity mediated by green tea.[88]

In an early in vitro and in vivo study, both green tea and EGCG significantly prolonged mouse tail bleeding time in conscious mice. They inhibited adenosine diphosphate- and collagen-induced rat platelet aggregation in a dose-dependent manner.[90] The antiplatelet activity can result from the inhibition of thromboxane A2 formation. Because adenosine triphosphate release from a dense granule is inhibited by catechins in washed platelets, thromboxane A2 formation may have been inhibited by preventing arachidonic acid liberation and thromboxane A2 synthase.[91,92] Regarding a possible adverse effect of green tea on platelets, one case report showed that after a patient consumed a weight-loss product containing green tea, thrombotic thrombocytopenic purpura developed.[93] Because green tea contains vitamin K, drinking green tea could antagonize the anticoagulant effects of warfarin.[94]

In a randomized, double-blind, placebo-controlled study, eight subjects received oral EGCG in a single dose of 50 to 1600 mg. In each dosage group, the kinetic profile revealed rapid absorption with a one-peak plasma concentration versus time course, followed by a multiphasic decrease consisting of a distribution phase and an elimination phase. The mean half-life values were observed between 1.9 and 4.6 hours.[95] In another pilot clinical study, after five healthy subjects took tea extract orally, the concentration of EGCG in plasma was determined. The half-life of EGCG was between 2.2 and 3.4 hours.[96] Based on pharmacokinetic data and possible antiplatelet activity, green tea should be discontinued at least 7 days before surgery.

KAVA

Kava is derived from the dried root of the pepper plant *Piper methysticum*. Kava has gained widespread popularity as an anxiolytic and sedative. The kavalactones appear to be the source of kava's pharmacologic activity.[97]

Because of its psychomotor effects, kava was one of the first herbal medications expected to interact with anesthetics. The kavalactones have dose-dependent effects on the central nervous system, including antiepileptic, neuroprotective, and local anesthetic properties. Kava can act as a sedative-hypnotic by potentiating inhibitory neurotransmission of γ-aminobutyric acid (GABA). The kavalactones increased barbiturate sleep time in laboratory animals.[98] This effect might explain the mechanism underlying the report of a coma attributed to an alprazolam-kava interaction.[99] Although kava has abuse potential, whether long-term use can result in addiction, tolerance, and acute withdrawal after abstinence is not known. Continuous kava use can increase γ-glutamyl transpeptidase levels, thus raising concern about hepatotoxicity.[100] With continuous use, kava produces "kava dermopathy," characterized by reversible scaly cutaneous eruptions.[101] Continuous kava use can elevate γ-glutamyl transpeptidase levels, raising concerns about hepatotoxicity.[100]

Kava use can influence coagulation and cardiovascular and hepatic functions. In an in vitro investigation, a kava compound (+)-kavain suppressed the aggregation of human platelets.[102] Kava inhibits cyclooxygenase with the potential to decrease renal blood flow and to interfere with platelet aggregation. Consumption of kava has potential cardiovascular effects that could manifest in the perioperative period.[103] The hepatotoxic effect is clinically important. Although kava has been banned in Europe since 2002, it is available in North America and many countries in the Pacific region. A concentration-based response relationship can occur with hepatotoxicity.[104] Despite safety concerns regarding liver toxicity,[105,106] even leading to numerous cases of liver transplantation, kava is still available in the United States.

Peak plasma levels occur 1.8 hours after an oral dose, and the elimination half-life of kavalactones is 9 hours.[107] Unchanged kavalactones and their metabolites undergo renal and fecal elimination.[108] Pharmacokinetic data and the possibility for enhancement of the sedative effects from anesthetics suggest that kava should be discontinued at least 24 hours before surgery. Earlier discontinuation probably should be considered when surgical procedures are expected to compromise hepatic function or blood flow.

SAW PALMETTO

Saw palmetto, which is used by more than 2 million men in the United States to treat symptoms associated with benign prostatic hypertrophy, is of questionable efficacy for this purpose.[109] The major constituents of saw palmetto are fatty acids and their glycerides (i.e., triacylglycerides and monoacylglycerides), carbohydrates, steroids, flavonoids, resin, pigment, tannin, and volatile oil. The pharmacologic activity of saw palmetto has not been attributed to a single compound.

Although the mechanism of action of saw palmetto is not known, multiple mechanisms have been proposed.[110] Saw palmetto extract, like finasteride, inhibits 5α-reductase in vitro; however, results of in vivo studies have been inconsistent.[110] Other proposed mechanisms are inhibition of estrogen and androgen receptors, binding of autonomic receptors, blocking of prolactin receptor signal transduction, interference with fibroblast proliferation, induction of apoptosis, inhibition of α_1-adrenergic receptors, and antiinflammatory effects.

In a patient undergoing craniotomy, saw palmetto was associated with excessive intraoperative bleeding that required termination of the procedure (see Chapter 70).[111] Another case of hematuria and coagulopathy in a patient who used saw palmetto was reported.[112] This complication was attributed to saw palmetto's antiinflammatory effects, specifically the inhibition of cyclooxygenase and subsequent platelet dysfunction. Because there are no pharmacokinetic or clinical data for saw palmetto, specific recommendations for preoperative discontinuation cannot be made.

ST. JOHN'S WORT

St. John's wort is the common name for *Hypericum perforatum*. A multicenter clinical trial concluded that St. John's wort is not effective in the treatment of major depression.[113] The compounds believed to be responsible for its pharmacologic activity are hypericin and hyperforin.[114] Commercial preparations are often standardized to a fixed hypericin content of 0.3%.

St. John's wort exerts its effects by inhibiting reuptake of serotonin, norepinephrine, and dopamine.[115] Concomitant use of this herb with or without serotonin reuptake inhibitors can create a syndrome of central serotonin excess.[116] Although early in vitro data implicated monoamine oxidase inhibition as a possible mechanism of action, a number of later investigations have demonstrated that monoamine oxidase inhibition is insignificant in vivo.[117]

Use of St. John's wort can significantly increase the metabolism of many concomitantly administered drugs, some of which are vital to the perioperative care of certain patients. There is induction of the cytochrome P450 3A4 isoform, with approximate doubling of its metabolic activity.[118] Interactions with substrates of the 3A4 isoform, including indinavir sulfate,[119] ethinylestradiol,[120] and cyclosporine,[121] have been documented. There are important clinical consequences of this metabolic effect, particularly in transplant patients. In two case reports of heart transplant patients, after taking St. John's wort, the patients' plasma cyclosporine concentrations became subtherapeutic and acute transplant rejection resulted. After stopping St. John's wort, plasma cyclosporine remained within the therapeutic range with no further episodes of rejection (Fig. 40-1).[122] In one series of 45 organ transplant patients, St. John's wort was associated with an average 49% decrease in blood cyclosporine levels.[123] Other P450 3A4 substrates commonly used in the perioperative period include alfentanil, midazolam, lidocaine, calcium channel

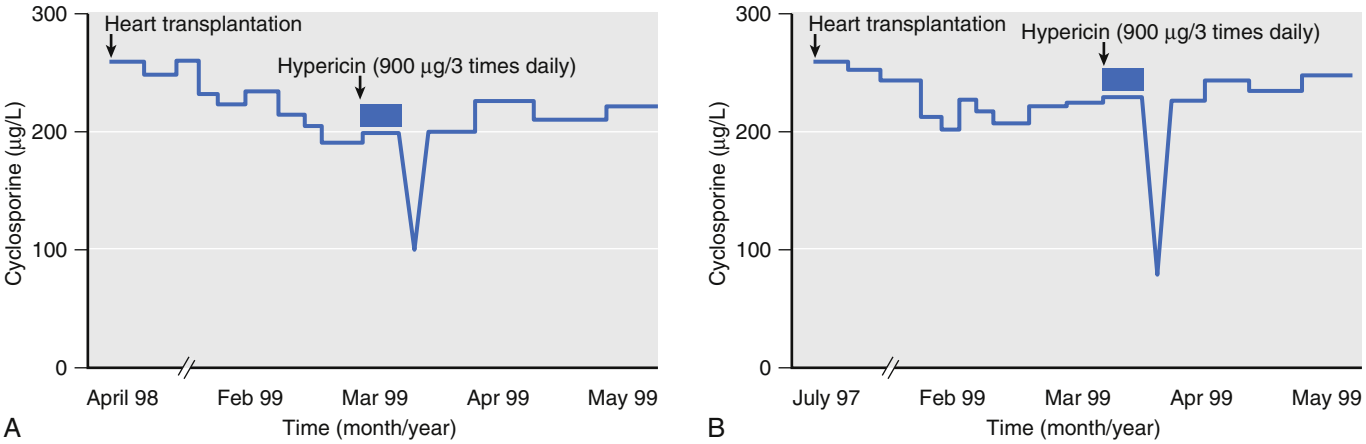

Figure 40-1. Cyclosporine concentrations in two patients (**A** and **B**) after heart transplantation. Treatment with St. John's wort extract containing 900 µg of hypericin was associated with a drop in cyclosporine values below the therapeutic range and acute transplant rejection.[122]

blockers, and 5-hydroxytryptamine receptor antagonists. In addition to the 3A4 isoform, the cytochrome P450 2C9 isoform also may be induced. The anticoagulant effect of warfarin, a substrate of the 2C9 isoform, was reduced in seven reported cases.[120] Other 2C9 substrates include the nonsteroidal antiinflammatory drugs. Furthermore, the enzyme induction caused by St. John's wort may be more pronounced when other enzyme inducers, which could include other herbal medications, are taken concomitantly. St. John's wort also affects digoxin pharmacokinetics.[117] St. John's wort markedly altered the intracellular accumulation of irinotecan and its major metabolite SN-38 in hepatocytes and glucuronidation of SN-38 in rats.[124]

The single-dose and steady-state pharmacokinetics of hypericin, pseudohypericin, and hyperforin have been determined in humans.[125,126] After oral administration, peak plasma levels of hypericin and hyperforin are achieved in 6.0 and 3.5 hours, respectively, and their median elimination half-lives are 43.1 and 9.0 hours, respectively. Long half-life and altered metabolism of many drugs make concomitant use of St. John's wort a particular risk in the perioperative setting. Pharmacokinetic data suggest that this herbal medication should be discontinued at least 5 days before surgery. Discontinuation is especially important in patients awaiting organ transplantation or in those who might require oral anticoagulation postoperatively. Moreover, these patients should be advised to avoid taking St. John's wort postoperatively.

VALERIAN

Valerian (*Valeriana officinalis*) is an herb that is native to temperate regions of the Americas, Europe, and Asia. It is used as a sedative, particularly in the treatment of insomnia, and virtually all herbal sleep aids contain valerian.[127] Valerian contains many compounds acting synergistically, but the sesquiterpenes are the primary source of valerian's pharmacologic effects. Commercially available preparations may be standardized to valerenic acid.

Valerian produces dose-dependent sedation and hypnosis.[128] These effects are probably mediated through modulation of GABA neurotransmission and receptor function.[129] Valerian increased barbiturate sleep time in experimental animals.[130] In several randomized, placebo-controlled trials in humans, there was a mild subjective improvement in sleep with valerian, especially when used for 2 weeks or more.[131,132] Objective tests have had less consistent results, with little or no improvement in sleep noted.[133] In one patient, valerian withdrawal appeared to mimic an acute benzodiazepine withdrawal syndrome characterized by delirium, cardiac complications after surgery, and attenuation of the symptoms by administration of a benzodiazepine.[134] Based on these findings, valerian should potentiate the sedative effects of anesthetics and adjuvants that act at the GABA receptor, such as midazolam (see Chapter 30).

The pharmacokinetics of valerian's constituents have not been studied, although their effects may be short-lived. Abrupt discontinuation in patients who may be physically dependent on valerian risks benzodiazepine-like withdrawal. In these individuals, this herbal medication should be gradually decreased with close medical supervision over the course of several weeks before surgery. If such tapering is not feasible, physicians can advise patients to continue taking valerian until the day of surgery. Based on the mechanism of action and a reported case of efficacy,[134] benzodiazepines can treat withdrawal symptoms should they develop in the postoperative period.

OTHER HERBAL MEDICINES

In a survey conducted in 2007,[1] the top 10 herbal medicines also included soy isoflavones, grape seed extract, and milk thistle. There are no reports of adverse effects or perioperative risks from these herbs.

Although boldo (*Peumus boldus*), Danshen (*Salvia miltiorrhiza*), Dong quai (*Angelica sinensis*), and papaya (*Carica papaya*) are encountered less frequently, it may be prudent to discontinue their use 2 weeks before surgery because they have shown antiplatelet aggregation activity and herb-drug interactions.[135]

COMMON DIETARY SUPPLEMENTS

Herbal medicines fall into the broader category of dietary supplements that also includes vitamins, minerals, amino

acids, enzymes, and animal extracts. Data on the safety of these agents in the perioperative period are scant. High-dose vitamin use, particularly of the fat-soluble vitamins (i.e., A, D, E, and K), can be associated with acute and chronic toxicity. Drug interactions for coenzyme Q_{10}, glucosamine, chondroitin, sulphate, and fish oil have been sufficiently documented to merit inclusion in this chapter.

COENZYME Q_{10}

Coenzyme Q_{10} (CoQ_{10}), or ubidecarenone, is a single-constituent antioxidant compound that is structurally related to vitamin K. It is widely promoted as an antioxidant. Endogenous CoQ_{10} can prevent the membrane transition pore from opening, because it counteracts several apoptotic events, such as DNA fragmentation, cytochrome c release, and membrane potential depolarization.[52] Of importance, this compound interacts with warfarin.

Interaction between CoQ_{10} and warfarin was investigated in rats.[136] Following oral administration of 1.5 mg/kg of racemic warfarin to rats during an 8-day oral regimen of CoQ_{10} (10 mg/kg daily), no apparent effect was observed on serum protein binding of warfarin enantiomers. Treatment with CoQ_{10} did not affect the absorption and distribution of the S- and R-enantiomers of warfarin, but it increased total serum clearance of both R- and S-warfarin. The increased clearance values are likely due to acceleration of certain metabolic pathways and renal excretion of the warfarin enantiomers.

An in vitro study using human liver microsomes led to a relatively accurate pharmacokinetic prediction of CoQ_{10} activity. A 32% and 17% increase in the total clearance of S- and R-warfarin, respectively, was predicted with coadministration of 100 mg CoQ_{10}.[137] CoQ_{10} may decrease the effects of warfarin,[138] but results were inconsistent in another controlled, clinical trial.[139] In 171 patients, coadministration of CoQ_{10} with warfarin appeared to increase the risk of bleeding.[140] Based on the clinical information regarding drug interaction and reported prolonged elimination half-life (38 to 92 hours) after a single oral dose,[141] CoQ_{10} should be discontinued at least 2 weeks before surgery.

GLUCOSAMINE AND CHONDROITIN SULFATE

Glucosamine and chondroitin sulfate are widely used for joint disorders by many patients undergoing orthopedic procedures. Standard therapies can alleviate the symptoms of osteoarthritis (OA) to some extent, but cannot prevent disease progression. A number of alternative substances are beneficial for OA. Although their mode of action may be complex, glucosamine and chondroitin sulfate have been widely accepted as supplements in the management of OA because they are the essential components of proteoglycan in normal cartilage.[142] When a large-scale trial evaluated glucosamine and chondroitin sulfate alone or in combination, pain was not reduced in a group of patients with OA of the knee. Exploratory analyses suggested that the two in combination might be effective in a subgroup of patients with moderate-to-severe knee pain.[143]

Long-term clinical data regarding the safety of glucosamine and chondroitin sulfate alone or in combination are limited. Use of chondroitin sulfate alone is well tolerated and without significant adverse drug interaction.[142] One concern regarding the use of glucosamine is its potential to cause or worsen diabetes in animal models[144]; this effect is supported by clinical studies.[145] However, in a report from the FDA MedWatch database, there were 20 cases of complications involving glucosamine or glucosamine-chondroitin sulfate use with warfarin. Coagulation was altered as manifested by increased INR or increased bleeding or bruising.[146]

When glucosamine is taken orally, 90% is absorbed. Because of extensive first-pass metabolism, only 25% bioavailability is achieved by oral administration compared with bioactivity of 96% with intravenous administration.[147] Peak plasma levels occurred 4 hours after an oral dose and declined to baseline after about 48 hours.[148] Chondroitin sulfate was absorbed slowly after oral ingestion with a plasma peak at 8.7 hours and decline to baseline at about 24 hours.[149] Considering the reported interaction between glucosamine-chondroitin and warfarin, these supplements should be discontinued 2 weeks before surgery, especially if warfarin will be given during the perioperative period.

FISH OIL

Intake of fish oil supplements containing omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid) reduces the incidence of many chronic diseases that involve inflammatory processes, including cardiovascular diseases, inflammatory bowel disease, cancer, rheumatoid arthritis, and neurodegenerative illnesses.[150] In a recent study, however, omega-3 did not reduce the rate of death in patients with cardiovascular risk factors.[151] A recent meta-analysis of efficacy concluded that omega-3 polyunsaturated fatty acid (PUFA) supplementation does not decrease the risk of all-cause mortality, cardiac death, sudden death, myocardial infarction, or stroke based on relative and absolute measures of association[152] This article included many studies of patients with complex risk factors.

Omega-3 fatty acids, however, can inhibit platelet aggregation and increase bleeding risk. In vitro experiments have demonstrated an antiplatelet aggregate effect of omega-3 fatty acids,[153] and inhibition correlated with platelet cyclic adenosine monophosphate levels.[154] In vivo studies show that omega-3 fatty acids decrease platelet aggregation but do not influence bleeding time.[155,156] In a clinical study, the inhibition of platelet aggregation by omega-3 fatty acid was gender specific.[157]

Although evidence for significant bleeding concerns is not found in clinical trials,[158,159] several case reports have illustrated a possible interaction between warfarin and omega-3 fatty acids.[160] Extremely elevated INR associated with warfarin in combination with omega-3 fatty acids was found in two cases.[161,162] These reports suggest that fish oil be discontinued 2 weeks before surgery, especially for patients taking large doses.

OTHER DIETARY SUPPLEMENTS

Other top 10 dietary supplements include flaxseed oil, fiber or psyllium, cranberry, melatonin,

methylsulfonylmethane (MSM), and lutein.[1] No special concerns have been published associated with bleeding or other perioperative risks from the use of these supplements.

SUMMARY

Commonly used herbal medications can have direct and indirect effects in the perioperative period. Although there is little direct evidence for discontinuation timing, emerging knowledge of the underlying biology of these medications and review of case reports suggest that herbal medications should be considered in the perioperative plan.

ACUPUNCTURE

MECHANISM AND GENERAL PRACTICE

Although acupuncture can reduce preoperative anxiolysis, intraoperative anesthetic requirements, postoperative ileus and support cardiovascular function, it has been most widely studied to control postoperative pain and to prevent or treat nausea and vomiting (see Chapter 97).[163]

Acupuncture is the stimulation of anatomic locations on the skin by a variety of techniques that can be classified as invasive (e.g., needles, injections) or noninvasive (e.g., transcutaneous electrical stimulation, pressure, laser). Needles inserted into the skin can be stimulated by manual manipulation, moxibustion (i.e., burning a substance to produce heat), pressure, laser, and electricity. There are Chinese, Japanese, Korean, French, and other acupuncture systems for identifying acupuncture points, but little research has compared these different systems. As a result, there are no standard or optimal acupuncture points. Practitioners consider acupuncture an art as much as a science.

The traditional theory of acupuncture is that it corrects disruptions in the flow of energy (i.e., qi) and restores the balance of dual forces (i.e., ying-yang) in the body. A scientific basis may exist for acupuncture. Acupuncture stimulates high-threshold, small-diameter nerves that activate the spinal cord, brainstem (i.e., periaqueductal gray area), and hypothalamic (i.e., arcuate) neurons, which trigger endogenous opioid mechanisms.[164] The effect of acupuncture analgesia can be reversed by administration of naloxone.[165] Other mechanisms such as modulation of immune function,[166] inhibition of the inflammatory response,[167] regulation of neuropeptide gene expression,[168] and alteration in hormonal levels[169] have been proposed. The development of neuroimaging tools, such as positron emission tomography[170] and functional magnetic resonance imaging (fMRI),[171,172] make noninvasive studies of acupuncture's effects on human brain activity possible. Studies using positron emission tomography have demonstrated that the thalamic asymmetry present in patients suffering from chronic pain was reduced after acupuncture treatment. Other studies using fMRI have pointed to relationships between particular acupoints and activation of the visual cortex.[173]

Many of the clinical acupuncture studies that have been published are of poor quality and suffer from insufficient sample size, high dropout rates, inadequate follow-up, and poorly defined illnesses, enrollment criteria, and outcome measures.[164] Acupuncture studies suffer from inherent methodologic problems, including difficulties in blinding patients and acupuncturists, using placebo or sham acupuncture, and choosing between different acupuncture techniques.

Although acupuncture was used clinically for centuries, the first trial of acupuncture for anesthesia was performed in China around 1960. Because anesthesia produced by acupuncture varies and takes too long to induce,[174] acupuncture has been used rarely as anesthesia for surgery[175] and more for pain relief afterward. Since 1970, clinical studies have been conducted on acupuncture for postoperative pain,[176] lower back pain,[177] osteoarthritis of the knee,[178] chronic headache,[179] shoulder pain,[180] and neck pain.[181] When compared with placebo, acupuncture treatment has proven efficacy for relieving pain.[182]

A review article that evaluated nine clinical trials found that auricular acupuncture to reduce postoperative pain was promising but not compelling.[183] Another review of six articles discussed the effect of acupuncture on postoperative pain.[182] Although early trials showed both equivocal[184] and negative results,[185] a later trial demonstrated short-term analgesia after acupuncture in patients who had oral surgery.[186] Such efficacy was supported by another clinical trial in 100 patients; the total amount of morphine required to control pain was significantly less in patients who received preoperative acupuncture than in patients in the control group.[176] The trial also demonstrated that acupuncture and electrical nerve stimulation at specific acupoints are valid for postoperative analgesia, and electrical stimulation increases the effect of acupuncture anesthesia.

ACUPUNCTURE FOR POSTOPERATIVE NAUSEA AND VOMITING

One of the most promising indications for acupuncture is to prevent postoperative nausea and vomiting (PONV; see Chapter 97). PONV results in patient dissatisfaction, delayed discharge, unanticipated hospital admission, and the use of resources. Drugs, the mainstay of management, have limited effectiveness, are associated with adverse effects, and can be costly. Acupuncture prevents PONV compared with placebo (e.g., sham acupuncture, no treatment).[163] In two early controlled trials, acupuncture prevented PONV in the pediatric population[187,188]; however, one review of 10 research studies of acupressure in adults concluded that it is not effective in preventing and managing PONV.[189] Other clinical studies have found that acupuncture prevents PONV and results in a greater degree of adult patient satisfaction.[190,191] For many of the trials in both adults and children, the PONV acupuncture point was P6 (i.e., Nei-guan or pericardium-6).[189,192] Intraoperative stimulation of the P6 acupuncture point reduced the incidence of PONV, and its efficacy was similar to that of antiemetic drugs.[193]

The P6 (i.e., Nei-guan or pericardium-6) acupuncture point is located between the palmaris longus and flexor

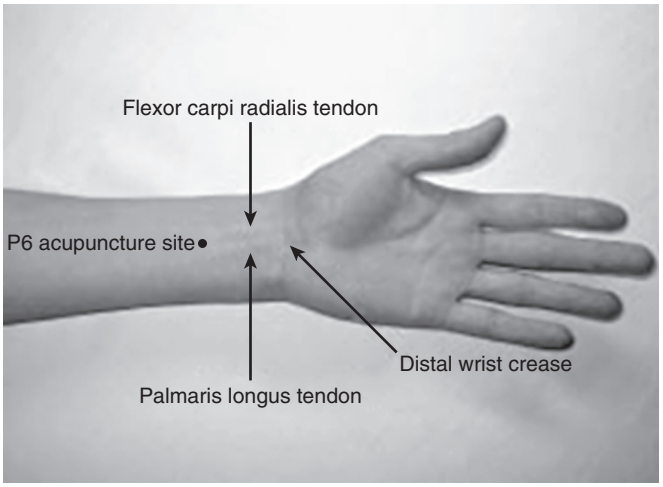

Figure 40-2. The P6 acupuncture point is located between the palmaris longus and flexor carpi radialis muscle tendons, 4 cm proximal to the distal wrist crease and 1 cm below the skin.

carpi radialis muscle tendons, 4 cm proximal to the distal wrist crease and 1 cm below the skin (Fig. 40-2). Korean hand acupuncture may be equally effective.[194] Studies often differ in acupuncture method: duration and timing of stimulation, unilateral versus bilateral stimulation, and type of stimulation (i.e., needles with or without additional stimulation, acupressure, transcutaneous electrical stimulation, cutaneous laser stimulation, injection of a 50% dextrose solution, or capsicum plaster). Data to compare the effectiveness, safety, and costs of different methods of stimulation are inadequate. Stimulation of the acupuncture point should be initiated before induction of anesthesia.[195] Postoperative stimulation may be just as or more effective.[196] In children, stimulation immediately before emergence and in the recovery room has been effective. Some anesthesiologists anecdotally report tapping a small needle cap or other piece of smooth plastic over the P6 point as an effective means of acupressure stimulation.

DEEP BREATHING

Deep breathing exercises are performed as part of a relaxation technique. With this method, a subject consciously slows breathing and focuses on taking deep breaths.[197] Deep breathing can help reduce abdominal and surgical pain.[198,199]

Studies of postoperative pain relief with breath control were reported in the 1970s.[200,201] Its efficacy against postoperative pain was reported by subsequent controlled trials in adult patients.[198,202] This intervention prevented postoperative pulmonary complications in patients who had upper abdominal surgery.[203] In a study of 50 children from 3 to 7 years of age who underwent dental treatment, deep breathing and exhalation decreased pain during treatment[199] (see Chapters 92 and 93).

Fast or forced deep breathing can also increase postoperative pain.[204] Thus, those who assist patients in postoperative pain management should encourage deep breathing exercises that are performed slowly, smoothly, and gently. Slow, deep breathing relaxation exercises have been used successfully as an adjunct to opioids for postoperative pain management in patients who had coronary bypass surgery;[205] however, after abdominal surgery, deep breathing was ineffective for pain reduction in older patients because pulmonary complications developed postoperatively.[206] Most patients who receive deep breathing education think it is useful, and the exercise was effective in increasing their feelings of rapport with staff and intention to follow their doctor's directives.[207] Results from a recent trial demonstrated that slow, deep breathing had analgesic effects with increased vagal cardiac activity.[208] Slow, deep breathing relaxation can also decrease the sensation of postoperative nausea.[209,210]

MUSIC THERAPY

Music therapy is the clinical, evidence-based use of music interventions to accomplish individualized therapeutic goals. Because music can be used for diverse applications, music therapists practice in a variety of health care and education settings.[211] Music for pain relief benefits individuals experiencing a low to moderate amount of pain more than those experiencing a high degree of pain.[212] A patient's preferred music should be considered when it is used for pain relief. The increase of endogenous opioids through music may be the reason for pain relief.[211]

Perioperatively, music can decrease preoperative anxiety, reduce intraoperative sedative and analgesic requirements, and increase patient satisfaction. Patient-selected music can reduce patient-controlled sedative requirements during spinal anesthesia and analgesic requirements during lithotripsy.[213] Music in the preoperative setting can reduce anxiety without affecting physiologic measures of stress.[214,215] Music can also increase patient satisfaction and reduce systolic blood pressure during cataract surgery after retrobulbar block.[216] Perioperative music can reduce arterial pressure, anxiety, and pain among women undergoing mastectomy for breast cancer.[217] As a noninvasive intervention, the low sensory stimulation of music reduced anxiety and increased cooperation in children undergoing induction of anesthesia.[218]

Music therapy interventions that have targeted nausea, both anticipatory or after treatment, have had conflicting results.[211] One study showed that a patient's preferred music for listening during chemotherapy infusion was effective in decreasing the onset and occasion of nausea.[219] In another study, listening to music with a personal message from the physician yielded no difference in chemotherapy-induced side effects compared with not listening to music during chemotherapy.[220] Some studies have found no effect on PONV from music therapy,[221,222] yet PONV was reduced in hospitalized transplant patients postoperatively.[223] Although the exact mechanism is not well understood, music therapy has been an alternative option to mainstream therapies in health care settings to reduce patient pain, anxiety, and perioperative stress.[224] Another use of music is in the intensive care unit. A recent clinical trial observed that among patients in the intensive care unit who received acute ventilatory support for respiratory failure, patient-directed music intervention resulted in more reduction in anxiety and sedation

frequency and intensity compared with usual care.[225] In addition, music can attenuate cardiovascular variability and nociceptive effects.[226,227]

CONCLUSION

One of the fastest changing aspects of health care is the growing public and scientific interest in CAM. To manage herbal medications in the perioperative period, their possible direct and indirect effects should be recognized based on an understanding of the underlying pharmacology. Surgery and anesthesia can usually proceed safely if potential complications are anticipated and can be minimized. As CAM therapies generally gain popularity in the United States, patients are likely to accept some alternative modalities such as acupuncture, deep breathing, and musical intervention. These modalities are easy to administer, have a rapid onset of action, are cost effective, and produce minimal side effects. Based on preliminary studies, perioperative use of CAM therapies may be an adjunct for management of pain, anxiety, nausea, and vomiting. Additional large, well-designed trials are required to verify current observations on the effectiveness of CAM and to answer the concerns of possible side effects. Although medical schools are beginning to incorporate CAM into their curricula, it is important for anesthesiologists already in practice to stay informed about CAM therapies (Table 40-2).

Chapter 41

Patient Positioning and Associated Risks

LYDIA CASSORLA • JAE-WOO LEE

Key Points

- Patient positioning is a major responsibility that requires the cooperation of the entire surgical team. A compromise between optimal surgical positioning and patient well-being is sometimes required.
- Many patient positions that are used for surgery result in undesirable physiologic consequences including significant cardiovascular and respiratory compromise. Anesthetic agents blunt natural compensatory mechanisms, rendering surgical patients vulnerable to positional changes.
- Peripheral nerve injuries, although rare, represent 22% of cases in the 1990-2007 American Society of Anesthesiologists (ASA) Closed Claims Project, second only to death.[1] The mechanisms of injury are stretching, compression, and ischemia. Longer procedures are a risk factor. Patient positioning is often suspected, although many times precautions have been taken and no specific cause for the injury is known.
- Brachial plexus injuries have become the most common postoperative nerve injury associated with general anesthesia in more recent closed claims data, followed by injuries to the ulnar nerve, spinal cord, and lumbosacral nerve roots.[2]
- Not all postoperative neuropathies, including ulnar neuropathy, are currently explainable and may not be entirely preventable. Many postoperative ulnar nerve deficits may not be related to intraoperative patient positioning since they appear days after surgery.
- The ASA issued a Practice Advisory in 2000 for the prevention of perioperative peripheral neuropathies that was updated in 2011. However, very few of the studies reviewed met the standard for a scientifically proven relationship between intervention and outcome.
- Postoperative visual loss is a rare but devastating complication that is associated with the prone position. It has multifactorial causes and is incompletely understood.
- Anesthetics administered outside the classic surgical unit present special challenges with regard to patient positioning because of monitoring and equipment limitations and differences in the work environment and culture.

INTRODUCTION

Positioning of patients in the operating room is a critical responsibility that requires the cooperation of the entire surgical team. Positions deemed optimal for surgery often result in undesirable physiologic changes such as hypotension from impaired venous return to the heart or oxygen desaturation as a result of ventilation-perfusion mismatching. In addition, peripheral nerve injuries during surgery remain a significant source of perioperative morbidity.[1-4] The surgeon primarily dictates the desired position; however, to maximize patient well-being and safety, anesthesiologists, surgeons, and intraoperative nurses must work together to achieve the *optimal* patient position. Vigilance regarding potential risks of position-related injuries involves foresight and monitoring, although all injuries may not be preventable.

Whenever possible, the patient's position during anesthesia care should be natural—one that would be well tolerated if the patient were awake and unsedated. Because optimal surgical exposure may require unusual positioning of the body and positions may be maintained for

long periods, preventing complications requires clinical judgment and, at times, compromise. Jewelry and hair ornaments are removed. Weight-bearing surfaces of the extremities and joints are well padded, and the curvatures of the body, including the lumbar spine, are supported. The head should ideally remain midline without substantial extension or flexion. The eyes are kept closed without external pressure. When more extreme positions cannot be avoided, their duration should be limited as much as possible. The need for tilting the surgical table during surgery should be anticipated and rehearsed before draping, and the patient should be secured accordingly. The use of safety straps and the prevention of falls from the surgical table to the floor are fundamental.

CARDIOVASCULAR CONCERNS

Complex arterial, venous, and cardiac physiologic responses have evolved to blunt the effects of positional changes on arterial blood pressure and to maintain perfusion to vital organs. Central, regional, and local mechanisms are involved. These mechanisms are particularly important for animals such as humans who maintain an upright posture, because of the vertical distance from the heart to the brain and its need for constant perfusion.

Normally, as a person reclines from an erect to a supine position, venous return to the heart increases as pooled blood from the lower extremities redistributes toward the heart. Preload, stroke volume, and cardiac output are augmented. The resultant increase in arterial blood pressure activates afferent baroreceptors from the aorta (via the vagus nerve) and within the walls of the carotid sinuses (via the glossopharyngeal nerve) to decrease sympathetic outflow and to increase parasympathetic impulses to the sinoatrial node and myocardium. The result is a compensatory decrease in heart rate and, ultimately, cardiac output. Mechanoreceptors from the atria and ventricles are also activated to decrease sympathetic outflow to muscle and splanchnic vascular beds. Lastly, atrial reflexes are activated to regulate renal sympathetic nerve activity, plasma renin, atrial natriuretic peptide, and arginine vasopressin levels.[5] As a result, during postural changes without anesthesia, systemic arterial blood pressure is normally maintained within a narrow range.

General anesthesia, muscle relaxation (paralysis), positive-pressure ventilation, and neuraxial blockade all interfere with the venous return to the heart, arterial tone, and autoregulatory mechanisms. Therefore patients receiving general and major regional anesthesia are particularly vulnerable to poorly compensated circulatory effects of changes in position. Volatile anesthetics for induction and the maintenance of anesthesia decrease venous return and systemic vascular resistance, frequently decreasing arterial blood pressure. Positive-pressure ventilation increases mean intrathoracic pressure, diminishing the venous pressure gradient from peripheral capillaries to the right atrium. Because relatively small pressure gradients are active in the venous circulation, cardiac filling, and, consequently, cardiac output may be adversely affected.[6] Positive end-expiratory pressure (PEEP) further increases mean intrathoracic pressure, as do conditions associated with low lung compliance such as airways disease, obesity, ascites, and light anesthesia (i.e., "fighting the vent"). Venous return and cardiac output may be further compromised.[7] The use of spinal or epidural anesthesia causes a significant sympathectomy across all anesthetized dermatomes, independent of the presence of general anesthesia, reducing preload and potentially blunting cardiac response. The sympathetic output to the heart is often affected even when the sensory blockade does not reach high thoracic levels.

For these reasons, arterial blood pressure is often particularly labile immediately after the start of anesthesia and during patient positioning. The anesthesia provider needs to anticipate, monitor, and treat these effects, as well as assess the safety of positional changes for each patient. Frequent blood pressure measurements should be made after the induction of anesthesia or when the neuraxial blockade is initiated. During this hemodynamic transition, adjustments to the level of anesthesia and administration of additional intravenous fluid or vasopressors may be required. Temporary use of the Trendelenburg head-down position can be helpful. At times, a delay in repositioning the patient for surgery may be necessary until the systemic blood pressure reaches an acceptable level of homeostasis. Interruptions in monitoring to facilitate positioning or turning of the surgical table should be minimized during this dynamic period. Patient positioning is always secondary to patient safety.

In addition, regional oxygen delivery to critical organs such as the brain and optic nerve may be compromised because of positional factors that limit perfusion pressure. Examples include reduced arterial pressure as a result of a position above the heart or increased venous pressure as a result of a position below the heart. In addition, patient positioning may inadvertently compress tissue or blood vessels, increasing the risk for ischemia or compartment syndrome, which is discussed in the section on the lithotomy position later in this chapter.

PULMONARY CONCERNS

Gas exchange depends largely on matching ventilation and perfusion. Anesthetized persons who are spontaneously breathing have a reduced tidal volume and functional residual capacity and an increased closing volume when compared with the nonanesthetized state. Positive-pressure ventilation with muscle relaxation may ameliorate ventilation-perfusion mismatches under general anesthesia by maintaining adequate minute ventilation and limiting atelectasis. However, the diaphragm assumes an abnormal shape because of the loss of muscle tone and is displaced less in the dependent portions of the lung.[8] These physiologic changes decrease ventilation-perfusion matching and, consequently, PaO_2 Patients undergoing neuraxial anesthesia lose abdominal and thoracic muscle function in affected dermatomes. However, diaphragmatic function may be retained if general anesthesia and muscle relaxation are not concurrently administered and if the neuraxial anesthesia is restricted to the lower dermatomes. In addition to these effects of anesthesia,

patient position has distinct effects on pulmonary function. In particular, any position that limits the movement of the diaphragm, chest wall, or abdomen may increase atelectasis and intrapulmonary shunt.

Spontaneous ventilation results from relatively small negative intrathoracic pressure shifts during inspiration because of diaphragmatic displacement and chest wall expansion. This pressure decrease also promotes venous return to the thorax by reducing the pressure in the great veins and right atrium, compared with the periphery. Normal distribution of ventilation is more complex than classically theorized, with factors including the excursion of the diaphragm, compliance of the lung, and the shape and movement of the lung and thorax.[9] When a person shifts from standing to a supine position, functional residual capacity decreases because of the cephalad displacement of the diaphragm. The relative contribution to ventilation of the chest wall, compared with the diaphragm, decreases from 30% to only 10%. With spontaneous ventilation in either position, diaphragmatic movement is greatest adjacent to the most dependent portions of the lung, helping to bring new ventilation to the zones of the lung that are preferentially perfused. Although less than previously thought, gravity affects the preferential perfusion of the dependent portions of the lung. The importance of other factors, such as pulmonary vascular length and the structure of the pulmonary vascular tree, are now increasingly appreciated as a result of newer, high-resolution imaging techniques.[8] Perfusion appears to follow a central-to-peripheral spectrum in each lobe that is maintained with changes in cardiac output.[10-12]

When patients are in the prone position, weight should be distributed to the thoracic cage and bony pelvis, allowing the abdomen to move with respiration as subsequently described. The prone position has been used to improve respiratory function in patients with adult respiratory distress syndrome (ARDS).[13,14] Under anesthesia, the prone position has advantages over the supine position with regard to lung volumes and oxygenation without adverse effects on lung mechanics,[15,16] including patients who are obese[17] (see also Chapter 71) and pediatric patients (see also Chapter 93).[18] Newer investigations using high-resolution imaging have shown the prone position to provide superior ventilation-perfusion matching in the posterior segments of the lung near the diaphragm when compared with the supine position. The aeration and ventilation of these posterior segments are better, while blood flow is maintained, despite their nondependent position.[9]

SPECIFIC POSITIONS

SUPINE

The most common position for surgery is the supine or dorsal decubitus position (Fig. 41-1). Because the entire body is close to the level of the heart, hemodynamic reserve is best maintained. However, because compensatory mechanisms are blunted by anesthesia, even a few degrees of head-down (Trendelenburg) or head-up (reverse Trendelenburg) position (Fig. 41-2) are sufficient to cause significant cardiovascular changes and are frequently used to effect temporary changes in venous return and cardiac output. Steep Trendelenburg and reverse Trendelenburg positions (up to 45 degrees) are used for some surgeries, including lengthy laparoscopic and robotic procedures with pneumoperitoneum. These positions impart associated risks, which are discussed in the section on the Trendelenburg position.

Associated Arm Position

In a supine position, one or both of the patient's arms may be abducted out to the side or adducted (tucked) alongside the body. It is recommended that upper extremity abduction be limited to less than 90 degrees to minimize the likelihood of brachial plexus injury by caudal pressure in the axilla from the head of the humerus.[19,20] The hand and forearm are either supinated or kept in a neutral position with the palm toward the body to reduce external pressure on the spiral groove of the humerus and the ulnar nerve[20-22] (Fig. 41-3). When the arms are adducted, they are usually held alongside

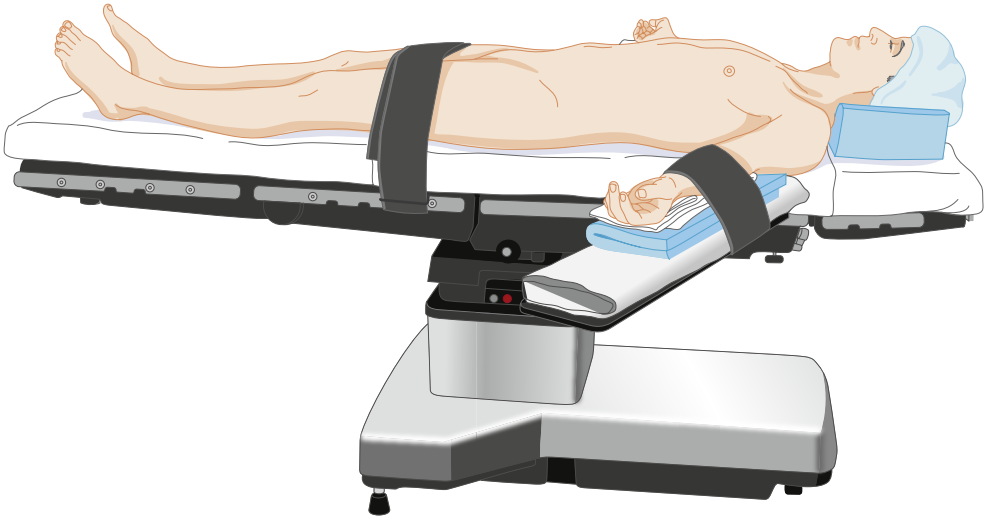

Figure 41-1. Supine position. The base of the table is asymmetrical. When positioned in the usual direction, the patient's center of gravity is over the base. Weight limits decrease when in reverse orientation to the base.

the body with a "draw sheet" that passes under the body, over the arm, and is then tucked directly under the torso (not the mattress) to ensure that the arm remains properly placed next to the body. Alternatively, in surgeries where access to the chest or abdomen is not necessary, curved arm cradles may be used. In all cases, the arms are placed in a neutral position.[20] The elbows and any protruding objects, such as intravenous fluid lines and stopcocks, are padded (Fig. 41-4).

Variations of the Supine Position

Several variations of the supine position are frequently used. The *lawn chair position* in which the hips and knees are slightly flexed (Fig. 41-5) reduces stress on the back, hips, and knees and is better tolerated by patients who are awake or undergoing monitored anesthesia care (see also Chapter 89). In addition, because the legs are slightly above the heart, venous drainage from the lower extremity is facilitated. In addition, the xiphoid-to-pubic distance is decreased, reducing the tension on the ventral abdominal musculature and easing the closure of laparotomy incisions. Proper positioning of the patient's hips at the break of the surgical table, adjusting the table back and leg sections, and using a slight tilt are required to achieve this position. Typically, the back of the bed is raised, the legs below the knees are lowered to an equivalent angle, and a slight Trendelenburg tilt is used to level the hips with the shoulders. These adjustments reduce venous pooling in the legs. The ability

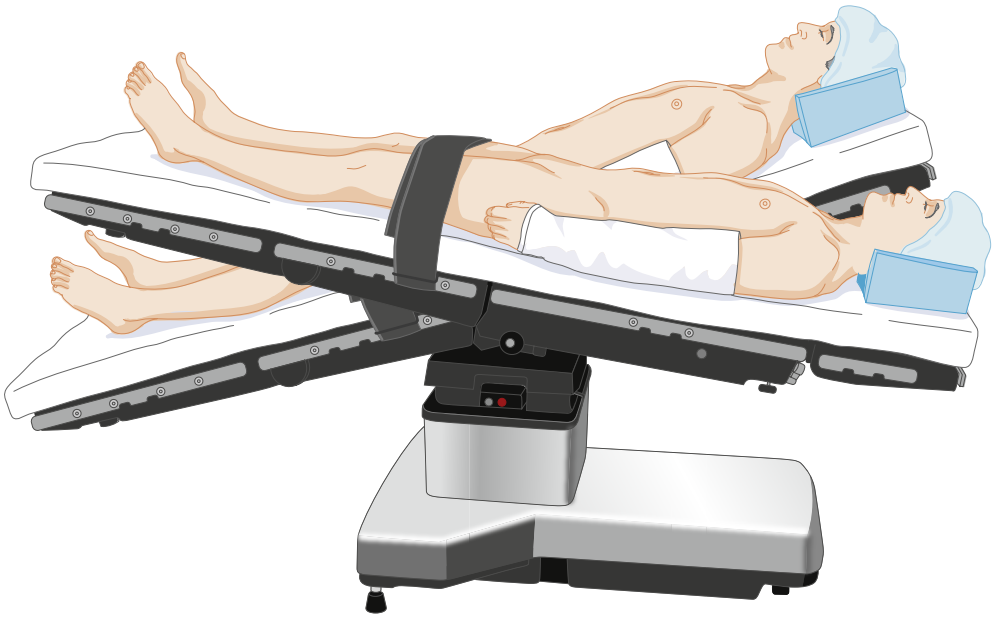

Figure 41-2. Head-down tilt (Trendelenburg) position and head-up tilt (reverse Trendelenburg) position. Shoulder braces should be avoided to prevent brachial plexus compression injuries.

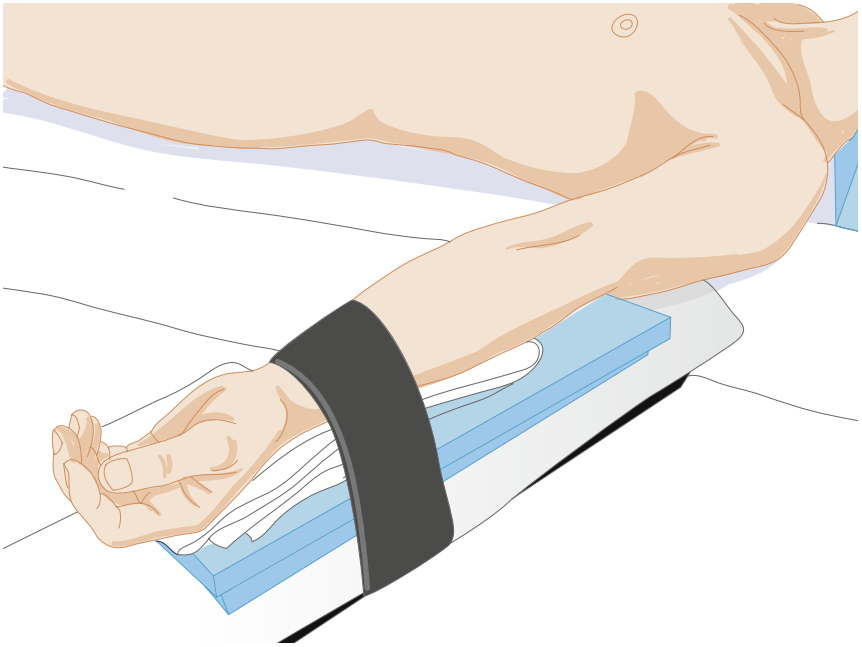

Figure 41-3. Arm position using the arm board. Abduction of the arm is limited to less than 90 degrees whenever possible. The arm is supinated, and the elbow is padded.

to use an arm board or table for upper extremity surgery is retained as the back is parallel with the floor.

The *frog-leg position*, in which the hips and knees are flexed and the hips are externally rotated with the soles of the feet facing each other, allows access to the perineum, medial thighs, genitalia, and rectum. Care must be taken to minimize stress and postoperative pain in the hips and to prevent dislocation by appropriately supporting the knees.

Tilting a supine patient head down, the *Trendelenburg position* (see Fig. 41-2), is often used to increase venous return during hypotension, to improve exposure during abdominal and laparoscopic surgery, and during central line placement to prevent air embolism and distention of the central vein. This position is linked by name to a nineteenth-century German surgeon, Friedrich Trendelenburg, who described its use for abdominal surgery.

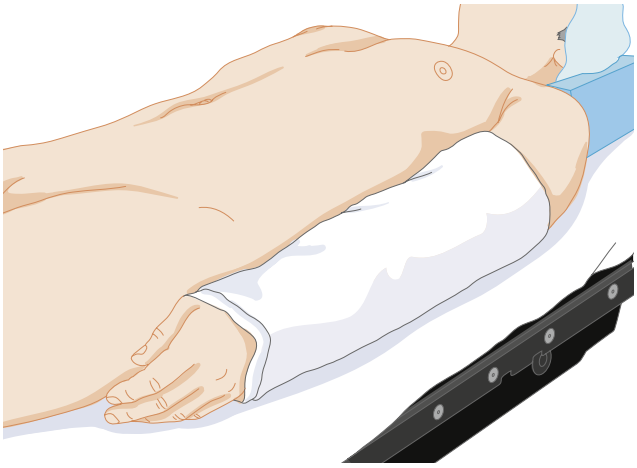

Figure 41-4. Arm tucked at patient side. The arm is in the neutral position with the palm to the hip. The elbow is padded, and the arm is well supported by the mattress.

The Trendelenburg position increases central venous, intracranial, and intraocular pressures and can have significant cardiovascular and respiratory consequences. A steep (30 to 45 degree) head-down position is now frequently used for robotic prostate and gynecologic surgeries. Robotic surgeries are often relatively long and present special challenges because once robotic instruments are set into position the table cannot be moved until the robotic portion is concluded without important consequences for the surgeon and additional procedure time. Patients undergoing robotic prostatectomies (see also Chapter 87) appeared in one study to tolerate the prolonged hemodynamic, respiratory, and neurophysiologic changes well, without evidence of harmful deviations from safe norms and cerebral perfusion pressures.[23]

Because of the augmented effects of gravity, care must be taken to prevent patients in steep head-down positions from slipping cephalad on the surgical table and to avoid compression of the brachial plexus by the torso against the shoulder girdle.[24,25] Techniques to restrain the patient from sliding include antiskid bedding, knee flexion, shoulder braces, beanbag cradling, and padded cross-torso straps.[26] Shoulder braces are not recommended because of the considerable risk of compression injury to the brachial plexus. Beanbag pads become rigid when suction is applied to set the shape, and their use in the Trendelenburg position has been associated with brachial plexus injuries.[27-29] If either shoulder braces or beanbag shoulder immobilization is used to prevent sliding, additional caution is recommended regarding abducting the arm; brachial plexus injuries on the side of the abducted arm have been reported in conjunction with beanbag shoulder immobilization and steep Trendelenburg positioning.[30] These injuries may be due to the fact that abduction of the arm stretches the upper and middle trunks of the brachial plexus as they course around the head of the humerus (Fig. 41-6).

Prolonged head-down positioning can also lead to swelling of the face, conjunctiva, larynx, and tongue with an increased potential for postoperative upper airway

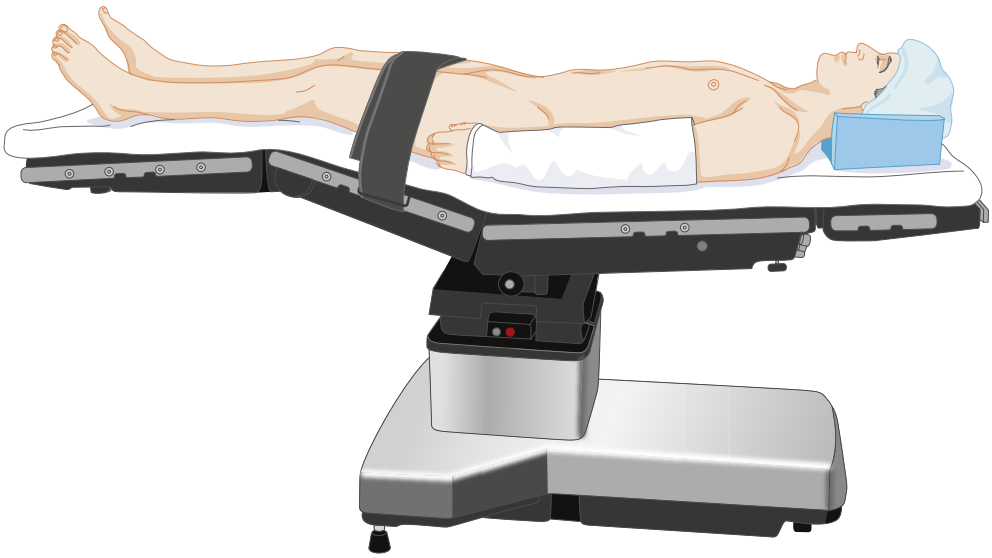

Figure 41-5. Lawn chair position. Flexion of the hips and knees decreases tension on the back.

obstruction. The cephalad movement of abdominal viscera against the diaphragm also decreases functional residual capacity and pulmonary compliance. In patients who are spontaneously ventilated, the work of breathing increases. In patients who are mechanically ventilated, airway pressures must be higher to ensure adequate ventilation. The stomach also lies above the glottis. Therefore endotracheal intubation is often preferred to protect the airway from aspiration of gastric contents related to reflux and to reduce atelectasis. Because of the risk of edema to the trachea and mucosa surrounding the airway during surgeries with patients in the Trendelenburg position for prolonged periods, verifying an air leak around the endotracheal tube or visualizing the larynx before extubation may be prudent.

The *reverse Trendelenburg position* (head-up tilt) (see Fig. 41-2) is often used to facilitate upper abdominal surgery by shifting the abdominal contents caudad. This position is increasingly popular because of the growing number of laparoscopic surgeries. Again, caution is advised to prevent patients from slipping on the table, and more frequent monitoring of arterial blood pressure may be prudent because hypotension may result from decreased venous return. In addition, the position of the head above the heart reduces perfusion pressure to the brain and should be taken into consideration when determining optimal blood pressure and the zero position of an arterial pressure transducer, when present.

In all positions in which the head is at a different level than the heart, the effect of the hydrostatic gradient on cerebral arterial and venous pressures should be considered when estimating cerebral perfusion pressure. Careful documentation of any potential arterial pressure gradients is especially prudent.

Supine Positions—Complications

Pressure alopecia, caused by ischemic hair follicles, is related to prolonged immobilization of the head with its full weight falling on a limited area, usually the occiput. Lumps such as those caused by monitoring cable connectors, should not be placed under the head; they may create focal areas of pressure. Hypothermia and hypotension during surgery, such as during cardiopulmonary bypass surgery, may increase the incidence of this complication. Consequently, ample cushioning of the head and, if possible during prolonged surgery, periodic rotation of the head, are prudent to redistribute the weight.

Backache may occur in the supine position because the normal lumbar lordotic curvature is often lost during general anesthesia with muscle relaxation or a neuraxial block due to their effects on the tone of the paraspinous muscles. Consequently, patients with extensive kyphosis, scoliosis, or a history of back pain may require extra padding of the spine or slight flexion at the hip and knee. Lastly, tissues overlying all bony prominences such as the heels and sacrum must be padded to prevent soft tissue ischemia as a result of pressure, especially during prolonged surgery.[31]

Peripheral nerve injury (discussed later in this chapter) is a complex phenomenon with multifactorial causes. The ASA published a Practice Advisory to help prevent perioperative neuropathies.[20,32] Ulnar neuropathy has historically been the most common lesion, although brachial plexus injuries have superseded ulnar neuropathies in more recent closed claims data associated with general anesthesia.[1,4] Regardless of the position of the upper extremities, maintaining the head in a relatively midline position can help minimize the risk of stretch injury to the brachial plexus.[27] Although no direct evidence suggests that positioning or padding alone can prevent

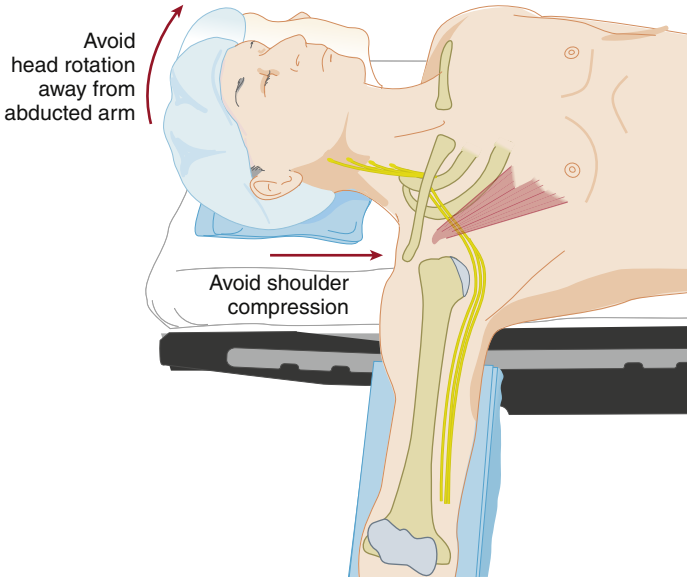

Figure 41-6. The brachial plexus, shown in yellow, is vulnerable to stretch and compression due to its long course. Arm abduction is limited to less than 90 degrees when supine because when the arm is raised the head of the humerus rotates caudad and stretches the plexus. Shoulder braces should be avoided; they may cause direct compression of the plexus medially between the clavicle and first rib or laterally below the head of the humerus. Excessive head rotation should be avoided, especially away from an abducted arm. Abduction of the arm should be avoided when in a steep head-down position if shoulder braces or a beanbag holds the shoulders.

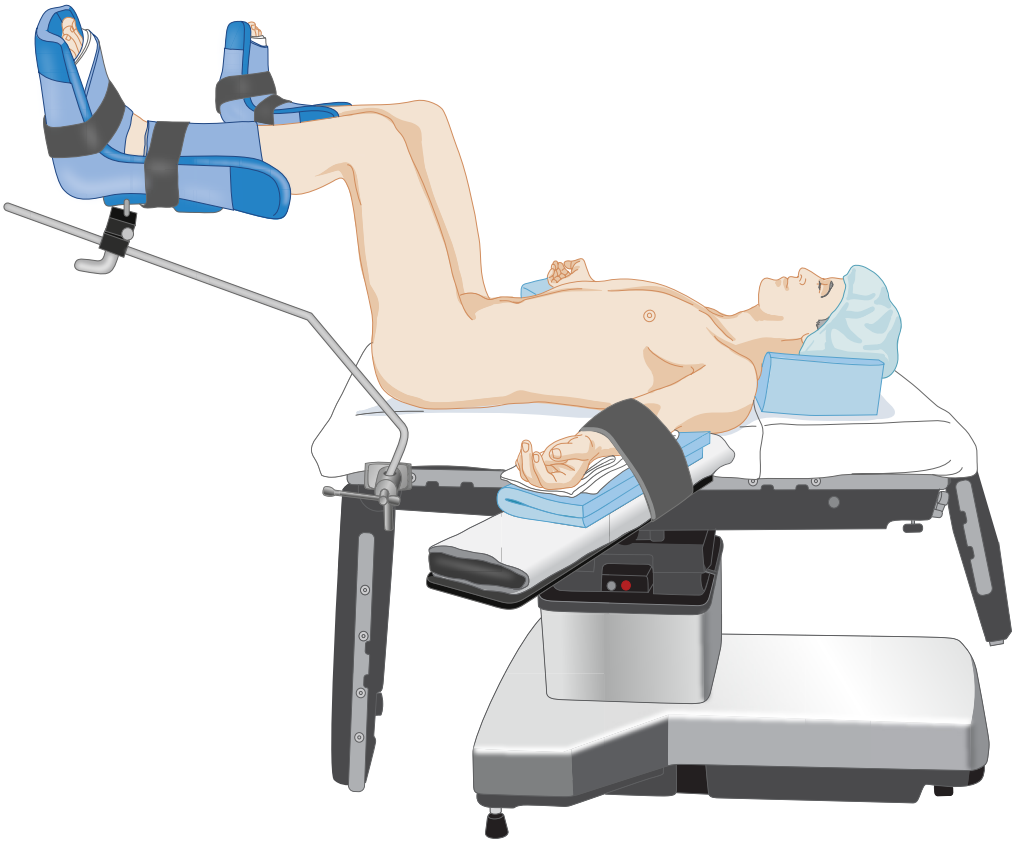

Figure 41-7. Lithotomy position. Hips are flexed 80 to 100 degrees with the lower leg parallel to the body. Pressure near the fibular head is absent. Arms are on armrests away from the hinge point of the foot section.

perioperative ulnar neuropathies, the ASA Practice Advisory recommends limiting arm abduction in the supine patient to less than 90 degrees at the shoulder with the hand and forearm either supinated or kept in a neutral position.[20]

The base of the surgical table is asymmetric, with the patient's torso generally over the base of the table (see Fig. 41-1). However, patients are often positioned with the torso over the open side of the table to improve surgical access or to permit the use of equipment such as C-arm x-ray devices. This position places the heaviest part of the body, and therefore the patient's center of gravity, opposite the weighted base of the table, with substantial leverage. When patients are heavy, caution is advised when placing them in reverse axis on the surgical table (see Chapter 71). The surgical table weight limits are significantly different when a patient is reversed, and should be strictly observed. The table can tilt and tip over if sufficient weight is placed away from the base, particularly if the leverage is increased yet further with table extensions or the Trendelenburg position.

LITHOTOMY

The classic *lithotomy position* (Figs. 41-7 to 41-9) is frequently used during gynecologic, rectal, and urologic surgeries. The hips are flexed 80 to 100 degrees from the trunk, and the legs are abducted 30 to 45 degrees from the midline. The knees are flexed until the lower legs are parallel to the torso, and supports or stirrups hold the legs, usually "candy cane," knee crutch, or calf support style. The foot section of the surgical table is lowered. If the arms are on the surgical table alongside the patient, then the hands and fingers may lie near the open edge of the lowered section of the table. When raising the foot of the table at the end of surgery, strict attention to the position of the hands must be paid to avoid a potentially disastrous crush injury to the fingers (Fig. 41-10). For this reason, when patients are in the lithotomy position, the recommended position of the arms is on armrests far from the table hinge point. If the arms must be tucked at the patient's side, then the hands need to be visualized and confirmed to be safe whenever the leg section of the surgical table is manipulated.

Initiation of the lithotomy position requires coordinated positioning of the lower extremities by two assistants to avoid torsion of the lumbar spine. Both legs should be raised together, simultaneously flexing the hips and knees. The lower extremities should be padded to prevent compression against the stirrups. After surgery, the patient must also be returned to the supine position in a coordinated manner. As previously mentioned, the hands should be positioned to prevent entrapment in any moving or articulating sections of the surgical table. The legs should be simultaneously removed from the holders, the knees brought together in the midline, and the legs slowly straightened and lowered onto the surgical table.

The lithotomy position may also cause significant physiologic changes. When the legs are elevated, venous return increases, causing a transient increase in cardiac

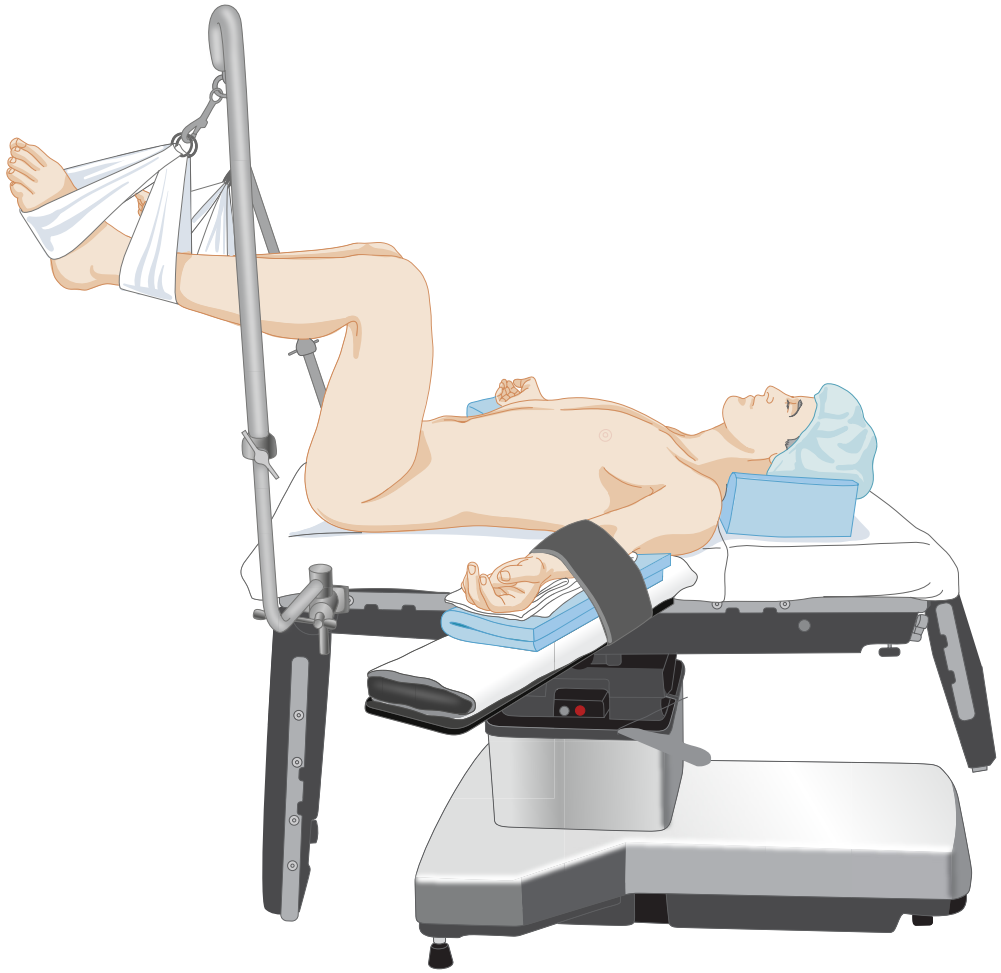

Figure 41-8. Lithotomy position with "candy cane" stirrup leg holders.

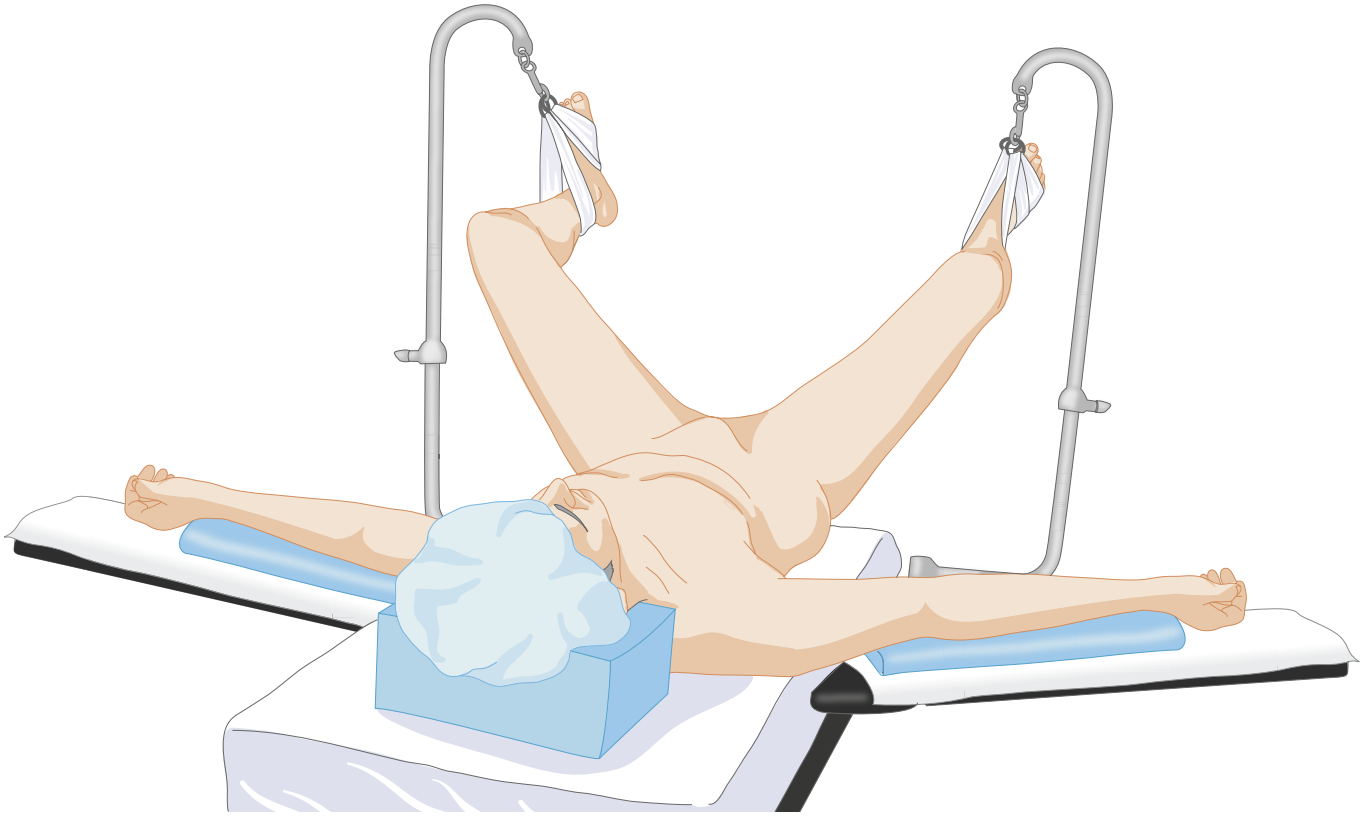

Figure 41-9. Lithotomy position. The correct position of "candy cane" supports is well away from the lateral fibular head.

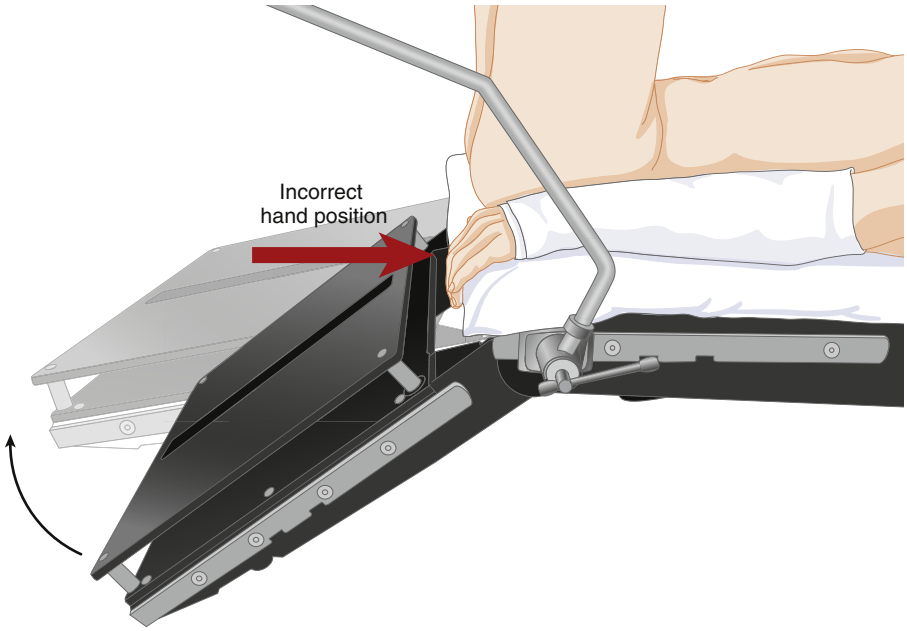

Figure 41-10. Improper position of arms in lithotomy position. The fingers are at risk for compression when the lower section of the bed is raised.

output and, to a lesser extent, cerebral venous and intracranial pressure in otherwise healthy patients. In addition, the lithotomy position causes the abdominal viscera to displace the diaphragm cephalad, reducing lung compliance and potentially resulting in a decreased tidal volume. If obesity or a large abdominal mass is present (e.g., tumor, gravid uterus), abdominal pressure may increase significantly enough to obstruct venous return to the heart. Lastly, the normal lordotic curvature of the lumbar spine is lost in the lithotomy position, potentially aggravating any previous lower back pain.[33]

In a retrospective review of 198,461 patients undergoing surgery in the lithotomy position from 1957 to 1991, injury to the common peroneal nerve was the most common lower extremity motor neuropathy, representing 78% of nerve injuries. A potential cause of the injury was the compression of the nerve between the lateral head of the fibula and the bar holding the legs. When the "candy cane" stirrups are used, special attention must be paid to avoid compression (see Fig. 41-9). The injury was more common with patients who had low body mass index, recent cigarette smoking, or prolonged duration of surgery.[34] Perhaps as a result of an increased awareness of potential injuries, no lower extremity motor neuropathies were reported in a prospective review of 991 patients undergoing surgery in the lithotomy position from 1997 to 1998. Paresthesias in the distribution of the obturator, lateral femoral cutaneous, sciatic, and peroneal nerves were reported in 1.5% of patients, and nearly all recovered. Surgical times longer than 2 hours were significantly associated with this complication.[35]

Lower extremity compartment syndrome is a rare complication caused by inadequate tissue perfusion that is associated with the lithotomy position.[36,37] Local arterial pressure decreases 0.78 mm Hg for each centimeter the leg is raised above the right atrium.[38] Leg compartment pressures initially increase in the lithotomy position for reasons that remain incompletely explained. This increase, combined with the decreased perfusion pressure in the elevated extremities, causes a vicious cycle of ischemia, edema, further ischemia, and eventually rhabdomyolysis. Reperfusion after an ischemic injury further increases edema, exacerbating the problem. Decompression fasciotomy is generally performed if tissue pressures are measured to be greater than 30 mm Hg. Irreversible muscle damage occurs with pressures over 50 mm Hg for several hours. In a large retrospective review of 572,498 surgeries, the incidence of compartment syndromes was higher in the lithotomy (1 in 8720) and lateral decubitus (1 in 9711) positions, as compared with the supine (1 in 92,441) position. Long procedure time was the only distinguishing characteristic of the surgeries during which patients developed lower extremity compartment syndromes.[36] A survey of urologists in the United Kingdom suggested that compartment syndrome after surgery in the lithotomy position is underreported and more common than appreciated. Compartment syndrome may occur in as many as 1 in 500 radical cystectomy procedures, which represented 78% of their cases. Affected patients had undergone surgeries with durations longer than 3½ hours.[39] Compartment pressures increase over time in the lithotomy position, and the legs should be periodically lowered to the level of the body if the surgery extends beyond 2 to 3 hours.[39-41] Additional risk factors include high body mass index and factors known to compromise tissue oxygenation such as blood loss, peripheral vascular disease, hypotension, and reduced cardiac output. The potential role of intermittent leg compression devices remains controversial.[38,42]

LATERAL DECUBITUS

The *lateral decubitus position* (Fig. 41-11) is most frequently used for surgery involving the thorax, retroperitoneal structures, or hip. The patient rests on the nonoperative side and is balanced with anterior and

Figure 41-11. Lateral decubitus position. The lower leg is flexed with padding between the legs, and both arms are supported and padded.

Figure 41-12. Lateral decubitus position showing placement of arms and head. Additional padding is under the headrest to ensure the alignment of the head with the spine. The headrest is kept away from the dependent eye.

posterior support, such as bedding rolls or a deflatable beanbag, and a flexed dependent leg. The arms are usually positioned in front of the patient, leading to some position-related risks to both the dependent and nondependent arms. The dependent arm rests on a padded arm board perpendicular to the torso. The nondependent arm is often supported over folded bedding or suspended with an armrest or foam cradle (Fig. 41-12). If possible, neither arm should be abducted more than 90 degrees. For some high thoracotomies, the nondependent arm may need to be elevated above the shoulder plane for exposure; however, vigilance is warranted to prevent neurovascular compromise.

The act of positioning a patient in the lateral decubitus position requires the cooperation of the entire surgical staff to prevent potential injuries. The patient's head must be kept in a neutral position to prevent excessive lateral rotation of the neck and stretch injuries to the brachial plexus. This adjustment may require additional head support (see Fig. 41-12). The dependent ear should be checked to avoid folding and undue pressure. The eyes should be securely taped closed before repositioning if the

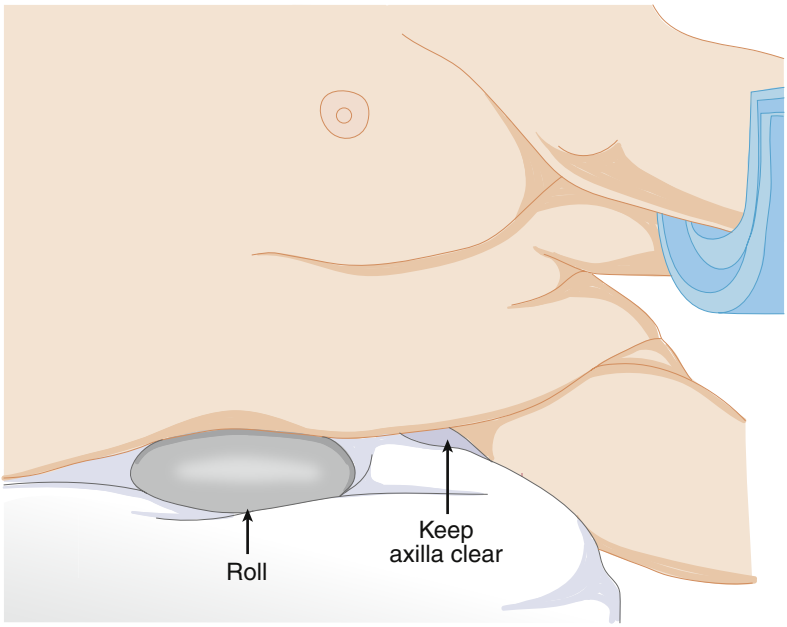

Figure 41-13. Use of chest roll in the lateral decubitus position. The roll, in this case, is a bag of intravenous fluid and is placed well away from the axilla to prevent compression of the axillary artery and brachial plexus.

patient is asleep. The dependent eye must be frequently checked for external compression.

To avoid compression to the dependent brachial plexus or blood vessels, an *axillary roll*, which is generally a bag of intravenous fluid, is frequently placed between the chest wall and the bed just caudal to the dependent axilla (Fig. 41-13). This roll should never be placed IN the axilla. The purpose of the axillary roll is to ensure that the weight of the thorax is borne by the chest wall caudad to the axilla and to avoid compression of the shoulder and axillary contents. Many practitioners do not use a roll if a deflatable beanbag is used to cradle the torso; however, the beanbag must not compress the axilla. Regardless of the technique, the pulse should be monitored in the dependent arm for early detection of compression to axillary neurovascular structures. Vascular compression and venous engorgement in the dependent arm may affect the pulse oximetry reading; a low saturation reading may be an early warning sign of compromised circulation. Hypotension measured in the dependent arm may be due to axillary arterial compression; therefore retaining the ability to measure blood pressure in both arms is useful. When a kidney rest is used, it must be properly placed under the dependent iliac crest to prevent inadvertent compression of the inferior vena cava. Lastly, a pillow or other padding is generally placed between the knees with the dependent leg flexed to minimize excessive pressure on bony prominences and stretch of lower extremity nerves.

The lateral decubitus position is also associated with pulmonary compromise.[43] In a patient who is mechanically ventilated, the combination of the lateral weight of the mediastinum and the disproportionate cephalad pressure of abdominal contents on the dependent lung favors overventilation of the nondependent lung. At the same time, the effect of gravity causes the pulmonary blood flow to the underventilated, dependent lung to increase. Consequently, ventilation-perfusion matching worsens, potentially affecting gas exchange and ventilation.

The lateral decubitus position is usually preferred during pulmonary surgery and one-lung ventilation. When the nondependent lung is collapsed, the minute ventilation is allocated to the dependent lung. This, combined with decreased compliance as a result of positioning, may further exacerbate the airway pressure required to achieve adequate ventilation. Head-down tilt in the lateral position worsens pulmonary function yet further, increasing shunt fraction.[44] Patients may be flexed while in the lateral position to spread the ribs during thoracotomies or to improve exposure of the retroperitoneum for renal surgeries. The point of flexion and the kidney rest, if raised, should lie under the iliac crest rather than the flank or ribcage to minimize compression of the dependent lung (Fig. 41-14). This position is often accompanied by a component of reverse Trendelenburg positioning, creating the potential for venous pooling in the lower body. For these reasons, the use of the flexed, lateral position is discouraged when not actively needed for surgical exposure.

PRONE

The *prone* or *ventral decubitus position* (Fig. 41-15) is primarily used for surgical access to the posterior fossa of the skull, the posterior spine, the buttocks and perirectal area, and the lower extremities. Regardless of whether the patient requires monitored anesthesia care or general anesthesia, the patient's legs should be padded and flexed slightly at the knees and hips. The head may be supported facedown with its weight borne by the bony structures or turned to the side. Both arms may be positioned to the patient's sides and tucked in the neutral position as described for the supine patient or placed next to the patient's head on arm boards—sometimes

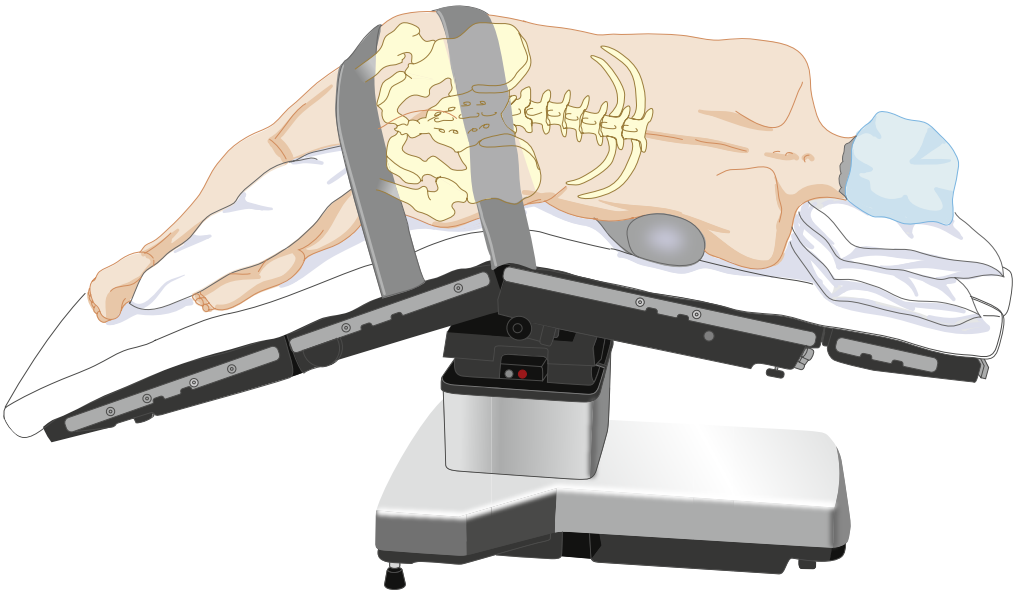

Figure 41-14. Flexed lateral decubitus position. The point of flexion should lie under the iliac crest, rather than under the flank or lower ribs to optimize ventilation of the dependent lung.

Figure 41-15. Prone position with Wilson frame. Arms are abducted less than 90 degrees whenever possible, although greater abduction may be better tolerated while prone. Pressure points are padded, and the chest and abdomen are supported away from the bed to minimize abdominal pressure and to preserve pulmonary compliance. Soft head pillow has cutouts for eyes and nose and a slot to permit endotracheal tube exit. Eyes must be checked frequently.

called the *prone superman position*. Extra padding under the elbow may be needed to prevent compression of the ulnar nerve. Again, unless necessary, the arms should not be abducted greater than 90 degrees to prevent excessive stretching of the brachial plexus, especially in patients with the head turned. Because of the effects of alterations in shoulder position on the brachial plexus, abduction of the arm greater than 90 degrees may be better tolerated in the prone position than in the supine position.[19] Finally, elastic stockings and active compression devices are used to minimize pooling of venous blood, especially with any flexion of the body.

When general anesthesia is planned, the trachea is first intubated on the stretcher, and all intravascular access is obtained as needed. The endotracheal tube is well secured to prevent dislodgement and the loosening of tape as a result of the drainage of saliva when prone. The anesthesia provider should consider using a wire-reinforced endotracheal tube to avoid kinking and obstruction as it exits the patient's mouth while in the prone position. If a head support device is used, then a corrugated extension of the endotracheal tube ensures that the anesthesia circuit Y is easily accessible, although this adds another connection in the airway circuit and a small amount of dead space ventilation. With the coordination of the entire surgical staff, the patient is then turned prone onto the surgical table, keeping the neck in line with the spine during the move. The anesthesiologist is primarily responsible for coordinating the move and for repositioning the head. An exception might be the patient in whom rigid pin fixation is used when the surgeon often holds the pin frame. Disconnecting blood pressure cuffs and arterial

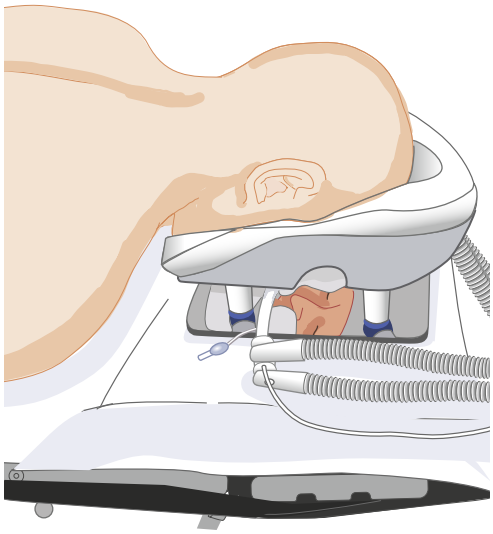

Figure 41-16. Mirror system for prone position. Bony structures of head and face are supported, and monitoring of the eyes and airway is facilitated with a plastic mirror. Although not illustrated, the eyes should be taped closed.

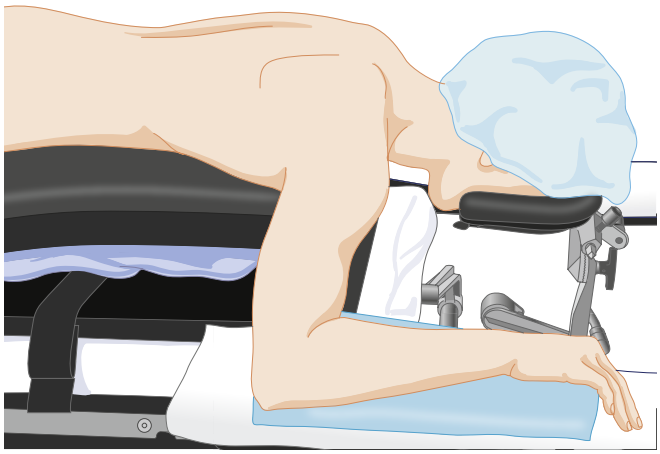

Figure 41-17. Prone position with horseshoe adapter. Head height is adjusted to position the neck in a natural position without undue extension or flexion.

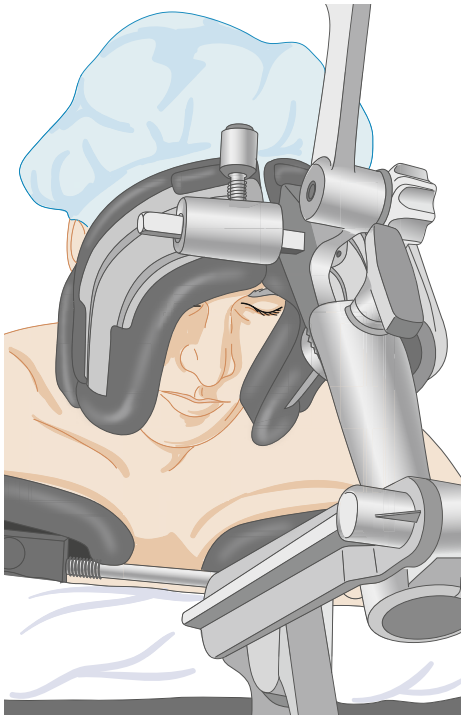

Figure 41-18. Prone position with horseshoe adapter. The face is seen from below. The horseshoe adapter permits superior access to the airway and visualization of eyes. The width may be adjusted to ensure proper support by facial bones.

and venous lines that are on the outside arm that rotates furthest is recommended to avoid dislodgment, although some prefer to disconnect all lines and monitors before moving. Pulse oximetry can usually be maintained if applied to the inside arm, and full monitoring should be reinstituted as rapidly as possible. Endotracheal tube positioning and adequate ventilation are immediately reassessed after the move.

Head position is critical. The patient's head may be turned to the side when prone if neck mobility is adequate. As in the lateral decubitus position, the dependent eye must be frequently checked for external compression. In addition, in patients with cervical arthritis or cerebrovascular disease, lateral rotation of the neck may compromise carotid or vertebral arterial blood flow or jugular venous drainage. In most cases, the head is kept in a neutral position using a surgical pillow, horseshoe headrest, or Mayfield head pins. A number of commercially available pillows are specially designed for the prone position. Most pillows, including disposable foam versions, support the forehead, malar regions, and chin, with a cutout for the eyes, nose, and mouth (see Fig. 41-15). The face is not always visible, however, making eye checks more difficult. Mirror systems are available to facilitate intermittent visual confirmation that the eyes are not impinged, although direct visualization or tactile confirmation is prudent (Fig. 41-16). The horseshoe headrest supports only the forehead and malar regions and allows excellent access to the airway; however, this headrest is rigid and therefore potentially dangerous if the head moves (Figs. 41-17 and 41-18). Mayfield rigid pins support the head without any direct pressure on the face. These pins allow access to the airway and firmly hold the head in one position that can be finely adjusted for optimal neurosurgical exposure (Fig. 41-19). Rigid pin fixation is rarely used outside cranial or cervical spine surgeries. When properly applied, the pins will cause significant periosteal stimulation. Patient movement must be prevented when the head is held in rigid pins; skidding out of pins can result in scalp lacerations or a cervical spine injury. Because horseshoe and pin headrests attach to adjustable articulating supports, any slippage or failure of this bracketing device may lead to complications if the head suddenly drops. Regardless of the head-support technique, the face must be periodically checked to ensure that the weight is borne only by the bony structures, that the airway is uncompromised, and that no pressure is placed on the eyes. Verification of proper positioning is frequently performed and noted in the anesthetic record. The face should be rechecked if any patient motion occurs during

Figure 41-19. Prone position with Mayfield head pins. Rigid fixation is provided for the cervical spine and posterior intracranial surgeries. The head position may include neck torsion or flexion that affects the depth of the endotracheal tube, and extreme head positions may increase the risk of cervical cord injury.

surgery or if the table position is significantly altered. The prone position is a risk factor for perioperative visual loss, which is discussed in a separate section later in this chapter. In addition, if motor-evoked potentials are used during spine or neurosurgery, then the position of the tongue and placement of bite blocks must be frequently checked; bite injuries are a vexing complication and can be severe if the tongue lies between the teeth.[45]

If the legs are in plane with the torso while in the prone position, then hemodynamic reserve is relatively maintained; however, if any significant lowering of the legs or tilting of the entire table occurs, then venous return may increase or decrease accordingly. The prone position does not alter the ability of pulse pressure variation to predict fluid responsiveness. However, the variation has been shown to be augmented at baseline; therefore fluid responsiveness is observed at a slightly greater level of variation than when supine.[46]

Because the abdominal wall is easily displaced, external pressure on the abdomen may elevate both intraabdominal and intrathoracic pressures. Therefore careful attention must be paid to the ability of the abdomen to hang relatively free and to move with respiration. During posterior spinal surgery, relatively low venous pressure is desirable to minimize bleeding and to facilitate surgical exposure. Abdominal pressure can transmit elevated venous pressures to the abdominal and spine vessels, including the epidural veins, which lack valves. Abdominal pressure may also impede venous return through compression of the inferior vena cava, decreasing cardiac output.

Pulmonary function may be superior to the supine and lateral decubitus positions if no significant abdominal pressure is present and if the patient is properly positioned.[47,48] External pressure on the abdomen may push the diaphragm cephalad, decreasing functional residual capacity and pulmonary compliance and increasing peak airway pressure. In one study of patients undergoing spine surgery in the prone position using the Wilson frame, pressure-controlled ventilation was found to cause less elevation of peak inspiratory pressures than volume-controlled ventilation with equal tidal volumes and end-tidal carbon dioxide concentrations.[49] In a randomized controlled trial studying patients undergoing spine surgery and ventilated with low versus high-tidal volume in the prone position, no difference in inflammatory markers or postoperative pulmonary function was exhibited.[50]

To promote low abdominal and thoracic pressures, firm rolls or bolsters placed along each side from the clavicle to the iliac crest generally support the torso. Multiple commercial rolls and bolsters are available including the Wilson frame (see Fig. 41-15), Jackson table, Relton frame, Mouradian/Simmons modification of the Relton frame, and gel bolsters. All devices serve to minimize abdominal compression by the surgical table and to maintain normal pulmonary compliance. To prevent tissue injury, pendulous structures, such as male genitalia and female breasts, should be clear of compression; the breasts should be placed medial to the gel bolsters. The lower portion of each roll or bolster must be placed under its respective iliac crest to prevent pressure injury to the genitalia and the femoral vasculature.[51] The prone position presents special risks for patients who are morbidly obese, whose respiration is already compromised, and who may be difficult to reposition quickly. At times, discussing alternate positioning options with the surgeon may be necessary to ensure patient safety.

SITTING

The sitting position, although infrequently used because of the perceived risk from venous and paradoxical air embolism, offers advantages to the surgeon in approaching the posterior cervical spine and the posterior fossa (Fig. 41-20) (see also Chapter 70). The main advantages of the sitting position over the prone position for neurosurgical and cervical spine procedures are excellent surgical

Figure 41-20. Sitting position with Mayfield head pins. The patient is typically semirecumbent rather than sitting; the legs are kept as high as possible to promote venous return. Arms must be supported to prevent shoulder traction and stretching of the brachial plexus. In a commonly used variation, the arms are placed on the abdomen and supported. The head support is preferably attached to the back section of the table to allow the back to be adjusted or lowered emergently without first detaching the head holder.

exposure, decreased blood in the operative field, and, possibly, reduced perioperative blood loss.[52] The main advantages to the anesthesiologist are superior access to the airway, reduced facial swelling, and improved ventilation, particularly in patients who are obese (see also Chapter 71).

The head may be fixed in pins for neurosurgery or taped in place with adequate support for other surgeries. Because gravity pulls the arms caudad, they must be supported to the point of slight elevation of the shoulders to avoid traction on the shoulder muscles and potential stretching of upper extremity neurovascular structures. The knees are usually slightly flexed for balance and to reduce stretching of the sciatic nerve, and the feet are supported and padded.[53]

The hemodynamic effects of placing a supine patient in the sitting position are dramatic. Because of the pooling of blood into the lower body under general anesthesia (see discussion earlier in this chapter), patients are particularly prone to hypotensive episodes. Incremental positioning and the use of intravenous fluids, vasopressors, and appropriate adjustments of anesthetic depth can reduce the degree and duration of hypotension. Elastic stockings and active leg compression devices can help maintain venous return.

The head and neck position while in the sitting position has been associated with complications during surgery to the posterior spine or skull. In a review of all cervical spinal cord injuries in the ASA Closed Claims Project database from 1970 to 2007, surgery in the sitting position was found to be associated with injury, whereas other factors often thought to be more important, such as airway management in the setting of neck trauma or cervical spine instability, were not.[54] The authors theorized that positional factors, such as sitting or hyperextension of the neck combined with unrecognized degenerative cervical spine disease, resulted in many of the cervical cord injuries in the ASA Closed Claims Project database. Excessive cervical flexion, which may occur with the head in pins, has a number of adverse consequences. It can impede both arterial and venous blood flow, causing hypoperfusion or venous congestion of the brain, and may impede normal respiratory excursion. Excessive flexion can also obstruct the endotracheal tube and place significant pressure on the tongue, leading to macroglossia. In general, maintaining at least two fingers' distance between the mandible and the sternum is recommended for a normal-sized adult, and patients should not be positioned at the extreme of their range of motion.[55] Extra caution with neck flexion is advised if transesophageal echocardiography (TEE) is used for air embolism monitoring, because the esophageal probe lies between the flexed spine and the airway and endotracheal tube, adding to the potential for compression of laryngeal structures and the tongue.

Because of the elevation of the surgical field above the heart and the inability of the dural venous sinuses to collapse because of their bony attachments, the risk of venous air embolism is a constant concern. Arrhythmia, desaturation, pulmonary hypertension, circulatory compromise, or cardiac arrest may occur if sufficient quantities are entrained. If the foramen ovale is patent, then even small amounts of venous air may result in a stroke or myocardial infarction as a result of paradoxical embolism. TEE has demonstrated some degree of venous air in a large majority of patients studied during neurosurgery in the sitting position.[56,57] Because of the risk of paradoxical embolus,

Figure 41-21. Sitting position adapted for shoulder surgery, often called the *beach chair position*. The arms must be supported to prevent stretching of the brachial plexus without pressure on the ulnar area of the elbow. As with all head-up positions, blood pressure should be regulated with the height of the brain in mind.

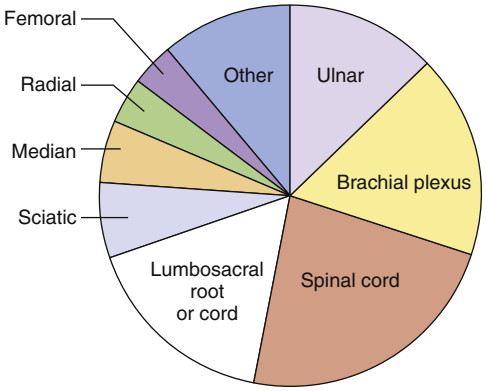
screening contrast echocardiography to investigate the patency of the interatrial septum is often performed before considering the sitting position for intracranial or cervical spine surgery. However, a patent foramen ovale may not always be detected.[58] Adequate hydration and early detection of entrained air with the use of TEE or precordial Doppler ultrasound may decrease the incidence and severity of venous air embolism.[56]

A variation of the sitting position, the *beach chair position* is increasingly used for shoulder surgeries, including arthroscopic procedures (Fig. 41-21). For the surgeon, its advantages versus the lateral decubitus position are superior access to the shoulder from both the anterior and posterior aspect and the potential for great mobility of the arm at the shoulder joint.[59] The beach chair position has been associated with neurologic injury, cervical neurapraxia, and hypotensive bradycardic events in association with the use of an epinephrine-containing interscalene block anesthetic.[59-62] The cause and incidence of these rare but catastrophic neurologic injuries are unknown. Theories include reduced cerebral perfusion in the beach chair position caused by reduced cardiac output, deliberate or permissive hypotension, loss of compensatory mechanisms caused by anesthesia, failure to compensate for the height of the head in the regulation of the blood pressure, dynamic vertebral artery narrowing or occlusion with the rotation of the head, and air emboli. Investigators have demonstrated positional effects on cerebral oxygen saturation,[62] as well as transient reductions in cerebral oxygen saturation associated with hypotensive periods during shoulder surgeries in the sitting position that reversed after use of ephedrine and phenylephrine to restore cerebral perfusion pressure.[62-64] Variation in the anatomy of the circle of Willis has been postulated as a cause of vulnerability to cerebral ischemia when sitting; however, causation remains unproven.[65,66] An observational study of 124 patients undergoing shoulder arthroscopy demonstrated cerebral desaturation by oximetry in 80% of those who were in the beach chair position and none in the lateral decubitus position.[67] Cerebral oxygen saturation monitoring may be helpful; however, no gold standard limits exist, and values may change along with alterations in patient position and carbon dioxide concentration. Therefore, if measured, trends in cerebral oxygen saturation are best interpreted during periods of constant ventilation and patient position.[68,69] Reasonable recommendations for patients undergoing shoulder surgery in the sitting position are to monitor blood pressure carefully in reference to the level of the brain, avoid and rapidly treat any hypotension or bradycardia, and position the head carefully to avoid extreme positions that may compromise cerebral vessels.[61] Monitoring of cerebral oxygen saturation, if available, may be useful when patients are in a steep head-up position. However, its value has not been established,[69] and the incidence of cerebral injury during shoulder surgery is estimated to be approximately 1 in 22,000.[70] The Anesthesia Patient Safety Foundation and the ASA Committee on Professional Liability in collaboration with the

ASA Closed Claims Project established the Neurologic Injury After Non-Supine Shoulder Surgery (NINS) Registry in 2010. They hope to collect a greater amount of data on such cases to clarify the details and risks associated with positioning. The NINS Registry can be accessed via the ASA Closed Claims Project web site (www.asaclosedclaims.org).

PERIPHERAL NERVE INJURY

Peripheral nerve injury remains a serious perioperative complication and a significant source of professional liability, despite the low incidence of approximately 0.11% of 81,000 anesthetics reviewed from 1987 to 1993,[71] and 0.03% of 380,680 anesthetics reviewed from 1997 to 2007.[72] Injuries occur when peripheral nerves are subjected to stretch, ischemia, or compression during surgery[73]; however, the precise mechanism of injury cannot be determined in many cases.[3] Injuries to patients under monitored anesthesia care, although infrequent, occur as well. During general or regional anesthesia, early warning symptoms of pain and the normal spontaneous repositioning that would occur are absent. Prolonged duration of surgery appears to be a risk factor.



Because scientific studies regarding rare events, such as position-related injuries, are difficult to conduct, much of what is known comes from case reports and the liability insurance industry. In 1984 the ASA developed a Closed Claims Project to evaluate adverse anesthetic outcomes from the closed claims files of 35 U.S. liability insurance companies. The most common cause for claims is death, representing 22% to 41% of claims, with a decreasing fraction over time. Since the initial report in 1990, nerve injury has remained the second most frequent cause for claims. The fraction has increased, from 15% during the 1970s, to 22% in the 2000s.[1,3,74,75] However, this increase appears to track growth in the use of regional anesthesia for both surgical and obstetric patients and is unlikely to represent an increase in position-related nerve injuries.[1] Although most patients with nerve injuries recover, in the 5280 closed claims from 1990 to 2007, 23% of the injuries were permanent; 15% occurred after regional anesthesia, 5% occurred after general anesthesia, and a few cases occurred after monitored anesthesia care.[1]

The ASA Closed Claims database recorded 1564 cases of nerve injury between 1970 and 2010. Overall, injuries to the ulnar nerve represent 21% of cases, followed by the brachial plexus (20%), spinal cord (19%), and lumbosacral nerve roots or cord (17%).[2] The distribution of nerve injuries resulting in claims has changed over time, with ulnar nerve injury decreasing from 33% in the first 2 decades of the project to 14% in the second 2 decades. Over the same periods, claims filed after brachial plexus injuries decreased from 21% to 19% and claims filed after spinal cord injuries increased from 9% to 25% (Table 41-1A). Subsets of claims from 1990

TABLE 41-1A TYPES OF NERVE INJURY—FOLLOWING ALL ANESTHETIC TYPES

	Total Nerve Injuries (1970-2010)		1970-1989		1990-2010	
	Count	*% of 1564*	*Count*	*% of 570*	*Count*	*% of 994*
Ulnar nerve damage	332	21%	188	33%	144	14%
Brachial plexus nerve damage	311	20%	122	21%	189	19%
Spinal cord injury	296	19%	51	9%	245	25%
Lumbrosacral nerve root or cord	268	17%	90	16%	178	18%
Sciatic nerve damage	100	6%	35	6%	65	7%
Median nerve damage	91	6%	30	5%	61	6%
Radial nerve damage	61	4%	21	4%	40	4%

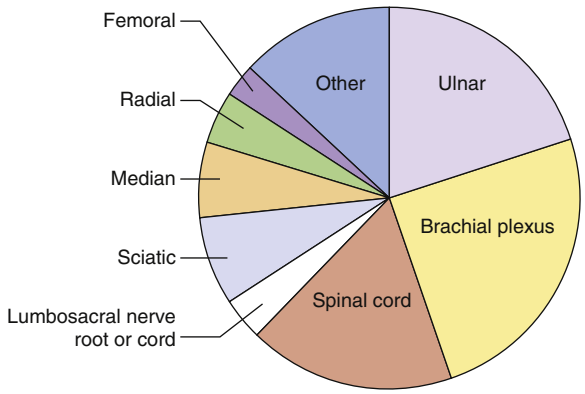
Nerve injury claims following all anesthesia types in the American Society of Anesthesiologists (ASA) Closed Claims Database 1970-2010 ($N = 1564$ of 5436 total claims in the database). Note the change in distribution over time, particularly a decrease in the fraction of ulnar nerve injuries and an increase in the fraction of spinal cord injuries.
Data from personal communication from Posner KL for publication in Miller's Anesthesia.



Nerve injury closed claims following all anesthesia types, 1990-2010, ($N = 994$).

to 2010 show that, after general anesthesia, the largest fractions were damage to the brachial plexus (27%) followed by the ulnar nerve (22%) and the spinal cord (19%) (Table 41-1B). For claims filed after regional anesthesia, the distribution included large fractions of injuries to the lumbosacral nerve roots (39%) and spinal cord (29%),[2] which are less likely to be related to positioning (Table 41-1C). Over the past 4 decades, the total number of claims for nerve injuries includes only 18 cases under monitored anesthesia care. In addition, 97 cases were recorded after combined general and regional anesthetics were administered, as well as a few cases for which the primary anesthetic was not recorded or no anesthetic was administered.

TABLE 41-1B TYPES OF NERVE INJURY—FOLLOWING GENERAL ANESTHESIA

	Total Nerve Injuries (1970-2010)		1970-1989		1990-2010	
	Count	*% of 886*	*Count*	*% of 346*	*Count*	*% of 540*
Ulnar nerve damage	280	32%	161	47%	119	22%
Brachial plexus nerve damage	235	27%	91	26%	144	27%
Spinal cord injury	123	14%	22	6%	101	19%
Lumbosacral nerve root or cord	30	3%	6	2%	24	4%
Sciatic nerve damage	66	7%	22	6%	44	8%
Median nerve damage	51	6%	13	4%	38	7%
Radial nerve damage	40	5%	11	3%	29	5%
Femoral nerve damage	26	3%	9	3%	17	3%
Other nerve injuries	98	11%	22	6%	76	14%

Nerve injury claims following general anesthesia in the American Society of Anesthesiologists (ASA) Closed Claims Database 1970-2010 (*N* = 886). Note that claims for brachial plexus injury outnumber those for ulnar nerve damage in the more recent data.
Personal communication from Posner KL for publication in Miller's Anesthesia.

Nerve injury closed claims following general anesthesia, 1990-2010, (*N* = 540).

TABLE 41-1C TYPES OF NERVE INJURY FOLLOWING REGIONAL ANESTHESIA

	Total Nerve Injuries (1970-2010)		1970-1989		1990-2010	
	Count	*% of 552*	*Count*	*% of 202*	*Count*	*% of 350*
Ulnar nerve damage	44	8%	23	11%	21	6%
Brachial plexus nerve damage	59	11%	29	14%	30	9%
Spinal cord injury	124	22%	23	11%	101	29%
Lumbosacral nerve root or cord	220	40%	83	41%	137	39%
Sciatic nerve damage	28	5%	11	5%	17	5%
Median nerve damage	33	6%	14	7%	19	5%
Radial nerve damage	10	2%	7	3%	3	1%
Femoral nerve damage	24	4%	8	4%	16	5%
Other nerve injuries	41	7%	11	5%	30	9%

Nerve injury claims following regional anesthesia in the American Society of Anesthesiologists (ASA) Closed Claims Database 1970-2010 (*N* = 552).
Note: Claims associated with chronic pain management excluded; claims with missing event decade excluded. The results from Tables 41-1B and 41-1C do not add up to the totals in Table 41-1A because of claims associated with monitored anesthesia care, combined anesthetic techniques, unknown primary anesthetic, or no anesthetic administered.
Personal communication from Posner KL for publication in Miller's Anesthesia.

In a detailed report published in 1999 of 670 claims related to peripheral nerve injury, the ulnar nerve was the most frequent site of injury (28%), followed by the brachial plexus (20%), lumbosacral nerve root (16%), and spinal cord (13%).[3] Data in that report showed the beginnings of a significant evolution in the distribution of nerve injuries. Ulnar neuropathy decreased from 37% of injuries in the early 1980s to 17% in the 1990s. Spinal cord injury increased from 8% of injuries in the early 1980s to 27% in the 1990s. Spinal cord injury and lumbosacral nerve root neuropathy were predominantly associated with regional anesthesia. Epidural hematoma and chemical injuries represented 29% of the known mechanisms of injury among the claims filed. The injuries were probably related to the use of neuraxial block in patients on anticoagulant therapy and the increased use of blocks to manage chronic pain.[3,76,77] In two reports on claims arising from anesthesia outside the surgical unit, nerve injuries appeared rare, making up only 4% to 7% of claims. Death represented 54% of claims in this subset, versus 24% for surgical cases. This high proportion was associated with the large fraction (58%) of monitored anesthesia care outside the surgical unit.[78] For claims after monitored anesthesia care, 40% were for patient death[79]; therefore the nonsurgical environment seems to impart additional risk of death as a cause for a claim.

In a 10-year retrospective study of 380,680 patients at a single university tertiary care institution, 112 peripheral nerve injuries were observed in the perioperative period, an incidence of 0.3%.[80] Risk factors were hypertension, diabetes, and tobacco use. General and epidural anesthesia appeared to be risk factors, compared with monitored anesthesia care, spinal anesthesia, and peripheral nerve blocks. Most injuries were sensory (60%) or combined sensory and motor (24%) with only 14% pure motor injuries. This study provides a significantly different numerator and denominator than the ASA Closed Claims Project, and its data contrast with the most recent claims data in which a greater fraction of claims were filed after the administration of regional anesthesia.

With the exception of spinal cord injuries, the mechanism of nerve injury remains incompletely explained by scientific studies. Most nerve injuries, particularly those to nerves of the upper extremity such as the ulnar nerve and brachial plexus, occurred in the presence of adequate positioning and padding. In a retrospective study of 1000 consecutive spine surgeries that used somatosensory-evoked potential (SSEP) monitoring, five arm positions were compared regarding SSEP changes in the upper extremities. A modification of arm position reversed 92% of upper extremity SSEP changes. The incidence of position-related upper extremity SSEP changes was significantly higher in the prone "superman" (7%) and lateral decubitus (7.5%) positions, compared with the supine arms out, supine arms tucked, and prone arms tucked positions (1.8% to 3.2%). Reversible SSEP changes were not associated with postoperative deficits[80] (see also Chapter 49).

Because of the significant morbidity associated with peripheral nerve injury, the ASA published a Practice Advisory for the prevention of peripheral neuropathies in 2000 that was updated in 2011.[20,32] However, the advisories were not based on scientific evidence but on the consensus of a group of expert consultants. Only 6 out of 509 studies reviewed for the original advisory "…exhibited sufficiently acceptable methods and analyses that provided a clear indication of the relationships between interventions and outcomes of interest"[32] (Box 41-1). Despite the addition of 50 new citations, the 2011 advisory stated, "No evidence linkage contained sufficient literature with well-defined experimental designs and statistical information to conduct an analysis of aggregated studies (i.e., a meta-analysis)…. In conclusion, the current literature has not been helpful in determining the efficacy of perioperative positioning techniques in reducing the occurrence of peripheral neuropathies."[20]

Because of the paucity of clear data on the causes and the prevention of peripheral injuries, individual practices vary. Good sense would avoid positions that permit stretching of the nerves and pressure to anatomic locations known to carry nerves prone to injury, such as the ulnar cubital tunnel and the peroneal nerve coursing over the fibular head (Table 41-2). Padding and support should distribute weight over as wide an area as possible; however, no padding material has been shown to be superior. Whenever possible, the patient's position should appear natural. Anesthesia and muscle relaxation increase the danger of malposition-induced injuries. Extremes of weight remain risks as well.

SPECIFIC NEUROPATHIES

ULNAR NERVE INJURY

The manner of causation of perioperative ulnar neuropathy is complex and incompletely understood. The ulnar nerve lies in a superficial position at the elbow. Although the incidence is low, the morbidity associated with ulnar neuropathy can be severe. In a prospective study among 1502 patients undergoing noncardiac surgery, 7 patients developed perioperative ulnar neuropathy, of which 3 patients had residual symptoms after 2 years.[81] The neuropathy, if permanent, results in the inability to abduct or oppose the fifth finger, diminished sensation in the fourth and fifth fingers, and eventual atrophy of the intrinsic muscle of the hands creating a clawlike hand.

Previously, the injury was thought to be associated with hyperflexion of the elbow and compression by the surgical table of the nerve at the condylar groove and the cubital tunnel against the posterior aspect of the medial epicondyle of the humerus. In a study on the effect of arm position on the ulnar nerve SSEPs in 15 healthy awake male volunteers, the supinated position was associated with the least pressure on the ulnar nerve, and the neutral position was the next most favorable. When in the neutral position on a surgical armrest, pressure decreased as the arm was abducted between 30 and 90 degrees. Interestingly, not all patients had symptoms of nerve compression when the SSEP was abnormal.[82]

BOX 41-1 ***Summary of the 2011 American Society of Anesthesiologists Practice Advisory for the Prevention of Perioperative Peripheral Neuropathies***

Preoperative Assessment

- When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.
- Body habitus, preexisting neurologic symptoms, diabetes, peripheral vascular disease, alcohol dependence, arthritis, and sex (e.g., male sex and its association with ulnar neuropathy) are risk factors for perioperative neuropathy.

Upper Extremity Positioning

- Limit arm abduction to 90 degrees in supine patients; patients who are positioned prone may tolerate arm abduction greater than 90 degrees.
- Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable.
- Flexion of the elbow may increase the risk of ulnar neuropathy; however, there is no consensus on the degree of acceptable flexion.
- Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided.
- Extension of the elbow beyond a comfortable range may stretch the median nerve.
- Periodic perioperative assessments may ensure maintenance of the desired position.

Lower Extremity Positioning

- Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve.
- Extension of the hip and flexion of the knee stretch the sciatic nerve and branches. Consider the effect of both when determining the degree of hip flexion.
- Avoid prolonged pressure on the peroneal nerve at the fibular head.
- Neither extension nor flexion of the hip increases the risk of femoral neuropathy.

Protective Padding

- The risk of neuropathy may be decreased by:
  - Padded armboards.
  - The use of chest rolls in laterally positioned patients.
  - Padding at the elbow.
  - Padding at the fibular head.
- If too tight, however, padding may increase the risk of neuropathy.

Equipment

- Properly functioning and positioned automated blood pressure cuffs on the arms do not affect the risk of upper extremity neuropathies.
- Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies.

Postoperative Assessment

- A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

Documentation

- Documentation of specific positioning actions may improve care by:
  - Helping practitioners focus attention on relevant aspects of patient positioning.
  - Providing information on positioning strategies that eventually leads to improvements in patient care.

From the Practice Advisory for the prevention of perioperative peripheral neuropathies: an updated report by the American Society of Anesthesiologists Task Force on prevention of perioperative peripheral neuropathies, Anesthesiology *114:741-754, 2011.*

TABLE 41-2 **MOST COMMON NERVE INJURIES IN THE ASA CLOSED CLAIMS DATABASE 1990-2010**[1]

Nerve Injury	Recommendations for Prevention
Ulnar nerve (14%)	• Avoid excessive pressure on the postcondylar groove of the humerus. • Keep the hand and forearm either supinated or in a neutral position.

Brachial plexus (19%)	• When utilizing a steep head-down (Trendelenburg) position:
	  ◦ Avoid the use of shoulder braces and beanbags when possible (use nonsliding mattresses).
	  ◦ Avoid abduction of the arm(s) when possible.
	• Avoid excessive lateral rotation of the head, either in the supine or prone position.
	• Limit abduction of the arm to <90 degrees in the supine position.
	• Avoid the placement of high "axillary" roll in the decubitus position— keep the chest roll out of the axilla to avoid neurovascular compression.
	• Use ultrasound to locate the internal jugular vein for central line placement.

Spinal cord (25%) and lumbosacral nerve root or cord (18%)	• Be aware that the fraction of spinal cord injuries is increasing, probably in relation to use of regional anesthesia. • Avoid severe cervical spine flexion or extension when possible. • Follow current guidelines for regional anesthesia in patients on anticoagulant therapy.*
Sciatic and peroneal nerves (7%)	• Minimize the time in the lithotomy position. • Use two assistants to coordinate simultaneous movement of both legs to and from the lithotomy position. • Avoid excessive flexion of the hips, extension of the knees, or torsion of the lumbar spine. • Avoid excessive pressure on peroneal nerve at the fibular head.

ASA, American Society of Anesthesiologists.
Data from ASA Closed Claims Project 1990-2010.
N = 994 nerve injuries. Excludes claims associated with chronic pain management. Personal communication from Posner KL.[2]
*Horlocker TT, Wedel DJ, Benzon H, et al: Regional anesthesia in the anticoagulated patient: defining the risks (The second ASRA Consensus Conference on Neuraxial Anesthesia and Anticoagulation), *Reg Anesth Pain Med* 28:172-197, 2003.

Current consensus is that the cause of ulnar nerve palsy is multifactorial and not always preventable.[83,84] In a large retrospective review of perioperative ulnar neuropathy lasting longer than 3 months, the onset of symptoms occurred more than 24 hours postoperatively in 57% of patients; 70% were men, and 9% experienced bilateral symptoms. Very thin or obese patients were at increased risk, as were those with prolonged postoperative bed rest. No association with intraoperative patient position or anesthetic technique was confirmed.[85] The ASA Closed Claims Project also demonstrated that perioperative ulnar neuropathy occurred predominately in men, in an older population, and with a delayed onset (median of 3 days).[3] In addition, although most ulnar damage claims were associated with general anesthesia, payment was also made for claims where the patient had been awake or sedated during regional anesthesia involving the lower extremity. Interestingly, in a prospective study of patients who did not undergo surgical procedures, 2 of 986 patients developed ulnar neuropathy.[86] The large predominance of ulnar injury in men may possibly be explained by anatomic differences. Men have a more developed and thickened flexor retinaculum with less protective adipose tissue and a larger (1.5×) tubercle of the coronoid process that can predispose this patient population to nerve compression in the cubital tunnel.[87,88] Other risk factors, including diabetes mellitus, vitamin deficiency, alcoholism, cigarette smoking, and cancer, require further studies to be substantiated. In the published ASA Closed Claims Project data, only 9% of ulnar injury claims had an explicit mechanism of injury, and in 27% of claims, the padding of the elbows were explicitly stated.[3] Postoperative ulnar nerve palsy can occur without any apparent cause, even when padding and positioning of the patient's arm were carefully managed and documented in the anesthetic record.[22]

BRACHIAL PLEXUS INJURY

The brachial plexus is susceptible to stretching because of its long superficial course from the neck to the arm via the axilla with two points of fixation—the cervical vertebrae and the axillary fascia. The nerves of the brachial plexus sling under the clavicle and the pectoralis muscles and are therefore variably stretched with many movements of the arm or head. The nerves are vulnerable to compression as they pass between the clavicle and the first rib because of the proximity and mobility of both the clavicle and the humerus (see Fig. 41-6). Among patients undergoing noncardiac surgeries, the incidence of brachial plexus injury is reported to be 0.02%.[89] After brachial plexus injury, the patient often complains of sensory deficit in the distribution of the ulnar nerve. This symptom is most commonly associated with intraoperative arm abduction greater than 90 degrees, lateral rotation of the head away from the side of the injury, asymmetric retraction of the sternum for internal mammary artery dissection during cardiac surgery, or direct trauma or compression. To avoid injury, patients should ideally be positioned with the head midline, arms kept at the sides, the elbows mildly flexed, and the forearms supinated, without pressure on the shoulders or the axilla.

Brachial plexus injury is particularly associated with the use of shoulder braces in patients undergoing surgery in the Trendelenburg position. Medial placement of the braces can compress the proximal roots, and lateral placement of the braces can stretch the plexus by displacing the shoulders against the thorax (see Fig. 41-6). The patient with injury often complains of painless motor deficit in the distribution of the radial and median nerves; however, pain may also be present. A report of three cases of upper- and middle-trunk brachial plexopathy after robotic prostatectomy highlights the potential risk of a combination of compression of the shoulder girdle against the thorax in the steep Trendelenburg position with abduction of an arm.[30] Signs of vascular compromise to the upper extremities, such as difficulty obtaining consistent blood pressure or a poor pulse oximetry signal, may be indications of compromise to the neurovascular bundle as reported in a case of bilateral injury related to shoulder braces with abduction of the arms in the Trendelenburg position.[90] Studies of the brachial plexus tension test in human volunteers and nerve strain in cadavers have demonstrated deleterious positional elements including arm abduction, rotation or flexion of the head away from the affected arm, elbow and wrist extension, and depression of the shoulder girdle.[29,91] For transaxillary robotic thyroidectomy, a recently developed approach has the arm abducted to 180 degrees. An incidence of brachial plexus injury has been reported to be 0.3%.[92] When an extreme position is used, neurophysiologic monitoring, such as motor-evoked potentials and SSEPs, has been shown to detect an evolving injury and allow for repositioning to prevent permanent damage.[93,94] Nerve function monitoring may therefore become increasingly common with newer surgical techniques that carry increased risk related to patient positioning.

In patients undergoing cardiac surgery requiring median sternotomy, brachial plexus injury has been specifically associated with the C8-T1 nerve roots. In a prospective study in which the incidence of injury was 4.9%, the authors found that 73% of the injuries occurred on the same side as the internal jugular vein cannulation; however, this study antedated the widespread use of ultrasound to guide cannulation.[95] Unilateral sternal retraction to harvest the mammary artery is associated with brachial plexus dysfunction, presumably caused by stretching the nerves. SSEP monitoring of the brachial plexus during sternal retraction has been shown to predict injury.[96]

In the 1999 ASA Closed Claims Project report, 10% of brachial plexus injuries were directly attributed to patient positioning. Of those, one half involved the use of shoulder braces in patients in the Trendelenburg position.[3] Consequently, nonsliding mattresses should be used, along with a concerted effort to avoid compression of the shoulders as much as possible.[25,26] Of the 311 brachial plexus injuries in the ASA Closed Claims Project, 59 (19%) occurred after a regional block without general anesthesia,[2] including axillary and interscalene blocks.[3] In those cases, the role of patient positioning cannot be determined.[3]

OTHER UPPER EXTREMITY NERVE INJURY

Although quite rare, the radial nerve can be injured from direct pressure as it traverses the spiral groove of the humerus in the lower one third of the arm. The injury often exhibits a wrist drop with an inability to abduct the thumb or extend the metacarpophalangeal joints. An isolated median nerve injury most often occurs during the insertion of an intravenous needle into the antecubital fossa in a patient who has been anesthetized where the nerve is adjacent to the medial cubital and basilic veins. Patients with this injury are unable to oppose the first and fifth digits and have decreased sensation over the palmar surface of the lateral three and one half fingers. Surprisingly, in an evaluation of the ASA Closed Claim database from 1970 to 2001, peripheral intravenous and arterial line insertion accounted for 2.1% of all claims filed, particularly among patients who underwent cardiac surgery where the arms were tucked and the lines were not visible for inspection.[97] Nerve injury accounted for 17% of intravenous line complications, second only to skin slough or necrosis (28%) and swelling, inflammation, and infection (17%).

LOWER EXTREMITY NERVE INJURY

Injuries to the sciatic and common peroneal nerves occur most often in the lithotomy position. Because of its fixation between the sciatic notch and the neck of the fibula, the sciatic nerve can be stretched with external rotation of the leg. The sciatic nerve and its branches cross the hip and knee joints and are stretched by hyperflexion of the hips or extension of the knees. The common peroneal nerve, a branch of the sciatic, is most often damaged from the compression between the head of the fibula and an external structure, such as the frame of a leg support. Most often, patients who suffer a peroneal nerve injury will complain of a foot drop and the inability to extend the toes in a dorsal direction or evert the foot. In a prospective study of 991 patients undergoing surgery under general anesthesia in the lithotomy position, the incidence of lower extremity neuropathies was 1.5%, with injuries to the sciatic and peroneal nerves representing 40% of the cases. Interestingly, symptoms were predominantly paresthesia with onset within 4 hours of surgery and resolution generally within 6 months. No motor deficits were noted, but in a previous retrospective study, the same authors found the incidence of severe motor disability in patients who underwent surgery in the lithotomy position to be 1 in 3608.[34,35]

Injury to the femoral or obturator nerves generally occurs from lower abdominal surgical procedures with excessive retraction. The obturator nerve can also be injured during a difficult forceps delivery or by excessive flexion of the thigh to the groin. A femoral neuropathy will exhibit decreased flexion of the hip, decreased extension of the knee, or a loss of sensation over the superior aspect of the thigh and medial or anteromedial side of the leg. An obturator neuropathy will exhibit an inability to adduct the leg with decreased sensation over the medial side of the thigh.

PERIOPERATIVE EYE INJURY AND VISUAL LOSS

Although quite rare, with an incidence of 0.056% in one retrospective review,[98] perioperative eye injuries are a source of significant morbidity and liability (see also Chapter 100). In the ASA Closed Claims database, eye complications made up 3% of all claims and were associated with greater monetary settlements as compared with nonocular injuries.[3]

Corneal abrasion continues to be the most common type of perioperative eye injury and is associated with direct trauma to the cornea from facemasks, surgical drapes, or other foreign objects. Corneal abrasion can also be associated with decreased basal tear production or swelling of the dependent eye in patients in the prone position. Patients complain of pain associated with a foreign body sensation in the eye upon awakening from surgery. This pain can also occur from a dried section of cornea. Symptoms are generally transient, and treatment is made up of supportive care and antibiotic ointment to prevent bacterial infection. In a prospective study of 671 patients undergoing nonocular surgery, 4.2% of patients reported a new onset of blurred vision lasting at least 3 days after surgery. For most patients, the symptoms resolved within 2 months without complication. However, 1% of patients required visits to eye care providers.[99] Precautionary measures to reduce the incidence of corneal abrasion include early and careful taping of the eyelids after the induction of anesthesia, an awareness of dangling objects when leaning over patients, and close observation as patients awaken. Before they are completely awake, patients often try to rub their eyes or nose with pulse oximeter probes, armboards, and intravenous lines attached, inadvertently endangering their eyes.

Postoperative visual loss is a devastating complication that has been associated with specific surgeries and patient risk factors. Chapter 100, "Postoperative Visual Loss," of this text is dedicated to this subject. Risk varies with the type of surgery. The incidence varies from a range of 1 in 60,965 to 1 in 125,234 for patients undergoing noncardiac, nonocular surgeries,[98,100] to 0.06% to 0.113% for patients undergoing cardiac surgery with cardiopulmonary bypass,[101,102] and 0.09% for patients undergoing spine surgery in the prone position.[103] Ischemic optic neuropathy (ION) and, to a lesser extent, central retinal arterial occlusion from direct retinal pressure are the conditions most cited as potential causes. Perioperative factors associated with an increased risk of ION include prolonged hypotension, long duration of surgery especially in the prone position, large blood loss, large crystalloid use, anemia or hemodilution, and increased intraocular or venous pressure from the prone position.[104,105] Intraocular pressure increases in the dependent eye in the lateral decubitus position as well.[106] In addition, steep Trendelenburg positioning for robotic prostatectomies has been shown to cause a time-dependent increase in intraocular pressure that is positively correlated with end-tidal carbon dioxide (ET_{CO_2}) concentration.[107] Patient risk factors associated with ION include hypertension, diabetes, atherosclerosis, morbid obesity, and tobacco use. However, with the exception of obvious

external compression of the eyes, the cause of perioperative visual loss appears to be multifactorial in nature with no consistent underlying mechanism.

In 1999, the ASA Committee on Professional Liability established the ASA Postoperative Visual Loss (POVL) Registry to better understand the complication. By 2005, 131 cases were reported to the registry, of which 73% of reported cases involved patients who underwent spine surgeries and 9% who underwent cardiac surgery.[108-110] Of the 93 patients with postoperative visual loss after prone spine surgery, Lee and associates reported that 89% were diagnosed with ION, predominantly posterior, and 11% with central retinal artery occlusion (CRAO). In patients who were diagnosed with ION, 66% had documented bilateral involvement, of which 42% had eventual improvement in vision, although often clinically insignificant. Compared with CRAO, patients with ION had significantly higher anesthetic duration (9.8 ± 3.1 versus 6.5 ± 2.2 hours), estimated blood loss (median 2 versus 0.75 liters) and crystalloid infusion (9.7 ± 4.7 versus 4.6 ± 1.7 liters). Patients with ION were also relatively healthy (64% ASA class I and II), and 73% were men.[110] Using a multicenter case-control design in a 2012 follow-up study, Lee and associates compared 80 patients who developed ION after spine surgery with 315 adult control patients without ION after spine fusion surgery, randomly selected from 17 institutions. After a multivariate analysis, they found that independent risk factors for ION after spine fusion surgery included obesity, male sex, Wilson frame use, longer anesthetic duration, greater estimated blood loss, and decreased percent of colloid administration.[111] However, although all of these patients were prone, the report does not include data on the tilt of the table, and cases for which multiple data fields (including table tilt) are missing, were eliminated from the POVL reports.

In 2006, the ASA issued a Practice Advisory for perioperative visual loss associated with spine surgery that was updated in 2012.[112,113] Positioning-related recommendations were the following:

- Avoid direct pressure on the eye to prevent CRAO.
- Position the high-risk patient to ensure that the head is level with or higher than the heart, when possible.
- Position the high-risk patient without significant neck flexion, extension, lateral flexion, or rotation, when possible.
- Avoid external compression of the abdomen or chest.

Although not scientifically proven, many consultants believed that the horseshoe head holder may increase intraocular pressure. No evidence suggests that facial edema or ocular compression causes anterior or posterior ION. Additional recommendations include frequent eye checks during surgery, although the required frequency has not been established; frequent checks may help prevent central retinal artery occlusion.[113] In addition, careful attention to factors related to oxygen delivery, including oxygen tension and the maintenance of adequate intravascular volume and cardiac output, is recommended.[114] The patient's vision should also be checked postoperatively when the patient is alert.[113] Unfortunately, no definite recommendations were made concerning the issue of induced hypotension, the use of vasopressors, specifically α-adrenergic agonists, or transfusion threshold because of the multifactorial nature and the low incidence of the injury.

Despite a lack of direct evidence, additional suggestions for patients at high risk for eye injury or visual loss who are undergoing complex spine surgery include the following:[112,113]

- Discuss the possibility of staging the spine surgery in consultation with the surgeon.
- Use colloids along with crystalloids to maintain intravascular volume. Consider placement of a central venous line for monitoring preload.
- For patients who are preoperatively anticipated to undergo procedures that are prolonged and have substantial blood loss (or both), consider informing the patients of a small, unpredictable risk of perioperative visual loss.

Until the causative factors of this devastating type of injury are better defined, debate regarding patient management strategies will likely continue. Intraocular pressures are increased in the dependent eye in the lateral position and in both eyes in the prone position in the absence of any external pressure. External eye pressure should be avoided at all times, time in the prone position should be limited whenever possible, and frequent eye checks should be documented when patients are in the prone position.

EVALUATION AND TREATMENT OF PERIOPERATIVE NEUROPATHIES

When a nerve injury becomes postoperatively apparent, performing and documenting a directed physical examination to correlate the extent of sensory or motor deficits with the preoperative examination and any intraoperative events is essential. Whether or not a cause is suspected, seeking consultation with a neurologist to help define the neurogenic basis, localize the site of the lesion, and determine the severity of injury is prudent to help determine the prognosis.[115,116] With proper diagnosis and management, most nerve injuries resolve; however, months to years may be required.[73] In addition, perioperative neuropathies associated with pain must be differentiated from surgically induced neuropathic pain, which is receiving increasing attention by surgeons because it postoperatively affects an estimated 10% to 40% of surgical patients postoperatively.[117]

For motor neuropathy, an electromyogram (EMG) can be performed to characterize the injury. An EMG examination involves recording the electrical activity of muscle from a needle electrode inserted within it. If present, abnormalities may point to the affected component in the motor unit, which consists of the anterior horn cell, its axon and neuromuscular junctions, and the muscle fibers that it innervates. Certain findings are suggestive of denervation, including the presence of abnormal spontaneous activity in the resting muscle (fibrillation potentials and positive sharp waves, which results from muscle irritability) and increased insertion activity. Insertion

activity increases within a few days of muscle denervation, whereas abnormal spontaneous activity takes 1 to 4 weeks to develop, depending on the distance from the nerve lesion to the muscle. From a medicolegal standpoint (see also Chapter 11), the presence of abnormal spontaneous activity in the acute setting may suggest the nerve injury was preoperatively present. In addition, depending on the pattern of abnormalities, an EMG study may distinguish between radiculopathies, plexopathies, and neuropathies. Electrodiagnostic testing will not, however, identify the cause of the neuropathy.

For anesthesiologists, nerve conduction studies may be more useful to evaluate potential peripheral nerve injuries, such as ulnar neuropathy. Nerve conduction studies permit the assessment of both motor and sensory nerves. To evaluate motor integrity, the nerve is supramaximally stimulated at two points along its course, and a recording is made of the electrical response of one of the muscles that it innervates. The size of the muscle action potential provides an estimate of the number of motor axons and muscle fibers that are activated by the stimulus. For sensory conduction studies, the nerve fiber is supramaximally stimulated at one point and the sensory nerve action potential is recorded from another point. The latency of the response can be interpreted as a reflection of the number of functioning sensory axons. Nerve conduction studies are useful for several reasons; they may reveal the presence of a subclinical polyneuropathy that made the individual nerves more susceptible to injury and help distinguish between axon loss and demyelination, which has significant implications regarding course and overall prognosis.

Most sensory neuropathies are generally transient and require only reassurance to the patient with follow-up visits, whereas most motor neuropathies include demyelination of peripheral fibers of a nerve trunk (neurapraxia) and generally take 4 to 6 weeks for recovery. Injury to the axon within an intact nerve sheath (axonotmesis) or complete nerve disruption (neurotmesis) can cause severe pain and disability. When reversible, recovery often takes 3 to 12 months. Interim physical therapy is recommended to prevent contractures and muscle atrophy.[115,116]

If a new sensory or motor deficit is found postoperatively, then electrophysiologic evaluation by a neurologist within the first week may provide useful information concerning the characteristic and temporal pattern of the injury. Another examination after 4 weeks, when enough time has elapsed for the electrophysiologic changes to evolve, will provide more definitive information about the site, nature, and severity of the nerve injury. Regardless, electrophysiologic testing must be interpreted within the clinical content for which it was obtained. No single test can define the cause of injury.

With regard to professional liability for perioperative nerve injuries, it is important for anesthesia providers to appreciate that case laws on assignment and apportionment of liability remain unsettled, largely because determining the patient's position during a procedure is not a core responsibility of the anesthesia provider.[118] In addition, injuries occur despite best practices. For perioperative ulnar neuropathy, opinion regarding its cause has evolved. Although once largely attributed to positioning in the surgical unit, the current consensus is that the cause is poorly understood, and injuries are not entirely preventable.[86,91] However, jurors and judges are not familiar with the surgical environment or practices, and the variety of "expert" opinions have contributed to a wide range of judicial outcomes with regard to the liability of anesthesiologists. Although the cooperation of the entire surgical team is required, the position for surgery is largely dictated and accepted or modified by the surgeon. National guidelines and institutional policies and procedures may help address the responsibility of team members regarding patient positioning and highlight the primary roles of the anesthesia provider, which are to protect the airway and vascular access and to promote physiologic homeostasis while the patient is in the requested position.[118]

ANESTHESIA OUTSIDE THE OPERATING ROOM

Anesthesia care providers are increasingly involved with procedures performed for gastrointestinal endoscopy, cardiac catheterization, interventional radiology, neuroradiology, magnetic resonance imaging, and computed tomography, as well as for office-based procedures (see also Chapter 90).[119] Anesthesia care may be specifically requested because an individual is not expected to tolerate the position required for the procedure because of comorbidities such as congestive heart failure, pulmonary disease, or morbid obesity. Additionally, although positions that are customarily used for procedures without anesthesia may be generally safe for patients who are awake, they may pose serious risks to those under anesthesia.

Because of the less familiar environment, relative lack of positioning equipment, and a variability in staff and nursing training with regard to patient positioning, vigilance is particularly important in settings outside the surgical unit to maintain patient safety. Many locations have not routinely had safety straps or arm supports available, for example. Diagnostic tables may not lend themselves to established intraoperative solutions to patient positioning challenges. The ability to initiate the Trendelenburg position to augment venous return and cardiac output rapidly is often lacking. When procedures are performed without securing the airway, accurate carbon dioxide monitoring is difficult. Detection of respiratory depression requires constant attention, because decreases in oxygen saturation are delayed if supplemental oxygen is being delivered. In some settings, such as magnetic resonance imaging and radiation therapy, the anesthesiologist is not in direct proximity to the patient, and vigilance is more challenging. Special monitors and video cameras are often required to supplement limited or no direct visibility of the patient or anesthesia equipment.

Currently, the number of claims in the ASA Closed Claims database for injuries during anesthesia care outside the surgical unit is extremely small (33 versus 4291 claims for intraoperative surgical anesthesia). However, 54% of these claims are associated with death, 63% with substandard care (predominantly the result of inadequate monitoring), and 58% involve monitored anesthesia

care among patients who were ASA class III to V, most of whom were at the extremes of age.[78] In such an environment, where practice patterns often evolve in the context of nonanesthetized patients, the anesthesiologist is especially important for verifying the safety of each patient's position and for implementing guidelines for patients under anesthesia.

CONCLUSION

The positioning of patients under anesthesia care is a major responsibility requiring great attention to detail and constant vigilance. Rapid positioning and optimal surgical exposure are virtues that may be instantly appreciated; however, the potential for lasting harm to patients from improper positioning and physiologic compromise must guide our actions. Each position has significant physiologic effects on ventilation and circulation. In addition, despite increased awareness, position-related complications, including peripheral nerve injuries, continue to remain a significant source of patient morbidity. As surgical techniques evolve, extreme positions sometimes permit advantages, such as smaller incisions and more effective displacement of internal organs to facilitate surgical exposure. Unfortunately, associated risks may increase with positions that would not be tolerated when patients are awake. Anesthesiologists, surgeons, and nurses must work together when each patient is positioned to promote comfort and safety in addition to the desired surgical exposure. Ideally, the final position should appear natural; that is, a position that the patient would comfortably tolerate if awake and unsedated for the anticipated duration of the procedure.

Chapter 42

Neuromuscular Disorders and Other Genetic Disorders

ALA NOZARI • ARANYA BAGCHI • RICHA SAXENA • BRIAN T. BATEMAN

Acknowledgment: The editors and publisher would like to thank Drs. Jie Zhou, Paul D. Allen, Isaac N. Pessah, and Mohamed Naguid for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Management of anesthesia in patients with acquired or inherited neuropathies introduces challenges for protecting the involved nerves against pressure, entrapment, or trauma associated with positioning of nerve blocks. Neurologic deficits are assessed and documented before the administration of regional anesthesia (see Chapters 56 and 57).
- Patients with autonomic dysfunction caused by conditions such as diabetes neuropathy or Guillain-Barré syndrome (GBS) are at increased risk for exaggerated hemodynamic response to anesthetics, as well as for aspiration of gastric contents from delayed gastric emptying.
- Prolonged immobility in patients who are critically ill is associated with a relative increase in immature acetylcholine receptors that can lead to insensitivity to nondepolarizing neuromuscular blocking drugs (NMBDs) or sensitivity to depolarizing neuromuscular blockers with the risk for increased potassium efflux (see also Chapter 34).
- Monitoring the neuromuscular transmission is mandatory in patients with myasthenia gravis (MG) if nondepolarizing NMBDs are to be administered. These patients may be extremely sensitive to nondepolarizing NMBDs and yet require a larger dose of succinylcholine than patients who do not have MG (see also Chapter 53).
- Lambert-Eaton myasthenic syndrome (LEMS) is caused by antibodies to the voltage-gated calcium channels on the presynaptic motoneuron terminals, with decreased acetylcholine release in the neuromuscular junction. Sensitivity to depolarizing and nondepolarizing NMBDs is increased, and the response to anticholinesterases is insufficient.
- Spinal anesthesia has been implicated in the postoperative exacerbation of multiple sclerosis (MS), but epidural application of low concentrations of local anesthetics has been successfully used in these patients.
- Because of the risk for rhabdomyolysis and hyperkalemia, succinylcholine should be avoided in patients with amyotrophic lateral sclerosis (ALS), Duchenne muscular dystrophy (DMD), and Becker muscular dystrophy (BMD) (see also Chapters 34 and 43).
- Cardiomyopathy and a progressive decline of pulmonary function are common in patients with DMD and may predispose them to perioperative pulmonary and cardiac complications. Volatile anesthetics are best avoided, and the use of total intravenous (IV) anesthesia should be considered in these patients when possible.
- Pulmonary complications caused by hypotonia, chronic aspiration of gastric contents, and central and peripheral hypoventilation are common in patients with myotonic dystrophy (DM) (see also Chapter 43). The possibility of prolonged postoperative mechanical ventilation should be considered. Cardiac manifestations of this disease include conduction abnormalities, arrhythmias, and cardiomyopathy.
- The extent of organ system involvement should be carefully assessed and documented in patients with mitochondrial disease, with particular emphasis on the degree of myopathy, endocrine and metabolic derangements, and neurologic function.

KEY POINTS—cont'd

- Evidence does not suggest that patients with hyperkalemic periodic paralysis (HyperPP) are susceptible to malignant hyperthermia (MH). Maintaining normothermia, preventing hyperkalemia, and avoiding hypoglycemia are important in these patients (see also Chapter 43).
- The genetics of mitochondrial disorders is a special case of mendelian disorders, and defects may be in mitochondrial DNA (mtDNA)–encoded or nuclear DNA (nDNA)–encoded structural or regulatory components of the mitochondrion. Recent genetic research has begun to unlock the basis for other complex diseases, which will facilitate a better understanding of perioperative implications and provide more effective and safe treatments for individual patients.

Diseases that affect peripheral nerves, neuromuscular junction, and muscles are rarely encountered in routine anesthetic practice but pose significant challenges to the perioperative management of the affected patient. Cardiovascular and respiratory systems are often involved, posing an increased risk for perioperative dysrhythmias, hypotension, or respiratory failure. Adverse reactions to neuromuscular blocking drugs (NMBDs) should be considered and may include severe hyperkalemia or prolonged paralysis. Autonomic dysreflexia, when present, increases the risk for cardiovascular instability or aspiration upon anesthesia induction. A thorough knowledge of organ system involvement is mandatory, and the choice of anesthetics and NMBDs has to be tailored to the specific needs of each patient.

In this chapter, some of the most common neuromuscular disorders and their anesthetic implications are reviewed. An overview of the genetics of the mendelian disorders and mitochondrial and complex diseases is also provided, and their implications for clinical translation and perioperative care are discussed. Lastly, because some of these disorders are related to malignant hyperthermia (MH), they are also discussed in Chapter 43. A comparison of these two conditions will provide additional points of view for the reader.

ACQUIRED AND HEREDITARY NEUROPATHIES

Lesions of peripheral nerves produce motor weakness or sensory disturbance and are accompanied by decreased muscle stretch reflexes. Mononeuropathies involve a single nerve and are commonly due to a compression associated with immobilization, entrapment, ischemia, or trauma with stretch or laceration. Carpal tunnel syndrome is the most common entrapment neuropathy caused by compression of the median nerve in the wrist, which results in pain, paresthesias of the hand and fingers, and sensory loss in the distal median nerve territory, including the thenar eminence.[1] Weakness of thumb adduction and opposition, resulting in a loss of grip strength, is a typical symptom. Comorbid conditions such as hypothyroidism and diabetes mellitus should be considered, and electromyography and nerve conduction study findings should be obtained for diagnosis and prognostication. Ulnar nerve compression and injury at the condylar groove, which lacks soft-tissue protection, is the most common perioperative peripheral neuropathy.[2] Symptoms include paresthesia of the fourth and fifth digits and weakness of the intrinsic muscles demonstrated as grip weakness and, in severe cases, clawhand. The brachial plexus with its relatively long course from the vertebral foramina to the axilla and its proximity to many mobile bony structures is particularly susceptible to injury from poor perioperative positioning.[3] Brachial plexus injuries may occur, nevertheless, despite appropriate positioning and padding during surgery. The association between hypertension and diabetes mellitus with perioperative peripheral nerve injuries[4] suggests a multifactorial etiologic origin. Over 40% of patients with diabetes are reported to develop clinical symptoms or electrophysiologic evidence of neuropathy.[5] Diabetic neuropathy includes a number of distinct clinical syndromes such as primary sensory polyneuropathy with symmetric and slowly progressive neuropathy of the feet and legs; autonomic neuropathy involving the bladder, bowel, and circulatory reflexes; and plexus neuropathy with severe hip, thigh, and knee pain, as well as weakness in the quadriceps muscles, which usually improves within weeks to months. Diabetic amyotrophy or Bruns-Garland syndrome (also known as *ischemic mononeuropathy multiplex*) is another form of plexus neuropathy with abrupt onset of asymmetric pain in the back, hips, thigh, or leg, and progressive muscle weakness.[6] Treatment is primarily expectant, although immunotherapy may be considered in severe cases. In patients who are critically ill, phrenic nerve mononeuropathy may develop as a result of prolonged systemic inflammation with immobilization during mechanical ventilation. This condition is diagnosed by electroneurography and diaphragmatic electromyographic recordings and may interfere with the ability to wean the patient from ventilator dependency and may prolong the stay in the intensive care unit (ICU).

Inherited neuropathies include Charcot-Marie-Tooth (CMT) diseases and hereditary neuropathy with liability to pressure palsies (HNPP). CMT affects approximately 1 in 2500 people and represents the most common inherited neurologic disorder.[7,8] It is not a single disease entity; rather, CMT represents a spectrum of disorders caused by mutations in myelin or axonal genes.[9]

Although traditionally classified as types 1 through 7, based on electrophysiologic, histologic, and clinical characteristics, multiple genetic subtypes[7,9] and mutations exist in more than 30 genes involving more than 40 distinct loci that give rise to the disorder.[7] The pattern of genetic inheritance is most commonly autosomal dominant, but X-linked and autosomal recessive forms also exist, as do sporadic cases as a result of new mutations.[7] In approximately two thirds of cases, demyelination as a result of mutations in genes expressed in Schwann cells causes the disorder; axonal dysfunction as a result of mutations expressed in neuronal cells cause the balance of the cases.[7,10] Demyelination, slowed motor nerve conduction velocities, and an autosomal dominant pattern of inheritance characterize CMT1, the most common type.[9] The most prevalent form of CMT1 is subtype CMT1A, which accounts for approximately 75% of CMT1 cases.[7] A 1.4 megabase (Mb) duplication in chromosome 17p11.2 causes CMT1A.[9,11] Patients with CMT typically experience progressive distal muscle weakness and wasting with hyporeflexia or areflexia. Mild sensory loss in a glove and stocking distribution, lower extremity deformity (peroneal muscle atrophy is typical), kyphoscoliosis, and neuropathic pain may also develop in some patients. Pes cavus (clawfoot) with hammer toes, footdrop, and frequent ankle sprains are not uncommon.[9] Onset generally occurs by 20 years of age; although the disorder does not compromise lifespan, it can cause significant disability. Variant forms of CMT exist, including Dejerine-Sottas neuropathy and congenital hypomyelination, which are characterized by onset in infancy and are sometimes fatal.[9]

Similar to CMT, HNPP is a slowly progressive neuropathy, but focal areas of irregular thickening of myelin sheaths (tomaculae) cause HNPP, and it demonstrates recurrent focal neuropathies caused by minor trauma.[12] HNPP typically develops during adolescence with attacks of numbness, muscle weakness, peroneal palsies, carpal tunnel syndrome, and other entrapment neuropathies. A nerve conduction study showed focal conduction block at the site of injury and generalized mild slowing, consistent with diffuse demyelinating disease. Some patients may have long-term neurologic dysfunction, but many show complete recovery after a focal neuropathy.

ANESTHETIC CONSIDERATIONS

Management of anesthesia in patients with mononeuropathies introduces challenges for protection of the involved nerve against further entrapment or trauma associated with positioning. Autonomic neuropathy may be associated with exaggerated hemodynamic response to the anesthetic as a result of involvement of the circulatory reflexes. Patients with diabetic autonomic neuropathy are also at greater risk for aspiration pneumonitis from delayed gastric emptying of food particles.[13]

Patients with CMT frequently require orthopedic surgery to correct the musculoskeletal manifestations of the disease, including foot and ankle defects, spinal deformities, and hip dysplasia.[14] Evidence regarding the anesthetic management of patients with CMT is limited and consists primarily of case reports and clinical series. Nevertheless, important concerns exist when anesthetizing patients with this condition, based on these reports and pathophysiologic considerations. Major considerations for the perioperative care of patients with CMT include the risk of adverse reactions to NMBDs, a susceptibility to MH, and the potential for respiratory weakness requiring prolonged ventilatory support. An increased sensitivity to hypnotic anesthetics has also been suggested, but intravenous and volatile anesthetics have been used in patients with CMT with no reported complications.[15] Nevertheless, multiple reports of worsening CMT symptoms have been recounted in patients exposed to nitrous oxide,[16] such that this agent should be avoided when possible. Other medications that are administered in the perioperative period that have been associated with worsening CMT include metronidazole, amiodarone, linezolid, and nitrofurantoin.[16]

The literature provides conflicting reports regarding the responses to NMBDs in patients with CMT. Pogson and associates reported an increased sensitivity to vecuronium,[17] whereas cisatracurium and mivacurium have been used with no evident prolongation of the neuromuscular blockade.[18-20] Because of the demyelination that occurs in the distal extremities, monitoring the neuromuscular blockade should preferentially occur at the facial rather than the ulnar nerve. Although succinylcholine has been successfully used in these patients,[21] clinicians are cautioned against its routine use, considering the risk of an exaggerated hyperkalemic response.[22] A single case report of MH associated with the administration of sevoflurane to a patient with CMT has been reported.[23,24] However, in the largest clinical series published to date, 77 patients with CMT were exposed to triggering anesthetics without complications.[25] No established association between CMT and MH has been established, and volatile anesthetics can be reasonably used in these patients.[24]

Regional anesthesia has been used in patients with CMT without clear evidence of associated complications.[25-28] Because of the concern for exacerbating the neurologic symptoms, however, regional anesthesia techniques are often avoided in these patients. Ultrasound-guided peripheral nerve blocks may reduce the risk of neurologic complications but should be reserved for patients with major risks for general anesthesia.[29] Neuraxial anesthesia has also been used for obstetric procedures in these patients, often with no reported exacerbation of their neurologic symptoms.[26,30] It is important that neurologic deficits are assessed and documented before administering anesthesia.[24]

As with CMT, patients with HNPP pose special concerns for their response to NMBDs, as well as the risk to exacerbate neurologic symptoms from patient positioning. The immobility associated with general anesthesia or regional block can potentially trigger pressure palsies in these patients. However, current literature provides no evidence against the use of neuraxial techniques or local anesthetics.[31] Despite the lack of evidence on the effects of surgical positioning in patients with HNPP, it is reasonable to assume that judicious positioning and thorough padding will reduce the risk of neurologic complications.

GUILLAIN-BARRÉ SYNDROME OR ACUTE INFLAMMATORY DEMYELINATING POLYRADICULOPATHY

Guillain-Barré syndrome (GBS) or acute inflammatory demyelinating polyradiculopathy (AIDP) is an acute onset of progressive peripheral neuropathy that is triggered by humoral and cell-mediated autoimmune response to a sensitizing event, such as a respiratory tract infection.[32] Its presentation is typically an ascending paralysis characterized by symmetric weakness that can vary from mild difficulty with walking to nearly complete paralysis of all extremities, facial, respiratory, and bulbar muscles. Mild variants can exhibit ataxia, ophthalmoplegia, or hyporeflexia without significant appendicular weakness. Fulminate cases can express severe ascending weakness leading to complete tetraplegia, as well as to paralysis of cranial nerves and phrenic and intercostal nerves leading to facial and respiratory muscle weakness that necessitates ventilatory support.[33] Autonomic dysfunction may occur and can cause hemodynamic instability and arrhythmias with the risk for sudden circulatory collapse and death.

Diagnosis is made based on clinical features such as areflexia and progressive motor weakness, cerebrospinal fluid (CSF) analysis with elevated protein but no pleocytosis (albuminocytologic dissociation), and electrophysiologic studies.[34] Electromyography and nerve conduction studies may be normal in the early acute period, but characteristic segmental demyelination and reduction of conduction velocity and dispersion or absence of F waves are usually observed within 1 to 2 weeks.

Management includes respiratory support, measures to prevent aspiration, and nutritional support. Early plasma exchange, typically five exchanges with 5% albumin repletion, may mitigate the course but is contraindicated in a setting of hemodynamic instability, prominent dysautonomia, and active bleeding.[35] Intravenous immunoglobulin (IVIG) is typically administered in the setting of dysautonomia or when a significant risk for catheter-related complications exist with plasmapheresis or when an exchange transfusion is performed.

ANESTHETIC CONSIDERATIONS

Cranial nerve paralysis and autonomic dysfunction predispose patients with GBS to an increased risk for aspiration. Aspiration precautions, including decompression of the stomach, should therefore be considered before the induction of anesthesia. An absence of compensatory cardiovascular responses may be associated with exaggerated hypotension at anesthesia induction or in response to hypovolemia. Conversely, laryngoscopy or noxious stimuli can be associated with an exaggerated increase in blood pressure. The hemodynamic instability is typically short-lived and self-limited, but small doses of short-acting and titratable vasoactive medications may be required.[36] Careful hemodynamic monitoring is essential, and continuous monitoring of the blood pressure with an arterial catheter is often considered. These patients may also exhibit abnormal responses to NMBDs, with a hyperkalemic response to succinylcholine *even after clinical resolution of symptoms*.[37] Nondepolarizing NMBDs can be used but are typically avoided because of the risk of prolonged muscle weakness. If these drugs are used, then the neuromuscular transmission should be closely monitored with a nerve stimulator since both resistance and sensitivity to these anesthetics have been reported.[38] Regional anesthesia is used by some practitioners,[39] but its use remains controversial because worsening neurologic symptoms have been reported.[40]

CRITICAL ILLNESS POLYNEUROPATHY AND CRITICAL ILLNESS MYOPATHY

Bolton and associates identified critical illness polyneuropathy (CIP) in 1987 and described this condition as a characteristically widespread axonal degeneration among motor and sensory fibers with subsequent extensive denervation atrophy of limb and respiratory muscle associated with polyneuropathy.[41] Although the true incidence of CIP is difficult to determine, critical illness neuropathy and critical illness myopathy (CIM) are believed to affect up to 50% of all patients remaining in the ICU for longer than 2 weeks.[42] Bolton also defined the myosin loss syndrome that is often observed in patients with CIM. This condition shows histologic signs of myosin loss, as opposed to actin, in skeletal muscle biopsies from affected muscles. The ratio of myosin to actin is typically below 1.0 with some patients showing a complete absence of myosin in skeletal muscle cells. The typical clinical manifestation consists of a profound symmetric limb weakness with reduced or absent tendon reflexes and diaphragmatic and intercostal weakness. CIM affects the lower extremities to a greater extent than the upper extremities and the distal muscle groups more severely than the proximal muscle groups. The autonomic function is not affected, and the extraocular eye movements remain intact. In CIP, no evidence of a neuromuscular junction disorder exists, and the electromyography and nerve conduction study findings are consistent with axonal motor and sensory polyneuropathy with amplitude reduction of motor and sensory action potentials and slowed conduction velocities. Serum creatine kinase levels are usually normal. Conversely, sensory nerve action potential is often normal in CIM, but compound muscle action potentials are diminished and electromyographic findings are consistent with myopathy. Serum creatine kinase levels may be elevated. No specific treatments are currently available, and management is supportive with aggressive and early rehabilitation. The use of sedation, paralytics, and corticosteroids should be limited,[43] and aggressive control of hyperglycemia can reduce the incidence of CIP by 44%.[44]

ANESTHETIC CONSIDERATIONS

Anesthetic considerations in these patients are similar to those with other acquired neuropathies (see previous text) and include protection of nerve compression sites, particularly the ulnar and peroneal nerves. Prolonged immobility in patients who are critically ill is associated with a relative increase in immature acetylcholine receptors that can lead to an insensitivity to nondepolarizing NMBDs.[45]

Conversely, the sensitivity to a depolarizing NMBD (succinylcholine) is increased, with a risk for increased potassium efflux after succinylcholine administration.[46]

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disorder of synaptic transmission caused by antibodies against nicotinic acetylcholine receptors (nAChRs). With an annual incidence of 1 in 200,000 to 500,000, MG has a prevalence of 0.5 to 14.2 per 100,000 in the United States and primarily affects women 20 to 30 years of age and men 60 to 80 years of age. Autoantibodies against the α-subunit of the muscle-type nAChRs destroy these receptors in the neuromuscular junction and cause transmission failure, manifested as muscle weakness and fatigue. The origin of these antibodies is not always known, but they may be associated with thymomas or thymic hyperplasia (80% of generalized MG and 30% to 50% of ocular MG). Autoantibodies against the muscle-specific tyrosine kinase (MuSK) are associated with the human leukocyte antigen (HLA)–B8 and the DRw3 antigen and are primarily identified in younger patients with MG.[47] Skeletal muscles innervated by cranial nerves are especially vulnerable, the involvement of which can lead to extraocular and facial muscle weakness or bulbar and oropharyngeal weakness. Speech and chewing may be affected, as well as the pharyngeal function and coordination of swallowing, placing the patient at an increased risk of pulmonary aspiration of gastric or oral contents. Skeletal muscle weakness in MG worsens with repetition or throughout the course of the day and, conversely, improves after rest. The clinical course may also be marked by periods of exacerbation and remission. Myocarditis, atrial fibrillation, heart block, takotsubo cardiomyopathy, and sympathetic hyperactivity with fluctuations in heart rate and blood pressure have been described in these patients.[48,49] The diagnosis of MG is made by neurologic examination and testing of the tendency to exhibit increased muscle weakness during exercise or repeated contractions. The response to edrophonium, which is administered as a 1- to 2-mg test dose followed by 8 mg intravenously, can confirm the diagnosis (Tensilon test). Improvement in the patient's preexisting weakness should be evident within 1 to 5 minutes of drug administration. Serologic studies include serum antibodies for acetylcholine receptor (present in 95% of patients), striated muscle, and MuSK (present in 65% of patients who are acetylcholine-receptor negative). Electromyography shows increased jitter, and nerve conduction studies with repetitive simulation produce decremental responses.[50] Management includes supportive care with mechanical ventilation as needed and the administration of cholinesterase inhibitors such as pyridostigmine.[51,52] Immunomodulatory drugs such as steroids and azathioprine are effective but have a delayed onset of action. Although steroids are shown to reduce the number of antibodies to the acetylcholine receptors and can significantly improve the symptoms, they may cause a transient worsening of the weakness at the initiation of therapy. IVIG and plasma exchange can be used for more rapid response in patients with severe bulbar and oropharyngeal dysfunction or those with MG crisis. Thymoma resection is helpful for paraneoplastic myasthenia, but its benefit in nonthymomatous autoimmune MG has not been conclusively established.[53]

ANESTHETIC CONSIDERATIONS

A thorough review of the neurologic symptoms and medications is of paramount importance. The ability of the patient with MG to protect and maintain a patent airway, to cough, and to clear secretions should be thoroughly assessed. These patients should be advised of the risk for worsening symptoms, which can require prolonged postoperative mechanical ventilation. Increased risk for postoperative myasthenic crisis and ventilatory support is possible if these conditions exist: prolonged duration of disease (longer than 6 years), presence of previous respiratory problems or coexisting lung disease, pyridostigmine doses of more than 750 mg/day, and preoperative forced vital capacity of less than 2.9 L have been suggested to predict increased risk for postoperative myasthenic crisis and ventilatory support.[54] The presence of bulbar symptoms, history of preoperative myasthenic crisis, preoperative serum antiacetylcholine receptor antibody level greater than 100 nmol/L, and intraoperative blood loss greater than 1000 mL have also been associated with postsurgical myasthenic crisis.[55] Elective surgeries should be performed during a stable phase of the disease and when the patient requires minimal immunomodulatory medication. Most of these medications do not interact with anesthetic agents, but azathioprine can inhibit nondepolarizing NMBDs and may extend the effect of succinylcholine. Most clinicians recommend that patients should keep taking their anticholinesterase medication on the day of surgery, but their interaction with the NMBDs should be considered.[56] A reduced number of functional acetylcholine receptors results in an increased sensitivity to nondepolarizing NMBDs.[57,58] Monitoring the neuromuscular transmission is mandatory, but clinicians should be cognizant of the possibility to overestimate the degree of neuromuscular blockade in these patients, particularly when the orbicularis oculi muscle responses are monitored. In addition, an uneven spread of muscle weakness exists; therefore, routine neuromuscular monitoring at one site (e.g., the hand) does not adequately represent the actual level of block in other muscle groups. The dose of these NMBDs should be cautiously titrated, such as by the administration of small increments corresponding to 0.1 to 0.2 times the 95% effective dose (ED_{95}) until the desired effect is achieved. Succinylcholine, on the other hand, often needs to be administered in larger-than-normal doses (ED_{95} 2.6 times the patient without MG) because of the decreased number of functional acetylcholine receptors.[59] A rapid desensitization of the myasthenic endplate receptors to succinylcholine has also been reported, indicating a susceptibility to developing phase II neuromuscular block.[60] Potent volatile anesthetics have been successfully used in patients with MG, and they commonly cause profound muscular relaxation, enough to allow most surgical procedures to be performed without the need for an NMBD.[61] Intravenous induction anesthetics and opioids have also been used

without significant adverse effects. If regional anesthesia is used, then careful monitoring of muscle function and ventilation is equally important. As ester-type local anesthetics are metabolized by the pseudocholinesterase, anticholinesterase treatment in patients with MG may potentiate their effects and lead to prolonged blockade. Although amide local anesthetics have been successfully used in patients with MG, judicious dosing is essential, as is the preparedness to manage worsening muscle weakness safely.[62,63]

LAMBERT-EATON-MYASTHENIC SYNDROME

Lambert-Eaton myasthenic syndrome (LEMS) is caused by antibodies to the voltage-gated calcium channels on the presynaptic motoneuron terminals, which lead to a decreased release of acetylcholine. This syndrome is frequently part of the paraneoplastic phenomenon (typically, a small-cell lung cancer is present in 50% to 60% of patients) but can also occur without associated cancer.[64] In more than 80% of patients with associated cancer, symptomatic onset of myasthenia precedes the diagnosis of their cancer. Symptoms are usually subacute at onset and are typically characterized by weakness in the proximal lower extremities, although upper extremity weakness, bulbar symptoms, and respiratory muscle weakness may also be present. Unlike MG, patients with LEMS are usually worse in the morning and gradually improve throughout the day. Their weakness also improves after brief exercise but can worsen with sustained physical activity. Improvement of muscle function with exercise is due to the accumulation of presynaptic calcium and subsequent improved release of acetylcholine. Autonomic dysfunction and cholinergic symptoms, including dryness of the mouth and impaired lacrimation, may be present. The diagnosis of LEMS is made by physical examination, showing proximal lower limb weakness, depressed tendon reflexes with posttetanic potentiation, and evidence of autonomic disturbances. Electromyography typically shows small compound muscle action potential (CMAP) amplitudes and a transient incremental CMAP response to rapid nerve stimulation (20 to 50 Hz) but a decremental response to slow nerve stimulation (1 to 5 Hz).[65] Autoantibodies against P/Q-type voltage-gated calcium channels are highly specific and have been detected in 85% to 90% of patients with LEMS.[66]

Cholinesterase inhibitors do not consistently produce improvement in these patients but may improve the muscle weakness or dry mouth in some. Aminopyridines (e.g., 3,4-diaminopyridine) are the first-line treatment for patients with symptomatic LEMS and improve the strength and autonomic function with minimal side effects in most patients.[67] Aggressive immunotherapy, plasma exchange, and immunoglobulin therapy result in rapid but transient improvement of symptoms.

ANESTHETIC CONSIDERATIONS

Similar to patients with MG, those with LEMS should be carefully assessed for the risk of postoperative respiratory failure and the need for prolonged mechanical ventilation. Sensitivity to depolarizing and nondepolarizing NMBDs is increased, and the response to anticholinesterases is insufficient. Autonomic dysfunction may be associated with an exaggerated response to vasodilators and anesthesia induction drugs. Close monitoring of the neuromuscular transmission is important, and in patients whose train-of-four responses are insufficient, monitoring of the tetanic stimulation and posttetanic facilitation should be considered.[68] Reversal of the neuromuscular blockade with anticholinesterase drugs may be ineffective in patients who receive aminopyridines, and a combination of oral aminopyridine and an anticholinesterase may be more effective.[69] Epidural anesthesia has been successfully used in these patients,[70] but, as with patients with MG, neuraxial anesthesia should be used with extreme caution in patients with LEMS, considering the possibility of increasing muscle weakness and respiratory failure.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a demyelinating disease of the optic nerves, cerebrum, and spinal cord where it primarily affects the corticospinal tract and posterior columns. It is considered an autoimmune disorder and is characterized by sensitization of the peripheral leukocytes to the myelin antigen and a subsequent inflammatory response, monocytic and lymphocytic perivascular cuffing and glial scars, with plaque formation within the central nervous system, especially in the periventricular white matter. Genetic predisposition and environmental factors have also been implicated in its pathophysiologic mechanisms. The disease affects mainly women between 10 to 60 years of age, with the greatest peak between ages 20 to 40 years. Exacerbations and remissions characterize its clinical course in most patients, but continuous neurologic deterioration is also reported in up to 10% of cases (primary progressive MS). Acute symptoms, which are related to the site and extent of sclerosing central nervous system plaque, commonly include visual disturbances (e.g., diplopia, blurring, field cuts), sensory abnormalities with numbness and paresthesias, and an electric shock sensation that radiates down the spine and into the limbs upon flexion of the neck (Lhermitte sign). Cranial nerve dysfunction, ataxia, and bladder and bowel disturbances are also common. A localized or, late in the course of the disease, generalized muscle weakness with the legs affected more than the arms is typical. Chronic symptoms can also include spastic paraparesis, appendicular tremor, and psychiatric disturbances such as depression or euphoria (la belle indifférence) and dementia. In severe cases, respiration may be involved with the development of hypoxemia. MS can be associated with autonomic dysfunction and, hence, an increased risk for exaggerated hemodynamic response to anesthetic induction, vasodilator, and sympathomimetic drugs.[71] A diagnosis of MS is currently based on a combination of clinical symptoms and laboratory tests, including CSF antibody analysis and radiology (detection of central nervous system plaque by magnetic resonance imaging). Diagnosing MS after

a single, acute remitting, clinically isolated syndrome is discouraged, whereas repeated attacks with increased CSF immunoglobulin G (IgG) and multifocal magnetic resonance imaging abnormalities are strongly supportive of the diagnosis.[72] Acute attacks are treated with various combinations of immunosuppression modalities including glucocorticoids, which have been shown to increase the rate of recovery but not an overall level of recovered function. Preventive therapy with interferon β1a or glatiramer acetate (a mixture of polypeptides synthesized to mimic myelin basic protein) may be used in individuals with the relapsing-remitting subtype of MS. Specific treatments aimed at chronic symptoms include baclofen and benzodiazepines for spasticity, anticonvulsants or propranolol for tremor, oxybutynin and propantheline for bladder spasticity, and selective serotonin reuptake inhibitors (SSRIs) or other antidepressive agents for mood disorders.

ANESTHETIC CONSIDERATIONS

MS symptoms may be intensified after physical and emotional stress or in the perioperative period. These patients should therefore be informed of the impact of surgical stress on the natural progression of the disease and the potential for aggravated symptoms in the postoperative period, regardless of the anesthetic approach. Increased body temperature is often cited as an offending mechanism, possibly by causing a complete block of conduction in demyelinated nerves. Body temperature should therefore be closely monitored and controlled during the perioperative period. Great care must also be exercised to minimize changes in fluid homeostasis and central hemodynamics (i.e., preload, afterload). In general, preoperative chronic immunosuppressive medications should be continued during the perioperative period. Although the literature provides no evidence to support the use of any specific inhaled or intravenous anesthetic, many clinicians believe that general anesthesia causes fewer exacerbations and is superior to neuraxial techniques in these patients. Avoiding administering depolarizing NMBDs such as succinylcholine to patients with MS is reasonable; denervation or misuse myopathy may lead to a risk for exaggerated release of muscle potassium, causing hyperkalemia and cardiac arrhythmias. Nondepolarizing NMBDs are safe to use but should be cautiously administered since both prolonged responses (increased sensitivity in patients with preexisting muscle weakness) and resistance to these NMBDs have been reported. Speculation suggests that the demyelination associated with MS renders the spinal cord susceptible to the neurotoxic effects of local anesthetics. Nevertheless, epidural application of low concentrations of local anesthetics has been successfully used in patients with MS.[73] Spinal anesthesia, on the other hand, has been implicated in postoperative exacerbations of MS symptoms. Because demyelination may also damage the blood-brain barrier, spinal anesthesia is usually not recommended for these patients. Clearly, the need for postoperative care is dependent on the preoperative symptoms, the type of surgery, and the expected complications. The need for extended postoperative care and respiratory support should be considered for those with severe preoperative weakness, respiratory compromise, and pharyngeal dysfunction.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is a mixed upper and lower motor neuron disease with degeneration of anterior horn α-motoneurons in the spinal cord and brainstem motor nuclei and corticospinal tracts. Patients demonstrate gradually spreading focal weakness and muscle atrophy (typically of the hands), spasticity, and hyperreflexia of lower extremities. Dysarthria and dysphagia, tongue atrophy, and fasciculations may also occur. Progressive weakness can lead to respiratory failure and death. Sensory functions, including intellectual capacity and cognition, as well as bowel and bladder function, are not usually affected in ALS.

ALS has an incidence of approximately 2 in 100,000 and prevalence of 4 to 6 per 100,000. The onset of the disease usually occurs between 50 and 75 years of age, and men are more often affected than women. Most cases are sporadic, and although the pathophysiologic process remains unclear, an association with superoxide dismutase (SOD) mutations has been suggested. SOD is an important antioxidant, and its mutation can lead to decreased clearance of free radicals, increased oxidative stress, and mitochondrial dysfunction. Most familial forms are associated with the mutation of *C9ORF72* on 9p21, *TDP43*, *FUS*, and *VCP* genes. Electromyographic and electroneurographic studies and neurologic examination, which demonstrates early spastic weakness of the upper and lower extremities, typical subcutaneous muscle fasciculations, and bulbar involvement affecting pharyngeal function, speech, and the facial muscles, confirm the diagnosis. No curative treatment is currently available, and patients are therefore treated symptomatically. Riluzole, a glutamate-release inhibitor, may provide neuroprotection and extend survival in these patients.[74] Tracheostomy and gastrostomy surgeries and other supportive treatments including mechanical ventilation are often required.

ANESTHETIC CONSIDERATIONS

Patients with ALS may have an increased sensitivity to the respiratory depressant effects of sedatives and hypnotics. Bulbar involvement, in combination with respiratory muscle weakness, leads to a risk for aspiration and pulmonary complications. Sympathetic hyperreactivity and the implications of autonomic dysfunction, often displayed as orthostatic hypotension and resting tachycardia, should be considered during the perioperative management of these patients.[75] Succinylcholine should be avoided because of the risk for hyperkalemia as a result of denervation and immobilization. Nondepolarizing NMBDs may cause prolonged and pronounced neuromuscular block and hence should be used with great caution.[76] General anesthesia may be associated with exaggerated ventilatory depression. Regional anesthesia is also often avoided for fear of exacerbating disease

symptoms. However, both general and epidural anesthesia have been successfully administered to these patients without reported complications.

DUCHENNE MUSCULAR DYSTROPHY

Genetic defects in components of muscle cells, which result in progressive skeletal and smooth muscle dysfunction, are the cause of a group of disorders collectively referred to as *muscular dystrophies*. The most common and severe form of muscular dystrophy is Duchenne muscular dystrophy (DMD), which affects approximately 1 in 5000 male births.[77,78] DMD is an X-linked recessive disorder caused by mutations in the gene that encodes the protein dystrophin.[79,80] A deletion within the gene most commonly causes DMD, but duplication and point mutation have also been described.[80] Although most cases are due to inherited mutations, approximately 10% are due to spontaneous mutations, which can be explained by the large size of the dystrophin gene.[79]

The dystrophin gene is expressed in skeletal, smooth, and cardiac muscle. Although it only accounts for 0.002% of protein in striated muscle,[81] dystrophin plays an important role in sarcolemmal stability and muscle membrane integrity. A cytoskeletal protein links intracellular actin to a group of cell membrane proteins called the *dystrophin-associated protein complex*.[82] This complex, in turn, links via laminin to the extracellular matrix (Fig. 42-1).[82] In DMD, not only is dystrophin absent, but an abnormal expression of the dystrophin-associated protein complex is evident.[82] A hallmark of the disease at its early stages is increased membrane permeability and leakage of intracellular components, including creatine phosphokinase out of the cell and extracellular ions (including calcium into the cell). Traditionally, the absence of dystrophin has been thought to render the sarcolemma fragile and susceptible to rupture with contraction and that this accounts for the increased membrane permeability.[83] Recently, however, this mechanism has been called into question, and evidence has suggested that the disease alterations in channel function in the early stages lead to an increase in intracellular calcium, which activates proteases and reactive oxygen species.[79,82]

Infants with DMD are often normal. Symptoms generally emerge between 2 and 5 years of age[84]; in one population-based sample, the first signs or symptoms were noted at a mean age of 2.5 years and definitive diagnosis was made at a mean age of 4.9 years[85] (see also Chapter 93). The common signs and symptoms at presentation include proximal muscle weakness[79] that results in gait disturbance (including waddling and toe walking), difficulty climbing stairs, calf hypertrophy, and the classic Gowers sign (in which the child uses his hands to climb up their thighs to stand).[84] Creatine kinase level provides a good screening test; in children with DMD, the level is elevated (usually between 5000 and 150,000 IU/L).[84] Motor development plateaus between ages 3 and 6 years, and by 9 to 12 years of age, most patients are wheelchair bound.[84]

After children become wheelchair bound, spinal deformity generally ensues secondary to truncal weakness.[86,87] This deformity, combined with progressive respiratory muscle weakness, can compromise the pulmonary function. These patients become highly susceptible, particularly in the setting of infection, to acute respiratory failure.[84] Additionally, they are vulnerable to upper airway dysfunction and sleep apnea.[79] Cardiomyopathy occurs in nearly all patients with DMD.[88,89] Dystrophin is present in cardiac muscle cells, and the degeneration of cardiomyocytes results in fibrosis.[89] This fibrosis initially affects the posterobasal segment of the left ventricle,[89] which leads to increased myocardial wall stress and a progressive decrease in left ventricular systolic

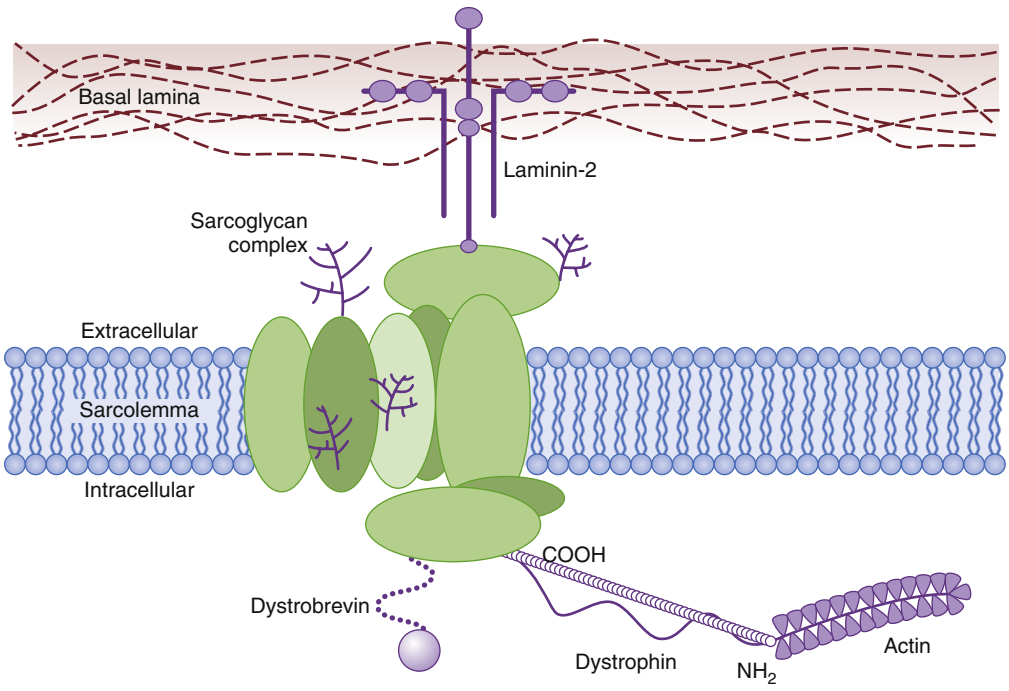

Figure 42-1. Diagram of the cell-surface and cytoskeleton protein complex. *(From Zhou J, Allen PD, Pesah IN, et al: Neuromuscular disorders and malignant hyperthermia. In Miller RD, editor:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Elsevier (Churchill Livingstone), pp 1171-1196.)*

function that eventually results in ventricular dilatation and dysfunction. These changes are evident as characteristic electrocardiographic abnormalities including tall R waves over V1; deep and narrow Q waves over I, V5, and V6; sinus tachycardia; and right axis deviation.[90] Initially, the echocardiogram will show areas of regional wall motion abnormalities at the sites of fibrosis, and, eventually, ventricular dysfunction will be apparent. Fibrosis of the posterior papillary muscle can result in significant mitral regurgitation.[91] As a consequence of the structural changes, patients with DMD are highly susceptible to a range of arrhythmias.[92]

The primary treatment for DMD is glucocorticoids. Meta-analysis of the available data suggests that treatment with glucocorticoids improves short-term muscle strength and function.[93] The most effective regimen appears to be prednisolone at 0.75 mg/kg/day.[93] Recent data suggest that the addition of bisphosphonates to steroids may be beneficial.[94] Management of the cardiomyopathy consists of angiotensin-converting enzyme (ACE) inhibitors, beta blockers, and diuretics.[89] Pulmonary support, including continuous positive airway pressure, bilevel positive airway pressure, and full ventilatory support after a tracheostomy, is frequently required.[84] Novel molecular therapies, including gene replacement therapy, mutation suppression, and exon skipping, are being developed and hold promise for the treatment of this disease.[95] The clinical course is one of progressive decline with death, usually from respiratory or cardiac failure that generally occurs in the third decade of life.[96]

ANESTHETIC CONSIDERATIONS

Patients with DMD have a frequent need for anesthesia for procedures including muscle biopsy, spine surgery for scoliosis, release of contractures, and fractures requiring operative intervention. The principal anesthetic concerns depend on the stage of the disease. In young patients when skeletal muscle is deteriorating, anesthetic triggers can cause profound rhabdomyolysis and hyperkalemia.[79] In older patients, including adolescents and adults, respiratory and cardiac concerns predominate.[79] Irrespective of age, a careful anesthesia consultation, along with consultations from other relevant medical specialists, is required for patients with DMD who undergo nonemergent surgery.[97-99]

Because progressive pulmonary function decline is a hallmark of the disease and the majority of deaths in patients with DMD are due to pulmonary causes, preoperative pulmonary assessment is required. Experts recommend the performance of preoperative pulmonary function tests including measurement of forced vital capacity (FVC), maximum inspiratory pressure, maximum expiratory pressure (MEP), peak cough flow (PCF), and oxyhemoglobin saturation measured by pulse oximetry in room air.[98] For patients with an FVC less than 50%, consideration should be given to preoperative training in noninvasive positive pressure ventilation.[98,100] Such training may result in higher rates of successful use in the postoperative period. Patients with DMD, defined in adults by a PCF less than 270 L/min or an MEP less than 60 cm of water, are considered at high risk for respiratory complications as a result of impaired cough. For these patients, experts recommend training in manual and mechanically assisted cough.[98]

As discussed, DMD results in a progressive dilated cardiomyopathy, which predisposes the patient to both acute heart failure and arrhythmias during the perioperative period.[99,101] Preoperative assessment with an electrocardiogram and echocardiogram and consultation with a cardiologist are generally recommended to ensure that patients are optimized for surgery.[98] However, normal preoperative cardiac workup does not preclude the possibility of perioperative cardiac decompensation.[101] Optimization of preoperative nutrition is also essential. Malnutrition can occur as a consequence of increased work of breathing or an inability to eat as a result of dyspnea.[98] The introduction of appropriate ventilatory support may help with this problem. Preoperative measurement of prealbumin and albumin may be indicated to identify patients with suboptimal nutrition status who are at risk for impaired wound healing.[98]

Because DMD is a terminal illness, experts recommend clarifying with patients and guardians resuscitation parameters and, when appropriate, instituting advanced directives before major surgery.[98]

Several intraoperative considerations are important for patients with DMD. First, succinylcholine is considered contraindicated in patients with DMD. Succinylcholine can precipitate hyperkalemia via two mechanisms in these patients: (1) excess potassium release as a result of the activation of extrajunctional fetal (although its presence in patients with DMD is controversial) and adult acetylcholine receptors[102]; and (2) massive rhabdomyolysis with muscle contraction secondary to an unstable sarcolemma.[79,103] Indeed, hyperkalemic cardiac arrest after the administration of succinylcholine to young male patients with undiagnosed DMD has led to a black box warning cautioning its use in children and adolescents.[79] Second, volatile anesthetics are probably best avoided in these patients,[24,79,104] and most experts suggest the use of total intravenous anesthesia when possible. Although rare, exposure to volatile anesthetics can precipitate a life-threatening MH-like reaction characterized by profound rhabdomyolysis.[103,104] This reaction can occur at low concentrations and may even develop postoperatively, which presents an argument for the use of a clean anesthesia machine.[79,104] Although some earlier reports suggest an association between DMD and MH, a shared genetic risk for DMD and MH is thought to be unlikely—the causal mutation for DMD is on the X chromosome, and the mutations associated with MH are generally on chromosome 19.[103] Rather, the mechanism of this adverse reaction to volatile anesthetics is thought to be isolated rhabdomyolysis and hyperkalemia without the signs of hypermetabolism.[104] As such, dantrolene is unlikely to be clinically useful in these circumstances,[104] and treatment should be focused on the standard management of hyperkalemia. Some authors argue that evidence for considering volatile anesthetics as absolutely contraindicated remains insufficient[79] and have argued that brief exposure in circumstances such as a difficult airway is reasonable.[104]

DMD presents several challenges with respect to airway management. First, the incidence of difficult intubation is likely higher in these patients. In a recent series involving 232 cases of patients with DMD undergoing orthopedic surgery, the incidence of difficult direct laryngoscopy was 4%,[105] likely owing to higher rates of macroglossia, obesity, limited mouth opening, and decreased cervical spine range of motion.[105] Decreased laryngeal reflexes and slowed gastric emptying, which increase the risk for aspiration, may further complicate airway management. Sleep disordered breathing including obstructive sleep apnea and hypoventilation are common in patients with DMD.[106] It is widely recognized that sleep disordered breathing increases sensitivity to opiates in children.[107,108] Therefore, opiates should be judiciously used and titrated to effect in patients with DMD.[79]

Patients with DMD exhibit increased sensitivity to the effects of nondepolarizing NMBDs with a given dose, resulting in greater train-of-four ratio depression and a longer period of neuromuscular block.[109,110] This may be due to the decrease in muscle mass observed with DMD.[79] A delay in the onset of block has also been observed for rocuronium, which may have implications for its use in rapid sequence induction.[110]

Data are mixed regarding whether a bleeding diathesis is present in DMD. Some studies have found evidence of platelet function deficiency,[111,112] whereas other studies have not.[113,114] A relatively recent study found that patients with DMD have increased bleeding times in the setting of normal platelet function. Based on the presence of dystrophin in normal vascular smooth muscle, the authors argued that the impaired hemostasis was due to a defect in vascular smooth muscle reactivity.[114] Some experts recommend the use of aminocaproic acid in patients with DMD who are undergoing major surgery.[79]

Regional anesthesia can be safely used in patients with DMD[115] and may be preferable in some clinical circumstances, considering the problems with volatile anesthetics and NMBDs previously described. Regional anesthesia may also have particular benefits for postoperative analgesia, considering the risks for postoperative respiratory complications in these patients.

The principal concerns in the postoperative care of patients with DMD include the potential for respiratory or cardiac compromise (or both). Careful consideration should be given to the postoperative care setting, and many patients are likely to benefit from admission to an ICU. For patients with an FVC less than 50%, extubation directly to noninvasive positive pressure ventilation should be considered.[98] In some circumstances, if adequate pain control is likely to result in hypoventilation or excessive sedation, then extubation may be delayed for 1 to 2 days.[98] Additional recommendations for postoperative care of these patients include manually or mechanically assisted coughing and the use of cardiology consultants to aid in the management of postoperative fluid shifts and other cardiac issues. Given the gastrointestinal motility issues that can accompany DMD, experts recommend the use of bowel preparation and prokinetic drug regimens and gastric decompression in appropriate patients.[98] Early enteral or parenteral nutritional support is also recommended when oral intake is not possible.[98]

BECKER MUSCULAR DYSTROPHY

Becker muscular dystrophy (BMD) is a milder form of DMD with an incidence that is approximately 20% that of DMD.[116] It affects approximately 14 per 100,000 males.[117] The onset of clinical symptoms in BMD generally occurs later than in DMD, with ambulation being maintained by most affected patients into the third decade of life.[118] Life expectancy is substantially longer than what is observed in DMD, often extending into the fifth decade of life.[79]

An important feature of BMD is the frequent presence of cardiac involvement, even in the presence of benign or subclinical myopathy. In one series, 72% of patients with subclinical myopathy exhibited cardiac involvement.[119] Early right ventricular involvement and later left ventricular dilatation and a reduced ejection fraction characterize the cardiac manifestations.[119] Since skeletal muscle is less involved in BMD, patients are hypothetically able to perform strenuous exercise, which creates cardiac stress that damages the dystrophin-deficient myocardial cells.[119]

ANESTHETIC CONSIDERATIONS

Anesthetic considerations are dependent on the severity of the disease but, in general, are similar to those for DMD. These patients appear to be susceptible to the anesthetic-induced rhabdomyolysis observed in DMD. In fact, case studies report patients with previously undiagnosed BMD who experienced massive rhabdomyolysis (without hypermetabolism) and cardiac arrest upon exposure to volatile anesthetics.[120] Accordingly, as with DMD, volatile anesthetics should be generally avoided. Succinylcholine is also contraindicated for these patients. Considering the high prevalence of cardiomyopathy in patients with BMD,[119] performing a preoperative electrocardiogram and echocardiogram in patients undergoing moderate- or high-risk surgery is prudent. The manifestations of the patient's disease, particularly cardiac status, and the type of surgical procedure will dictate the type of postoperative monitoring and care.

LIMB-GIRDLE MUSCULAR DYSTROPHY

Limb-girdle muscular dystrophies are a clinical and genetically heterogeneous group of myopathies characterized by progressive weakness that begins in the proximal muscles, typically the shoulder or pelvic girdle muscles, sparing other muscle groups at early disease stages.[121,122] The age of onset can be from childhood to late adulthood, depending on the subtype. Inheritance pattern can be autosomal dominant or recessive. To date, 24 genetically distinct limb-girdle muscular dystrophies have been identified, and that number is likely to increase substantially with advances in next-generation sequencing.[122] Treatment, at present, is supportive.

ANESTHETIC CONSIDERATIONS

The literature on the anesthetic management of patients with limb-girdle muscular dystrophy is primarily limited to case reports.[123-125] The clinical manifestations of

the disease and the planned procedure should dictate the anesthetic plan. Preoperative discussion with a neuromuscular disease specialist to understand the clinical features of the patient's disease subtype is warranted. Some types of limb-girdle muscular dystrophy will have a prominent cardiac component and therefore require preoperative cardiac testing. The patients may be susceptible to the same volatile anesthetic-induced rhabdomyolysis observed in DMD and BMD[123]; therefore, avoiding these agents may be prudent. Succinylcholine should be avoided.

MYOTONIC DYSTROPHIES

Myotonic dystrophies (DMs) are autosomal dominant multisystem diseases characterized by myotonia, muscular dystrophy, cardiac conduction defects, cataracts, and endocrine disorders.[126] DMs have two major subtypes: myotonic dystrophy type 1 (DM1), classically known as Steinert disease or Batten-Gibb disease; and myotonic dystrophy type 2 (DM2). An expanded cytosine-thymine-guanine (CTG) repeat in the 3′ untranslated region on chromosome 19 encoding the dystrophia myotonica-protein kinase gene causes DM1.[126] Normal individuals generally have fewer than five of these repeats, whereas those who are affected can have repeats into the thousands.[127] In DM1 disease, onset and severity generally correlates with the number of repeats,[128] and DM1 is often divided into congenital, childhood onset, and adult onset. An expanded CTG repeat in intron 1 of the zinc finger protein 9 gene causes DM2.[126] Although both disorders share the same core clinical manifestations, in general, DM2 develops later and has a milder clinical course.[126]

Facial muscle weakness and wasting is a prominent component of DM1, resulting in a characteristic "hatchet face" appearance.[129] In addition, weakness of the neck flexors and external rotators of the arm are characteristic[130]; other muscle groups, including hands, ankles, and pharyngeal muscles, can also be involved. Proximal muscle weakness, particularly of the lower extremity is a common component of DM2 and was previously referred to as *proximal myotonic myopathy*.[131] DM has, in general, important cardiac manifestations, and these patients have a relatively high incidence of sudden cardiac death.[129] DM1 is associated with conduction abnormalities, tachyarrhythmias (particularly atrial tachyarrhythmias), cardiomyopathy, and valvular disorders.[132] Cardiomyopathy may not always be clinically apparent because of the limited capacity for exertion secondary to the myopathy.[132] In general, the cardiac manifestations are less severe in patients with DM2, compared with those with DM1.[129]

Patients with DM1 are also susceptible to respiratory complications including aspiration (as a result of pharyngeal muscle weakness) and hypoventilation (as a result of diaphragm weakness and decreased central respiratory drive).[129] Respiratory complications are less common in patients with DM2. Similarly, patients with DM1 are at risk for a number of gastrointestinal problems, including impaired esophageal peristalsis, delayed gastric emptying, and dysphagia.[129]

ANESTHETIC CONSIDERATIONS

Because of the high risk for perioperative respiratory complications, the possibility of prolonged postoperative mechanical ventilation should be considered in all patients with DM1, in particular those with severe muscular disability (as assessed by proximal muscle weakness) or those who are scheduled for upper abdominal surgery.[133] In a series of pediatric patients with DM1, the risk of postoperative respiratory complications was related to the degree of muscular impairment, the number of CTG repeats, and the duration of surgery. The use of muscle relaxants without reversal was a potentially modifiable risk factor.[134] In general, perioperative complications in patients with DM2 are less common than in DM1.[135,136]

Because of the cardiac manifestations of this disease, including conduction abnormalities, arrhythmias, and cardiomyopathy, consulting with a cardiologist may be appropriate to ensure that all of these conditions are identified and optimized before surgery. In some circumstances, an echocardiogram and even electrophysiologic studies may be necessary before surgery.[129] The potential for impaired gastrointestinal motility should also be evaluated before surgery and taken into consideration in planning the approach to airway management. Finally, these patients may show enhanced sensitivity to the respiratory depressant effects of anesthetic medications[137] and sedatives. Anesthetic and analgesic medications should therefore be carefully titrated to effect.

MYOTUBULAR OR CENTRONUCLEAR MYOPATHY

Similar to other congenital myopathies, specific structural changes in muscle fibers, early onset with hypotonia and weakness, and a genetic basis and nonprogressive course characterize myotubular myopathy (MTM) or centronuclear myopathy (CNM).[138] MTM was originally described in 1966, and early childhood weakness affecting the extraocular, facial, neck, and limb muscles characterized this disorder. MTM is now divided into three groups based on clinical and genetic features[139]: the severe X-linked recessive (myotubular) form, the autosomal (centronuclear) recessive form, and the relatively mild autosomal dominant form with late onset. The estimated frequency of the X-linked form is 1 in 50,000 male newborns.[140] The X-linked recessive MTM is the most severe form of the disease. The gene responsible for MTM has been localized to *Xq28*, which encodes myotubularin, a tyrosine phosphatase protein.[141,142] Onset is commonly in utero and may be associated with polyhydramnios and reduced fetal movement.[138] Affected male newborns typically exhibit severe floppiness at birth, feeding difficulties, and respiratory distress that requires assisted ventilation. Cardiac muscle is spared, and, in the absence of cerebral hypoxia, cognitive development is normal. Other characteristic features include birth length more than the 90th percentile, macrocephaly (+/– hydrocephalus), a narrow elongated face, and slender, long digits.[143] Serum creatine kinase levels, electromyography, and motor nerve conduction velocities are typically normal. The characteristic

histologic feature is the presence of centrally placed nuclei in muscle fibers resembling fetal myotubules.[138] The long-term prognosis is poor, although studies have reported survival of affected patients for as long as 27 years, with most patients being partially or completely ventilator dependent.[144] Liver function tests may be altered in some patients.[144]

The autosomally inherited forms of MTM or CNM are rare, both familial and sporadic forms.[138] The majority of patients with autosomal recessive CNM demonstrate the disorder in infancy or early childhood. Clinical features include hypotonia, respiratory distress, bulbar weakness, and ophthalmoplegia. The course may be slowly progressive, with development of scoliosis and a loss of ambulation by adolescence. Laboratory findings are similar to other patients with MTM. A late onset, autosomally dominant form has also been described that has a milder course than the other two forms. Autosomal recessive CNM is associated with mutations in the *BIB1* gene that encodes for amphyphysin-2,[145] whereas autosomal dominant CNM has been linked to the gene that encodes for dynamin-2.[146] Treatment is entirely supportive.

ANESTHETIC CONSIDERATIONS

A primary concern when providing anesthesia for a patient with a congenital myopathy is the risk of precipitating MH with triggering anesthetics (e.g., volatile anesthetics, succinylcholine).[147] Some of the congenital myopathies (e.g., central core disease, multiminicore myopathy, nemaline rod myopathy) are clearly linked with the risk of MH because they may all be associated with mutations in the ryanodine (*RYR1*) gene.[148] The risk of MH in MTM or CNM is likely to be low, but all reported cases have used nontriggering anesthetics, such as propofol and remifentanil.[149] However, one case study reports MH-like symptoms developing during cardiopulmonary bypass in a patient with late-onset CNM, even in the absence of administering triggering anesthetics.[150] Thus the most prudent course in patients with MTM or CNM is probably avoiding volatile anesthetics and succinylcholine. A risk of prolonged paralysis with nondepolarizing muscle relaxants exists.[151] However, avoiding the use of muscle relaxants altogether should be easy, considering the hypotonia in these patients.

DISORDERS OF MUSCLE ENERGY METABOLISM

The source of energy used by muscle for metabolism depends on several factors, most importantly the type, intensity, and duration of exercise. At rest, muscles predominantly use fatty acids. At submaximal exercise (70% to 80% of maximum oxygen consumption [VO_{2max}]) aerobic metabolism of glycogen is the most crucial source of energy. At intensities close to VO_{2max}, anaerobic glycolysis is the major source of energy.[152] Glycogen serves as a dynamic but limited reservoir of glucose, mainly stored in skeletal muscle and liver. Glycogen storage disorders (GSDs) are a group of metabolism disorders caused by enzyme deficiency or dysfunction. They reduce effective glucose storage by interfering with normal glycogen synthesis and degradation. Synthetic errors cause decreased normal glycogen, whereas degradation errors tend to block the breakdown of glycogen. Subsequently, hypoglycemia and the accumulation of glycogen in tissues could occur as a result of defective substrate use. More than 12 types of GSDs are assigned Roman numerals based on the enzyme deficiencies. Type II, acid maltase deficiency (AMD), is discussed in this text.

GLYCOGEN STORAGE DISEASE TYPE II (ACID MALTASE DEFICIENCY)

Acid maltase is a lysosomal α-glucosidase that releases glucose from maltose, oligosaccharides, and glycogen. Three clinical forms of AMD have been described. The infantile form (Pompe disease) is the most common, and symptoms are typically expressed during the first 3 months of life. The affected patients develop severe muscle weakness, cardiomegaly, hepatomegaly, and respiratory insufficiency. Cardiorespiratory failure usually causes death before 2 years of age.[153] Presentation of the childhood form of AMD is primarily a myopathy. Motor milestones are delayed, and weakness is greater in the proximal than in the distal muscles. Calf enlargement can occur, resulting in a clinical picture that simulates muscular dystrophy. The disease progresses relatively slowly; however, most patients die of respiratory failure by the second decade of life.[153] The adult form usually begins in the third or fourth decade of life but can begin as late as the seventh decade. Respiratory failure and diaphragmatic weakness are often initial manifestations, heralding progressive proximal muscle weakness. The heart and liver are not involved.[154]

The plasma creatine kinase is elevated by as much as 10-fold in the infantile and childhood forms but may be normal in adult-onset disease. Electromyography demonstrates a myopathic pattern with distinctive myotonic discharges, trains of fibrillation and positive waves, and complex repetitive discharges. The muscle biopsy in infants typically reveals vacuoles containing glycogen and the lysosomal enzyme, acid phosphatase. However, muscle biopsies in late-onset AMD may demonstrate only nonspecific anomalies.[154]

Pompe disease is inherited as an autosomal recessive mutation of the α-glucosidase gene. Enzyme replacement therapy (ERT) with intravenous recombinant human glucosidase has been shown to be beneficial in infantile-onset Pompe disease.[155] Clinical benefits in the infantile disease include reduced heart size, improved muscle function, reduced need for ventilatory support, and longer life. In late-onset cases of Pompe disease, ERT has not been associated with the dramatic response that can be seen in classic infantile Pompe disease, yet it appears to stabilize the disease process, somewhat improving motor and respiratory function.[156]

ANESTHETIC CONSIDERATIONS

Anesthesia reports in patients with AMD are rare, but paying close attention to the cardiac function in infantile Pompe disease is reasonable, considering the associated cardiomyopathy. In a series of five infants with Pompe

disease, Ing and colleagues observed that the left ventricular mass, assessed by echocardiography, was between four and five times greater than normal.[157] Isolated intraoperative cardiac arrest during halothane anesthesia in infantile AMD has been documented.[158] Despite the problem noted with halothane, enflurane and sevoflurane have been used without complications.[157] Although halothane may make the myocardium more prone to arrhythmias, meticulous attention to the hemodynamic parameters and prevention of a vicious cycle of hypotension and compromised myocardial perfusion are likely more important than the choice of a volatile anesthetic agent. Some have suggested that ketamine might be preferable to propofol or sevoflurane induction, primarily because ketamine is an indirect sympathomimetic.[159] Although ketamine is certainly a reasonable choice in these patients, its side effects, such as tachycardia and the consequent increase in myocardial oxygen consumption, need to be kept in mind.

In patients with late onset AMD, the degree of preoperative weakness and respiratory compromise should be considered to plan for the anesthetic accordingly. Epidural analgesia, used as an adjunct to general anesthesia, has been administered with success in a patient with adult-onset Pompe disease.[160] Femoral nerve blocks and caudal blocks have also been successfully used in children with Pompe disease.[161] A combined epidural-spinal technique has also been reported in the management of a pregnant woman with adult-onset Pompe disease for a cesarean section.[162]

Succinylcholine should be avoided because of the risk of hyperkalemia in a patient with myopathy. Nondepolarizing NMBDs are safe to use, provided close attention is paid to neuromuscular monitoring.[163] It should be noted that prolonged postoperative weakness has been reported even without NMBDs.[164]

MITOCHONDRIAL MYOPATHIES

The concept of disease as a result of mitochondrial dysfunction was first introduced in 1962 when Swedish investigators described a patient with severe hypermetabolism without thyroid dysfunction.[165] These investigators defined mitochondrial disease on the basis of (1) morphologic evidence of abnormal mitochondria in muscle, (2) biochemical documentation of "loose coupling" between oxidation and phosphorylation in isolated mitochondria, and (3) correlation between biochemical abnormalities and clinical features (hypermetabolism).[166] Mitochondrial diseases may be classified in terms of defects in the five main steps of mitochondrial metabolism: substrate transport, substrate utilization, the Krebs cycle, the electron transport chain, and oxidation and phosphorylation coupling.[167] The terms *mitochondrial encephalomyopathies* and *mitochondrial myopathies* are reserved for those disorders that are the result of defects in the respiratory or electron transport chain.[166] The respiratory chain is composed of five multimeric complexes (I to V) embedded in the inner mitochondrial membrane, plus two small mobile electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome *c*, for a total of more than 80 proteins. mtDNA encodes 13 of these proteins, and nDNA encodes all others. mtDNA is different from nDNA in several aspects: (1) mtDNA is circular and contains no intron, (2) it has a greater number of copies than nDNA and a significantly higher spontaneous mutation rate, and (3) its inheritance is maternal. Considering the dual genetic control of the respiratory chain, that is, of both mtDNA and nDNA, multiple mutations in either can give rise to mitochondrial disease.[166]

Primary mtDNA mutations may include point mutations in polypeptide, transfer RNA (tRNA), or ribosomal RNA (rRNA) encoding regions and large-scale rearrangements, duplications, or deletions. Some of the common conditions caused by point mutations include myoclonic epilepsy with ragged-red fibers (MERRF); mitochondrial encephalopathy, lactic acidosis, and strokelike episodes (MELAS); neuropathy, ataxia, and retinitis pigmentosa (NARP); Leigh disease; and Leber hereditary optic neuropathy (LHON). Sporadic large-scale mutations may lead to Kearns-Sayre syndrome (KSS), progressive external ophthalmoplegia, and Pearson syndrome. nDNA mutations can cause deficiencies in complexes I to IV and in CoQ_{10} of the electron transport chain.[166]

Mitochondrial diseases present a diagnostic challenge as a result of their clinical heterogeneity. Since mitochondria are ubiquitous, mtDNA mutations can affect every tissue in the body. Disorders as a result of nDNA mutations follow a mendelian pattern and thus are phenotypically "all or none," whereas inheritance of mtDNA is stochastic, leading to greater variability. The overall incidence of mitochondrial myopathy is estimated to be 1 in 4000.[168] Clinically, certain symptoms or signs are "red flags" for mtDNA-related conditions because of their frequency. These include syndromic or isolated sensorineural hearing loss, short stature, progressive external ophthalmoplegia, axonal neuropathy, diabetes mellitus, and hypertrophic cardiomyopathy.[169] Pure myopathies vary considerably in the age of onset, distribution of weakness, and course, ranging from early onset severe disease with respiratory failure to adult onset with mild or even reversible weakness. In addition to fixed weakness, patients with mitochondrial myopathies complain of exercise intolerance and premature fatigue; some experience recurrent myoglobinuria.[166] The histologic hallmark of these diseases is the "ragged-red fiber" when muscle tissue is stained with the Gomori trichrome stain.[170] Common laboratory findings include a high lactate-to-pyruvate ratio (50 to 250), instead of a normal ratio (less than 25:1), increased blood levels of free carnitine, and occasionally low levels of folate (as in KSS). Computed tomography and magnetic resonance imaging of the brain may be helpful. For example, patients with MELAS demonstrate basal ganglia calcifications and strokelike patterns not confined to vascular territories.[170] Clinical features of two relatively common encephalomyopathies, MELAS and MERRF, are briefly discussed in the following text.

MITOCHONDRIAL MYOPATHY, ENCEPHALOPATHY, LACTIC ACIDOSIS, AND STROKELIKE EPISODES

MELAS is the most common mitochondrial encephalomyopathy. Onset is most commonly before age 20 years.

Seizures are common and strokelike episodes (*strokelike* because they do not conform to vascular distributions) may produce hemiparesis, hemianopia, and cortical blindness. Any patient younger than 40 years of age with a history of stroke should be assessed for MELAS. Associated findings include diabetes mellitus, hearing loss, pituitary and thyroid hypofunction, and lack of secondary sexual characteristics. In its full expression, MELAS leads to dementia, a bedridden state, and death. No specific treatment is currently available.[154]

MYOCLONIC EPILEPSY WITH RAGGED-RED FIBERS

MERRF is a multisystem disorder characterized by myoclonus, generalized epilepsy, ataxia, and ragged-red fibers on muscle biopsy. Other clinical features may include hearing loss, peripheral neuropathy, optic atrophy, dementia, short stature, and exercise intolerance.[166] Cardiomyopathy is occasionally present. Laboratory features include an increased lactate level at rest and with exercise, and a myopathic picture on an electromyogram and electroencephalogram shows generalized spike and wave discharges with background slowing. Only supportive treatment is available.

ANESTHETIC CONSIDERATIONS

The anesthesiologist may be involved in the care of patients with mitochondrial disease in multiple situations and often in the setting of obtaining a muscle biopsy in a child with an undiagnosed myopathy.[171] These patients may also have surgical procedures related to the disease (such as implantation of a permanent pacemaker in a patient with KSS),[172] for incidental medical problems, as well as in the labor and delivery suite for labor analgesia.[173] The diversity of clinical presentations encountered in the mitochondrial myopathies dictates that each patient be thoroughly evaluated and that the anesthetic plan be tailored to the patient's specific needs.

Preoperatively, the extent of organ system involvement should be carefully assessed and documented with particular emphasis on the degree of myopathy and neurologic function. Looking for evidence of cardiomyopathy or rhythm disturbances is imperative. In addition, close attention should be paid to endocrine issues because myotonic dystrophies may frequently be present together with other metabolic derangements such as electrolyte imbalances.[174] Varying degrees of respiratory compromise may be exhibited, and these patients may be at a higher risk of postoperative respiratory complications.[168] Baseline blood gases and lactate levels are helpful as well, although a normal lactate level certainly does not rule out a mitochondrial process.

Every class of anesthetics is associated with a theoretic risk of complications in patients with mitochondrial disease. Volatile anesthetics and succinylcholine raise the specter of MH. Propofol and midazolam are known to inhibit the mitochondrial respiratory chain in a dose-dependent manner.[175] Indeed, mitochondrial dysfunction has been postulated as a mechanism for the propofol-related infusion syndrome (PRIS).[176] NMBDs are associated with the risk of prolonged paralysis, and narcotics may worsen preexisting respiratory depression.[177] Even local anesthetics have been reported to cause mitochondrial toxicity.[178] Fortunately, notwithstanding the potential pitfalls previously mentioned, almost every anesthetic technique has been safely used in patients with mitochondrial disease.[174,179] The caveat, of course, is that given the rarity of the mitochondrial diseases, all anesthetic experiences reported to date take the form of individual case reports or small series that do not permit definitive conclusions.

The association of MH to patients with mitochondrial disease probably dates back to a single case described in 1985 by Ohtani and associates.[180] Another patient with a mitochondrial myopathy had a positive halothane contracture test but did not have clinical evidence of MH.[181] On the other hand, volatile anesthetics have been used on numerous occasions in this patient population without any adverse effects.[173,182] At present, evidence does not support an association between MH and mitochondrial disease. However, avoiding succinylcholine in patients with extensive myopathy to minimize the risk of hyperkalemia may be prudent, although the safe use of succinylcholine has been documented in at least one patient with KSS.[183] Similarly, propofol has been safely used in patients with MELAS, and PRIS has never been described in this group of patients. Nevertheless, propofol should not be used as an ICU sedation in patients with mitochondrial dysfunction. Although using propofol as an anesthetic-induction drug is safe, using a propofol infusion for long periods should probably be avoided.

Several studies report sensitivity to nondepolarizing muscle relaxants, including mivacurium, atracurium, vecuronium, and rocuronium, although resistance to cisatracurium in a patient with MELAS is also reported.[174] Being cautious when using muscle relaxants in patients with myopathies is important. Finally, several studies report the successful use of spinal and epidural anesthetics in patients with mitochondrial diseases.[173,184,185] Before choosing a neuraxial technique, close attention should be paid to any preexisting neurologic dysfunction.

Perhaps more important than the specific choice of anesthetics are the implications of the patient's comorbidities and metabolic status. Normothermia should be maintained during surgeries, and intravenous fluids should be warmed to body temperature. Lactated Ringer solution should probably be avoided, considering the risk of preexisting lactic acidosis, although evidence does not indicate that lactated Ringer solution has worsened acidosis when used.[174] Multiple studies have reported hyponatremia (and occasionally hyperkalemia) in these patients.[174,186,187] In such situations, adrenal insufficiency should be considered, particularly when accompanied by hypotension.[174] Finally, these patients are at increased risk of cardiac conduction abnormalities and cardiomyopathy that should be taken into consideration when formulating an anesthetic plan.

PERIODIC PARALYSES

The periodic paralyses are a group of disorders that are characterized by alterations of function in voltage-gated

ion channels; these diseases are sometimes termed *skeletal muscle channelopathies*.[188] The symptoms of the particular channelopathy depend on the specific ion channel involved and can be divided into three broad categories: (1) chloride channelopathies—myotonia without paralysis, such as myotonia congenita; (2) sodium channelopathies—myotonia with paralysis, such as hyperkalemic periodic paralysis; and (3) other cation channelopathies—paralysis without myotonia, such as hypokalemic periodic paralysis (HypoPP).[189]

HYPERKALEMIC PERIODIC PARALYSIS

Hyperkalemic periodic paralysis (HyperPP) is an autosomal dominant disease with a high penetrance that equally affects males and females. It has a prevalence of approximately 1 in 200,000.[189] The term *hyperkalemic* can be misleading because patients may have normal potassium levels during attacks. This characteristic led to the erroneous categorization of such patients as having *normokalemic periodic paralysis*. However, normokalemic periodic paralysis has now been unequivocally established as a variant of HyperPP.[190] The defining characteristic of the disease is paralysis precipitated by potassium administration.[191] Mutations at various sites on the voltage-gated sodium channel *SCN4A* gene cause HyperPP. The mutant channels, once activated by a depolarizing agent such as potassium, cannot inactivate; they flicker between open and inactivated states. This action produces persistent depolarization (causing muscle weakness) and a shift of sodium into the muscle cells and potassium to be released from the muscle cells (causing hyperkalemia). When potassium diuresis relieves the hyperkalemia, the cycle is probably terminated.[189]

Attacks of weakness begin in the first decade of life, are generally short-lived and infrequent, although they may later increase in frequency and severity. Precipitating factors include potassium-rich foods and rest after exercise. In addition, a cold environment, emotional stress, fasting, glucocorticoids, and pregnancy can provoke or worsen the attacks. In between attacks, a mild myotonia is common but does not impede activity. Laboratory studies may show elevated or normal potassium levels during attacks. Creatine kinase levels are often elevated. It is rare for serum potassium to reach cardiotoxic levels, and the electrocardiogram is usually normal. Electromyographic recordings will often show myotonic discharges during and between attacks. Muscle biopsies may show small peripheral vacuoles in the sarcoplasm. Treatment includes medication with acetazolamide (a carbonic anhydrase inhibitor) and mexiletine (an antiarrhythmic with a mechanism of action similar to lidocaine). Behavioral modification, such as avoiding potassium-containing foods, strenuous exercise, fasting, and exposure to cold, are also important.[189]

HYPOKALEMIC PERIODIC PARALYSIS

Familial hypokalemic periodic paralysis (HypoPP) is the most common form of the periodic paralyses, although its prevalence is only 1 in 100,000.[192] It is autosomal dominant with a reduced penetrance in women and affects men more commonly. Genetically, two types of HypoPP are clinically identical. Patients with type 1 HypoPP (the more common) have a mutation in the L-type calcium channel gene *CACN1AS*.[193] Type 2 HypoPP is the result of mutations in the same sodium channel gene (*SCNA4*) that causes HyperPP.[194] Although it remains unclear how defects in the same gene (*SCNA4*) give rise to pathologic characteristics with diametrically opposing clinical manifestations, it has been speculated that HyperPP is a "gain-of-function" sodium channelopathy, whereas type 2 HypoPP is a "change-of-function" channel disease.[194]

The presentation of HypoPP occurs between childhood and the third decade of life. Proximal muscles are disproportionally affected, with rare ocular and bulbar muscle involvement. Respiratory muscle weakness, although unusual, may be life threatening. Continuous physical activity and carbohydrate-rich meals may provoke the attacks. Other triggers include bacterial or viral infections, alcohol ingestion, fasting, lack of sleep, dehydration, prolonged bed rest, stress, menstruation, and pregnancy.[189] Remaining aware of the differences in the clinical features between HyperPP and HypoPP is important. HypoPP is not associated with myotonia; a spontaneous attack is associated with hypokalemia (a diagnostic criterion), potassium is a remedy, and glucose triggers an attack.[189] Treatment is centered on the identification and avoidance of triggers. Potassium administration can be useful in the treatment of an acute attack. The prophylactic medication of choice in type 1 HypoPP is acetazolamide[195]; however, acetazolamide can worsen symptoms in type 2 HypoPP.[196] Such patients may respond to potassium-sparing diuretics such as spironolactone.[197]

THYROTOXIC PERIODIC PARALYSIS

Thyrotoxic periodic paralysis (TPP) clinically resembles HypoPP. TPP occurs later in life than HypoPP, has a strong male predominance, and is significantly more common in patients of oriental descent. Loss-of-function mutations in the inward rectifying potassium channel gene (*Kir2.6*) may be involved in some cases of TPP.[198] The condition responds to antithyroid medications such as methimazole.[189]

ANESTHETIC CONSIDERATIONS

Knowledge of the pathophysiologic processes and precipitating conditions for the different types of periodic paralyses guide the anesthetic approach to patients with these disorders. Salient features are discussed in the following text.

HyperPP

If possible, all patients with HyperPP should be preoperatively admitted to allow preoperative fasting to be accompanied by the administration of a dextrose-containing, potassium-free intravenous fluid.[199] Depolarizing agents such as potassium, succinylcholine, and anticholinesterases aggravate the myotonia in HyperPP and are contraindicated.[189] Nondepolarizing NMBDs may be safely used.[199,200] Although succinylcholine can cause masseter

spasm and rigidity in HyperPP,[201,202] these are related to severe myotonic reactions and are not due to MH. No evidence suggests that patients with HyperPP are susceptible to MH.[148] The safe use of both volatile anesthetics and propofol has been documented.[199,200,203] Myotonic contractions during anesthesia may be improved with the administration of lidocaine, as chronic myotonic symptoms are improved by mexiletine.[189]

Intraoperatively, maintaining normothermia, preventing hyperkalemia, and avoiding hypoglycemia are important.[200] Both spinal and epidural techniques have been successfully used in these patients,[204,205] including the use of epidural labor analgesia.[206] Nonneuraxial regional techniques have not been extensively investigated; however, a recent report documents the use of a femoral nerve block in a single patient with HyperPP.[207]

HypoPP

Patients with HypoPP undergoing general anesthesia have been reported to exhibit weakness and respiratory distress in the postoperative period.[208,209] Important triggers to avoid include perioperative stress, glucose loading, hypothermia, and depolarizing NMBDs.[189] Although the safe use of intermediate- and short-acting nondepolarizing NMBDs such as atracurium and mivacurium has been documented,[210-212] avoiding long-acting muscle relaxants is probably prudent.[213] The use of epidural (including for labor analgesia) and spinal techniques appears to be safe,[212-214] although hypokalemia has been documented with the use of epidural techniques, both with and without epinephrine.[215] Unlike HyperPP, an association between HypoPP and MH cannot be categorically ruled out,[148] although the use of isoflurane in HypoPP has been reported.[212] A number of MH-like metabolic crises in patients with HypoPP have been reported.[216-218] Contracture-like responses to succinylcholine have also been described.[219] In one of the prior descriptions, two unrelated mutations conferring both HypoPP and sensitivity to MH in the same patient seemed likely.[218] Consequently, although the probability of MH in a given patient with HypoPP is likely to be remote, it cannot be ruled out, and the safest course might be the use of a nontriggering anesthetic. If volatile agents are used, then they should be used with extra vigilance.[148]

GENETICS OF MENDELIAN, MITOCHONDRIAL, AND COMPLEX DISEASES

With the emergence of technologies that perform genetic sequencing quickly, accurately, and inexpensively, an understanding of the genetic basis of heritable diseases has recently accelerated. The conditions discussed in this chapter generally focus on diseases that have mendelian or mitochondrial inheritance. Recent research has also begun to unlock the genetic basis for complex diseases, including coronary artery disease, diabetes, and hypertension, with which anesthesiologists interact in the course of their clinical practice. The pace of genetic discovery is expected to accelerate in the upcoming decades and become a more integral component of clinical practice. It is important for anesthesiologists to be familiar with modern approaches to genetic study; therefore, an overview of the genetics of mendelian, mitochondrial, and complex diseases is presented.

MENDELIAN DISEASES

Over the last two decades, gene discovery has led to an understanding of the causal mechanisms underlying rare, familial genetic disorders.[220] This understanding has transformed diagnosis, management, treatment, and anesthetic practice for patients with these disorders. Mendelian, or single-gene disorders, exhibit simple autosomal or sex-linked inheritance patterns with variable expressivity and penetrance. Traditionally, genes for these disorders have been identified by positional cloning, which includes linkage analysis (a measure of cosegregation of chromosomal markers with disease phenotype in families) to localize a disease gene to a subchromosomal region, and subsequent sequencing of genes and transcripts under the linkage peak in affected and unaffected family members to identify causal mutations. In the last few years, direct mutation screening using next-generation sequencing of the entire exome (protein coding region of all known genes in the genome) or entire genome in a small number of affected and unaffected family members has revolutionized gene identification for mendelian diseases.[221,222] To date, causal genes for more than 3600 common diseases have been identified, demonstrating a large extent of locus heterogeneity (in which mutations in different genes lead to the same phenotype) and allelic heterogeneity (in which different mutations in the same gene are present in patients from different families. (Visit Online Mendelian Inheritance in Man [http://www.ncbi.nlm.nih.gov/omim].)[220]

MITOCHONDRIAL DISEASES

The genetics of mitochondrial disorders is a special case of mendelian disorders because defects may be in mtDNA- or nDNA-encoded structural or regulatory components of the mitochondrion.[223] Maternal inheritance is observed in mtDNA disorders, which often exhibit a range of systemic phenotypes with varying severity, as discussed in the previous section on mitochondrial disorders. Typically, affected members from these pedigrees carry germline mutations in mtDNA, but their tissues and organs may contain both normal and mutant copies of mtDNA (heteroplasmy). Because each cell consists of hundreds to thousands of mitochondrial DNA genomes that may segregate unevenly during mitosis, the relative ratio of normal-to-mutant mitochondrial genomes in the body can influence the variability in disease phenotypes.[224] Sequencing of the 16.6 kb mtDNA molecule in affected family members, with a comparison against the background mitochondrial haplogroup as defined by lineage-specific polymorphisms, and determining the functional consequences on respiratory chain activity in vitro typically identify mutations that cause disease.[225-227] Mitochondrial disorders caused by nDNA-encoded components of the mitochondrial machinery are similar to

other mendelian disorders with variable phenotypes, and genes encoding these are increasingly being identified because of better catalogs of the mitochondrial proteome and next-generation sequencing methods.[228]

COMPLEX DISEASES

The discovery of genes for complex diseases is a powerful approach to identify important biologic pathways contributing to disease pathogenesis. Mechanistic insights gained from an understanding of these pathways can lead to new strategies for disease prevention, diagnosis, and treatment. Common diseases are complex traits influenced by multiple genes and environment, in contrast to rare diseases caused by single gene defects (mendelian traits). The heritability of a complex trait is the sum of the genetic contribution to the trait,[229,230] and the demonstration of significant heritability in twin or family studies is usually the first step in justifying gene discovery efforts. Causal genetic variation contributing to the genetic component of a trait can arise as a single nucleotide substitution (termed a *single nucleotide polymorphism* when its frequency is present in more than 1% of the population), or an insertion, duplication, or deletion ranging from one base to hundreds of kilobases in length (termed a *copy number polymorphism* when its frequency is present in more than 1% of the population). This variation can either directly alter the coding sequence of the protein encoded by the gene disrupting protein function or influence the regulatory regions of genes altering gene expression, splicing, or transcript stability. Genetic variation between humans is limited, and most variations in the genome are common.[231] Deleterious mutations in single genes causing mendelian diseases do not reach appreciable frequencies in the population because these mutations decrease reproductive fitness and are thus subjected to purifying selection. Common diseases are not subject to negative selection because they typically do not influence reproductive fitness and often have a late onset.[232] Similarly, for complex pharmacogenetic traits, drug exposures have not occurred until recently in evolutionary history; consequently, drug targets or metabolizing enzymes may not have been subjected to selective pressure.

GENETIC ARCHITECTURE OF COMPLEX TRAITS

Emerging evidence suggests that the genetic architecture of common diseases typically spans the continuum from mendelian subtypes of a common trait featuring very rare, highly deleterious mutations in a single gene, through a low-frequency range of single nucleotide or copy number variants with medium individual effect, to more common single nucleotide polymorphisms (SNPs) or copy number polymorphisms (CNPs) of modest effect segregating in the larger population.

Linkage analysis, which measures cosegregation of chromosomal markers with disease phenotypes in families, has been successful in positional cloning of genes for mendelian disease, but genetic association analysis is a study design better powered to detect the role of common genetic variation underlying complex traits.[233] Genetic association studies search for statistically significant allele frequency differences in covariate- and ethnicity-matched cases and controls to identify genetic variants altering the risk of disease. Candidate gene–association studies with the aim to validate the role of known biologic pathways identified through model organism or in vitro studies of disease physiologic processes have met with some success but have been plagued with inconsistency and irreproducibility primarily because of a lack of power in small, individual studies, insufficient accounting for population structure, technical problems with genotyping, or lack of stringent statistical thresholds for multiple testing correction.[234] Genome-wide association studies (GWASs) have been the breakthrough method that has validated candidate disease genes and revealed many more new, unsuspected genes contributing causally to common disease. GWASs typically interrogate more than 1 million common SNPs and copy number variants across the genome for statistically significant differences in allele frequency between large sets of carefully matched cases or controls. GWASs can also be used to identify genetic variants contributing to the variation in disease-related quantitative traits, highlighting roles of genes in specific disease processes. Several key advances over the last decade have made GWASs possible. These include the availability of the human genome reference sequence; catalogs of common variation, mapping of the correlation structure between variants in continental populations through the International HapMap Consortium[235]; advances in oligo array technology leading to high-throughput, cost-effective, and high-quality genotyping[236]; and analytic approaches that account for systematic biases such as population structure.[237] Although over 10 million common variants have been identified in human populations, GWASs enable testing of approximately 85% of all common variations over 5% frequency because of the phenomenon of linkage disequilibrium, in which neighboring genetic variation is inherited together in "blocks" disrupted only by ancestral recombination events that occur at hotspots (linkage disequilibrium).[231,238] Thus, SNPs in close proximity are highly correlated to each other, and one marker can serve as a surrogate for multiple variants. Common genetic variation in humans can be categorized into one of a small range of haplotypes or specific patterns of variation with populations of recent African ancestry showing the most diversity, whereas populations that arose out of Africa have fewer haplotypes and longer regions of linkage disequilibrium.[239]

Successful designs for GWASs require careful phenotype and covariate definition, sample selection and matching, high-throughput genotyping and quality control, including the removal of low-quality, cryptically related or population outlier samples and the removal of SNPs with a low-genotyping call rate or departure from Hardy-Weinberg equilibrium.[240] Population stratification, or differences in allele frequency between ethnic populations unequally apportioned between cases and controls, can be a major source of type 1 error and can be overcome by selecting a homogeneous study population or by analytic methods that adjust for genome-wide variation patterns.[237] Rigorous statistical significance

thresholds are typically set at 5×10^{-8}, correcting for the approximately 1 million common independent tests in the genome identified by simulation studies.[241] Finally, replication of significant association signals from GWASs in independent samples in a multistage design is important to distinguish true, reproducible signals from potential sources of error or bias in the original GWAS.[240]

The National Human Genome Research Institute catalogs the growing and significant GWASs reported in the literature. To date, more than 8000 associations to disease, biomarker, or behavioral traits have been identified (http://www.genome.gov/gwastudies/).[242] GWASs have led to new insights on the genetic architecture of complex traits, namely:

1. Many human traits are highly polygenic, sometimes with more than 100 loci contributing modest effects to disease risk.
2. Most individual common variant effects are modest, with an odds ratio in the range of 1.1 to 1.5; therefore, large sample sizes (1000s to 100,000s) are needed to have sufficient power to detect these effects robustly.
3. Causal SNPs and genes are challenging to pinpoint under an association peak and require intensive bioinformatic and experimental follow-up, especially since many signals are far from known genes and may represent distant regulatory elements.
4. A single gene may harbor rare alleles of strong effect and one or more common independent alleles of weak effect, contributing to disease etiologic origin.
5. Most discovered loci were not previously suspected as biologic candidates, emphasizing the fruitfulness of an unbiased genome-wide screen.
6. Most effects are observed across multiple ethnic groups, but the relative role of a genetic variant may be different across populations based on differing allele frequencies across populations.
7. Both the overlap of associations between traits (e.g., the same SNP influencing type 2 diabetes and a related trait, insulin secretion) and the unexpected pleiotropy across traits are expected.[232]

The contribution of rare variants to complex disease is being investigated, largely based on rapid advances in next-generation sequencing.[243,244] Large-scale sequencing projects (e.g., the 1000 genomes project[245] and the National Heart, Lung and Blood Institute [NHLBI]–funded Exome Sequencing Project[246]) have now sequenced tens of thousands of individuals, leading to deeper catalogs of rare variation than that queried by GWASs. These projects provide a window into querying the role of low-frequency variation (0.1% to 5% frequency) in disease, especially in protein-coding regions of all known genes in the genome (the exome) in which the impact of a protein-altering variant can be predicted in silico and is amenable to easier interpretation than regulatory variation. Recently, the exome chip, made up of approximately 240,000 validated protein-altering variants (>1:1000 frequency) has been developed.[247] This genotyping array includes novel missense, splice-site and nonsense variants, and is predicted to capture 95% of exome variation in an average individual. Even more rare variants contributing to common disease are being sought by exome or whole genome sequencing of thousands of cases and controls for many complex disease traits.[248] Since these variants are individually rare, methods to test the aggregate mutation burden or perform association analysis across gene regions have been developed.[248] Exome sequencing has proven immensely successful at identifying novel causal mutations in families with mendelian segregation of traits, including in mendelian subtypes of common disease, and is an unbiased approach that allows for combined positional cloning (using linkage) and direct-coding mutation detection.[221]

Efforts are now directed toward identifying the entire allelic spectrum of mutations for many common diseases. Even when all causal genetic variations contributing to a complex trait are defined, understanding gene-gene and gene-environment interactions will be important to explain the full genetic variance of a trait.[249] More sophisticated systems' biologic approaches, such as network medicine that integrates genetics with multiple genomic technologies, may also help understand the underlying perturbations of biologic networks that result in disease.[250]

IMPLICATIONS FOR CLINICAL TRANSLATION

Advances in complex disease gene identification should lead to clinical advances of benefit for all patients and in some scenarios to *personalized medicine*, depending on a patient's genetic risk. Identification of novel causal pathways provides new opportunities for the identification of therapeutic targets for drug development for disease treatment or prevention in all patients. Identification of causal pathways should also lead to new biomarkers to improve diagnoses, monitor disease progression, and response to therapy. Validated genetic markers are also proving to be valuable tool to determine whether relationships between existing biomarkers and disease are causal through mendelian randomization studies.[251] In certain clinical scenarios, personal disease risk prediction based on the genetic risk variant profile may lead to personalized therapy, as is now common in cancer therapeutics. However, for most diseases, such clinical use is still in the future because in the aggregate, known genetic variation explains such a small fraction of disease risk.

IMPLICATION FOR ANESTHESIOLOGISTS

The greatest clinical promise of complex trait genetics in anesthesiology is to predict and understand the response to anesthetics or the pharmacologic drugs used for pain medicine to tailor the most effective and safe treatment.[252,253] Mendelian and mitochondrial genetics have led to the identification of genes of rare diseases as presented in this chapter, and the biologic understanding of the disease has led to anesthetic considerations that maximize safety and efficacy. Pharmacogenomics is the study of genetic variation that contributes to the interindividual variability in treatment response, which is a complex trait. Although many biologic and lifestyle factors such

as age, sex, liver and kidney function, diet and exercise, smoking and alcohol use, and severity of illness may contribute to the variability in the treatment response, if variability persists after accounting for these covariates, then genetic factors may be considered.[254] Two categories of genes are recognized to harbor variants influencing drug response: pharmacokinetic (PK) and pharmacodynamic (PD) genes.

PK genes influence interindividual differences in drug metabolism including absorption, distribution, metabolism, and excretion (ADME). PK gene variability may lead to either slower or more rapid drug uptake and conversion and excretion, leading to either the elimination of the drug before the therapeutic effect is achieved or the drug remaining too long or in too high a dose in the body, thereby increasing the risk of adverse effects. Many metabolizing enzymes in the liver, including the cytochrome *P450* gene family, are important PK genes with poor or ultrarapid metabolizing alleles, such as the gene *CYP2D6*, which contributes to metabolism of up to 25% of drugs in clinical use today.[255]

PD genes are either drug-target receptors or molecular components in the signal transduction pathway targeted by the drug. Variation in PD genes is likely to be involved when the variation in drug response is dose independent and may involve synergistic, independent, or antagonistic interactions among multiple components of the signaling pathway. Thus PD effects are likely more complex than PK effects, and early pharmacogenetic studies suggest that they contribute more to the variation in treatment response than PK effects. For example, PK and PD effects are seen in warfarin anticoagulation therapy, which displays tenfold variation in treatment response among individuals. Although carriers of poor metabolizer alleles of the metabolizing enzyme *CYP2C9* (PK gene) require lower doses and have a higher risk of bleeding, genetic variation in a subunit of the warfarin target VKOR (*VKORC1*, a PD gene) is the major determinant of the amount of warfarin required to achieve a therapeutic effect.

Progress in the field of pharmacogenomics has been slow. Most pharmacogenetic discoveries have come from candidate gene studies of PK and PD genes; however, GWASs and sequencing approaches are beginning to be applied.[256,257] Importantly, several challenges remain. First, thorough phenotyping is critical to measure the variation in response precisely and to identify nongenetic factors influencing the variability that should be accounted for. Second, genetic study designs should include well-powered, large samples from a homogenous population of preferably one ancestry and analytic methods with adequate quality control for technical or population artifacts and correction for multiple testing. Studies must be relatively large because predicting how large an individual gene effect may be is not possible beforehand; *a priori* power calculations to calculate sample size are not possible. Replication in an independent sample is necessary, but finding a replication sample with the same phenotype may be difficult for some pharmacogenomic studies. Encouragingly, small early pharmacogenomic GWASs have detected genome-wide significant findings with $n = 100$ cases suggesting that effect sizes of pharmacogenomic alleles seem to be larger than those of disease susceptibility alleles and may involve fewer genes.[256] In the next few years, unbiased, whole genome genetic approaches should lead to a greater understanding of the genetic basis of PKs and PDs of anesthetics and pain drugs.

Chapter 43

Malignant Hyperthermia and Muscle-Related Disorders

JIE ZHOU • DIPTIMAN BOSE • PAUL D. ALLEN • ISAAC N. PESSAH

Key Points

- Malignant hyperthermia (MH) is an anesthetic-related disorder of increased skeletal muscle metabolism. It is an inherited condition in an autosomal dominant pattern.
- Skeletal muscle accounts for approximately 40% of body weight; its increased metabolism therefore has a profound effect on whole-body metabolism.
- Signs of MH, including tachycardia, increased end-tidal carbon dioxide (CO_2), muscle rigidity, and increased temperature, are related to increased metabolism.
- The abnormal function of the skeletal muscle ryanodine receptor (RyR1) in MH-susceptible (MHS) individuals is associated with abnormal intracellular calcium handling, which is controlled by compensatory mechanisms within the cell when it is not exposed to triggering agents.
- Loss of compensatory control of intracellular calcium on exposure to triggering agents or heat stress leads to marked metabolic stimulation within the cell to provide extra adenosine triphosphate to drive the calcium pumps that restore calcium to its reservoirs (e.g., sarcoplasmic reticulum, mitochondria, extracellular fluid).
- Dantrolene significantly attenuates myoplasmic calcium (Ca^{2+}) concentrations and thereby allows restoration of normal metabolism, with a reversal of the signs of metabolic stimulation.
- MH is inherited; one RyR1 mutation accounts for all porcine MH, whereas more than 210 mutations in RyR1 and 4 mutations in $Ca_V1.1$ account for human MH.
- Evaluation of persons susceptible to MH includes contracture of a skeletal muscle biopsy specimen with halothane and caffeine and evaluation of DNA to identify mutations. Only DNA testing is needed to evaluate swine MH.
- Future MH goals include advancements of genetic evaluations in North American and European medical programs and stronger finances to support genetic studies, the identification of the mode of action of dantrolene, a determination of the immediate cause of triggering MH, and the development of effective, noninvasive tests for MHS.
- Whereas the risk for an MH mutation in patients with Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) is similar to those in the general population, the incidence of MH-like anesthetic events has been reported to be 0.002 with DMD and 0.00036 with BMD.
- Dystrophin, along with dystrophin-associated glycoproteins, is involved in sarcolemmal stability. Mutations in this gene that cause an absence or truncation of dystrophin are responsible for DMD and BMD.
- Succinylcholine is contraindicated in patients with DMD or BMD because of the risk of rhabdomyolysis and hyperkalemia as a result of their unstable sarcolemmal membrane.
- Most complications in patients with myotonic dystrophy are pulmonary related that result from hypotonia, chronic aspiration of gastric contents, and central and peripheral hypoventilation.
- There is no evidence of increased risk of MH in patients with sodium channel pathology.
- Some of these neuromuscular disorders are also discussed in Chapter 42. A comparison of both of these discussions should provide an in-depth knowledge of these rather rare but important diseases for anesthesia.

Malignant hyperthermia (MH) is one of the most devastating anesthesia-related complications. This fulminant syndrome is elicited by the administration of triggering anesthetic agents, such as a volatile anesthetic or a depolarizing neuromuscular blocking agent. MH has been and continues to be a life-threatening complication of anesthesia if the diagnosis is not promptly made and treatment is not begun in a timely fashion. Unlike other disorders described in this chapter, MH has virtually no characteristic phenotype before exposure to the triggering agent and is truly an example of the interaction of genes and the environment. Also covered in this chapter are some of the neuromuscular disorders, although rarely encountered in a routine anesthetic practice. This group of disorders challenges both perioperative management and intensive care. They affect the normal function of the peripheral nerves, the neuromuscular junction, and/or muscles. Although such diseases are thought to be rare, the number of patients that a clinician may encounter is increasing because of better medical care, increasing longevity, and possibly other unidentified factors. Neuromuscular disorders have a significant potential to interact with an improper anesthetic plan, and all affected patients require special perioperative attention for anesthetic management. In this area, the armamentarium of invasive and noninvasive diagnostic tools is being developed, especially in genetics.

MALIGNANT HYPERTHERMIA

MH is a pharmacogenetic clinical syndrome that, in its classic form, occurs during anesthesia with a volatile halogenated alkane such as halothane and/or the administration of the depolarizing muscle relaxant succinylcholine. The fulminant MH episode observed clinically produces rapidly increasing body temperature (by as much as 1° C in 5 minutes) and extreme acidosis as a result of an acute loss of control of intracellular calcium levels and compensatory uncontrolled increases in skeletal muscle metabolism that may proceed to severe rhabdomyolysis. Although MH was initially associated with a mortality rate of 60%, earlier diagnosis and the use of dantrolene have reduced the mortality to less than 1.4%.[1] Current cases of MH are restricted in severity because of diagnostic awareness, early detection through end-expired carbon dioxide (CO_2), the use of less potent anesthetic triggers, and the administration of drugs that attenuate the progression of the fulminant episode. The incidence of fulminant MH was reported to be 1 case per 62,000 anesthetics administered when triggering agents were not used, but the number of suspected cases was 1 case per 4500 anesthetics administered when triggering agents were administered.[2] The prevalence of MH events in Japan was calculated to be between 1:60,000 to 1:73,000.[3,4] However, the prevalence of MH mutations within kindred known to transmit MH-susceptibility (MHS) mutations may be as high as 1:2000.[5] Males appear to be more susceptible to developing a clinical MH episode than females.[3,6] A gender difference in MHS has also recently been demonstrated in knock-in mice expressing human MH mutation RyR1-T4825I.[7] The pediatric population accounts for 52.1% of all MH reactions.[8,9]

Between 50% and 80% of genotyped patients who have had a clinical MH syndrome and a positive muscle biopsy have had their disease linked to 1 of more than 210 mutations in the type 1 ryanodine receptor (RyR1; sarcoplasmic reticulum [SR] Ca^{2+} release channel) gene and 4 mutations in the pore subunit of the slow inactivating L-type Ca^{2+} channel $Ca_V1.1$ (dihydropyridine receptor [DHPR]).[10] The genetics of MH and the related abnormal function of RyR1, the DHPR, and associated proteins are being investigated at the molecular biologic level, with a porcine model and several new mouse models providing intricate details about the cause of the disorder. Parallel studies in humans are limited by scarce material for scientific study and are complicated by the fact that phenotypes within a genotype vary as a result of sex, age, genetic, epigenetic, and environmental modifiers.

Public education and communication in the United States are provided by Malignant Hyperthermia Association of the United States (MHAUS, 11 E. State Street, P.O. Box 1069, Sherburne, NY 13460-1069; telephone: 1-607-674-7901; fax: 1-607-674-7910; e-mail: info@mhaus.org; website: http://www.mhaus.org), and by emergency consultation with the MH Hotline (1-800-MHHYPER or 1-800-644-9737). The North American Malignant Hyperthermia Registry (NAMHR), a professional subsidiary of MHAUS, collates findings from muscle biopsy centers in Canada and the United States and provides access to specific patient data through the hotline or its director, Dr. Barbara W. Brandom (NAMHR, Room 7449, Department of Anesthesiology, Children's Hospital, University of Pittsburgh, 3705 Fifth Avenue at DeSoto St., Pittsburgh, PA 15213-2583; telephone: 1-888-274-7899; fax: 1-412-692-8658; e-mail: bwb@pitt.edu; website: https://www.mhreg.org).

HISTORY

Between 1915 and 1925, one family experienced three anesthetic-induced MH deaths with rigidity and hyperthermia and was puzzled for decades regarding the cause of these deaths.[11,12] MHS was eventually confirmed in three descendants by in vitro muscle biopsy tests.[11] In 1929, Ombrédanne described anesthesia-induced postoperative hyperthermia and pallor in children accompanied by significant mortality but did not detect any familial relationships.[13] Critical worldwide attention to MH began in 1960 when Denborough and Lovell reported a 21-year-old Australian with an open leg fracture who was more anxious about anesthesia than about surgery because 10 of his relatives died during or after anesthesia.[14] Denborough and Lovell initially anesthetized him with the then-new agent halothane, halted it when signs of MH appeared, successfully treated the symptoms, aborted the syndrome, and subsequently used spinal anesthesia. Further evaluations by George Locher in Wausau, Wisconsin, and Beverly Britt in Toronto, Canada, led to the discovery that the risk for MH was indeed familial.[15] The cause of the syndrome was also found to be the result of skeletal muscle involvement rather than central loss of temperature control by the recognition of increased muscle metabolism or muscle rigidity early in the syndrome, low-threshold contracture responses, and elevated creatine kinase (CK) values.[16]

Interestingly, a similar syndrome was discovered in swine inbred with breeding patterns designed to produce a rapid growth rate and superior muscle development (e.g., Landrace, Piétrain, Duroc, and Poland China). *Porcine stress syndrome*,[17] which is associated with increased metabolism, acidosis, rigidity, fever, and death from rapid deterioration of muscle and results in pale, soft, exudative pork,[18] can be triggered by any stress, such as separation, shipping conditions, weaning, fighting, coitus, or preparation for slaughter, and had become a significant problem for meat production. In 1966, Hall and co-workers reported that a syndrome that appeared to be identical to MH could be induced in stress-susceptible swine by the administration of halothane and succinylcholine.[19] The cause of this syndrome in pigs was discovered to be a single missense mutation in *RYR1*, and all susceptible swine have the same Arg615Cys mutation in the SR calcium release channel RyR1.[20]

In 1975, Harrison described the efficacy of dantrolene in preventing and treating porcine MH,[21] which was rapidly confirmed in humans by a multihospital evaluation of dantrolene used to treat anesthetic-induced MH episodes.[22] Today, dantrolene still remains the primary pharmacologic approach for successful MH therapy.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF EXCITATION-CONTRACTION COUPLING AND MALIGNANT HYPERTHERMIA

MH is a syndrome caused by dysregulation of excitation-contraction (EC) coupling in skeletal muscle. Normal muscle contraction is initiated by nerve impulses arriving at the neuromuscular junction (i.e., the motor end plate) that trigger the release of acetylcholine from the nerve terminal. Acetylcholine activates nicotinic acetylcholine receptors (nAChRs), nonselective cation channels located postsynaptically within the neuromuscular junction, which are essential for local depolarization of the muscle membrane and for initiating action potentials that rapidly propagate along the surface membrane of the muscle. Invaginations of the surface membrane (transverse or T tubules) act as conduits to direct action potentials rapidly and uniformly deep within the myofibrils where they transduce a conformational change in the voltage sensor integral to $Ca_V1.1$. Conformational changes in $Ca_V1.1$ are mechanically transmitted to the Ca^{2+} release channels (RyR1) residing in the junctional face of the SR. The mechanical coupling of DHPRs and RyR1 channels that occurs at specialized junctions (*triadic junctions*) is essential for linking the electrical signals arriving at the T tubules with the release of Ca^{2+} stored within the SR. Release of SR Ca^{2+} causes the free, cytoplasmic (sarcoplasmic) Ca^{2+} concentration to increase from 10^{-7} μM to approximately 10^{-5} μM. The Ca^{2+} binds to contractile proteins (troponin C and tropomyosin) in the thin filament to expose the myosin-binding sites on actin that activate the thick filament (myosin) and cause a shortening of the muscle fibers (i.e., muscle contraction). The entire process is termed *excitation-contraction (EC) coupling*. Intracellular Ca^{2+} pumps (i.e., sarcoplasmic/endoplasmic reticulum Ca^{2+}-adenosine triphosphatase [ATPase] or SERCA pumps) rapidly sequester Ca^{2+} back into the SR lumen, and muscle relaxation begins when the Ca^{2+} concentration falls below 10^{-6} μM and ends when the resting sarcoplasmic Ca^{2+} concentration is restored to 10^{-7} μM. Because both contraction and relaxation are energy-related processes that consume adenosine triphosphate (ATP), knowing the molecular events that contribute to EC coupling and the associated relaxation is essential to understanding the cause of MH (Fig. 43-1). Clinical and laboratory data from swine and humans indicate that the fulminant MH syndrome is associated with a persistent

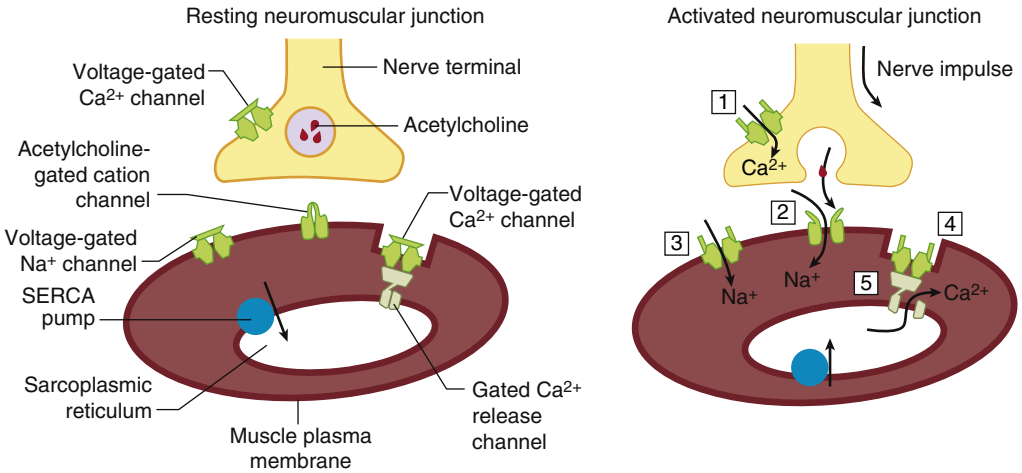

Figure 43-1. Key ion channels involved in neuromuscular transmission and excitation-contraction coupling. Nerve impulses arriving at the nerve terminal activate voltage-gated Ca^{2+} channels *(1)*. The resulting increase in cytoplasmic Ca^{2+} concentration triggers the exocytosis process of acetylcholine. Binding of acetylcholine to postsynaptic nicotinic acetylcholine receptors (nAChRs) activates an integral nonselective cation channel that depolarizes the sarcolemma *(2)*. Depolarizing the sarcolemma to threshold activates voltage-gated Na^+ channels *(3)*, which initiates action potential impulses that propagate deep into the muscle through the transverse tubule system. Within the transverse tubule system, L-type voltage-gated Ca^{2+} channels sense membrane depolarization and undergo a conformational change *(4)*. A physical link between the α1 subunit ($Ca_V1.1$) of the dihydropyridine receptor (DHPR) and the ryanodine receptor (RyR1) is the means by which the electrical signal is transferred from the T tubule to Ca^{2+} release from the SR *(5)*. *(Modified from Alberts B, Bray D, Lewis J, et al:* Molecular biology of the cell, *ed 3. New York, 1994, Garland Press.)*

increase in the concentration of sarcoplasmic Ca^{2+}.[23-26] The increased activity of pumps and exchangers trying to correct the increase in sarcoplasmic Ca^{2+} increases the need for ATP, which in turn produces heat. Thus the end result is hyperthermia. The rigidity that is frequently seen during a fulminant MH episode is the result of the inability of the Ca^{2+} pumps and transporters to reduce the unbound sarcoplasmic Ca^{2+} below the contractile threshold. Dantrolene is therapeutic because it reduces the concentration of sarcoplasmic Ca^{2+}. However, the pathway by which dantrolene lowers sarcoplasmic Ca^{2+} is complex and still not fully understood.

MALIGNANT HYPERTHERMIA IS THE RESULT OF ABNORMAL FUNCTION OF MUSCLE CALCIUM RELEASE UNITS

RYANODINE RECEPTORS

Ryanodine receptors (RyRs), which in muscle are synonymous with the junctional foot protein/SR calcium release channel, are so named because they specifically bind the toxic plant alkaloid ryanodine.[27,28] Three RyR isoforms are encoded by three genes located on human chromosomes 19q13.1,[29] 1q42.1-q43,[30] and 15q14-q15[31]—the skeletal (RyR1), cardiac (RyR2), and brain (RyR3) isoforms, respectively. Each functional RyR consists of four identical subunits (~5000 amino acids each), and each subunit binds with an accessory protein, calstabin 1 (FK506 12-kDa binding protein [FKBP12]).[32-35] The total mass of the tetramer exceeds 2 megadaltons and is one of the largest known proteins and the largest known channel in the mammalian species. Evidence of direct coupling of $Ca_V1.1$ and RyR1 has been demonstrated by expressing chimeric $Ca_V1.1/Ca_V1.2$ complementary DNA (cDNA) in dysgenic myotubes that lack constitutive expression of $Ca_V1.1$.[36,37] Such studies have provided compelling evidence that the cytoplasmic region between repeats II and III (i.e., cytosolic II-III loop) contains a stretch of 46 amino acids (L720 to Q765) that are essential for engaging bidirectional signaling with RyR1.[38]

In the past decade, understanding of EC coupling has significantly increased by identifying protein-protein interactions that regulate both the release and sequestration of Ca^{2+} within skeletal muscle. The elemental unit of function has been named the Ca^{2+} release unit (CRU), and it is localized within junctional regions of T-tubule and SR membranes.[39] The CRU is a macromolecular assembly of interacting proteins that participate in tightly regulating EC coupling. RyR1 is a high-conductance channel that regulates the release of SR Ca^{2+} and is the central component of the CRU. The functional RyR1 tetramer anchored within the SR membrane physically spans the junctional space to interact with tetrads made up of four voltage-activated $Ca_V1.1$ subunits within the T-tubule membrane. This physical interaction engages a form of bidirectional signaling that tightly regulates the function of both proteins. Moreover, the interaction of $Ca_V1.1$ and RyR1 does not occur in isolation; rather, this interaction is further subjected to regulation by a number of proteins localized within the triad junction, including Homer 1, which physically binds and functionally couples target proteins, calstabin 1, triadin, junctin, Mg29, junctophilin 1 and 2, calsequestrin, calmodulin, the catalytic and regulatory subunits of protein kinase A, and protein phosphatase 1.[40-44] It is likely that this list is not complete and that the CRU represents a tightly regulated macromolecular complex. More importantly, increasing experimental evidence suggests that mutations found in RyR1 ($_{MH}$RyR) or $Ca_V1.1$ can alter protein-protein interactions in the CRU,[45-47] as well as alter the functional fidelity of bidirectional signals.[48-52]

In the presence of certain chemical substances, MH mutations in RyR1 or DHPR cause severe dysregulation of RyR1 channel function. This dysregulation can be observed in vitro as heightened sensitivity to volatile anesthetics, 4-chloro-*m*-cresol, caffeine, ryanodine, and potassium depolarization.[53-55] Chemically induced dysfunction of the RyR1 complex appears to be the principal cause of triggering uncontrolled skeletal muscle metabolic acidosis (aerobic and glycolytic), rigidity, and hyperkalemia, but the mechanisms governing the syndrome are unclear. The relationship among exertional heat illness, exertional rhabdomyolysis, and MHS is also unclear and is an area that requires investigation and controlled clinical studies.[56]

Two essential cations greatly shape the kinetics and magnitude of Ca^{2+} release in response to depolarizing triggers: Ca^{2+} itself and magnesium (Mg^{2+}). The normal RyR1 complex responds to Ca^{2+} in a biphasic manner. First, Ca^{2+} activates the channel in a graded manner between 100 nM and 100 μM, whereas higher concentrations inhibit channel activity.[57,58] This biphasic action is thought to occur via binding of Ca^{2+} to two classes of regulatory sites on RyR1, a high-affinity stimulatory site and a low-affinity inhibitory site.[42] Mg^{2+}-induced inhibition is the second important physiologic regulator of RyR1 activity in skeletal muscle.[59,60] Mg^{2+} inhibits RyR1 in a cooperative manner ($n_H \approx 2$; 50% inhibitory concentration [IC_{50}] ≈ 650 μM). It is likely that Mg^{2+} acts by competing with Ca^{2+} at its activator sites and by binding to yet unidentified low-affinity inhibitory sites.[61,62] Possibly, MH mutations introduce allosteric instability into the RyR1 complex, which leads to a reduction of inhibition rather than directly altering the binding properties of Ca^{2+} or Mg^{2+} (or both) at the activator or inhibitor sites. Therefore hypersensitivity to pharmacologic agents is likely to be closely tied to altered responses to physiologic ligands. However, whether MHS channels are primarily hyposensitive to inhibition by Mg^{2+} or Ca^{2+} (or both),[63,64] are hypersensitive to activation by Ca^{2+}, or exhibit altered sensitivities in both directions to both ions seems to be highly dependent on the location of the MH mutation.[65,66] Studies have also pursued the *leaky channel* hypothesis by examining SR preparations from homozygous R615C MHS pigs and heterozygous R163C and C512S mice; they observed a significantly lower Ca^{2+} loading capacity (38%, 23%, and 22% lower than matched wild-type mice, respectively) primarily mediated by the presence of leaky channels that remain active even with 100 nM extravesicular Ca^{2+}.[67,68] Recent studies indicate that the expression of $Ca_V1.1$ represses the basal activity of the ryanodine-insensitive RyR1 leaky

state.[50] Importantly, MHS mutations appear to not only alter bidirectional signaling during EC coupling[51,52] and inherent regulation of RyR1 channel functions,[65,66] but they also weaken negative regulation conferred by $Ca_V1.1$ on the RyR1 Ca^{2+} leak.[48] These recent findings at the molecular and cellular level using knock-in MHS mice confirm earlier measurements made in MHS muscles, myotubes, and myoball preparations and in dyspedic myotubes expressing $_{MH}$RyR1s, all of which have been shown to have chronically elevated resting cytoplasmic $[Ca^{2+}]_i$.[47,54,69]

Some experimental evidence suggests that long-range interdomain interactions between regions of RyR1 are involved in channel regulation by stabilizing protein conformations critical for normal channel transitions.[70] A three-dimensional reconstruction of RyR1 by Samso and co-workers shows that the RyR1 architecture is designed to support long-range allosteric pathways such as coupling with $Ca_V1.1$ and binding to ligands such as calmodulin and FKBP12.[71]

VOLTAGE-GATED CALCIUM CHANNELS: ROLE OF $CA_V1.1$

Although the majority of mutations that confer MHS reside in the *RyR1* gene, recently three mutations in the *CACNA1S* gene encoding for the $Ca_V1.1$ subunit of skeletal muscle have been linked to MHS.[5,72-74] The R1086H mutation in the intracellular loop connecting homologous repeats III and IV of Ca_V represent the first MH-causing mutation so far identified in a protein other than RyR1. Physiologic characterization of the mutation further demonstrated that sensitivity of RyR1 activity is significantly enhanced by membrane depolarization or by pharmacologic activators of RyR1 (e.g., caffeine).[75] In addition, Pirone and colleagues have identified an MHS-causing Thr-to-Ser mutation at position 1354 in the S5-S6 extracellular pore-loop region of the homologous repeat IV of $Ca_V1.1$ Expression of the T1354S mutation also accelerated L-type Ca^{2+} current kinetics and also contributed to an increase in RyR1-mediated Ca^{2+} release.[74] The R174W $Ca_V1.1$ MH mutation occurs at the innermost basic residue of the IS4 voltage-sensing helix, a residue conserved among all Ca_V channels. Unlike the other $Ca_V1.1$ MHS mutations, R174W ablates the L-type current but has no influence on normal EC coupling. Nonetheless, R174W-expressing myotubes have a chronic elevation of free sarcoplasmic resting Ca^{2+} and an increased sensitivity of Ca^{2+} release to caffeine and halothane, compared with myotubes expressing wild-type $Ca_V1.1$.[48,76]

FACTORS OTHER THAN RYANODINE RECEPTOR ABNORMALITIES

Other cellular processes can affect MH episodes. It has been demonstrated that concurrent administration of nondepolarizing neuromuscular blocking drugs and triggering agents can delay or prevent the onset of clinical MH syndrome. Pretreatment of MHS pigs with sufficient nondepolarizing neuromuscular blocking agent to abolish completely the muscle twitch elicited by electrical stimulation of the nerve prevented halothane from triggering the clinical syndrome for 90 minutes, the longest time tested.[77] However, in the continued presence of halothane, when the function of the neuromuscular junction was restored by administering the cholinesterase inhibitor, neostigmine, clinical MH was immediately triggered. This result suggested a close relationship between functional neurochemical transmission within the neuromuscular junction or depolarization of the sarcolemma (or both) and the clinical syndrome.

Recently, sarcolemmal excitation-coupled Ca^{2+} entry (ECCE) has been shown to be sensitive to the conformation of the RyR1 and is enhanced by several mutations in RyR1, including MH mutations.[40,46,78] ECCE appears to be an inherent property of $Ca_V1.1$ during long or repetitive depolarization,[79] possibly mediated by shifting $Ca_V1.1$ to the mode 2–gating conformation. Nevertheless, enhanced ECCE in MHS muscle may contribute to an increased sensitivity to depolarization and appears to be one target for dantrolene's abrogation of responses to both electrical and potassium chloride depolarization.[45] In addition to ECCE, classic store-operated capacitive Ca^{2+} entry pathways similar to the store-operated Ca^{2+} entry (SOCE) observed in nonexcitable cells[80] have been shown to be present in skeletal muscle[81-83] and could be more active in MHS muscles as a response to chronic store depletion. These SOCE channels have also been suggested to be a target for dantrolene.[84] Together, these data suggest that $_{MH}$RyRs or $_{MH}Ca_V1.1$ assume a conformation that enhances Ca^{2+} entry via ECCE or SOCE (or both). This enhanced entry, when combined with decreased sensitivity of $_{MH}$RyRs to Ca^{2+} and Mg^{2+} inhibition, could provide cellular conditions that heighten sensitivity to triggering agents and perpetuate the fulminant clinical MH syndrome.

DANTROLENE

Dantrolene is the only medication that has been shown to be effective in reversing the symptoms of MH. Preadministration of dantrolene will also prevent the development of fulminant MH in homozygous pigs or heterozygous MH mice when exposed to a triggering stimulus. Dantrolene sodium is a hydantoin derivative (1-[[[5-(4-nitrophenyl)-2-furanyl]methylene]imino]-2,4-imidazolidinedione) that does not block neuromuscular transmission but causes muscle weakness by direct action on the striated muscle cell. The properties of dantrolene have been closely correlated with its ability to reduce efflux of Ca^{2+} from the SR in vitro.[85] Dantrolene (20 μM) counteracts the effect of reduced Mg^{2+} inhibition in MH-affected muscle.[86] Dantrolene (20 μM) can inhibit the enhanced sensitivity to caffeine observed in MH muscles, and both dantrolene and its water-soluble analogue, azumolene (150 μM), have been shown to reduce depolarization-induced release of Ca^{2+} in both muscle and triadic vesicles.[87] The idea that dantrolene suppresses SR Ca^{2+} release as a result of direct interactions with RyR1 is somewhat controversial. Paul-Pletzer and associates demonstrated that [^{3}H] azidodantrolene specifically labels the amino terminus of RyR1 defined by the 1400–amino acid residue N-terminal calpain digestion fragment of RyR1.[88] More detailed

analysis further localized the [^{3}H]azidodantrolene binding site to a single domain containing the core sequence corresponding to amino acid residues 590 through 609 of RyR1.[88] However, to date, no evidence suggests that dantrolene has a direct action on single RyR1 channels studied in lipid bilayers, even in the presence of FKBP12, ATP, and activating concentrations of Ca^{2+}, suggesting that dantrolene's main action is to alter key protein-protein interactions.

GENETICS

RYR1 mutations have been found in 50% to 80% of patients and relatives who are labeled MHS by positive in vitro contracture tests (IVCTs) and in almost all families with central core disease (CCD) and King-Denborough syndrome. More than 202 missense mutations and 8 deletions associated with MH have thus far been detected. Another 29 missense mutations are associated with CCD and multiminicore disease in patients with unknown MH testing status.[10] Interestingly, 40% of missense *RYR1* mutations occur at CpG dinucleotide sequences. Five other chromosomal loci (17q21-24, 1q32, 3q13, 7q21-24, and 5p) have been linked to families with positive contracture tests and an unusual response to anesthesia and have been designated MHS loci 2 through 6, respectively. However, of these five, the only gene other than *RYR1* that has been shown to be associated with MH is *CACNL1A3* in the MHS3 locus,[89] which codes for $Ca_V1.1$ (the α_{1S}-subunit of DHPR). Four causative mutations in this gene are linked to less than 1% of MHS families worldwide. In some of the other loci, all genes within the locus have been ruled out as causing MHS. Hence, for practical reasons, the *RYR1* gene remains the primary target for current clinical genetic analysis.

DISTRIBUTION OF *RYR1* MUTATIONS

The missense mutations associated with MHS, CCD, or, in some cases both, are dispersed throughout the coding region of the *RYR1* gene, and all allow transcription of a protein that is putatively functional.[10,90] Until recently, it was thought that most *RYR1* mutations were clustered in three hot spots: MH/CCD region 1—between amino acid residues 35 and 614, MH/CCD region 2—between amino acid residues 2163 and 2458 in the sarcoplasmic foot region of the protein, and MHS/CCD region 3—between amino acids 4643 and 4898 in the carboxyl-terminal transmembrane loop or pore region[91] (Fig. 43-2). It appears that the supposition that hot spots existed was simply caused by bias in the sample analysis, inasmuch as the missense mutations associated with MH or CCD (or both) are scattered over 54 of the 107 exons of *RYR1*. Approximately 41% of reported MH mutations are found in multiple families. CCD mutations are predominantly found in the C-terminal region of the gene (exons 85 to 103), and only 10 mutations (17%) have been described in more than one family: R4861H ($n = 14$), V4849I ($n = 9$), I4898T ($n = 7$), L4824P ($n = 4$), A4940T ($n = 4$), G4638D ($n = 3$), R4893W ($n = 3$), R4861C ($n = 2$), R4893Q ($n = 2$), and G4899E ($n = 2$).

The true ethnic distribution of MH and CCD is difficult to ascertain. MH and CCD have been predominantly reported in Western populations, but, more likely than not, this predominance is incorrect and the result of the manner and frequency in which cases are reported. Some mutations appear to be clustered in a given region of the world, but the distribution and frequency appear to be somewhat population specific. In the United Kingdom, 69 *RYR1* mutations have been discovered, 25 of which were found in a single family. G2434R has been found in approximately 40% of the 434 mutation-positive MH families investigated in the United Kingdom, with the

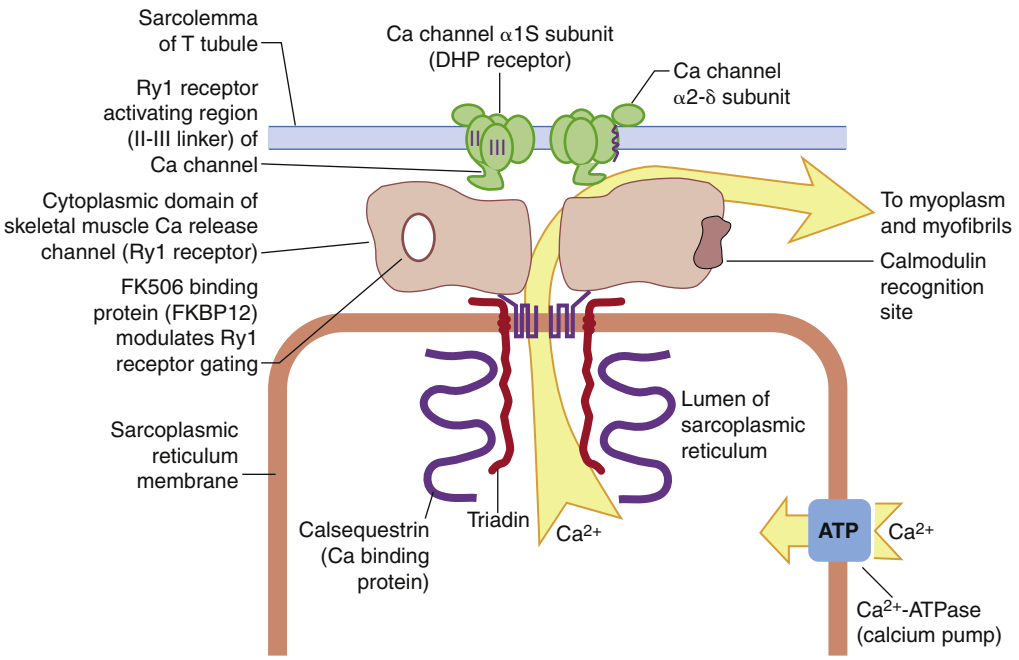

Figure 43-2. Schematic representation of the triadic junction of skeletal muscle shows the junctional foot protein (ryanodine [Ry1] receptor) and its associated proteins. In skeletal muscle, the α_{1S}-subunit of the dihydropyridine receptor (DHPR) participates in excitation-contraction coupling. These physical links transmit essential signals across the narrow gap of the triadic junction that activate the Ry1 receptor and release Ca^{2+} from the sarcoplasmic reticulum. *(Modified from Pessah IN, Lynch C III, Gronert GA: Complex pharmacology of malignant hyperthermia,* Anesthesiology *84:1275-1279, 1996.)*

next most common mutations being T2206M (10%) and G341R (8%). In Switzerland, V2168M and I2336H have been the predominant mutations,[92] and in Germany, R163C (MH and CCD), R614C (MH), T2206M (MH), G2434R (MH), and R2454H (MH) have each been detected in five or more independent cases.[93,94] G341R and R614C have been common mutations in France,[95] and R614C has also been found in several MH families from Italy[95] and Canada.[96] G341R has frequently been found in Belgium.[95] The mutation common to Europe and North America has been G2434R, which has occurred in 4% to 7% of European and 5.5% of North American families.[97] Single-family mutations have been the most common mutations reported in Japanese, Chinese, Taiwanese, Australian, and New Zealand MH families,[98-100] but likely, these findings may reflect the small number of cases investigated there. Because genetic screening in European and North American studies has predominantly targeted only regions 1 and 2 of the original hot spots in the gene, the absence of *RYR1* mutations in some of the screened population could be explained by *RYR1* mutations located outside these two regions or by involvement of other genes.

INHERITANCE AND PENETRANCE OF MALIGNANT HYPERTHERMIA

Inheritance of human MH can no longer be considered to be solely autosomal dominant with variable penetrance because more than one MH-linked mutation has been identified in some probands and families. Six nonconsanguineous families harbor at least two *RYR1* mutations that have both been linked to MHS; and in two families, one is an *RYR1* mutation and the second is a $Ca_V1.1$ mutation.[5] Although MHS homozygosity is common in affected pigs, it is rare in the human population and variable in the transgenic mouse population. The known MHS homozygous humans appear clinically normal but exhibit stronger responses to caffeine and halothane in IVCTs than heterozygous individuals do.[101-104] Homozygosity of two MH mutations in hot spot 1 leads to perinatal lethality in mice.[67,68] In humans, double heterozygous individuals do not appear to show any additive effect of the second mutation on IVCT.[5] However, recent development of the T4826I-*RYR1* knock-in mouse has revealed that an MHS mutation within the S4-S5 cytoplasmic linker of *RYR1* confers genotype- and sex-dependent susceptibility to pharmacologic and environmental stressors that trigger fulminant MH and promote myopathy.[7]

IN VITRO CONTRACTURE TEST AND CAFFEINE HALOTHANE CONTRACTURE TEST

The current gold standard for diagnosis of MH is the halothane and caffeine muscle contracture test, also known as the IVCT or the caffeine halothane contracture test (CHCT). Two protocols have been developed—the first by the European Malignant Hyperthermia Group (EMHG) and the second by the North American Malignant Hyperthermia Group (NAMHG).[9] These two protocols are similar but not identical. For the purpose of differentiation, the EMHG protocol is designated as IVCT and the NAMHG protocol as CHCT.

For the IVCT, the muscle biopsy is performed on the quadriceps (either vastus medialis or vastus lateralis).[105,106] The study consists of three parts: a static caffeine test, a static halothane test, and a dynamic halothane test.[106] For the static caffeine test, a stepwise increased concentration (0.5, 1, 1.5, 2, 3, 4, and 32 mmol/L) is applied. The lowest concentration of caffeine that produces a sustained increase of at least 0.2 g in baseline tension is reported as the caffeine threshold. Then the halothane threshold is obtained using the same method by exposing the muscle to halothane concentrations of 0.5%, 1%, 2%, and 3%. The dynamic halothane test is performed with the muscle stretched at a constant rate of 4 mm/min to achieve a force of approximately 3 g and held at the new length for 1 minute after a 3-minute exposure to halothane. For each cycle, halothane concentration will be increased from 0.5%, 1%, 2%, to 3%. The concentration of halothane that produces a sustained increase of at least 0.2 g in the muscle tension, compared with the prehalothane control, is defined as the *dynamic halothane threshold*.[106] The IVCT protocol classifies the patients into three groups: (1) MHS group with a caffeine threshold at the caffeine concentration of 2 mmol or less and a halothane threshold of 2% halothane or less; (2) MH normal (MHN) group with a caffeine threshold at the caffeine concentration of 3 mmol or more without a halothane threshold at 2% or less; and (3) MH equivocal (MHE) group with all results other than the aforementioned.[105,106]

For CHCT, a muscle biopsy can be taken from the following sites in the order of preference: (1) the vastus group, (2) the rectus abdominus, and (3) other muscle groups under special circumstances.[107] Required tests include exposure of muscle to 3% halothane alone and to incremental caffeine concentrations (0.5, 1, 2, 4, and 8.0 mmol if the response at 4 mmol is less than 1 g and 32 mmol) alone. Optional tests include exposure of muscle to a combination of both 1% halothane and incremental caffeine concentrations and to 2% halothane alone.[107] According to the CHCT protocol, an individual is MHS when either of the halothane or the caffeine test is positive and is MHN when both tests are negative.[107]

The sensitivity and specificity of IVCT was reported to be 99.0% (95% confidence interval [CI] 94.8%-100%) if the MHE group is considered susceptible and 93.6% (95% CI 89.2%-96.5%),[106] and of CHCT 97% (95% CI 84%-100%) and 78% (95% CI 69%-85%), respectively.[108] Recently, fluoroquinolones and statins, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, were found to induce significant contractures in MHS muscle bundles but not in MHN muscles.[109,110] Ondansetron and 3,4-methylenedioxymethamphetamine (MDMA) may also dose-dependently induce contracture or increase the sensitivity of the contractile apparatus to calcium in both MHS and MHN fibers.[111,112] Modifications to the IVCT protocol by adding ryanodine[113] or 4-chloro-*m*-cresol,[114,115] a ryanodine receptor–specific agonist has been reported but has not been included in the standard protocol. Furthermore, Metterlein and associates studied the possibility of replacing halothane with newer volatile agents in IVCT. At increasing concentration, except for sevoflurane, all newer volatile agents, including enflurane, isoflurane, and desflurane, induced significantly

greater contractures in MHS muscle compared with MHN bundles. However, within the MHS muscle bundles, halothane produced significantly higher contractures and was considered the strongest discriminator for MH using the IVCT protocol.[116] A direct application of high sevoflurane concentration of 8%, instead of the stepwise application, has been shown to induce significantly stronger contractures in MHS patients.[117] Nevertheless, from the retrospective analysis of the Japanese MH database, there was no evidence between the severity of MH triggered by sevoflurane and isoflurane or other agents, suggesting sevoflurane is not a weak or weaker MH-triggering agent.[118]

DISCORDANCE BETWEEN GENETIC AND CONTRACTURE MALIGNANT HYPERTHERMIA TESTING

Discordance between genetic and contracture test results has confounded linkage analysis worldwide. Examples include patients diagnosed as MHN carrying an *RYR1* mutation associated with MH and patients diagnosed as MHS who do not carry the familial *RYR1* mutation. Several explanations are possible, the most likely being that IVCT or CHCT is not clinically precise and that the thresholds for IVCT or CHCT are inexact, which would lead to errors in determining whether a patient is MHN or MHS. A second possibility is variable penetrance with possible allelic silencing,[119] and a third possibility is that individuals with discordance have mutations in other unknown genes or modifier genes that affect the function of *RYR1* and its phenotypic penetrance. The discrepancy between incidence estimates of MH events and prevalence estimates also points to possible epigenetic factors at work. Carpenter and colleagues have suggested that the severity of MHS may be related to the *RYR1* variant and mutation found within the highly conserved regions of *RYR1* gene.[72] The rarity of large kindreds with MH makes linkage analysis and understanding variability in clinical manifestations difficult. Robinson and associates demonstrated with the transmission disequilibrium test (TDT) that loci on chromosomes 5 and 7 and, to a lesser extent, loci on chromosomes 1 and 7 influence susceptibility to MH.[95]

GUIDELINES FOR GENETIC SCREENING

In 2000, the European MH group formulated guidelines for *RYR1* mutation screening with linkage data to other loci for some MH families, but all MH investigators emphasized the vital role of IVCT in the diagnosis of MH.[120] These guidelines for screening have reduced the number of relatives requiring contracture testing without increasing the risk of misdiagnosis[121,122] and include the following: (1) confirmation of MHS in a family member (preferably a proband) by IVCT before genetic testing; (2) use of 15 *RYR1* mutations characterized by in vitro functional assays for the genetic protocol; (3) confirmation of MHS and omission of IVCT if a causative mutation is detected in a first-degree relative; and (4) need for performance of IVCT before MHN is diagnosed if a familial mutation is not detected in a first-degree relative.

Only a small number of MHS families have been extensively investigated in North America by phenotyping, linkage analysis, and screening of specific genes. Collaborative protocols over the past several years between MH biopsy centers and molecular biologists have screened 209 unrelated patients diagnosed as MHS for mutations in the *RYR1*gene (see "Distribution of *RYR1* Mutations").

A recent consensus meeting agreed to the following: (1) limitations of genetic testing include low sensitivity because of the diversity of mutations and genes; (2) the *RYR1* gene is the primary focus for genetic testing, but further studies are required for a more complete understanding of the relationship between mutations and susceptibility; (3) guidelines for referral and education are needed to establish clinical testing in a Clinical Laboratories Improvement Act (CLIA)–certified laboratory; and (4) a North American MH *RYR1* Mutation Panel was not changed from the original panel set out in 2002 (Table 43-1).

Larach and co-workers reported a 34.8% morbidity rate in 181 patients with MH reported to the NAMHR between 1987 and 2006.[123] The occurrence of MH episodes was most frequent in young men (75%), and approximately one half of the patients reported having undergone two or more unremarkable general anesthetics in the past. In a more recent analysis of over 5 million nonbirth-related hospital discharges, diseases of the musculoskeletal system and connective tissue were significantly associated with MH diagnosis in children.[124]

FULMINANT MALIGNANT HYPERTHERMIA

Fulminant MH is rare. Acute episodes of MH depend on four variables: (1) a genetic predisposition, (2) the absence of inhibiting factors, (3) the presence of an anesthetic or nonanesthetic trigger, and (4) the presence of environmental factors that could potentiate the action of one or more of the other three variables.

ANESTHETIC TRIGGERING

Anesthetic drugs that trigger MH include ether, halothane, enflurane, isoflurane, desflurane, sevoflurane, and depolarizing muscle relaxants, succinylcholine being the only anesthetic drug currently used. Desflurane and sevoflurane appear to be less potent triggers than halothane and produce a more gradual onset of MH.[125,126] The onset may be explosive if succinylcholine is used. MHS swine were traditionally screened by induction with a volatile anesthetic, which led to pronounced hind limb rigidity within 5 minutes, frequently sooner.[127] Prior exercise, even an hour before induction of anesthesia, increased the severity and hastened the onset of rigidity in swine.[127] Similarly, in the new knock-in mouse models, the onset of limb rigidity after commencing exposure to volatile anesthetics was rapid. In addition, several modifying factors are more likely to be present in humans than in pigs or mice and can alter (or even prevent) the onset of clinical MH. Mild hypothermia and the preadministration of barbiturates, tranquilizers, propofol, or nondepolarizing neuromuscular blockers delay or prevent the onset of MH[25,127-129] in humans who are MHS, thus making them respond less predictably than swine or knock-in mice with MH. Many instances have occurred during

TABLE 43-1 FINDINGS OF THE NORTH AMERICAN MALIGNANT HYPERTHERMIA MUTATION PANEL, 2002

Exon	Mutation*	RyR1 Amino Acid Change	No. of Families in North America†	Estimated Incidence in Europe (%)	Phenotype

CCD, Central core disease; *MHS,* malignant hyperthermia susceptibility; *RyR1,* ryanodine receptor type 1.
*Criteria for the 17 mutations: (1) they occur in more than one family in North America or Europe, and (2) previous testing of a sequence variant shows that the mutation is not a polymorphism.
†Data collaboration of the Uniformed Services University of the Health Sciences, Thomas Jefferson University, Wake Forest University, University of California, Davis, and Barrow Neurological Institute. The number in parentheses indicates those also found in Canada (e.g., for exon 45, four families with the mutation G2434R were found in Canada).

which fulminant MH has been reported in patients who previously tolerated potent triggers without difficulty.[130] The reason this occurs is unknown, but it is likely to be related to prior or concurrent administration of drugs that prevent or delay the onset of the syndrome, as described earlier, or unknown environmental influences that help provoke the positive incident. Thus the onset of the syndrome in humans is extremely variable both in initial symptoms and in the time of onset of the syndrome. Its onset is so variable that making the diagnosis in the setting of a clinical anesthetic can be quite difficult. Although not perfect, the clinical grading scale developed by Larach and colleagues[131] is a useful way for clinicians to determine retrospectively whether a patient who responds abnormally to anesthesia is in any way likely to actually have had a clinical MH episode. However, MH is most easily diagnosed prospectively by vigilance, recognizing its signs and symptoms and knowing how to treat the syndrome.

The two classic clinical manifestations of fulminant MH syndrome may start with one of the following two scenarios:

1. Rigidity after induction with succinylcholine but successful intubation, followed rapidly by the symptoms listed after scenario 2
2. Normal response to induction of anesthesia and uneventful anesthetic course until the onset of the following symptoms:
   - Unexplained sinus tachycardia or ventricular arrhythmias (or both)
   - Tachypnea, if spontaneous ventilation is present
   - Unexplained decrease in oxygen (O_2) saturation (because of a decrease in venous O_2 saturation)
   - Increase in end-tidal partial pressure of CO_2 (P_{CO_2}) with adequate ventilation and, in most cases, unchanged ventilation
   - Unexpected metabolic and respiratory acidosis
   - Central venous desaturation
   - Increase in body temperature above 38.8° C with no obvious cause

The usually muted onset of MH (scenario 2) is, in most cases, quickly detected by the development of tachycardia, increased levels of expired CO_2, and muscle rigidity. It can be delayed for several reasons and may not be overt until the patient is in the recovery room. Once initiated, the course of MH can be rapid. When clinical signs such as increased expired CO_2, muscle rigidity, tachycardia, and fever suggest MH, more than one abnormal sign must be observed before making the diagnosis, because according to a meta-analysis of many reported cases, a single adverse sign does not usually indicate MH.[131] The mechanism by which anesthetics and depolarizing muscle relaxants trigger MH is unsolved, but the facts that they are etiologic agents and that early diagnosis is critical for successful treatment cannot be ignored. A recent retrospective review of the *Adverse Metabolic/Musculoskeletal Reactions to Anesthesia* (AMRA) reports demonstrated that the onset of MH has been observed later during desflurane and isoflurane anesthesia than during exposure to sevoflurane. There has been an increased delay of MH signs to appear in the second and third hours of anesthesia than before. In MH cases with one unique first sign, the first MH signs most often encountered were hypercarbia (30.7%), masseter spasm (24.8%), and sinus tachycardia (21.1%).[131a]

NONANESTHETIC MALIGNANT HYPERTHERMIA

Fulminant MH can be easily triggered in swine subjected to environmental stress such as exercise, heat, anoxia, apprehension, and excitement (see "History" earlier in

this chapter).[9,127] Reports of MH-like episodes in humans after stressful situations or heat exposure have been reported.[132-137] Measurement of plasma catecholamine levels during exercise showed no differences between MHS and normal individuals.[138,139] Therefore it is unlikely that these responses were provoked by sympathetic overdrive or catecholamine surge.[140]

Wappler and associates reported *RYR1* mutations in 3 of the 12 unrelated patients with exercise-induced rhabdomyolysis; 10 of the same 12 patients had an abnormal contracture response with IVCT.[141] One had an equivocal response. Increased ambient temperature has been shown to trigger fulminant MH in all reported strains of MH mice.[68,69] An epidemiologic study has shown that exercise-induced symptoms, including rhabdomyolysis, occur more frequently in patients who are MHS.[141] Furthermore, an Arg401Cys *RYR1* mutation was present in three cases of exercise-induced rhabdomyolysis.[98] Other reports are largely anecdotal and relate heat stroke, sudden and unexpected death, unusual stress and fatigue, or myalgias to possible "awake" MH episodes. Stresses associated with these episodes include exercise and environmental exposure to volatile nonanesthetic vapors.[134,142,143] MHAUS has provided recommendations of adverse effects of heat and exercise in relation to MH susceptibility.[144]

MALIGNANT HYPERTHERMIA–ASSOCIATED SYNDROMES

MASSETER SPASM (HALOTHANE-SUCCINYLCHOLINE RIGIDITY)

A masseter spasm or trismus is defined as jaw muscle rigidity in association with limb muscle flaccidity after the administration of succinylcholine. The masseter and lateral pterygoid muscles contain slow tonic fibers that can respond to depolarizing neuromuscular blockers with a contracture.[145,146] This contracture is clinically manifested on exposure to succinylcholine as an increase in jaw muscle tone and defined by van der Spek and associates.[147] A spectrum of responses exists: a tight jaw that becomes a rigid jaw and then a very rigid jaw (Fig. 43-3). This jaw rigidity may occur even after pretreatment with a defasciculating dose of a nondepolarizing relaxant. If rigidity of other muscles develops in addition to trismus, then the association with MH is absolute; anesthesia should be halted as soon as possible and treatment of MH begun.

However, in more than 80% of patients with trismus but no rigidity of other muscles. It is a variant found in normal patients. If trismus occurs, then proper monitoring should include end-expired CO_2; examination for pigmenturia; and arterial or venous blood sampling for CK, acid-base status, and electrolyte levels, particularly potassium. Although scientifically unproven, it is thought that the initial tightness of the jaw and its duration may predict the gravity of the response. MHAUS recommends following CK and urine myoglobin for 36 hours with 6-hour intervals.[148] Patients with masseter spasm should be closely observed for at least 12 hours.

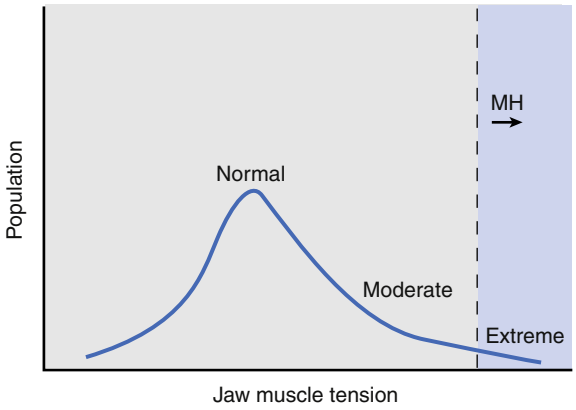

Figure 43-3. Succinylcholine usually increases jaw muscle tone slightly. In some patients, this increase is moderate; in a very few, the effect is extreme (i.e., "jaws of steel"). As many as 50% of this latter group may be susceptible to malignant hyperthermia (MH). Somewhere in the area of the declining curve is the boundary for the MH population.

CORE MYOPATHIES

CCD is a rare hereditary disease and was first reported in 1956 by Magee and Shy.[149] A recent population study in northern England revealed a prevalence of 1:250,000.[150] In1971, Engel and colleagues reported a related congenital myopathy, multicore disease (MCD).[151,152] Subsequently, various designations of the terms were reported for the variations of the disease, including minicore myopathy and multiminicore myopathy.[151] Multiminicore disease (MmD) is now the most official term for these variations sponsored by the European Neuromuscular Centre.[151]

As mentioned, most CCD cases are due to a dominant missense mutation in *RYR1*. Clinically, patients diagnosed with CCD exhibit muscle weakness of a variable degree and histologically with central cores in type I skeletal muscle fibers.[153] MmD is considered a recessively inherited myopathy with severe axial weakness, and respiratory, bulbar, and extraocular muscles are commonly affected.[153] MmD has a heterogenous genetic association with recessive mutation in *SEPN1* gene on chromosome 1p36 and in *RYR1*,[153] and in MmD, both type 1 and type 2 fibers may be affected.[151]

Serum CK levels in patients with CCD are often normal but may be elevated 6 to 14 times in rare cases. Muscle ultrasound often demonstrates increased echogenicity in the quadriceps muscle with relative sparing of the rectus muscle. A characteristic pattern of selective involvement of muscle on a magnetic resonance image has been reported in the patients with typical CCD,[151] which seems to be distinctive to conditions linked to *RYR1* locus.

The relationship between CCD and the MHS is complex. A positive IVCT has been confirmed in many patients with CCD, whereas MHS has been excluded in others. In consideration of the strong link and potential risk, considering all patients with CCD to be at risk for MH is advisable, unless the patient has a negative IVCT. Although MHS has not been reported in *SEPN1*-related myopathies, applying a nontriggering approach to patients with MmD is prudent, considering the potential

risk in *RYR1*-related MmD. Clinical MH reactions have been reported in patients with MmD.[154,155]

KING-DENBOROUGH SYNDROME

King-Denborough syndrome (KDS) features the dysmorphic facial and skeletal abnormalities similar to Noonan syndrome and congenital myopathy with proximal muscle weakness.[156] Sporadic cases have been reported in the literature.[157-166] The inheritance pattern of the disease is not clear. Elevated baseline CK appears in approximately one half of the patients with KDS. A heterozygous A97G point mutation in exon 2 of the *RYR1*, causing a substitution of lysine for glutamine at amino acid residue 33 (Lys33Glu), has been reported.[167] This substitution creates a major polarity change, from positive to negative, in a known hot spot for MH causative mutation. Dowling and associates recently identified *RYR1* mutation in three out of the four patients with KDS, which supports the hypothesis of its genetic heterogeneity.[168] Considering the strong evidence for MHS in patients with KDS, MH triggering agents should be avoided for anesthesia on patients with KDS.

DIAGNOSIS IN THE SURGICAL AND POSTANESTHESIA CARE UNITS

As stated earlier, fulminant MH is rare, and the early signs of clinical MH may be subtle (Box 43-1). These signs must be distinguished from other disorders with similar signs (Box 43-2).

When the diagnosis is obvious (i.e., fulminant MH or succinylcholine-induced rigidity with rapid metabolic changes), significant hypermetabolism and heat production occur, and little time may be left for specific therapy to prevent death or irreversible morbidity. If the syndrome begins with slowly increasing end-tidal CO_2 ($ETCO_2$), specific therapy can await a complete clinical workup before treatment. In general, MH is not expected to occur when no triggers are administered (see "Anesthesia for Susceptible Patients" later in this chapter). However, several confirmed fulminant nonanesthetic cases of MH that resulted in death have been reported (see "Nonanesthetic Malignant Hyperthermia" earlier in this chapter).[141]

When volatile anesthetics or succinylcholine are used, MH should be suspected whenever an unexpected increase in $ETCO_2$, undue tachycardia, tachypnea, arrhythmias, mottling of the skin, cyanosis, muscle rigidity, sweating, increased body temperature, or unstable blood pressure develop. If any of these occur, signs of increased metabolism, acidosis, or hyperkalemia must be pursued. The most common cause for sudden $ETCO_2$ during general anesthesia and sedation is hypoventilation. Increased minute ventilation should correct the problem.

The analysis of arterial or venous blood gases that demonstrate a mixed respiratory and metabolic acidosis can support the diagnosis of MH[169]; however, the respiratory component of acidosis may be predominate in the early stage of onset of fulminant MH. O_2 and CO_2 change more significantly in the central venous compartment than in arterial blood; therefore end-expired or venous CO_2 levels more accurately reflect whole-body stores. Venous CO_2, unless the blood drains an area of increased metabolic activity, should have P_{CO_2} levels of only approximately 5 mm Hg greater than that of expected or measured Pa_{CO_2}. In small children, particularly those without oral food or fluid for a prolonged period, the base deficit may be 5 mEq/L because of their smaller energy stores.

In North America, any patient suspected of having an MH episode should be reported to the NAMHR of MHAUS

BOX 43-1 *Clinical Signs of Malignant Hyperthermia*

Early Signs

Elevated end-tidal carbon dioxide (CO_2)
Tachypnea and/or tachycardia
Masseter spasm, if succinylcholine has been used
Generalized muscle rigidity
Mixed metabolic and respiratory acidosis
Profuse sweating
Mottling of skin
Cardiac arrhythmias
Unstable blood pressure

Late Signs

Hyperkalemia
Rapid increase of core body temperature
Elevated creatine phosphokinase levels
Gross myoglobinemia and myoglobinuria
Cardiac arrest
Disseminated intravascular coagulation

BOX 43-2 *Conditions and Disorders That May Mimic Malignant Hyperthermia*

Anaphylactic reaction
Alcohol therapy for limb arteriovenous malformation
Contrast dye injection
Cystinosis
Diabetic coma
Drug toxicity or abuse
Environmental heat gain more than loss
Equipment malfunction with increased carbon dioxide (CO_2)
Exercise hyperthermia
Freeman-Sheldon syndrome
Heat stroke
Hyperthyroidism
Hypokalemic periodic paralysis
Hypoventilation or low fresh gas flow
Increased end-tidal carbon dioxide ($ETCO_2$) from laparoscopic surgery
Insufficient anesthesia or analgesia (or both)
Intracranial free blood
Malignant neuroleptic syndrome
Muscular (Duchenne and Becker) dystrophies
Myotonias
Osteogenesis imperfecta
Pheochromocytoma
Prader-Willi syndrome
Rhabdomyolysis
Sepsis
Thyroid crisis
Ventilation problems
Wolf-Hirschhorn syndrome

via the AMRA report available from the web site at http://www.mhaus.org/registry/downloads. In addition, MHAUS has an emergency MH hotline available in the United States at 1-800-644-9737 or outside the United States at 1-209-417-3722.

TREATMENT

Acute management for MH can be summarized as follows:

1. Discontinue all anesthetic agents and hyperventilate with 100% O_2 with a fresh flow to at least 10 L/min. With increased aerobic metabolism, normal ventilation must increase. However, CO_2 production is also increased because of neutralization of fixed acid by bicarbonate; hyperventilation removes this additional CO_2.
2. Reconstitute dantrolene in sterile water (not saline), and administer rapidly (2.5 mg/kg intravenously [IV] to a total dose of 10 mg/kg IV) every 5 to 10 minutes until the initial symptoms subside.
3. Administer bicarbonate (1 to 4 mEq/kg IV) to correct the metabolic acidosis with frequent monitoring of blood gases and pH.
4. Control fever by administering iced fluids, cooling the body surface, cooling body cavities with sterile iced fluids, and, if necessary, using a heat exchanger with a pump oxygenator. Cooling should be halted when the temperature approaches 38° C to prevent inadvertent hypothermia.
5. Monitor urinary output, and establish diuresis if urine output is inadequate. Administer bicarbonate to alkalinize urine to protect the kidney from myoglobinuria-induced renal failure.
6. Blood gases, electrolytes, CK, temperature, arrhythmia, muscle tone, and urinary output guide further therapy. Hyperkalemia should be treated with bicarbonate, glucose, and insulin. Effective doses of dantrolene to reverse MH are the most effective way to lower serum potassium levels. In severe cases, calcium chloride or calcium gluconate may be used.
7. Analyze coagulation studies (e.g., international normalized ratio [INR], platelet count, prothrombin time, fibrinogen, fibrin split degradation products).

Adequate personnel support is critical to the successful management of such a crisis. Discontinuation of the trigger may be adequate therapy for acute MH if the onset is slow or if exposure was brief. Changing the breathing circuit and CO_2 absorbent can be time consuming. However, application of activated charcoal filters may rapidly reduce the volatile anesthetic concentration to an acceptable level in less than 2 minutes and should be used in the acute situation if they are readily available.[170]

Dantrolene is packaged in 20-mg bottles with sodium hydroxide for a pH of 9.5 (otherwise, it will not dissolve) and 3 g of mannitol, which converts the hypotonic solution to isotonic. The initial dose should be 2.5 mg/kg dantrolene reconstituted in sterile water and administered IV. Dantrolene must be reconstituted in sterile water rather than salt solutions or it will precipitate. Prewarming sterile water may expedite the solubilization of dantrolene, compared with water in ambient temperature.[171] In 2009, a newer, rapid soluble dantrolene became available for IV use. It reconstitutes in approximately 20 seconds, which is significantly faster than the older version.[172]

In awake, healthy volunteers, the maximum twitch depression occurs at a dantrolene dose of 2.4 mg/kg.[173] Therefore it is not surprising that at therapeutic concentrations, dantrolene may prolong the need for intubation and assisted ventilation. Brandom and associates reviewed the complications associated with the administration of dantrolene from 1987 to 2006, using the dataset in the NAMHR via the AMRA reports, and found that the most frequent complications of dantrolene were muscle weakness (21.7%), phlebitis (9%), gastrointestinal upset (4.1%), respiratory failure (3.8%), hyperkalemia (3.3%), and excessive secretions (8.2%).[174] Considering its high pH, administering dantrolene through a large-bore IV line is advisable, but its administration should not be delayed if a large-bore IV line is not already in place. Dantrolene interferes with EC coupling of murine intestinal smooth muscle cells,[175] rat gastric fundus, and colon,[176] which, in part, explains it gastrointestinal side effect. Caution should be used when ondansetron is to be used in this setting. As a serotonin antagonist, ondansetron may increase serotonin at the 5-HT_{2A} receptor in the presynaptic space. In an individual with MHS, agonism of 5-HT_{2A} receptor may precipitate MH.[177]

The clinical course will determine further therapy and studies. Dantrolene should probably be repeated at least every 10 to 15 hours, since its half-life is at least 10 hours in children and adults.[173,178] The total dose of dantrolene that can be used is up to 30 mg/kg in some patients. Recrudescence of MH can approach 50%, usually within 6½ hours.[179,180] When indicated, calcium and cardiac glycosides may be safely used and can be lifesaving during persistent hyperkalemia. Slow voltage-gated calcium channel blockers do not increase porcine survival.[181,182] Rather, a recent study by Migita and co-workers demonstrated that dihydropyridine (i.e., nifedipine), phenylalkylamine (i.e., verapamil), and benzothiazepine (i.e., diltiazem) all led to increased $[Ca^{2+}]_i$ in human skeletal muscle cells. Interestingly, the potency of such calcium release is correlated with the number of binding sites on the DHPR; that is, nifedipine > verapamil > diltiazem.[183] Clinical doses of dantrolene were only able to attenuate 20% of the nifedipine-induced $[Ca^{2+}]_i$ surge.[183] Current recommendations of MHAUS discourage the use of calcium channel blockers in the presence of dantrolene, because they can worsen the hyperkalemia, resulting in cardiac arrest.[148] The administration of magnesium sulfate could not prevent the development of MH and did not influence the clinical course.[184] Permanent neurologic sequelae, such as coma or paralysis, may occur in advanced cases, probably because of inadequate cerebral oxygenation and perfusion for the increased metabolism and because of the elevated body temperature, acidosis, hypo-osmolality with fluid shifts, and potassium release.

For patients with MH who are diagnosed in ambulatory surgical centers, guidelines have been recently proposed for transferring care to receiving hospital facilities.[185]

Although immediate treatment and onsite stabilization of the patient are preferable, several factors need to be considered before implementing a transfer plan after completing an initial dantrolene treatment, which include the capabilities of the available professionals at the initial treatment and receiving facilities, the clinical best interests of the patient, and the capabilities of the transfer team.[186]

If uncertain at any time, the physician should contact the MH Hotline (United States: 1-800-644-9737; outside the United States: 1-315-464-7079) to verify treatment and report the case to the NAMHR (1-888-274-7899). The MHAUS web site (https://medical.mhaus.org) also provides online support and resources to direct management.

ANESTHESIA FOR SUSCEPTIBLE PATIENTS

Safe anesthetics consist of nitrous oxide, barbiturates, etomidate, propofol, opiates, tranquilizers, and nondepolarizing neuromuscular blocking drugs. Volatile anesthetics and succinylcholine must be avoided at all times, even in the presence of dantrolene. Anecdotal reports suggest that some patients have experienced a hypermetabolic state, despite these precautions, but they have always responded favorably to the administration of IV dantrolene. Preoperative dantrolene is never needed, because the use of nontriggering agents is almost always associated with uneventful anesthesia. Regional anesthesia is safe and may be preferred. Amide anesthetics, such as lidocaine, were once considered dangerous in susceptible patients because they were thought to induce or worsen muscle contractures in vitro as a result of their effect of increasing calcium efflux from the SR. Porcine and human studies, however, have consistently demonstrated the lack of danger of amide anesthetics.

Before administering anesthesia for MHS patients, anesthetic machines may be "cleansed" of potent volatile agents by disconnecting or removing the vaporizers from the anesthesia workstation, renewing the CO_2 absorbent, and using a new, disposable breathing circuit and, if possible, a fresh gas hose. If a dedicated machine is not available for the patient who is MHS, flushing the anesthesia workstation to less than five parts per million (ppm) of the volatile anesthetic agents' concentration is generally accepted.[187] Flushing the workstation may take 10 to 104 minutes with different machines.[170,188-197] This preparation process also should be directed on the basis of the halogenated volatile agents that have been used. Jones and colleagues demonstrated that desflurane required longer purge time than sevoflurane on both the Datex-Ohmeda Aestiva and Aisys machines.[196] Application of activated charcoal filters have been shown to accelerate successfully the process of cleansing.[170,198-200] Such filters should be placed on both the inspiratory and the expiratory limbs of the anesthesia machine and replaced with a new set every 60 minutes.[170] MHAUS recommends flushing and preparing the anesthesia workstation according to the manufacturer's recommendations or published studies.[201] During the case, lowering the fresh gas rate after the washout period may allow the concentration of volatile anesthetic agents to reaccumulate.[192] Fresh gas flow should be kept to at least 10 L/min to avoid this rebound.

It is important to be aware that the National Institute for Occupational Safety and Health (NIOSH) issued "Criteria for a Recommended Standard. Occupational Exposure to Waste Anesthetic Gases (WAGs) and Vapors."[202] No worker is exposed to halogenated anesthetic agents at concentrations greater than 2 ppm when used alone or more than 0.5 ppm when used in combination with nitrous oxide over a sampling period not to exceed 1 hour. Anesthetic gas machines, nonrebreathing systems, and T-tube devices shall have an effective scavenging device that collects all WAGs. In addition, Occupational Safety and Health Administration (OSHA) has guidelines for workplace exposures.[203]

The anesthesiologist should confidently discuss anesthetic care with patients who are MHS and assure them that all will be done to avoid difficulties with MH and that the appropriate drugs, knowledge, and skills are immediately at hand if any problems should occur. Many of these patients have uneventfully undergone procedures, such as dental analgesia and obstetric anesthesia, before the diagnosis of susceptibility was made. The patient can enter the therapeutic environment in a reassured, relaxed, and comfortable state. Outpatient procedures are feasible in most environments; the time of discharge depends on the usual outpatient criteria.

Any anesthesia provider using MH triggers on an inpatient or outpatient basis should have dantrolene immediately available. The current recommendation by MHAUS to stock 36 vials of dantrolene is based on the quantity of dantrolene needed to treat an MH crisis on a patient weighing 70 kg.[172]

EVALUATION OF SUSCEPTIBILITY

Evaluation of susceptibility includes a history and physical examination to detect any subclinical abnormality. A genealogy with specific information about anesthetic exposure and agents can estimate the likelihood of exposure to triggering agents. Blood CK values, when determined in a resting, fasting state without recent trauma, reflect muscle membrane stability. When the CK level is elevated in a close relative of a person with known MHS, the relative may be considered to have MHS without contracture testing. If the CK level is normal on several occasions, no predictive value exists and contracture studies are necessary. The patient must travel to the test center for a surgical biopsy to ensure viability and accurate results. Muscle biopsy contracture studies, performed at approximately 30 centers around the world, involve exposure of the muscle biopsy sample to halothane, caffeine, and, in the North American test, to halothane plus caffeine.[120] Sensitivity to 4-chloro-*m*-cresol or ryanodine have also been used by some centers.[46] It is also important to note that contracture responses are sometimes positive in patients with myopathies that bear no direct relationship to MH and therefore may not indicate susceptibility. Dantrolene must be avoided before biopsy because it masks the response to contracture-producing drugs. After a patient is diagnosed as being MHS, DNA

testing for mutations should follow. When a mutation is detected, other relatives with that mutation should be considered to be MHS without the need for an invasive contracture test, and they need not travel to a testing center (see "Genetics" earlier in this chapter).

Advice should be given to susceptible patients and, if not biopsy tested, all patients with a clinical picture that suggests a high probability for MHS. Precautions are necessary regarding general anesthesia, and triggers include all potent volatile anesthetics agents and succinylcholine. Awake episodes are uncommon, and, if not experienced before diagnosis, then they are an unlikely problem. The true predictive value (i.e., percentage of positive results that are true positives) or efficiency (i.e., percentage of all results that are true, whether positive or negative) of contracture testing in determining susceptibility in the general population cannot be estimated because of the selection process that has been used to date for testing (i.e., limited to those with anesthesia reactions who do not have any other muscular pathologic disease). False-positive results from cautious interpretation or decreased specificity are masked because the patient will never be exposed to triggering agents. A promising innovative in vivo human application involves physiologic-based microdialysis infusion of caffeine or halothane into muscle of patients who are MHS to trigger exaggerated localized changes in acid-base balance.[204-208] White blood cells express *RYR1*-MH mutations and provide a substrate for a less invasive analysis for susceptibility but have the limitation that not all causative mutations are expressed in the white blood cells.[209-213] Nuclear magnetic resonance spectroscopy is promising,[214,215] but, to date, it has been difficult to standardize a stress, such as forearm ischemia, that can differentiate those who are susceptible from those who are not.

For anesthesia assessment of the pregnant patient who is non-MHS and carrying a potential MHS fetus, the patient should be treated as MHS until the fetus is delivered.[216-218] For emergencies in such patients, the use of succinylcholine, although little of the drug crosses the placenta, is controversial.[219]

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is an autoimmune disorder characterized by T cell–mediated autoantibodies against myelin and a subsequent inflammatory response in the central nervous system (CNS) (brain and spinal cord). Thus MS is a disorder of the myelinated part of the axon that leads to secondary nerve conduction failure. The disease mainly affects women, primarily between 20 and 40 or 45 and 60 years of age. Although the cause is unknown, speculation suggests that environmental factors, combined with a genetic predisposition, cause MS. Naturally, researchers have focused on identifying key events and the genetic origin of the disorder to provide diagnostic and possibly therapeutic tools for the management of patients with MS.

Patients with MS frequently report paresthesias, muscle weakness, and sensory disturbances. Typically, a localized or (late in the course of disease) generalized muscle weakness develops with the legs affected more than the arms. In severe cases, respiration may be involved with the development of hypoxemia. Diplopia and other cranial nerve–dependent impairments are early and frequent signs, along with sensory abnormalities and sometimes disturbed bowel and bladder function. As a rule, symptoms are closely related to the site affected within the CNS, and the amount of symptoms is related to the extent of sclerosing CNS plaque. Notably, MS can be associated with impaired autonomic function, which may lead to adverse reactions to sympathomimetic drugs.[220]

Diagnosis of MS is currently based on a combination of clinical and laboratory tests, including cerebrospinal fluid (CSF) antibody analysis and radiology (detection of CNS plaque by magnetic resonance imaging). Medication consists of various combinations of immunosuppression modalities.

Anesthetic Considerations

It has been speculated that general anesthesia and surgery may increase the risk for aggravation of MS.[221] At present, no general consensus on this matter exists, and patients should therefore be informed of the potential for aggravated symptoms in the postoperative period. In general, preoperative chronic immunosuppressive medication should be continued during the perioperative period. Patients with MS are sensitive to physical (e.g., pain, fever, infection) and emotional stress, which will more likely cause symptoms to be intensified in the perioperative period. Great care must be exercised to minimize changes in body temperature, fluid homeostasis, and central hemodynamics (preload, afterload) and to maintain respiration. Although IV agents and volatile anesthetics have been safely used, avoiding the administration of depolarizing neuromuscular blocking drugs to patients with MS is wise. MS-induced denervation or disuse myopathy may lead to a risk for succinylcholine-induced hyperkalemia, which can result in fatal cardiac arrhythmias (see also Chapter 34). Using nondepolarizing neuromuscular blockers is likely safe. Epidural anesthesia has been considered safe in patients with MS, although there is some evidence that patients with MS might benefit from lower doses of local anesthetics. Spinal anesthesia is controversial in MS and is therefore needed to proceed with caution because of potentially increased sensitivity of the spinal cord to local anesthetics due to demyelination. Notably, postpartum worsening of MS symptoms is noted in 20% of women (see also Chapter 77). The need for more extended postoperative care is dependent on the preoperative symptoms, type of surgery, and status of the patient at the end of the surgical procedure. In this context, patients with MS with severe weakness and respiratory distress, including pharyngeal dysfunction, may need extended postoperative care, such as noninvasive respiratory support and intense physiotherapy, to avoid further impairment of their pulmonary function.

MOTOR NEURON DISORDERS

Motor neuron disorders involve either the upper or the lower motor neurons of the cerebral cortex, brainstem, and spinal cord. Some forms are mixed, whereas others have predominantly upper or lower motor neuron involvement. Amyotrophic lateral sclerosis (ALS) is the

most common disease within this group and involves both upper and lower motor neurons. Other examples of motor neuron disease are Kennedy disease (spinobulbar muscular atrophy), Friedreich ataxia (mixed upper and lower motor neurons), and spinal muscular atrophy (lower motor neurons).

Progressive and variable loss of motor neurons within the cerebral cortex, medullary nuclei of cranial nerves, and nuclei of the ventral horn in the spinal cord characterize ALS (Lou Gehrig disease). Degenerative loss of these neurons leads to progressive muscle weakness, muscle atrophy, and loss of neuronal mass in these locations. Sensory functions, including intellectual capacity and cognition, as well as bowel and bladder function, are not usually affected in ALS.

ALS has an incidence of approximately 2 in 100,000 per year, and onset of the disease usually takes place around 40 to 50 years of age, with men more often affected than women. Most cases are sporadic, but rare familial forms (autosomal dominant and recessive forms) exist. The underlying mechanism or mechanisms for this selective and progressive motor neuronal death are thus far unclear, but it has recently been suggested that superoxide dismutase mutations may play a key role in the increased formation of free radicals observed in subsets of patients. The diagnosis is made by electrophysiology (electromyography [EMG] and electroneurography) and by neurologic examination, which demonstrates early spastic weakness of the upper and lower extremities, typical subcutaneous muscle fasciculations, and bulbar involvement affecting pharyngeal function, speech, and the facial muscles. No curative treatment is currently available, and patients are therefore treated symptomatically.

Anesthetic Considerations

Bulbar involvement in combination with respiratory muscle weakness leads to the risk for aspiration and pulmonary complications. Notably, these patients may have increased sensitivity to the respiratory depressant effects of sedatives and hypnotics. Sympathetic hyperreactivity and autonomic failure have been reported.[222] Succinylcholine should be avoided because of the risk for hyperkalemia as a result of denervation and immobilization. Nondepolarizing neuromuscular blocking agents may cause prolonged and pronounced neuromuscular blockade and hence should be used with great caution.[223] General anesthesia combined with epidural anesthesia has been used without complications. Careful postoperative monitoring of respiration and oxygenation are important in these patients because there might be inherent instability of respiratory control.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is an acute inflammatory polyneuritis caused by an immunologic reaction. Although the cause is unknown, a timely association with a viral (influenza-like) or bacterial infection or even lymphomatous disease can be demonstrated in many patients.[224] Symmetric peripheral flaccid muscle weakness and sensory loss develop. The lower extremities are affected first, after which the disease progresses to the upper extremities and cranial nerve–innervated muscles in some patients. Importantly, patients may also have autonomic involvement that could lead to sudden fatal cardiac and circulatory collapse. The diagnosis is made after careful neurologic examination, clinical electrophysiologic testing, and CSF analysis. CSF analysis may show a typical increase in CSF protein in combination with a normal cell count, which is a classic sign of the disease. Treatment focuses on respiratory support, nutritional support, and early initiation of plasmapheresis.

Anesthetic Considerations

Succinylcholine should not be used because of the risk of hyperkalemia. Notably, case reports have described patients having clinically recovered from GBS who, after receiving succinylcholine during induction of anesthesia, rapidly developed life-threatening hyperkalemia. Nondepolarizing muscle relaxants are not contraindicated but should be avoided as a result of the increased sensitivity and risk for prolonged muscle weakness in the postoperative period. The risk for autonomic dysfunction, respiratory failure, and aspiration may require assisted or mechanical ventilation, even in the postoperative period. Great care should be taken to maintain circulatory stability, including adequate cardiac preload and afterload. Careful hemodynamic monitoring is therefore essential in these patients. General anesthesia can be used; however, the combination of general anesthesia and epidural anesthesia is more controversial.[225]

HEREDITARY MOTOR-SENSORY NEUROPATHIES, INCLUDING CHARCOT-MARIE-TOOTH DISEASE

Hereditary motor-sensory neuropathies include a spectrum of peripheral neurologic disorders, among which Charcot-Marie-Tooth (CMT) disease is often listed. These neuropathies are caused by a specific mutation in one of several myelin genes that results in defects in myelin structure, maintenance, and formation. Hereditary motor-sensory neuropathies have been classified into seven types and multiple subtypes according to the age at onset, mode of inheritance, predominantly involved muscle groups, and genotypes.[227,228] CMT types 1 and 2 are the most common hereditary peripheral neuropathies, with an estimated prevalence of 40 per 100,000.[228] Patients with CMT disease typically experience slow and progressive distal muscle weakness and wasting. Damage to sensory axons may also lead to sensory loss, resulting in frequent tripping and falls. Neuropathic pain may develop in some patients. Patients with CMT usually have normal life expectancy. CMT type 3, also known as Dejerine-Sottas neuropathy, is a very severe condition with an early onset of hypotonia during infancy. Typically, nerve conduction velocity is significantly reduced to less than 10 msec.[228] The genetic inheritance pattern for CMT disease is heterogeneous.

Anesthetic Considerations

The anesthesia experience in patients with CMT disease is limited because of the small number of cases. Major considerations include the use of hypnotic agents,

muscle relaxants, volatile agents, and neuraxial techniques. Patients with CMT type 1 have been reported to have significantly increased sensitivity to thiopental at induction that correlates with the severity of both motor and sensory defects. However, total intravenous anesthesia (TIVA) has been successfully performed in a number of patients without any reported problems.[229-231]

Because of the reduced number of acetylcholine receptors, sensitivity to nondepolarizing muscle relaxants is elevated and the response to succinylcholine is also reduced.[232] Although succinylcholine has been used without adverse effects,[233,234] the risk of an exaggerated hyperkalemic response may be sufficient to preclude it from being used in patients with suspected muscular denervation.[234] Prolonged neuromuscular block with vecuronium has been reported.[235] As a result of the large variety of disabilities in this patient group, careful baseline assessment of neuromuscular status should be conducted before the use of nondepolarizing neuromuscular relaxants. Normal response to atracurium and mivacurium has been demonstrated.[236,237] Both TIVA and volatile anesthetics have been safely used in a series of patients with CMT.[233] Neuraxial techniques for obstetric procedures have been reported to be generally successful in patients with CMT.[238-241] However, the use of regional anesthesia can be controversial, considering that the possible complications may exacerbate the neurologic symptoms.[242] Similar medicolegal concerns may apply to the surgical and anesthesia positioning of patients with CMT because of the sensory deficits and limb deformities.

DUCHENNE MUSCULAR DYSTROPHY AND BECKER MUSCULAR DYSTROPHY

Duchenne muscular dystrophy (DMD) is the most common and severe type of muscular dystrophy with an incidence of 1 per 3500 live male births[243] and a total male prevalence of approximately 50 to 60 × 10^{-6}.[244] Becker muscular dystrophy (BMD) is relatively rare and has an incidence of approximately 1 in 18,000 live male births and a prevalence of 23.8 × 10^{-6}.[244] Both DMD and BMD are X-linked recessive diseases. The defect is located on the short arm of the X chromosome at the Xp21 region, which contains the gene for the large protein Dp427, also known as *dystrophin*. The dystrophin gene is 2500 kilobases long with more than 70 exons.[244] Dystrophin is distributed not only in skeletal, cardiac, and smooth muscle but also in the brain.[245] Because of the large size of the dystrophin gene, spontaneous new mutations are common and account for one third of new cases.[246]

The most common form of mutation is a deletion within the gene (65% to 70% of patients with DMD and more than 80% of those with BMD). Duplication and point mutations are responsible for the rest. In addition, hot spots also appear in the first 20 exons and in the central region of the gene (exons 45 to 55) where deletion and duplication are likely to occur.[244] Female patients with DMD have been reported with the 45,X and 46,XX karyotypes. The disease mechanism for the female 46,XX karyotype is thought to be preferential loss of the paternal X chromosome by postzygotic nondisjunction and manifestation of the DMD gene from the maternal X chromosome in muscle cells.[247] BMD is usually milder in severity than DMD because disruption of the translation process occurs in the relatively distal part of the gene, which leads to a reduced amount of truncated dystrophin protein.[244,248]

Dystrophin, along with dystrophin-associated glycoproteins (DAGs), is involved in sarcolemmal stability. Dystrophin is responsible for the maintenance of muscle membrane integrity, despite the fact that it accounts for only approximately 0.002% of the protein in striated muscle.[249] Dystrophin aggregates and links to actin (at its N terminus) and the DAG complex (at its C terminus) to form a stable structure that interacts with laminin in

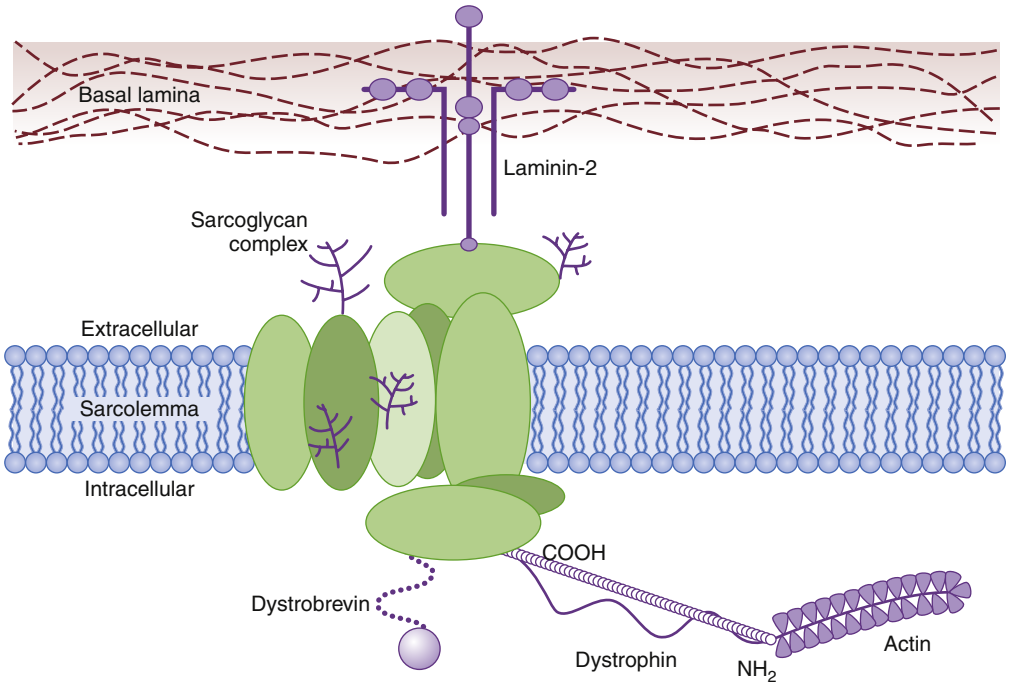

Figure 43-4. Diagram of the cellsurface and cytoskeleton protein complex.

the extracellular matrix (Fig. 43-4). Lack or dysfunction of dystrophin leads to cellular and membrane instability, with progressive leakage of intracellular components and elevation of CK levels. Eventually, damaged muscle cell units are invaded by macrophages and destroyed. A current study suggests that cytotoxic T cells are probably the culprit. Consequently, clinical pseudohypertrophy of the muscle occurs when the dead muscle shells are replaced by fibrofatty infiltrates. Loss of muscle units accounts for the weakness and contracture.[245]

Progressive weakness and wasting of predominantly the proximal musculature characterize both DMD and BMD. Pseudohypertrophy of the calves and other muscle groups is common. As the more severe of the two diseases, DMD tends to be symptomatic early in life. Of the children with DMD, 74% were found to exhibit the disease by 4 years of age.[243] Patients with DMD do not usually begin to walk until they are approximately 18 months of age or later.

The initial clinical findings include a waddling gait, frequent falling, and difficulty climbing stairs because of proximal muscle weakness in the pelvic girdle. The classic Gowers sign describes rising from a sitting to a standing position with the help of both arms. Patients may also show weakness in the shoulder girdle and trunk erectors that leads to thoracolumbar scoliosis. Earlier clinical onset of DMD has been associated with a more rapid progression of the disorder. In most cases, children with DMD are unable to walk by the age of 9 to 11 years. Proximal deep tendon reflexes in the upper extremities and patella may also disappear, despite the lack of denervation.[248] Nevertheless, the tendo Achillis reflex remains intact even in later stages of the disease. Approximately 60% of patients will have pseudohypertrophy of the calves, and 30% will have macroglossia. Some may also suffer from pain in the calves with activity.

The intellectual impairment that can be associated with the disease was thought to be related to the limitation of educational opportunities. However, with equalization of educational opportunities, psychometric studies have revealed a significantly lower average intelligence quotient in patients with DMD than in healthy groups.[250] This lower quotient implies a possible effect of dysfunctional dystrophin in the brain on learning.

Death in patients with DMD occurs in their 30s and is commonly due to cardiopulmonary compromise.[243] BMD is a mild form of DMD. The mutation that causes BMD produces dystrophin that retains partial function. The onset of symptoms occurs in the second or third decade of life. As a result, the lifespan of patients with BMD can reach the early 40s. Pneumonia is the most common cause of death (Fig. 43-5).[248]

The heart is also affected to varying degrees, depending on the stage of the disease and the type of mutation. Cardiac degeneration is due to the replacement of myocardium by connective tissue or fat, which leads to dilated cardiomyopathy.[251] Cardiac involvement starts early in the course of the disease, although clinical signs are not usually obvious in the early stage. No correlation has been established between the severity of cardiac disease and the severity of skeletal disease. Studies at necropsy have shown that the cardiomyopathy in DMD involves the posterobasal and contiguous lateral left ventricular walls as initial and primary sites of myocardial dystrophy in the absence of small vessel coronary artery disease in these areas.[252] Typical initial manifestations on the electrocardiogram (ECG) in DMD and BMD are sinus tachycardia, tall R waves in the right precordial leads, prominent left precordial Q waves, increased QT dispersion, and inverted T waves from scarring of the posterobasal portion of the left ventricle. Initially, echocardiography is normal or shows regional wall motion abnormalities in areas of fibrosis. With the spreading of fibrosis, left ventricular dysfunction can be seen, and ventricular arrhythmias frequently occur as well. In the final stages of the disease, systolic dysfunction may lead to heart failure and sudden death. Subclinical or clinical cardiac involvement is present in approximately 90% of patients with DMD or BMD but is the cause of death in only 20% of those with DMD and 50% of patients with BMD. Angiotensin-converting enzyme inhibitors are recommended in early stages of the disease, and β-blockers may be an additional option, if indicated.[251]

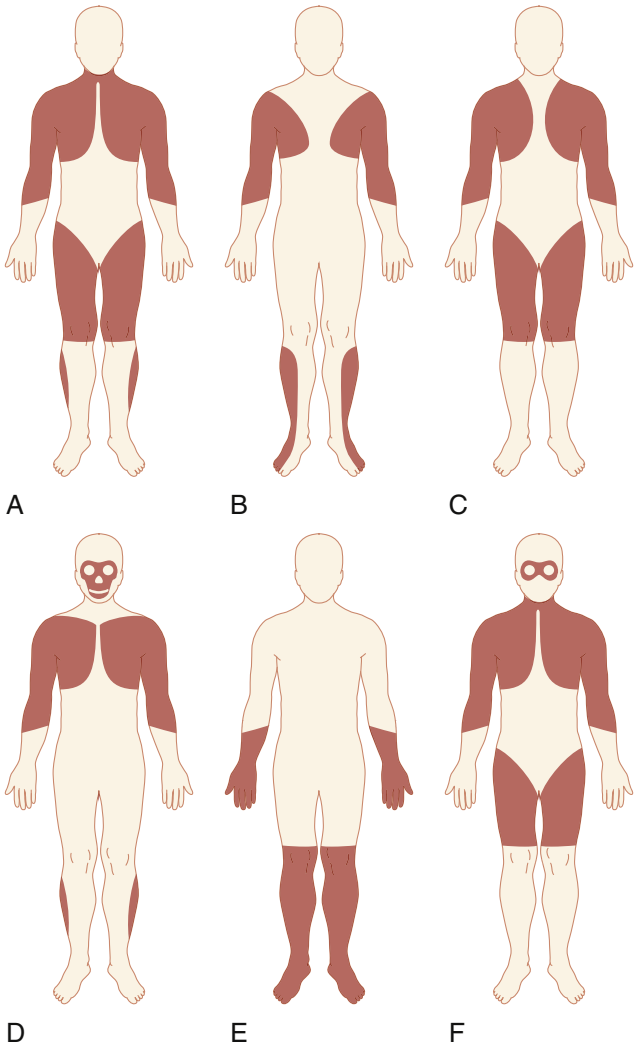

Figure 43-5. Distribution of predominant muscle weakness in different types of dystrophy: **A,** Duchenne type and Becker type; **B,** Emery-Dreifuss; **C,** limb girdle; **D,** facioscapulohumeral; **E,** distal; and **F,** oculopharyngeal. *(Redrawn from Emery AE: The muscular dystrophies,* Br Med J *317:991-995, 1998.)*

Pulmonary insufficiency is a leading cause of morbidity and mortality in DMD.[253] Usually, expiratory muscle function is affected first because of the early onset of abdominal muscle weakness. By contrast, inspiratory muscle function is relatively preserved in the first decade of life, implying sparing of the diaphragm.[254] Vital capacity (VC) increases in the first decade because of overall body growth, plateaus in early adolescence, and then dramatically declines as the diaphragmatic weakness progresses.[254] Other measured lung volumes such as inspiratory reserve volume and total lung capacity (TLC) follow the same pattern. A disproportionate loss of VC and TLC relative to the respiratory muscle dysfunction results, in part, from additional factors such as altered chest wall and lung mechanics, modifications in the distribution of surfactant, microatelectasis, and local fibrosis secondary to recurrent pneumonia.[254] Scoliosis further impairs pulmonary function. On average, for each 10 degrees of thoracic scoliosis curvature, forced vital capacity (FVC) decreases by 4%.[249] In 90% of patients, a curvature of greater than 20 degrees develops 3 to 4 years after they are wheelchair bound. Respiratory failure inevitably occurs in the second decade of life and is the most common cause of death.[255]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Chronic elevation of the serum CK level is a general indication of muscle disease. Three serum tests showing elevated CK levels obtained 1 month apart is diagnostic of muscular dystrophy. CK represents leakage of enzyme from muscle cells and does not correlate with the severity of the disease. CK could reach 50 to 300 times the normal value in early stages of the disease. The level tends to decrease with the loss of muscle mass. Elevation of the MB fraction of CK precludes its use as a marker for cardiac injury.[248] EMG can be supportive of the diagnosis; however, it can be extremely difficult to perform on children. Muscle biopsy, followed by immunostaining or Western blot analysis for dystrophin, is recommended for diagnostic testing. Multiple polymerase chain reaction is also useful in detecting more than 98% of the existing deletions.[245] The result is usually available within 24 hours, which may render muscle biopsy, the old gold standard, obsolete.

Anesthetic Considerations

Patients with DMD and BMD may require anesthesia for muscle biopsy, correction of scoliosis, release of contractures, and exploratory laparotomy for ileus,[248] as well as for dental[256] and obstetric[257] procedures. As the natural course of the disease progresses, the risk of surgery increases, concomitant with the increased comorbid conditions associated with the later phase of the disease. However, perioperative complications are not proportional to the severity of the disease. They even occur in patients who are mildly affected. Consequently, patients should undergo careful preoperative consultation and evaluation.

Of the patients with muscular dystrophy, 50% to 70% demonstrate some cardiac abnormality, although it is clinically significant in only 10%.[248] Preoperative cardiology assessment with an ECG and echocardiography is essential. Continuous cardiac Holter monitoring is necessary if an arrhythmia is captured on the ECG or if the patient describes symptoms that can be related to cardiac arrhythmias. Echocardiography will demonstrate mitral valve prolapse in 10% to 25% of patients. It may also show posterobasilar hypokinesis in a thin-walled ventricle and a slow relaxation phase with normal contraction characterizing the cardiomyopathy observed in DMD.[248] However, echocardiography may not always reflect the ability of the diseased myocardium to respond to perioperative stress. Stress echocardiography using angiotensin to detect latent heart failure and to identify inducible contraction abnormalities has been advocated.[258]

An estimated 30% of deaths in individuals with DMD are due to respiratory causes.[259] Therefore careful preoperative pulmonary assessment is important. Webster demonstrated that the manual muscle strength test has a strong statistical correlation with all of the timed functional tests. Peak expiratory flow was not only easy to perform but also statistically correlated with all timed functional tests.[260] The correlation was not significant for VC or forced expiratory volume in 1 second (FEV_1).

Intraoperatively, in terms of airway management, patients with DMD and BMD may have decreased laryngeal reflexes and prolonged gastric emptying time, which increases the risk for aspiration.[261] Decreased ability to cough up the accumulation of oral secretions predisposes patients with muscular dystrophy to postoperative respiratory tract infections.[248] Masseter spasm is also a possible complication during induction of anesthesia in these patients.[262] Preparedness for a difficult airway is necessary, especially in patients with potential airway problems.

Postoperatively, patients with DMD are at an increased risk for respiratory compromise.[263] Retrospective reviews have indicated that the incidence of prolonged postoperative ventilation (>36 hours) was greatest in patients with DMD who had a preoperative FVC of less than 40% of the predicted value.[264,265] Preoperative pulmonary function studies are valuable in determining the postoperative course. Patients with a VC greater than 30% of the predicted value can usually be extubated immediately after surgery.[248] Sleep apnea may also compound the condition and contribute to the development of pulmonary hypertension. Continuous positive airway pressure and bilevel positive airway pressure have been demonstrated to be effective in the management of postoperative respiratory depression. Delayed pulmonary insufficiency may occur up to 36 hours postoperatively, despite the apparent recovery of skeletal muscle strength.[266]

Reports have suggested a relationship between DMD or BMD and MH, but this association is not based on good rational grounds.[267] Whereas the risk for an MH mutation in patients with DMD or BMD is similar to that of the general population, the incidence of MH-like anesthetic events has been reported to be 0.002 with DMD and 0.00036 with BMD.[268] Unexplained cardiac arrest[262,269] and acute heart failure[270] have been reported in patients with DMD or BMD. Succinylcholine is contraindicated in these patients because of the potential for rhabdomyolysis and hyperkalemia as a result of their unstable sarcolemmal membrane. Succinylcholine-induced hyperkalemia during acute rhabdomyolysis is more likely to

result in cardiac arrest and unsuccessful resuscitation than is the potassium efflux resulting from the upregulation of acetylcholine receptors in patients with burns.[266] An increase in both maximal effect and duration of action usually accompanies the use of nondepolarizing muscle relaxants.[271] Narcotics can be used, but small incremental dosing and short-acting medications are recommended, given the respiratory depression associated with these medications. Recently, TIVA has become more popular[272] because of reports of inadvertent reactions to volatile anesthetics.[248] However, consideration needs to be given to the myocardial status of the patient when propofol or barbiturates are used because they may lead to profound hypotension and reduced organ perfusion.[248,273] Regional anesthesia may be used as an alternative to general anesthesia in that it avoids the risk of triggering agents and respiratory depression and enables the use of local anesthetics for postoperative analgesia. It may also facilitate postoperative chest physiotherapy.[274]

LIMB-GIRDLE MUSCULAR DYSTROPHY

Limb-girdle muscular dystrophy (LGMD) is a group of disorders with heterogeneous causes. To date, at least 18 genes have been identified as being responsible for this disease, with 7 being autosomal dominant and 11 autosomal recessive.[275] Mutations within the same gene may result in different phenotypes that sometimes are not consistent with LGMD. Proximal muscle (shoulder or pelvic) girdle weakness is the characteristic feature of this group of diseases. Considering the significant genetic heterogeneity, clinical manifestations of the disease vary. Autosomal recessive forms are approximately 10 times more common than autosomal dominant forms. Fukutin-related protein (*FKRP*) and calpain 3 (*CAPN3*) gene mutations have been associated with LGMD. In addition, a number of other disorders not strictly included under LGMD in this classification may have LGMD-like phenotypes.[275]

ANESTHETIC CONSIDERATIONS

Sporadic cases of LGMD have been reported in the anesthesia literature.[276-278] General approaches to these patients are the same as for those patients with DMD or BMD.

MYOTONIC DYSTROPHY

Myotonic dystrophy (MD) is an inherited muscular disorder characterized by progressive muscle weakness and wasting. Two types of MD result from either a mutation in the dystrophia myotonica–protein kinase (*DMPK*) gene, located on chromosome 19q13.3 (MD type 1 [MD1], also known as Steinert disease); or CysCysHisCys (CCHC)-type zinc finger, nucleic acid–binding protein (*CNBP*) gene, located on chromosome 3q21 (MD type 2 [MD2]).[279]

The incidence of MD is 1 in 8000. MD1 is by far the most common of the two types and accounts for approximately 98% of all cases. MD1 is caused by an expansion of a cytosine-thymine-guanine (CTG) trinucleotide repeat in the *DMPK* gene and is inherited in an autosomal dominant manner.[280] Typical signs and symptoms include muscle weakness and wasting (most prominent in the cranial and distal limb musculature), periodic myotonia, progressive myopathy, insulin resistance, defects in cardiac conduction, neuropsychiatric impairment, cataracts, testicular atrophy, and frontal balding in men. The typical cranial muscle weakness and wasting are exhibited not only in the facial, temporalis, masseter, and sternocleidomastoid muscles but also in the vocal cord apparatus. Mitral valve prolapse is found in 20% of patients.[266] The severity of the disease is related to the number of extra trinucleotide repeats.[86] Patients with MD1 may also have mildly elevated CK levels. Myotonic discharges can be identified on EMG, as well as an inability to relax from a handgrip. During pregnancy, the symptoms may be exacerbated. Uterine atony and retained placenta may also complicate vaginal delivery. First-degree atrioventricular heart block is a common finding on ECG before the onset of symptoms.[266]

MD2 is also called *proximal myotonic myopathy*. Intron 1 of the *CNBP* gene contains a complex repeat motif, (TG)n(TCTG)n(CCTG)n, and the expansion of the CTG repeat was determined as the cause of MD2. Patients with MD2 suffer from myotonia (90% of those affected), muscle dysfunction (82% with weakness, pain, and stiffness), and, less commonly, cardiac conduction defects, iridescent posterior subcapsular cataracts, insulin-insensitive type 2 diabetes mellitus, and testicular failure.[281]

No case report in the literature links MD to MH.[282] Lehmann-Horn and colleagues performed IVCT in 44 patients with myotonias and periodic paralyses, which revealed 4 positive results, 10 equivocal results, and 30 negative results.[283]

Anesthetic Considerations

General considerations for MD are similar to those for other muscular dystrophies. Mathieu and co-workers conducted a retrospective study on the anesthetic and surgical complications of MD. The majority of complications were found to be pulmonary related and significantly more frequent in patients undergoing an upper abdominal surgical procedure and those with severe disability as assessed by the presence of proximal limb weakness.[284] The pulmonary complications of MD are the result of hypotonia, chronic aspiration, and central and peripheral hypoventilation.[248] Smooth muscle atrophy, which leads to poor gastric motility, promotes aspiration when coupled with a diminished cough reflex.

Succinylcholine will produce contractions lasting for several minutes, thus making intubation and ventilation a challenge. These contractions are not antagonized by nondepolarizing muscle relaxants. Other agents, including methohexital, etomidate, propofol, and even neostigmine, may also induce myotonic reactions. Short-acting nondepolarizing muscle relaxants or avoidance of relaxation is therefore advised.[248] Triggering factors, such as hypothermia, shivering, and mechanical or electrical stimulation, may cause a myotonic reaction.[285] The reaction can be treated with phenytoin (4 to 6 mg/kg/day) or quinine (0.3 to 1.5 g/day).[248] Furthermore, patients with MD can be extremely sensitive to anesthetic agents, with hypersomnolence and CO_2 retention sometimes being

observed. Careful titration with relatively short-acting anesthetic agents may be beneficial. Close cardiac monitoring is required for patients with MD. Pacing equipment should be readily available because one third of those with first-degree atrioventricular blocks may not respond to atropine.[248] All patients should be treated as though they have both cardiomyopathy and conduction defects.

MYOTONIA CONGENITA

Myotonia congenita (MC) is a congenital form of muscular dystrophy characterized by uncontrolled temporary skeleton muscle excitability as a result of mutations in the muscle chloride channel gene (*CLCN1*). Two forms of MC have been described—one with autosomal dominant and the other with recessive inheritance. Type 1 is also known as Thomsen disease, and type 2 is also known as Becker myotonia. A forceful muscle contraction, particularly after rest for at least 10 minutes, usually initiates the myotonia in patients with MC. The myotonic muscle stiffness then becomes increasingly obvious after a second and third short but forceful contraction. Further contractions usually dampen the myotonia.[286]

Thomsen disease was the first myotonic disease to be described. Patients may have a hypertrophic and athletic appearance. The sign of percussion myotonia is described as an indenting-appearing myotonia triggered by tapping the muscle. Lid lag is common and muscle stretch reflexes are normal.[286] Myotonia symptoms in Becker myotonia usually start at 10 to 14 years of age or even later and are more severe than those of Thomsen disease. Becker myotonia may be associated with severe generalized stiffness, resulting in falling. It can be frequently misdiagnosed as epilepsy. Antiepileptic medications do improve the symptoms, however.[286]

Anesthetic Considerations

As with many muscle diseases, reports suggest that patients with MC are predisposed to MH, but, as is the case for almost all of them, no data exist that support this hypothesis.[287-289] However, depolarizing muscle relaxant can lead to severe masseter spasm in patients with MC. Generalized spasm involving the respiratory and skeletal muscles has been reported.[287] The findings resemble those of MH; therefore dantrolene is sometimes administered.[286] Because dantrolene is an inhibitor of calcium release from the SR, it can usually abolish the myotonia effectively.[287,288] Some believe that local anesthetics and class Ib antiarrhythmic drugs such as lidocaine should be used for myotonic reactions rather than dantrolene.[290] Because shivering in the surgical unit can trigger the myotonic reaction, patients with MC should be kept normothermic during surgery.[286]

MYOTUBULAR MYOPATHY

Myotubular myopathy (MTM) is pathologically defined by the presence of centrally placed nuclei in the majority of extrafusal muscle fibers, an appearance resembling fetal myotubes during normal muscle development. Consequently, MTM is also called *centronuclear myopathy* (CNM).[291] However, MTM now mostly refers to the X-linked form of the disease, whereas CNM is used for the autosomal form.[291]

MTM and CNM are rare. The estimated incidence of MTM is 1 in 50,000 male newborns.[291] MTM has been linked to the myotubularin (*MTM1*) gene on Xq28. Pregnancy is often complicated by polyhydramnios and reduced fetal movements. Affected male infants typically have severe floppiness and weakness and respiratory distress at birth. Cardiac muscles are not generally involved. The patient usually has a normal response to pain, but tendon reflexes are absent. The long-term prognosis for MTM is extremely poor.[291] In patients who survive the first year of life, most are either completely or partially ventilator dependent.[292] These patients often have abnormal liver function.[292] Both autosomal recessive and autosomal dominant forms have been observed in patients with CNM. Its clinical features include respiratory distress, hypotonia, bulbar weakness, ophthalmoplegia, ptosis, and facial diplegia. Although the exact genetic mechanism is not fully understood, the *MTM1*, myotubularin-related protein (*MTMR2*), and myotubularin-related phosphatase (*MTMR3*) genes have been implicated.[291] Pathologically, MTM and CNM share a similar, characteristic histologic feature: predominantly type 1 fibers with centrally placed nuclei are observed on hematoxylin-eosin staining of formalin-fixed, paraffin-embedded tissue.[291]

Anesthetic Considerations

Reports of anesthesia for patients with MTM are sparse.[293-298] Nontriggering general anesthesia has been used because of the unfounded concern of possible susceptibility to MH. Agents such as propofol, fentanyl, remifentanil, and nitrous oxide have been successfully used without adverse effects.[293-298] The possibility of a prolonged effect of nondepolarizing muscle relaxants has been suggested with mechanomyography.[293-298] However, in reality, intubation of such patients may not require any muscle relaxant because of their hypotonic state. Costi and van der Walt suspected that the defect in MTM is distal to the neuromuscular junction,[294] whereas Dorchies and co-workers suggested that muscle in MTM might be intrinsically normal, with myotubularin-deficient motor neurons involved in the development of the disease.[299]

METABOLIC MYOPATHIES

Two major energy sources for muscle exist: glycogen and fatty acid. Glycogen serves as a dynamic but limited reservoir of glucose that is mainly stored in skeletal muscle and liver. Glycogen storage disorders (GSDs) are a group of metabolism disorders caused by enzyme deficiency or dysfunction. They reduce effective glucose storage by interfering with normal glycogen synthesis and degradation. Synthetic errors cause decreased normal glycogen, whereas degradation errors tend to block the breakdown of glycogen. Subsequently, hypoglycemia and accumulation of glycogen in tissues could occur as a result of

substrate use. More than 12 types of GSD are assigned Roman numerals, based on the enzyme deficiencies. Types I and II are discussed in the following text.

GLYCOGEN STORAGE DISEASE TYPE I

The incidence of GSD type 1 (GSD I) is approximately 1 in 100,000 live newborns.[300] The incidence in non-Ashkenazi Jews from North Africa may be as high as 1 in 5420 people.[300] The defective enzyme causing the disease is glucose-6-phosphatase, which is the enzyme that converts glucose 6-phosphate (G6P) to glucose in the liver. GSD type Ia (von Gierke disease) is due to a deficiency in G6P hydrolase (catalytic subunit) activity and accounts for more than 80% of cases. GSD types Ib (G6P transporter deficiency), Ic, and Id represent allelic defects in the translocase associated with G6P. Their inheritance is autosomal recessive. The G6P gene (*G6PC*) encoding the hydrolase resides at 17q21, with the gene encoding G6P translocase (*G6PT*) located at 11q23. Mutations responsible for GSD I have been described in patients with both types Ia and Ib.[300]

Impaired glycogenolysis results in an accumulation of glycogen and G6P in the liver, kidney, intestine, skeletal muscle, and heart, producing hepatomegaly, renomegaly, proximal tubular dysfunction, and diarrhea.[301] Fasting hypoglycemia is the initial manifestation of the disease. As a result, both up-regulation of the synthesis and transport of counter-regulatory hormones, such as glucagon, cortisol, catecholamines, and growth hormone, become obvious and lead to the release of pyruvate, lactate, and free fatty acid. Lipid deposition in lean tissues such as the liver, skeletal muscle, cardiac muscle, and pancreas results in lipotoxicity and organ failure, including pulmonary hypertension, steatohepatitis, end-stage renal disease, insulin resistance, cardiac contractile dysfunction, and pancreatic beta cell failure.[300] For GSD Ib disease, specific problems such as neutropenia and neutrophil dysfunction are prominent. Patients may have recurrent infections and inflammatory bowel disease.[302]

Anesthetic Considerations

Anesthesia case reports for patients with GSD I are rare.[303,304] Patients with GSD I diseases should be given IV glucose-containing fluid preoperatively when they have fasted. Lactate-containing solutions should be avoided because these patients are not able to convert the lactic acid to glycogen.[248] Patients need to be monitored frequently to avoid hypoglycemia.

GLYCOGEN STORAGE DISEASE TYPE II (ACID MALTASE DEFICIENCY)

The incidence of acid maltase deficiency (AMD) is estimated to be 1 in every 14,000 to 40,000 births. Its inheritance is autosomal recessive with a few exceptions.[305,306] Mutations of the acid maltase gene on chromosome 17q25 cause deficiency of lysosomal acid maltase (acid α-1,4-glucosidase).[306] Cases of AMD have been arbitrarily classified into three groups—infantile, childhood, and adult—according to the age at onset or death, rate of progression, and tissue-organ involvement.[306]

Acid maltase is a lysosomal enzyme that catalyzes the one-way hydrogenation of glycogen to G6P and is found in all tissues, including skeletal and cardiac muscle.[307] Consequently, glycogen accumulates within the muscle tissues of patients who are maltase deficient. Infantile AMD, also known as Pompe disease, is usually evident within the first few months of life as rapidly progressive weakness and hypotonia and an enlargement of the tongue, heart, and liver. Massive amounts of glycogen (8% to 15% of the wet weight of the tissue) accumulate in the heart, liver, and skeletal muscle, with relatively smaller deposits in smooth muscle, eyes, kidneys, endothelial cells, lymphocytes, brain, and spinal cord. Accumulation of glycogen in cardiac muscle leads to cardiac failure in the infantile form.[306] Echocardiography demonstrates significant thickening of the interventricular septum and posterior left ventricular wall, left ventricular outflow obstruction, and trabecular hypertrophy.[306] Ventricular wall thickness may be increased to up to 25 mm.[308] Wolff-Parkinson-White syndrome has been reported.[309] The signs and symptoms of infantile AMD may resemble those of DMD. Death usually results from cardiorespiratory decompensation within several years of disease progression.[310]

Childhood AMD occurs in infancy to early childhood and exhibits clinical signs of myopathy. Respiratory muscles tend to be selectively affected. Calf enlargement can also occur. The disease progresses relatively slowly in this form, with a few patients surviving beyond the second decade of life.[306] Tongue, heart, and liver enlargement infrequently occur.[311] However, involvement of vascular smooth muscle is more severe than in the infantile form. Extensive glycogen deposition in the arterial wall, causing basilar aneurysms, has been reported.[311]

Adult AMD usually occurs after age 20 years and is characterized by slow progressive myopathy or symptoms of respiratory failure.[306] The weakness in proximal muscles is more prominent than the weakness in distal muscles. One third of adult patients with AMD suffer from respiratory failure with a restrictive pattern. Weakness in the diaphragm causes extensive atelectasis. VC may be significantly reduced.[306]

Anesthetic Considerations

Anesthesia reports in patients with AMD are rare.[312-315] Isolated intraoperative cardiac arrest during halothane anesthesia in infantile AMD has been documented.[315] Despite the problem noted with halothane, both enflurane[313] and sevoflurane[314] have been used without complications. Theoretically, TIVA with propofol may cause a reduction in afterload, leading to an increased risk for myocardial ischemia. This complication may become significant when the patient develops tachycardia.[314]

Subendocardial ischemia may occur in patients with a thickened ventricular wall and result in higher left ventricular end-diastolic pressure at lower ventricular volume.[314,316] Close cardiac monitoring is therefore necessary. A central venous or pulmonary artery catheter is not essential in patients who are normovolemic without preexisting heart failure.[314] Adequate filling pressure and normal-to-high systemic vascular resistance

(SVR) are required to ensure effective coronary perfusion.[314] Ketamine has been successfully used in a number of patients because of its ability to maintain SVR and contractility. Respiratory failure and muscle weakness are the other concerns for anesthesiologists. A spectrum of uses of muscle relaxants from none[313] to atracurium[312] or rocuronium[314] has been attempted. Low-dose rocuronium, 0.5 mg/kg, with close monitoring of neuromuscular function and the adequate use of reversal agents, has been sufficient to prevent prolonged postoperative weakness.[314] Depolarizing agents should be avoided because of the potential risk of hyperkalemia and rhabdomyolysis.[314,315]

MITOCHONDRIAL MYOPATHIES

Mitochondrial diseases refer to defects in the five main steps of mitochondrial metabolism: (1) substrate transport, (2) substrate utilization, (3) the Krebs cycle, (4) the electron transport chain, and (5) oxidation-phosphorylation coupling.[317] However, the term *mitochondrial myopathy* has been reserved for disorders caused by defects in the respiratory chain.[317] The respiratory chain is made up of five multimeric complexes (I to V) embedded in the inner mitochondrial membrane, plus two small mobile electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome *c*, for a total of more than 80 proteins,[317] among which 13 are encoded by mitochondrial DNA (mtDNA) and all others by nuclear DNA (nDNA). mtDNA is different from nDNA in several aspects: (1) mtDNA is circular and contains no intron, (2) it has larger numbers of copies than nDNA and a much higher spontaneous mutation rate, and (3) its inheritance is maternal. Diagnosis of mitochondrial diseases is difficult because of their clinical heterogeneity.

Primary mtDNA mutations may include point mutations in polypeptide, transfer RNA (tRNA), or ribosomal RNA (rRNA) encoding regions and large-scale rearrangements, duplications, or deletions.[318] Some of the common conditions caused by point mutations include myoclonic epilepsy with ragged-red fibers (MERRF); mitochondrial encephalopathy, lactic acidosis, and strokelike episodes (MELAS); neuropathy, ataxia, and retinitis pigmentosa (NARP); maternally inherited Leigh disease; and Leber hereditary optic neuropathy (LHON).[317] Sporadic large-scale mutations may lead to Kearns-Sayre syndrome, progressive external ophthalmoplegia, and Pearson syndrome.[317] nDNA mutations can cause deficiencies in complexes I to IV and in CoQ_{10} of the electron transport chain.[317]

Mitochondrial myopathy is estimated to have an incidence of 1 in 4000.[319] Among all the mitochondrial functions, abnormalities in electron transport and oxidative phosphorylation are the most common causes of mitochondrial myopathies.[320] Proximal muscle weakness with increased lactic acid and positive muscle biopsy for mitochondrial cytopathy characterize mitochondrial myopathies.[321] The hallmark of mitochondrial myopathies is the *ragged-red fiber* when muscle biopsy specimens are stained with modified Gomori trichrome stain,[322] and specific defects in the activity of these enzymes have been demonstrated in patients with mitochondrial disease.[323] Fatigue and poor stamina are prominent clinical features. Movement disorders such as ataxia, dystonia, myoclonus, chorea, athetosis, and tremors have also been described as being the result of mitochondrial abnormalities.[323]

Anesthetic Considerations

Preoperative Evaluation. Considering the heterogeneous types of mitochondrial disease, patients with mitochondrial disease need a comprehensive preoperative evaluation with a particular focus on neurologic, cardiac, respiratory, musculoskeletal, endocrinopathic, and metabolic compromise (see also Chapters 38 and 39). An ECG and echocardiogram should be considered in patients with signs and symptoms of cardiomyopathy or conduction defects (or both). Although normal lactate and glucose levels cannot rule out mitochondrial diseases, laboratory studies consisting of glucose, electrolytes with anion gap, complete blood count, blood urea nitrogen, lactate, pyruvate, ammonia, CK, biotinidase, acylcarnitines, and blood and urine amino and organic acids could be used as initial investigation for suspected mitochondrial disorders.[324] Further workup should include an erythrocyte sedimentation rate, glycosylated hemoglobin (HbA_{1C}), liver and renal profiles, thyroid function tests, arterial blood gas, and urinanalysis.[319,323] Multidisciplinary consultation with special laboratory and imaging studies may be required.[323]

Induction and Maintenance of Anesthesia. Anesthesia has a significant impact on mitochondrial function. Both barbiturates and propofol inhibit complex I of the electron transport chain.[324] Local anesthetics have been demonstrated to disrupt oxidative phosphorylation and decrease the bioenergetic capacity of mitochondria.[324] Sensitivity to IV barbiturates and etomidate has been reported.[325,326] However, midazolam,[327] thiopental,[328] propofol,[329,330] remifentanil,[331] and ketamine[330] have all been safely used. Premedication should avoid respiratory depression caused by impaired respiratory responses to hypoxemia. Volatile agents such as halothane, isoflurane, and sevoflurane have been shown to inhibit complex I.[324] This direct inhibition of mitochondrial electron transport system enzymes and altered mitochondrial bioenergetics in the heart were thought to be the mechanism of cardiac preconditioning by volatile anesthetics.[332,333] Inhaled sevoflurane has been widely used for induction because of its low pungency.[321] In some cases, halothane[327] and isoflurane[327,334] have also been used. Isoflurane has been recommended as the agent of choice in patients with Kearns-Sayre syndrome because rhythm disturbances have been reported with halothane in such patients.[327,334] In addition, artificial pacing capability is recommended when dealing with this specific subset of patients.[321] With use of the bispectral index, higher sensitivity to volatile agents has been suggested in children with mitochondrial diseases, especially with dysfunction of complex I.[335] However, its methodology has been criticized.[336] A decreased minimum alveolar concentration of halothane in patients with mental retardation has also been reported.[337]

Despite no real evidence and the fact that volatile anesthetics are frequently the anesthetic of choice when

muscle relaxants are considered, several studies have expressed concern that these myopathies are associated with increased sensitivity to MH. No data support this conclusion. Increased sensitivity to nondepolarizing muscle relaxants has been documented for mivacurium,[338] atracurium,[339] and rocuronium.[339,340] In contrast, normal responses to depolarizing and nondepolarizing neuromuscular blocking drugs such as pancuronium,[341] vecuronium,[342] and atracurium[329,343] are also reported. Although muscle relaxants are not absolutely contraindicated, based on current literature, administering depolarizing or nondepolarizing neuromuscular blockers with caution to patients with mitochondrial diseases and using neuromuscular monitoring are both necessary.[319]

Nonsteroidal antiinflammatory drugs[321] and regional techniques consisting of local,[321,344] spinal,[345] and epidural administration have been reported. However, it is suggested that regional anesthesia be performed when neurologic abnormalities of the spinal cord and peripheral nerves have definitely been ruled out.[345] Importantly, coagulation function should be assessed because of the possibility of hepatic dysfunction.[321]

Opioids should be used with caution because of the increased risk for respiratory depression and their potential to induce respiratory acidosis in addition to the underlying metabolic acidosis.[321] Because patients with mitochondrial diseases have dysfunctional aerobic metabolism, any increase in the basic metabolic rate should be prevented.[323] Shivering, hypoxia, fasting, and hypotension in such patients may exacerbate the lactic acidosis and should therefore be avoided.[346] Finally, the increased postoperative infection rate in patients with mitochondrial diseases may be due to reductions in hepatic mitochondrial activity, phagocytosis by Kupffer cells, and activity of the reticuloendothelial system.[347]

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disorder of the neuromuscular junction. Autoantibodies against the α-subunit of the muscle-type nAChR destroy acetylcholine receptors of the neuromuscular junction and cause classic transmission failure with muscle weakness and fatigue. Sparing of other α-subunits of neuronal-type nAChRs provides an explanation for the lack of autonomic or CNS involvement of the disease. The incidence of MG varies between geographic regions, being 1.2 per million in Japan and approximately 14 per 100,000 in some areas of the United States.[348,349] In younger age groups, females are affected more often than males, whereas in older adult age groups (>60 years), men are more frequently affected.

The association between MG and hyperplasia of the thymus is striking, with more than 70% of patients with MG having thymus hyperplasia and 10% having thymomas.[349] MG may also be observed as a part of a paraneoplastic syndrome.[349]

Typically, patients first report bulbar symptoms consisting of diplopia and ptosis. The bulbar symptoms are often followed by unevenly distributed muscle weakness and fatigue of the extremities and face. Speech and chewing may be affected, as well as pharyngeal function and coordination of swallowing, with a subsequent increased frequency of aspiration of oral contents. The muscle weakness is often exacerbated during exercise and throughout the course of the day. Apart from the patchy distribution of muscle weakness, symptoms may also vary from day to day, and periods of remission of varying duration may occur.

The diagnosis of MG is made by neurologic examination and testing of the tendency to fatigue and the tendency to exhibit increased weakness during exercise or repeated contractions. The diagnosis can be confirmed by the Tensilon test (administration of an anticholinesterase, edrophonium). Improvement is usually observed within 5 minutes after administering the drug and lasts for approximately 10 minutes. In addition, electrophysiologic evaluation is often performed and shows a classic decrement in the compound muscle action potential after repetitive nerve stimulation.

Anesthetic Considerations

Ideally, careful neurologic consultation in addition to preoperative evaluation should be performed on patients with MG with the goal of optimizing drug therapy and preparing for postoperative care. Pulmonary function tests may be indicated to determine the need for postoperative mechanical ventilation.[338] As a general rule, patients should keep taking their anticholinesterase medication and be informed about the possibility of postoperative ventilator support. Succinylcholine can be used if needed for rapid tracheal intubation. However, patients with MG might need larger than normal doses (1.5 to 2.0 mg/kg body weight) because of the decreased number of functional acetylcholine receptors.[350] On the other hand, as a result of the decrease in cholinesterase activity achieved by anticholinesterase treatment, neuromuscular blocks with succinylcholine or mivacurium are frequently prolonged.[351,352] Nondepolarizing neuromuscular blockers can be used in patients with MG but should be administered with caution because their effects are highly unpredictable and the distribution of muscle weakness is often uneven. Consequently, monitoring of neuromuscular function with a peripheral nerve stimulator is not always reliable in patients with MG, and dosing of any nondepolarizing muscle relaxant should be increased in small increments corresponding to 0.1 to 0.2 times the 95% effective dose (ED_{95}) until the desired neuromuscular blocking effect is achieved. Perioperative anticholinesterase treatment will modify the response to cholinesterase inhibitors because of the already existing acetylcholinesterase block, and recovery of neuromuscular function after the administration of a reversal agent has been reported to be prolonged in some patients.[353] Recently, multiple case reports recommend an alternative approach for the complete reversal of residual vecuronium or rocuronium neuromuscular block in patients with MG with the use of sugammadex in appropriate dosages.

Potent volatile anesthetics have been successfully used in patients with MG. Because of the impaired margin of safety at the neuromuscular junction, a volatile anesthetic usually provides adequate muscular paralysis to allow most surgical procedures to be performed without the

need for a neuromuscular blocking agent. Epidural and spinal anesthesia can be used in patients with MG, provided that muscle function and ventilation are carefully monitored perioperatively, similar to general anesthesia. (Baraka[354] and Abel and Eisenkraft[355] offer a more detailed review [see "References" at the end of this chapter].)

EATON-LAMBERT MYASTHENIC SYNDROME

Eaton-Lambert myasthenic syndrome (ELMS) is an immune-mediated channelopathy caused by a decreased release of acetylcholine as a result of autoantibodies against presynaptic voltage-gated calcium channels and other presynaptic elements.[356] Patients with ELMS have muscle weakness and fatigability, generally of the proximal limb muscles, with the lower extremities affected more often than the extraocular and bulbar muscle groups. The syndrome is frequently part of a paraneoplastic phenomenon, usually associated with small cell lung carcinoma. Unlike MG, patients with ELMS are usually worse in the morning with gradual improvement throughout the day. Improvement of muscle function with exercise is due to the accumulation of presynaptic calcium and the subsequent improved release of acetylcholine.[357] A minority of patients exhibit autonomic dysfunction. The diagnosis of ELMS is made by careful physical examination, combined with clinical electrophysiologic testing showing the typical facilitation of motor action potential with high-frequency nerve stimulation (30 Hz to 50 Hz). Anticholinesterase treatment has little effect on patients with ELMS. Plasmapheresis, immunoglobulin therapy, and 3,4-diaminopyridine (DAP) result in transient improvement.

Anesthetic Considerations

As in patients with MG, those with ELMS should be carefully evaluated for the risk of postoperative respiratory failure and the need for prolonged respiratory monitoring in the postoperative period. Sensitivity to depolarizing and nondepolarizing neuromuscular blocking agents is usually increased. In patients treated with DAP or an anticholinesterase agent, reversal of a neuromuscular blockade may be ineffective.

PERIODIC PARALYSIS (HYPERKALEMIC, HYPOKALEMIC, AND NORMOKALEMIC)

Tyler and associates first described hyperkalemic periodic paralysis (HyperPP) as an autosomal dominant disorder in 1951.[286] Attacks of flaccid weakness associated with increased serum potassium characterize HyperPP.[358] A potassium-rich meal or rest after strenuous exercise may precipitate an attack. Stressful situations may also provoke the onset of paralysis. The paralysis may last for 15 minutes to 1 hour, with decreased tendon reflexes. In the interictal state, HyperPP is usually associated with mild myotonia that does not impede voluntary movements.[286]

The pathogenetic development of HyperPP involves mutations in *SCN4A* encoding the voltage-gated sodium channel $Na_V1.4$ of mature muscle fibers. Such mutations lead to pathologically increased sodium current and an increased tendency of the muscle fiber to become depolarized.[286,358] Simultaneous efflux of potassium and hyperkalemia accompany the influx of sodium into the muscle. Mutant channels exhibit sustained sodium currents that lead to prolonged membrane depolarization, causing myotonia, followed by membrane desensitization (or inactivation) and resulting in paralysis. In patients with HyperPP, serum CK can be elevated, sometimes 5 to 10 times above the normal limit, whereas serum sodium and potassium levels are normal in the interictal state.[286] Recent studies consider normokalemic periodic paralysis as a variant of the HyperPP, not a distinct disease, because all participants exhibited clinical and laboratory features of the HyperPP.[359-361]

A decrease in potassium levels in blood characterizes hypokalemic periodic paralysis (HypoPP). Rigorous exercise, stress, high-carbohydrate or high-salt meals, pregnancy, menstruation, hypothermia, or drugs such as insulin can trigger attacks of HypoPP.[362,363] EMG does not usually show myotonia.[358] The severity of attacks is usually greater than those occurring in patients with HyperPP. HypoPP is an autosomal dominant disease with a higher penetration in males. The disease is due to a loss of function of one of the two different ion channel types: $Ca_V1.1$ and $Na_V1.4$.[358] The most common muscle groups affected are those in the arms and legs; however, the disorder can also affect swallowing and respiratory muscles, which can be fatal in severe cases.[364] The diagnosis of HypoPP is made by laboratory testing demonstrating hypokalemia during attacks and normokalemia between attacks. Mutations in the skeletal muscle voltage-gated calcium channel encoded by *CACNA1S* (HypoPP type 1) and *SCN4A* (HypoPP type 2) have been identified.[282] Theoretical association of HypoPP to MH was made because a few patients with MH were known to have mutations in the *CACNA1S*.[282] However, the risk of susceptibility of patients with HypoPP to MH is generally accepted to be similar to that of the general population. The exact mechanisms leading to hypokalemic paralysis, however, remain unclear.

Anesthetic Considerations

Potassium, cholinesterase inhibitors, and depolarizing muscle relaxants will aggravate the myotonia in patients with HyperPP.[286] Prolonged muscle weakness has been reported when succinylcholine is used.[365] Although one third of patients had no signs of myotonia,[366] masseter spasm and respiratory and skeletal muscle stiffness could still occur during intubation and ventilation.[286] Therefore neostigmine and succinylcholine should be contraindicated in patients with HyperPP. Ideally, all patients with HyperPP need to be admitted preoperatively to ensure that proper preoperative fasting is accompanied by the administration of dextrose-containing potassium-free maintenance fluid.[367] Postoperatively, patients with HyperPP may remain paralyzed for up to several hours. Preventive measures such as maintaining normal body temperature and low serum potassium levels and avoiding hypoglycemia are helpful in limiting such paralysis.[368] Although patients with a pathologic sodium channel response have

often been considered to be MHS, an increased risk for MH in these patients is not supported.[283] General anesthesia with and without nondepolarizing neuromuscular blocking drugs has been shown to have satisfactory outcomes.[365,367-370] Regional techniques may also be appropriate for this patient group.[366,369,370] Abortion of the hyperkalemic attack may be accomplished by administering glucose, insulin, epinephrine, and calcium supplements, or, alternatively, glucagon may be used. β-Adrenergic treatment with metaproterenol has also been shown to prevent attacks and facilitate recovery.[367]

Management of patients with HypoPP should focus on avoiding triggers and medications that cause a shift of potassium. General anesthesia, postoperative stress, glucose-containing IV solutions, and long-acting neuromuscular blockers are associated with postoperative paralytic events.[362] Epidural analgesia has been shown to reduce both pain-related hyperventilation and serum catecholamines, thereby minimizing changes in serum potassium levels.[362] The sympathomimetic effect of epinephrine-containing local anesthetics may also precipitate hypokalemia.[362]

SUMMARY

MH is a subclinical myopathy featuring an eerie and erratic metabolic mayhem that is unmasked on exposure to potent volatile anesthetics or succinylcholine. Skeletal muscle acutely and unexpectedly increases its sarcoplasmic Ca^{2+} concentration, thereby leading to increased O_2 consumption and lactate production and resulting in greater heat production, respiratory and metabolic acidosis, muscle rigidity, sympathetic stimulation, and increased cellular permeability. MHS skeletal muscle differs from normal muscle in that it is always closer to loss of control of Ca^{2+} concentration within the muscle fiber, and it can involve a generalized alteration in cellular or subcellular membrane permeability. This EC coupling defect is the result of an alteration in protein-protein interaction in the CRU. It is a homozygous, single-point mutation of *RYR1* in swine and a heterozygous disorder in humans, in whom a modification of *RYR1* protein function may also occur by interacting structures, membranes, or enzymes. Diagnosis rests on the acute awareness of the signs and symptoms of this syndrome, of which hyperthermia is a late sign. Specific treatment is the administration of dantrolene to lower intracellular muscle Ca^{2+} levels; symptomatic treatment consists of the reversal of the acid-base and temperature changes. Analysis of drug-induced muscle contractures (by European IVCT and North American CHCT protocols) and genetic testing of DNA samples are used to evaluate affected families. General or regional anesthesia is safe for patients susceptible to MH, provided that care is taken to specially prepare the anesthesia machine and to avoid all potent volatile anesthetics and succinylcholine if a general anesthesia technique is chosen. Research on MH has yielded insight into the physiologic progression of metabolism and into the molecular biologic makeup of genetic muscle disorders. Remaining challenges include the identification of all genetic mutations responsible for human MH, the elucidation of the mechanism that links exposure to subsequent loss of control of Ca^{2+}, the development of noninvasive and nondestructive testing for susceptibility, and the determination of the mode of action of dantrolene.

Chapter 44

Fundamental Principles of Monitoring Instrumentation

JAMES SZOCIK • STEVEN J. BARKER • KEVIN K. TREMPER

Key Points

- Accuracy and precision are different. Accuracy is how close a value is to the true value. Precision is how repeatable the measurements are. An inaccurate but precise monitor can be recalibrated to be accurate, but an imprecise monitor cannot be improved.
- Filtering can improve the signal display, but it can also result in smoothing and a loss of information.
- A signal can be extracted from noise by repeated measurements, because the noise is random over time but the signal is not.
- Electrical signals can be converted from analog to digital. Conversion can introduce some artifacts but can allow for greater storage and analysis capabilities.
- Invasive pressure monitors are affected by damping and resonance. Damping leads to distortion, signal loss, and lowering of peak values. Resonance can lead to amplification and overestimation of the peak value.
- Pulse oximetry combines analysis of optical plethysmography and absorption analysis with empirical data to produce an estimate of arterial oxygen saturation (Sao_2).
- Wavelength and frequency are related to the speed of the wave by the following formula: speed = wavelength × frequency. Shorter wavelengths improve the resolution of both light and ultrasound measurements.
- Flow measurements are one of the most difficult to obtain and usually involve indirect measures. (For example, a temperature change or pressure drop is measured and a flow value is derived. A small error in the initial measurement leads to a much larger error in the derived flow value.)

WHY FUNDAMENTAL PRINCIPLES ARE IMPORTANT

Patient monitoring has been a key aspect of anesthesiology since its beginnings as a medical specialty. As anesthesiology has grown more sophisticated and complex, so have the monitors and the data that they produce. The anesthesiologist's senses of sight, hearing, and touch, at first expanded with the stethoscope, sphygmomanometer, and electrocardiograph, are now supplemented by the pulse oximeter, expired gas analyzer, evoked potential monitor, and transesophageal echocardiography. The complexity of some of these devices can be intimidating, but they are an important part of clinical responsibility. Anesthesiologists must be able to understand and interpret the data from monitors but also anticipate and recognize errors associated with their use. Understanding how these devices work is a vital part of our necessary knowledge.

First, the scientific principles underlying the design and function of the most commonly used monitors are described. Some concepts of basic physics are followed by more detailed descriptions of the principles and their monitoring applications. The text and figures explain these principles predominantly in a qualitative manner. For those desiring a more quantitative explanation, the relevant physics and equations are provided in the appendixes at the end of this chapter.

BASIC PRINCIPLES

NATURE OF PHYSICS AND MEASUREMENT

Physics is the science of matter and energy and the interactions between the two; that is, physics is the study of everything in the physical universe. Physics encompasses

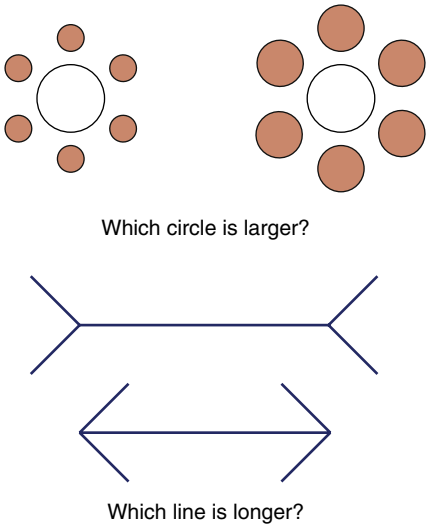

Figure 44-1. Optical illusions. We perceive the circles to be different sizes because we infer the size by relative dimension. The closeness of the smaller circles makes the inner circle appear smaller, and vice versa. The lines appear to be different sizes because we use straight-line perspective to estimate size and distance. This illusion reportedly does not work in cultures in which straight lines are not used. Therefore our internal perceptions lead us to err in estimating size and length. In the same way, the internal programming of our monitors can lead us to misinterpret results.

everything from the motions and inner workings of the atom to those of galaxies. Physics is quantitative, and mathematics is the language of physics. In fact, Isaac Newton and Gottfried Leibnitz invented *the calculus* as a mathematical tool for expressing and studying the laws of physics. Monitors are also quantitative. Before the complexity of modern anesthetic monitors can be discussed and understood, we must quantitatively define what they are attempting to measure, as well as understand the limitations of measurement.

Anesthesiologists measure and monitor mass and energy: how much of a substance is present and in what energy state does it exist. Much of what we desire to monitor is outside the range of human physical senses. Therefore, we must make measurements in this insensible realm with devices that enhance or extend our senses. Just as the senses have limitations and can be "fooled" under certain circumstances (Fig. 44-1), the design of physiologic monitors is limited and can also be fooled under some conditions. Intelligent users of these devices must understand their basic design assumptions to predict when they are likely to produce erroneous data.

ACCURACY AND PRECISION OF MEASUREMENTS

All measurements have errors. Comparing a measurement with the *gold standard* of that measure usually determines an error. Unfortunately, all measurements, even the so-called gold standards are subject to errors with respect to reproducibility. From a clinician's perspective, a physiologic measurement must be accurate to the degree required for clinical decision making. For example, arterial blood pressure can be measured in several ways, ranging from listening to Korotkoff sounds by the use of a sphygmomanometer cuff and stethoscope to continuous measurement via an intraarterial cannula. Unfortunately, each of these techniques provides slightly different arterial blood pressure values and different sources of error. The choice of method may be determined by accuracy or by the need for the frequency of the data and the ease of retrieving these data. An automatic oscillometric device is usually chosen over manual auscultatory measurements for ease of acquisition and reproducibility. Two people taking auscultatory blood pressure measurements may hear the Korotkoff sounds at slightly different points and record different arterial blood pressures. The smallest change in the measured variable that could affect a clinical decision determines the required accuracy of a clinical monitor. The requirements for *absolute accuracy* (Is the measured value correct?) may be different from the requirements for *relative accuracy* (Does the measured value follow trends?).

Consider a theoretic device that estimates hemoglobin (Hb) concentration by measuring in vivo light absorbance. This Hb concentration measured by absorbance (SpHb) of the finger is compared with the total Hb (tHb) concentration determined from in vitro laboratory analysis. SpHb is significantly dependent on the perfusion (temperature) of the finger (see Chapter 61). Yet, tHb can be associated with errors with arterial blood sampling and in vitro analysis of the sample by any method. Nevertheless, in vitro laboratory analysis is considered to be the gold standard in this comparison of methods.

The SpHb value can be compared with that of the tHb by the determination of bias and precision as recommended by Bland and Altman[1] (Fig. 44-2). Bias is the average difference between simultaneous values from the two methods, termed the *systematic error* or *offset*. If the SpHb reads an average of 5 g/dL higher than the tHb, then it has a bias of 5 g/dL and we can adjust for that systematic error by recalibrating the device. Precision is the standard deviation of the difference between the two measurements, and it quantifies the random error or *scatter*. A higher value for precision indicates a larger random error. (This statistic may be more appropriately called *imprecision*.) If the random error is too large, then the device may not be clinically useful. We can adjust for systematic error (bias) by recalibration, but no method exists to adjust for a random error. Proportional bias is yet another issue. Both the bias and the precision may vary over the range of values of clinical interest. A monitor may give accurate and precise values in the normal range but have a bias or precision error at the very range we are interested in to make a clinical decision. For example, a Hb measurement device may accurately read Hb values from 11 to 14 g/dL but have significant errors with values less than 11 g/dL (see Chapter 61), which is the range most clinically important (i.e., affecting transfusion decisions). Such a monitor may pass initial scrutiny but be clinically useless or harmful by inducing us to initiate or withhold treatment based on poor information.[2]

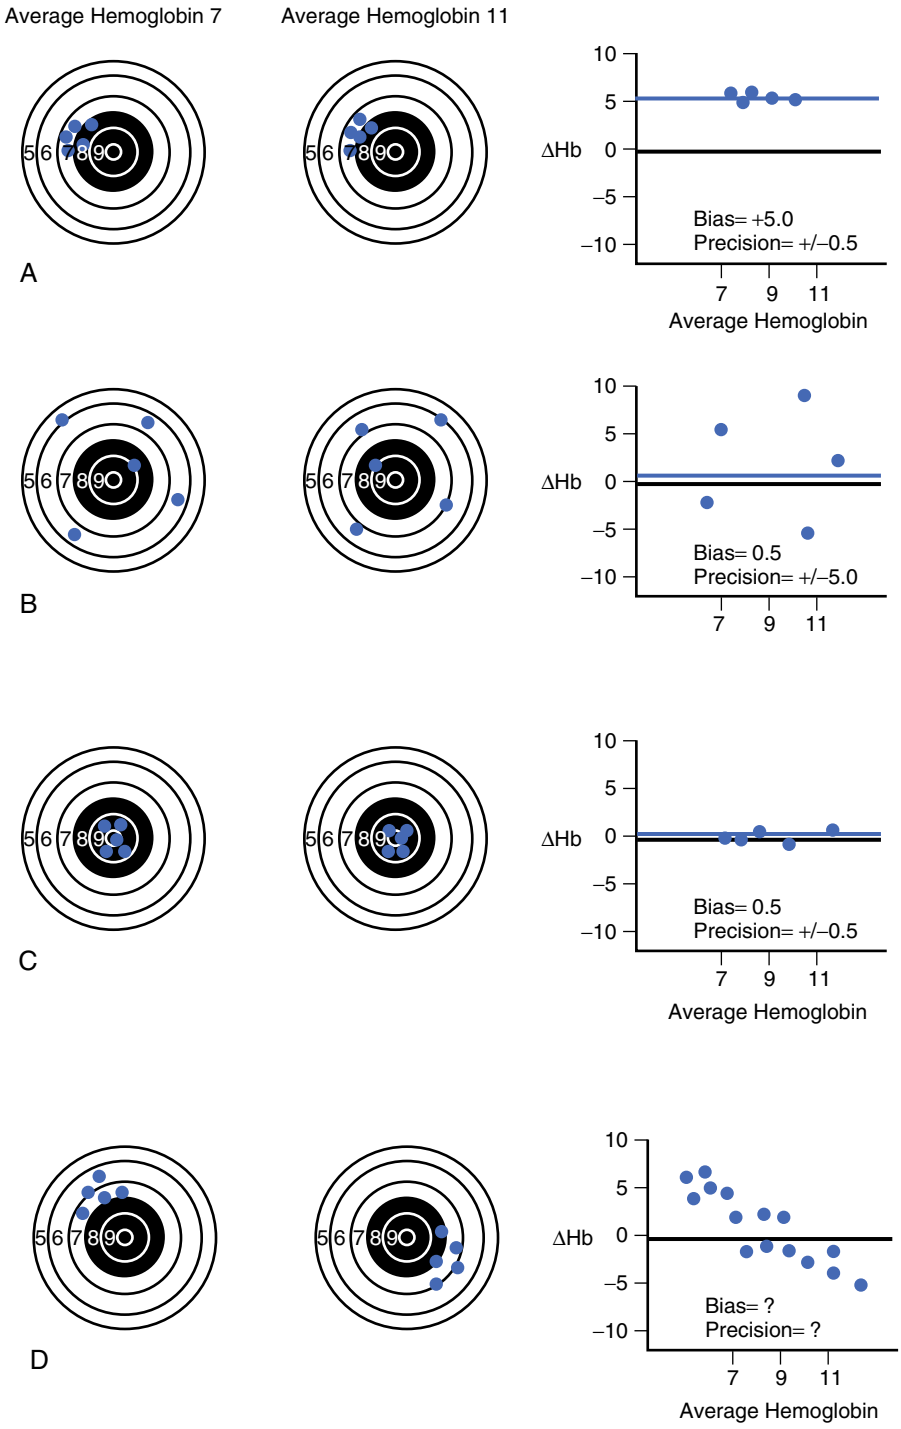

Figure 44-2. Accuracy and precision. The bias plot is a way to compare two different methods of measuring the same variable. Examples are plotted on the *right* for hemoglobin (Hb) values, blood analysis versus Hb absorbance. It is a plot of the difference between the two measurements being compared versus the average of those two measurements. **A,** If one method constantly measures slightly higher than the other by a consistent value, then the method has a positive bias. If it has only a slight variation around that bias, then the method is said to have low random error or precision, which equals the standard deviation of the differences. **B,** The values are randomly scattered, such that the average difference is near zero, but the precision value is large. This large random error makes the device unusable because calibration will not improve this random error. **C,** This is the optimal device, in that it has a bias near zero and a small precision (i.e., standard deviation of the differences) over the entire range of measurements. **D,** This device has reasonable precision at any given value, but the bias varies, depending on the value, leading to a useless device with undefined accuracy and precision over the clinical range necessary.

MEASUREMENT OF MASS

Measurement is the determination of a physical quantity. A *dimension* is a specific category or type of physical quantity; for example, mass, length, time, energy, or any of their derivatives. Units are specific ways of measuring a given dimension. Examples of units include the meter (length), second (time), kilogram (mass), ampere (current), and degree Kelvin (temperature). Describing a measurement without defining the unit is meaningless. A 30° day in Fahrenheit is literally freezing; a 30° day in Celsius is rather hot. Units can be base units or derived units. The International System of Units (SI; *Le Système International d'Unités*), which is a system used in science, has seven base units—meter, kilogram, second, ampere, degree-Kelvin, mole, and candela—from which multiple other units can be derived.

When weighing a patient, the force of gravity acting upon the patient's mass is determined. We generally mean this to be on the earth's surface, but the concept of weight is applicable to other locations. (On the surface of Jupiter, for example, a 70-kg man would weigh 12 times his earth weight, but his mass would still be 70 kg.) Since Force = mass × acceleration as a result of gravity (Newton's second law), we *balance* the force on the patient with a known

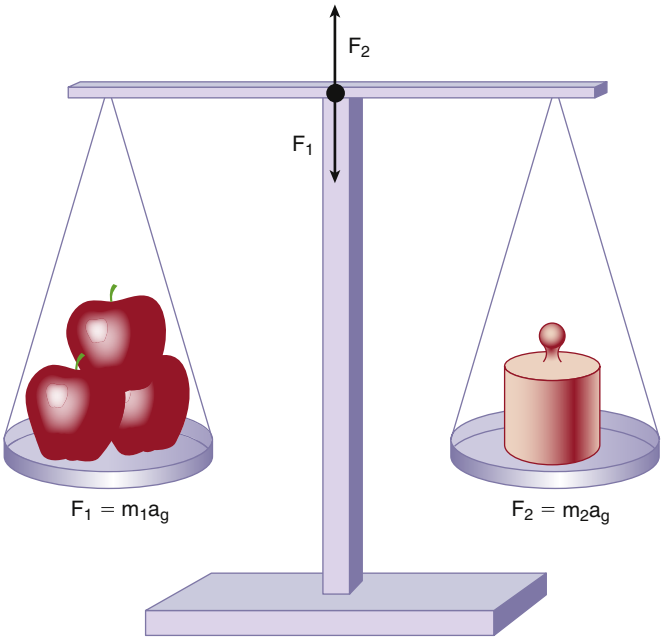

Figure 44-3. Balance. A scale is in balance when the forces are equal and in opposite directions. The force of gravity on the unknown mass of fruit is balanced by the known standard masses on the opposite side of the balance. $F_1 = F_2$, hence $m_1 a_g = m_2 a_g$; because $a_g = a_g$, m1 = m2. (a_g = acceleration due to gravity.) (See Appendix 44-1.)

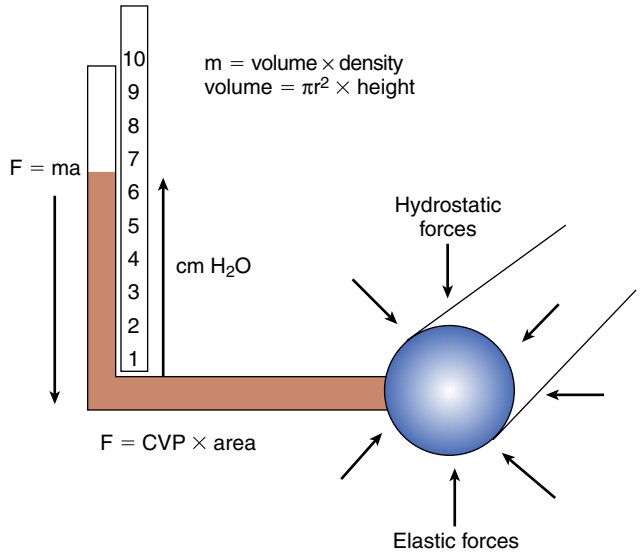

Figure 44-4. Manometer. A water manometer uses a balance of forces. In this case, the downward pressure of the fluid, as determined by its density and height, balances the upward pressure of the central venous system, caused by hydrostatic and elastic recoil forces.

mass to determine the patient's weight (the SI units of force or weight are *Newtons*) and mass (kg) (Fig. 44-3). The concept of balancing forces applies to multiple other monitoring modalities. When we measure the central venous pressure using a simple manometer, we are observing the balance of forces between the venous pressure and the force of gravity acting upon a fluid column (Fig. 44-4). When the same pressure is electronically measured, we are balancing a Wheatstone bridge (a system of resistors used to determine an unknown resistance) (Fig. 44-5).

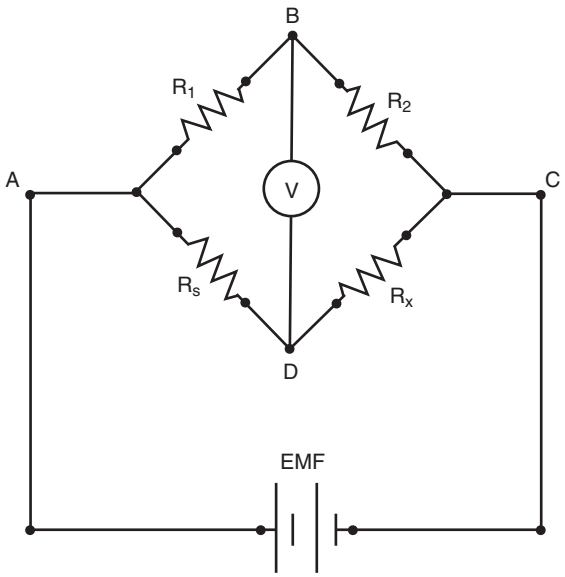

Figure 44-5. Wheatstone bridge. A Wheatstone bridge is an electronic circuit designed to enable an unknown resistance to be calculated by knowing two sets of variables: (1) the voltage drop across the bridge, and (2) the other resistances in the circuit (see Appendix 44-3).

TABLE 44-1 COMPARISON OF ENERGY LEVELS OF COMMON AND UNCOMMON EVENTS

Event	Energy
1 kg mass falling 1 meter on Earth	9.8 Joules
Heartbeat	10 J (at rest, 60 bpm, 10 watts)
Internal defibrillation for ventricular fibrillation	30 J
Maximum output of surface defibrillator	360 J
1 kilocalorie	4186 J
Car battery	1.8 MJ = 1.8×10^6 J
Kilogram of fat	3.8×10^7 J
Ton of TNT	4.2×10^9 J
Atomic bomb (Hiroshima)	15 kilotons=$15 \times 10^3 \times 4.2 \times 10^9$ J = 6.3×10^{14} J
Hydrogen bomb	1 megaton = 4.2×10^{15} J
1 kg converted completely to energy	8.987×10^{16} J
The sun (4.2×10^9 kg matter/sec)	3.8×10^{26} J/sec

Modified from Hecht E: Physics: algebra/trig. *Pacific Grove, Calif, 1994, Brooks/Cole.*

MEASUREMENT OF ENERGY

Energy can exist in many different forms. Even matter is related to energy, mathematically defined by Einstein's famous $E = mc^2$ equation. That is to say, matter and energy are different forms of the same stuff. In the absolute sense, usually reserved for thermonuclear weapons, atomic reactors, and the sun, matter can be converted into energy and vice versa (Table 44-1). The energy of motion is described as kinetic energy ($KE = \frac{1}{2} mv^2$). Temperature is a form of kinetic energy at the molecular level. Acoustic energy (sound) is a wave of pressure energy transmitted through matter. Light is a form of electromagnetic energy. Potential energy is stored energy and

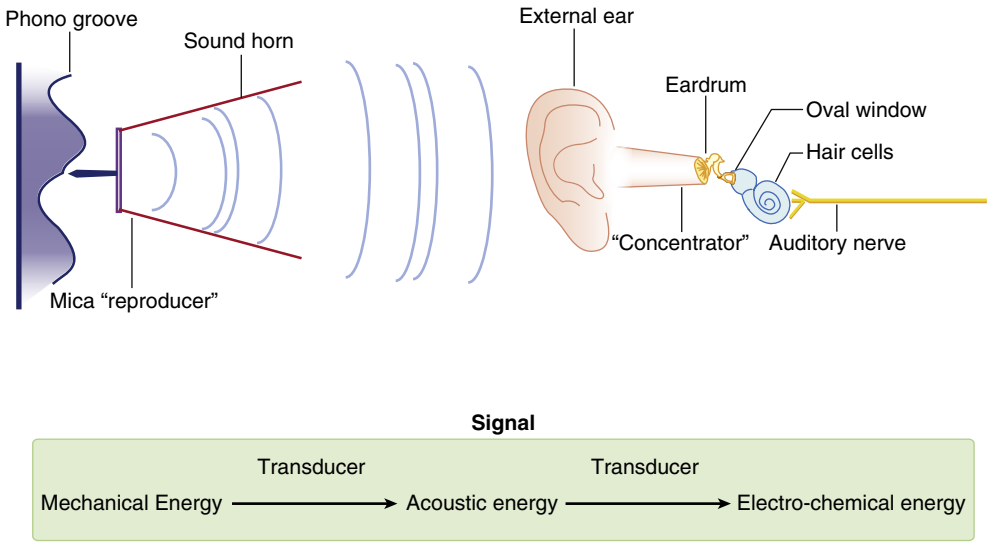

Figure 44-6. Transduction in mechanical and biologic systems. Mechanical energy of the winding mechanism causes the cylinder of the phonograph to rotate. The bumps and curves in the cylinder then move the needle, converting that energy into acoustic energy (a longitudinal wave). The mechanical vibrations are thus reproduced as longitudinal sound waves. These sound waves enter the human ear, impact the eardrum, causing it to vibrate, which moves the ossicular chain and results in an amplification of the pressure at the oval window, transmitted through the fluid of the inner ear where the appropriate hair cell resonates and generates a neural signal (transduction). A loss of hair cells leads to deafness, most commonly in the higher frequency range as one ages. This loss is analogous to a monitor lacking sensitivity in the desired range.

can be of many forms, including gravitational, chemical, pressure, and electromagnetic. The fundamental law of conservation of energy (energy and matter can neither be created nor destroyed, only changed from one form to another) is at the core of understanding many of our anesthetic monitors.

SIGNAL PROCESSING AND INFORMATION THEORY

When a quantity varies over time, it can be said to contain a *signal*. The recording of vital signs and patient data, first begun a century ago by Harvey Cushing,[3] is a primitive form of signal analysis. To quote Dr. Cushing[4]:

In all serious or questionable cases the patient's pulse and blood-pressure, their usual rate and level having been previously taken under normal ward conditions, should be followed throughout the entire procedure, and the observations recorded on a plotted chart. Only in this way can we gain any idea of physiological disturbances—whether given manipulations are leading to shock, whether there is a fall of blood-pressure from loss of blood, whether the slowed pulse is due to compression, and so on.

Often the signals (the energy or concentration of matter) we are interested in monitoring are too small for our senses to define changes adequately. Therefore we must either concentrate or amplify the signal. Often, this information is *transduced* or changed from one form to another for amplification and processing. An old style gramophone is a good example. The information stored in the shape of the record groove moves a needle attached to a mica diaphragm (the reproducer), which is then connected to a sound horn. The mechanical vibrations are thus reproduced as longitudinal sound waves. These sound waves enter the human ear, impact onto the ear drum, causing it to vibrate. This vibration moves the ossicular chain, resulting in an amplification of the pressure at the oval window transmitted through the fluid of the inner ear where the appropriate hair cell resonates and generates a neural signal transduction (Fig. 44-6). This progression is analogous to the process by which arterial pressure transducers work (Fig. 44-7).

DATA PROCESSING

When an analog signal (e.g., voltage versus time) is amplified, both the background noise and the desired signal are amplified (Fig. 44-8). Various techniques can be used to enhance the signal-to-noise ratio. For instance, most pulse oximeters assume that a pulse rate is between 30 and 300 beats per minute (bpm). Therefore the instrument filters out any pulsations that occur at frequencies below 30 or above 300 (see "Alternating current" and Fig. 44-23). Filtering can remove the noise that is outside of this frequency range, improving our ability to discern the signal of interest. Improper filtering can destroy the true signal. In some cases, a desired periodic signal can be repeated and summated, and the accompanying random noise becomes a smaller fraction of the signal. Evoked potentials are an excellent example of this process of *ensemble averaging*. The evoked-response signal for a single stimulus is actually significantly smaller than the random noise, but this signal is nearly identical after each stimulus. Therefore by summing the potentials after many stimuli, the evoked-response signal, but not the noise, is reinforced (Fig. 44-9).

Finally, the waveform of any periodic signal can be represented by a summation of sinusoidal waves, called a *Fourier series* (Fig. 44-10). The component sine waves can be described by their frequency and amplitude (or power,

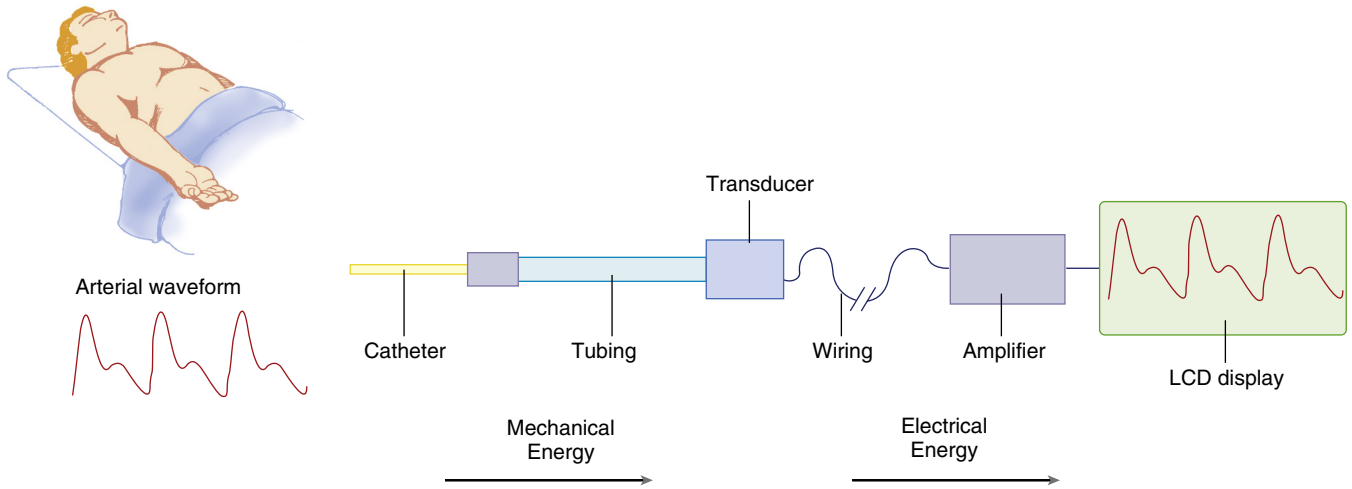

Figure 44-7. Transducer. A transducer changes a signal from one form of energy to another. A common transducer in anesthesia changes mechanical energy (e.g., an arterial pulse) into electrical energy, which is then displayed as time versus amplitude on a liquid-crystal display (LCD) or cathode ray tube (CRT) display. Microphones and speakers are also examples of transducers.

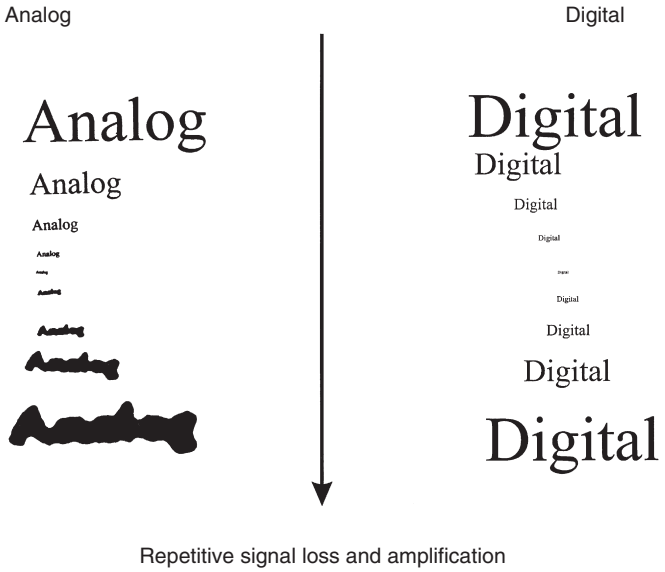

Figure 44-8. Digital and analog signal processing. The analog signal shows distortion and a loss of fidelity as it is reduced and then amplified. The digital signal shows no such loss. To create the analog example, a copying machine was used to shrink the text and then enlarge it. For the digital signal, the font size was reduced, the text copied, and the process reversed.

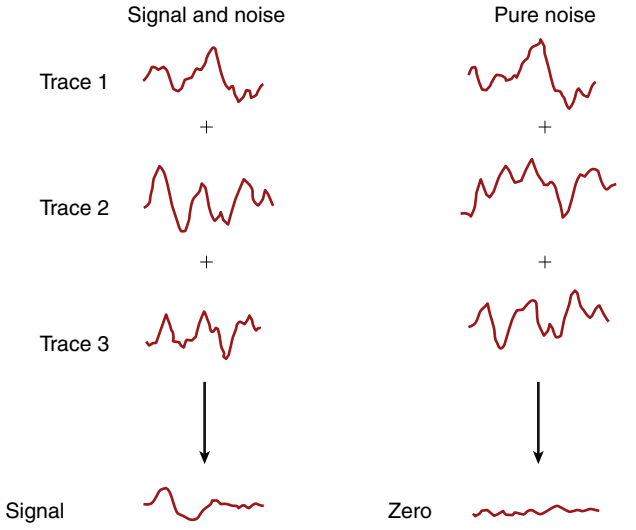

Figure 44-9. Somatosensory evoked potentials. A background signal can be separated from random noise by repeatedly adding the signals. The noise (random) is equally likely to be positive or negative; hence, adding positive and negative yields zero with multiple summations.

which is proportional to the square of the amplitude). Thus a waveform originally expressed as amplitude versus time is transformed into a plot of power versus frequency. The resulting plot, called the *power spectrum*, was a common form for displaying and interpreting some types of waveform data, such as the electroencephalogram (EEG). Most common monitors of EEG now use computer analysis to convert aspects of the power spectrum into a single, easy-to-interpret number (see Chapter 49).

ERRORS IN SIGNAL ANALYSIS

Multiple types of errors exist in signal analysis. The simplest is just missing data. Attempting to locate a 1-mm nerve using a 1-cm probe will not be successful because of a lack of spatial resolution, analogous to scanning a finely detailed print with a crude scanner, resulting in lost information. Another kind of error is *aliasing*, in which a false signal is presented. We have all seen movies where car wheels appear to be rotating backward while the car is moving forward. This is the result of temporal aliasing that occurs when the sampling frequency is too slow to capture the rapid variations of the true signal (Fig. 44-11). Aliasing can also happen with ultrasound, in which the display may show echoes from objects that do not actually exist. When dealing with nonmoving objects, spatial aliasing can occur when the resolution is too low. Figures in this book are submitted with at least a 300 dot per inch (dpi) resolution in an attempt to avoid aliasing. Figure 44-8 is an example of aliasing when the small digital signal has been reduced to "jaggies" by too low of a resolution.

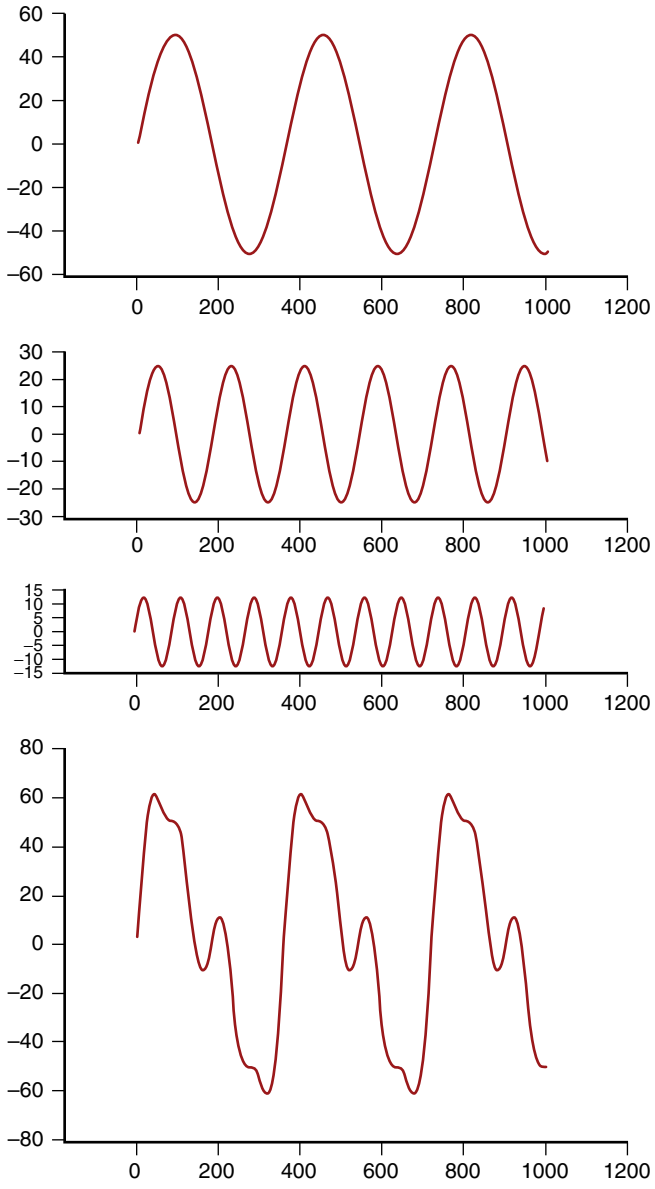

Figure 44-10. Fourier series. This pseudoarterial waveform was generated by adding the three sine waves with the following characteristics: y = 50 sinx; y = 25 sin2x; y = 12 sin4x.

In mechanical systems, such as the conventional liquid-filled tubing and pressure transducer for measuring arterial blood pressure, frictional forces can damp the signal. The signal can also be distorted by resonant amplification, in which the energy of the signal is temporarily stored in the compliance of the tubing and then released (see Appendix 44-4) (Fig. 44-12). If our display rate is too rapid, then important signals can be missed. The systolic pressure variation (SPV) (i.e., the alteration in systolic blood pressure with positive pressure ventilation)[5,6] has been used to determine volume responsiveness in hypotension. Because this change happens more slowly than the heart rate and because many displays use "auto gain", that is, the size of the display is controlled to maintain constant waveform amplitude (e.g., the plethysmographic display of most pulse oximeters), the SPV has been clinically neglected for many years.

With modern data recording and storage, Cushing's original rationale of correlating patient physiologic changes to intraoperative events can now be applied to entire populations, as well as to individuals. The original signal, whether an observed pupillary sign, palpated pulse, transduced pressure, or auscultated breath sound that was integrated, interpreted (Is this real or an artifact?), and charted (data storage) by the anesthetist, can now be automatically processed. This point is important because it introduces new possibilities in monitoring (e.g., trends, signals, feedback to user) and new pitfalls. Imagine an anesthesia record that would alert you to future potential physiologic issues from currently monitored data and predictive algorithms; in other words, an intelligent anesthesia record. New problems are introduced by such technology: security, potential loss of data (loss of not only a single chart or data point, but a loss of all the charts), and erroneous signal processing (imagine a faulty algorithm denying the very information Dr. Cushing sought to use to improve patient care).

PRESSURE MEASUREMENT

Principles of Pressure Measurement

With the basics of measurement, an example of clinical measurement will be processed. As part of a clinical examination, we can note the distention of the jugular vein. We can visualize the reflection of light off of the patient's skin, changing as the underlying structure (the jugular vein) fills and collapses; but what are the physics of this distention? If we were to insert a clear tube into the vein and hold the tube vertical with respect to gravity, then we would observe the mass of blood in the tube raised a certain distance (in centimeters) against the force of gravity by the central venous pressure (CVP) until a balance point is reached. Energy is lost in the work done in raising the fluid column, distending the tubing, and frictional losses. Therefore the actual CVP is slightly greater than we can reasonably measure. Despite these limitations, a liquid manometer is a simple and effective way to determine CVP.

The units of pressure measurement can tell us something about how the measurement is made. We commonly talk of pressure in terms of millimeters of mercury (mm Hg) or centimeters of water (cm H_2O) or pounds per square inch (psi) or atmospheres (atm). What is measured in a clear manometer tube is a pressure in centimeters of blood. Given that the content of blood in the tube can vary, more standard units than centimeters of patient blood are needed. The physics of the manometer must be understood. The density of a fluid is its mass per unit volume, which has SI units of kilograms per cubic meter (kg/m^3) or, more commonly, grams per milliliter (g/mL). The pressure exerted by a liquid column of height z and density ϱ is simply ϱgz (see Appendix 44-2 for derivation). If the manometer liquid is mercury, which has a density of 13,600 kg/m^3 (13.6 g/mL), then the manometer pressure in pascals (Pa) (the SI unit of pressure) is:

$$P\,(\text{Pa}) = 13{,}600 \times 9.8 \times z\ (\text{m}) = 1.333 \times 10^5 \times z\,(\text{m})$$

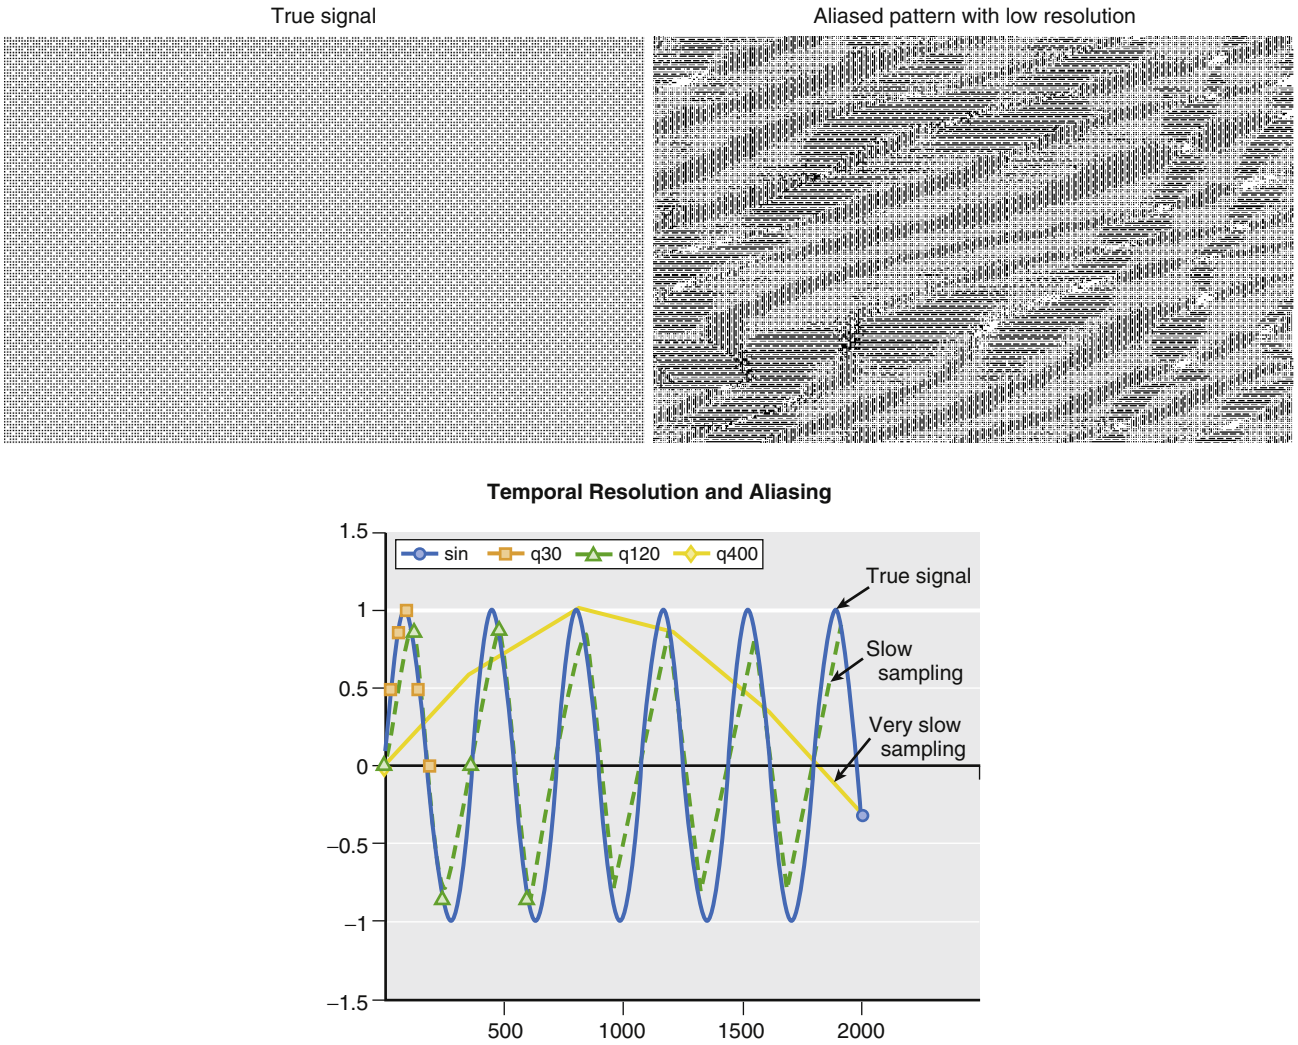

Figure 44-11. Aliasing and resolution. Spatial: Too low of a resolution results in a complete loss of information or spatial aliasing. Temporal: Improper sampling leads to an erroneous waveform. A slower sampling rate results in a change in the amplitude and wavelength.

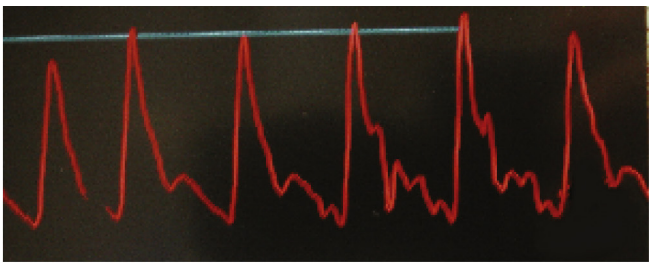
Because these large numbers are rather awkward, P is often expressed in kilopascals (kPa) and z in mm Hg:

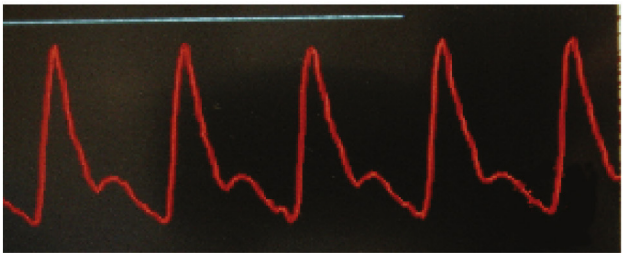
$$P\,(\text{kPa}) = 0.1333z\ (\text{mm Hg})$$

A useful reference for the various pressure units in use today is the pressure of the earth's atmosphere at sea level, called *one atmosphere* or 1 atm:



$$\begin{aligned} 1\ \text{atm} &= 101.3\ \text{kPa} \\ &= 760\ \text{mm Hg} = 29.92\ \text{inches-Hg} \\ &= 14.7\ \text{psi} \\ &= 988\ \text{cm}\ H_2O \end{aligned}$$

If a fluid-filled catheter is connected to the circulatory system of a patient, then the height of the fluid in the manometer determines the mean pressure at the tip of the catheter. If the pressure measured is CVP, then these data can be used to infer right ventricular preload. For slowly changing pressures, a water or mercury manometer is simple and dependable (see Fig. 44-4). The manometer cannot quickly respond to rapid changes in pressure because of its inertia; that is, the mass of the liquid column resists rapid changes in height.



Dynamic Pressure Measurement (Transducer)

Accurate measurement of a rapidly changing pressure signal, such as arterial blood pressure, is more difficult and complex. Many characteristics of the arterial pressure–versus-time waveform (Fig. 44-13) might need to be determined. Systolic, diastolic, and mean arterial pressure is given by the maximum, minimum, and average pressure values during the cardiac cycle. In addition, the maximum upward slope of the waveform during systole, which is related to the speed of ventricular ejection, can be measured. An abnormally rapid downslope after aortic valve closure (indicated by the dicrotic notch) suggests possible aortic insufficiency. Thus the details of the pressure-time waveform, as well as its maxima and minima, are important to the clinician. Despite the display of the waveform on a vertical axis, remembering that the arterial pressure is not a transverse wave (such as a wave on the ocean) but a longitudinal wave (such as a sound wave or a pulse transmitted through a coiled spring) is important (Fig. 44-14).

A modern pressure transducer is a device that changes either electrical resistance or capacitance in response to

A

B

Figure 44-12. Arterial waveform resonance. **A,** A peaked arterial waveform indicates some resonance with an overestimation of the systolic blood pressure. **B,** The same patient is depicted when damping is added to the system.

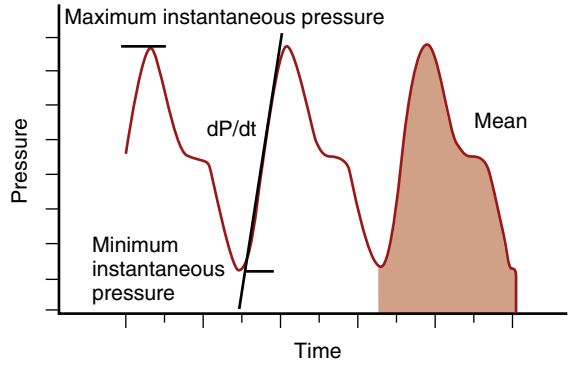


Figure 44-13. Arterial waveform. Systolic pressure is defined as the instantaneous maximal pressure; diastolic pressure is defined as the instantaneous minimum pressure; and the mean pressure is defined as the average pressure over a cycle. dP/dT refers to the upstroke of the arterial pressure (i.e., the rate of pressure generation). The mean pressure is estimated as the diastolic plus ⅓ the pulse pressure (systolic–diastolic) when only the systolic and diastolic pressures are known.

changes in pressure on a solid-state device. The variable transducer electrical resistance is placed in a circuit involving three known resistances—Wheatstone bridge (see Fig. 44-5 and Appendix 44-3)—and the change in resistance is thereby converted into electrical voltage. The moving part of the transducer, itself, is small and has little mass. This system of a fluctuating driving pressure (i.e., the arterial pressure being measured), a liquid-filled tube, and a pressure transducer is mechanically equivalent to the mass-spring harmonic oscillator (Fig. 44-15). The mass (m) represents the mass of the fluid in the tubing. The spring represents the elasticity of the tubing and transducer. The damper, shown

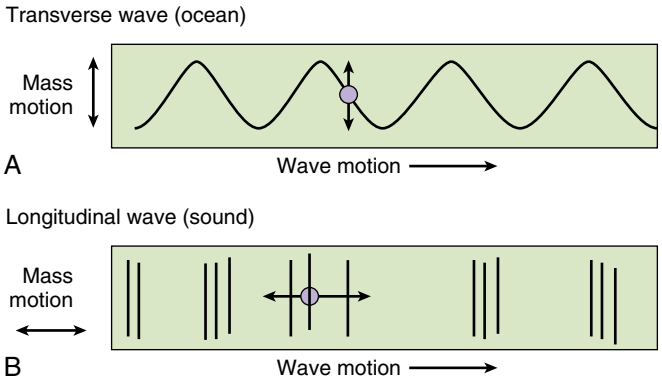

Figure 44-14. Transverse and longitudinal waves. **A,** In transverse waves (e.g., ocean waves), the particles move perpendicular to the motion of the wave. **B,** In longitudinal waves (e.g., sound waves), the particles move back and forth in the direction of the wave. The actual matter in either wave does not move much. The energy transfers without mass transfer. In arterial systems, this illustration clarifies the fact that energy transfer (blood pressure) does not mass transfer (blood flow).

schematically as a piston moving in oil, represents the friction generated by the fluid moving to and fro in the tubing.

A more commonly encountered harmonic oscillator is that of a car driving down a bumpy dirt road (see Fig. 44-15). In this case, the bumps in the road provide the oscillating driving pressure, which forces the car wheels to oscillate up and down. The car springs are analogous to the compliance of the arterial pressure tubing, and the car's shock absorbers, which oppose motion of the wheel in either direction, are analogous to the friction of the fluid moving back and forth in the fluid-filled tube. Depending on the frequency of the bumps (i.e., driving pressure frequency), the system can either suppress the bumpy road or may initiate dramatically increased oscillations. The frequency of the driving force that causes maximal amplification of the signal is called the *natural* or *resonant frequency* (Fig. 44-16). The degree of amplification is directly related to the mass and inversely related to the amount of friction present; for large amounts of friction, attenuation rather than amplification occurs (see Appendix 44-4).

To visualize this concept intuitively, hang a weight on the end of a rubber band while holding the upper end of the band in your hand. If you move your hand up and down slowly, the weight follows your hand movements almost exactly. As you increase the frequency of your hand oscillations, the weight begins to lag behind your hand, and the amplitude of the weight movement begins to increase. As you approach the natural frequency of this simple system, you will observe the phenomenon of *resonance* when the amplitude of the weight motion becomes extremely large. If you try different rubber bands and weights, you will find that stiffer bands or smaller weights yield higher natural frequencies. The same is true of our fluid-coupled pressure transducer system. Stiffer (i.e., less compliant) tubing or a shorter length of tubing (less mass) produces higher natural frequencies in this system; that is, it requires a much higher pulse rate before amplification.

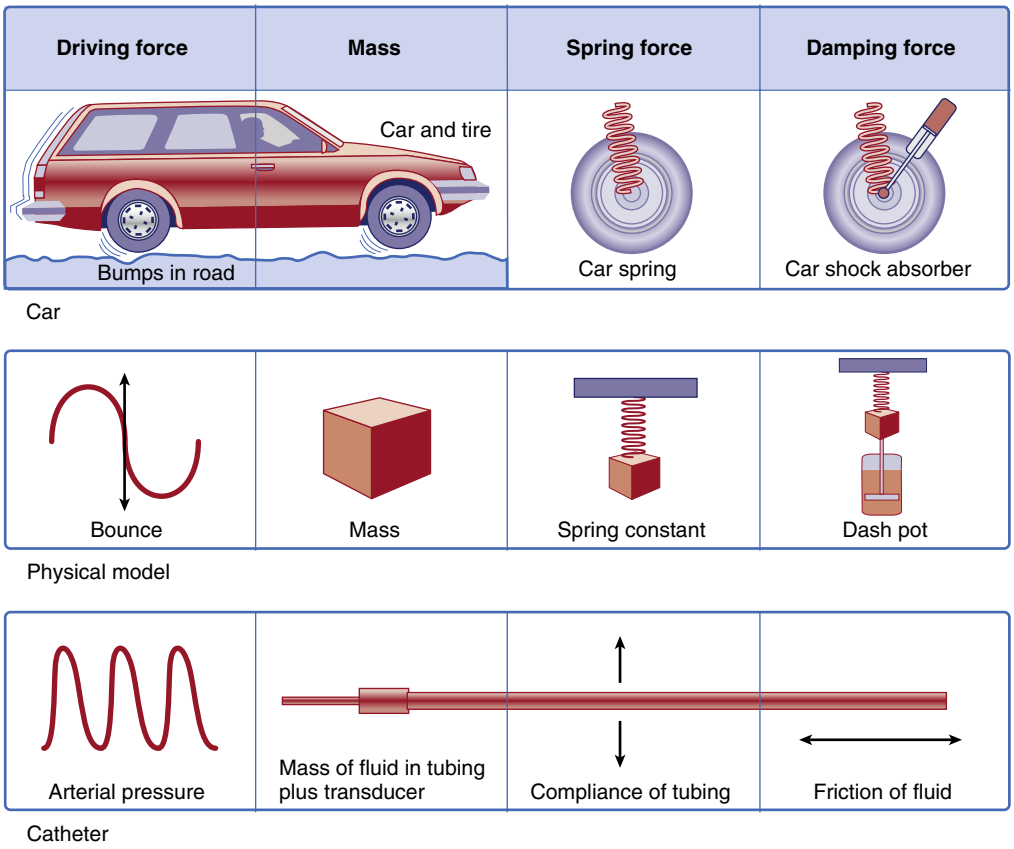

Figure 44-15. Damping and resonance. Pressure measured in an invasive arterial catheter can actually overshoot or amplify the real blood pressure. This phenomenon is referred to as the *dynamic frequency response* of the fluid-filled arterial line and transducer system. This phenomenon has a physical model, which can generate an equation to predict the output pressure response, depending on the frequency of the input pressure and several physical parameters of the system. In the physical model *(middle row)*, the driving pressure (i.e., the arterial blood pressure) acts on a mass (i.e., the fluid within the arterial pressure tubing), pushing it up and down against a spring, which stores energy (i.e., the compliant pressure tubing), and a dash pot, which opposes motion in either direction (i.e., the resistance of the fluid as it moves to and fro within the pressure tubing). Depending on the input frequency, the output may go through an amplification as it reaches a specific frequency, known as the *resonant frequency* of the system. In the *top row*, a common phenomenon is noted when a car drives along a bumpy dirt road. In this situation, the driving forces are the bumps in the road, which act on the tire. The car spring is equivalent to the compliance of the pressure tubing, and the shock absorber corresponds to the resistance of fluid moving back and forth in the arterial line. The mass of the fluid is analogous to the mass of the front of the car. You may have experienced the phenomenon in which you reach a certain speed as you are driving along a bumpy road when the front of the car starts to oscillate with increasing amplitude. If you speed up or slow down, then this phenomenon disappears. The car bounces highest when you have reached the resonant frequency of this harmonic oscillator (see Appendix 44-4 for detailed mathematical description of this process).

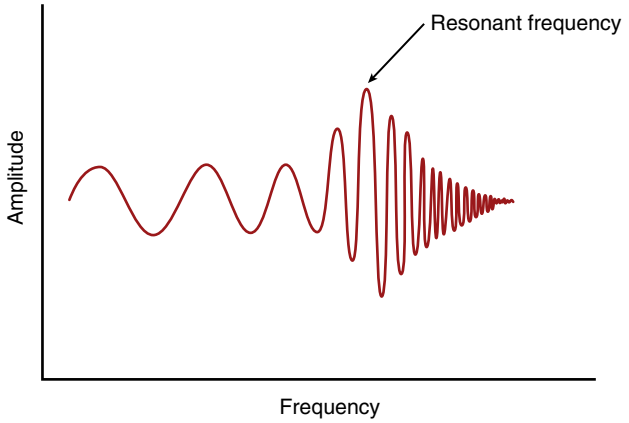

Figure 44-16. Amplitude and frequency. As the frequency increases, the amplification can increase to a maximum, and then the signal becomes attenuated. *(Modified from Sykes MK, Vickers MD, Hull CJ:* Principles of measurement and monitoring in anesthesia and intensive care, *ed 3. Oxford, 1991, Blackwell.)*

To minimize the potential of amplification of the real arterial pressure, the system should have noncompliant (i.e., stiff) tubing, and the total mass of liquid in the system should also be minimized, which can be accomplished by having small-diameter tubing and as short a length as possible. In most clinical systems, the natural resonant frequency is 10 to 15 Hz, which is significantly higher than the primary frequency of the arterial waveform (the heart rate is 60 to 120 bpm or 1 to 2 Hz). However, the arterial waveform is not a sine wave; rather, it is a more complex shape (see Figure 44-10) and made up of a summation of sine waves of frequencies that are various multiples of the heart rates—a Fourier series. The higher frequency components of the arterial waveform (higher harmonics) are those that are closer to the natural frequency of the system and are therefore amplified. This is why a *whip* is seen in the waveform when the peak systolic pressure and the initial upstroke are significantly amplified above the true systolic pressure,

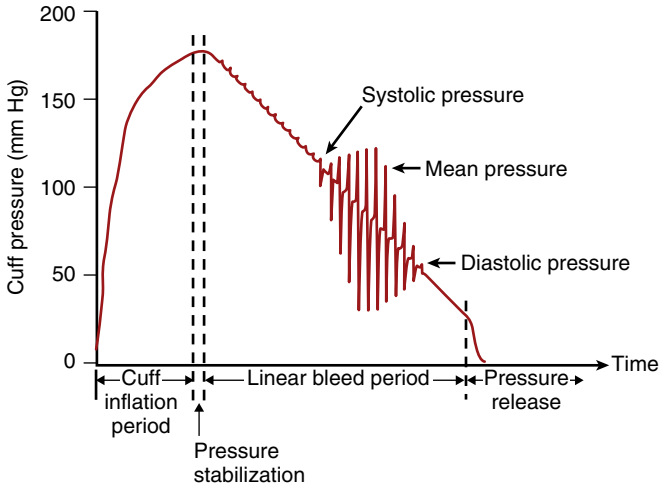

Figure 44-17. Noninvasive blood pressure measurement. Using the signal from the arterial pulse, oscillometric blood pressure measurements are obtained by determining the point at which the signal is first detected, its maximal amplitude, and the signal decay rate. *(Modified from Ehrenwerth J, Eisenkraft J:* Anesthesia equipment: principles and applications*, St Louis, 1993, Mosby.)*

although the heart rate, itself, is not near the resonant frequency. In theory, mean arterial pressure should be the same because this amplification of systolic pressure also produces a reduction in diastolic pressure (see Appendix 44-4).

Signal-Processed Pressure Measurement (Noninvasive Blood Pressure Monitor)

Systolic pressure can be estimated by noting the return of the flow pulse after occlusion of the brachial artery by a cuff. The return of flow can be detected by (1) simple palpation of the radial artery, (2) recording with a Doppler device over the radial artery, or (3) the use of a pulse oximeter. Most anesthesiologists are familiar with the loss of pulse oximeter signal when the noninvasive blood pressure monitor is cycling.

The automated noninvasive blood pressure monitoring devices in surgical units use a more sophisticated application of this principle. These devices monitor the oscillating signal generated in the cuff by the arterial pressure changes. The cuff first inflates to above systolic pressure, at which point the signal and oscillations are abolished. Then the cuff slowly deflates in a stepwise fashion. The pressure at which the oscillating pressure signal first appears is interpreted as the systolic pressure. The signal increases in amplitude as the cuff pressure decreases. The point at which the signal is at maximal amplitude is interpreted as mean arterial pressure. As cuff pressure decreases further, the oscillations rapidly drop off. Diastolic pressure is mathematically inferred from the systolic and mean values (Fig. 44-17).[7] Errors can be introduced in the same manner as for manual auscultation of Korotkoff sounds; too small or too large a cuff requires a higher or a lower pressure, respectively, to occlude arterial flow, and stiff atherosclerotic arteries are resistant to compression. External compression caused by patient motion or the surgeon leaning on the blood pressure cuff can cause pressure oscillations that are not related to arterial pressure and may result in an erroneous reading, most commonly a higher diastolic pressure.

Mercury sphygmomanometers are being phased out of use in most countries and hospitals, which leads to questions regarding the accuracy and precision of alternative devices such as the aforementioned automated noninvasive blood pressure monitors and aneroid sphygmomanometers.

MEASUREMENTS USING SOUND ENERGY (LONGITUDINAL PRESSURE WAVE)

Principles of Sound

Sound waves are small fluctuations in pressure, density, and velocity that can propagate through matter of any form—solid, liquid, or gas (see Fig. 44-14). Unlike electromagnetic waves such as light (see "Measurement Using Light Energy" later in this chapter), sound cannot propagate in a vacuum. The commonly used unit of sound, the decibel (dB), is not an SI unit but a logarithmic ratio of the sound energy referenced to 20 microPascals (μPa) (or 0.0002 millibar), the threshold of normal human hearing.

Sound has been used for many years in medical diagnosis and monitoring. It can be used as a diagnostic method in two ways: passive and active. In a passive examination, the sounds generated by the patient are studied. The basic examination of this type of examination uses the stethoscope. In an active examination, acoustic energy is transmitted into the patient, and the resulting interaction of this energy with the patient is analyzed for information. Both types of examination use the same physical principles.

In 1842, Christian Johann Doppler first described the apparent change in pitch of a sound that occurs when either the source of the sound or the listener is moving. This Doppler effect now has several applications in patient monitoring, including precordial and esophageal Doppler ultrasound monitoring of local blood velocities or cardiac output.

When a sound source is moving toward the listener, the apparent pitch increases, and vice versa. The exact amount of frequency shift depends on whether the listener or the sound source is moving (Fig. 44-18) (see Appendix 44-7). Because changes in the frequency of sine waves can be precisely measured, the Doppler principle provides an accurate method of measuring the velocities of moving sound reflectors. At the high frequencies often used (>5 MHz), objects as small as red corpuscles can scatter enough sound for detection.

PASSIVE SOUND EXAMINATION (STETHOSCOPE)

Vibrations, such as those caused by the closing and opening of heart valves or air moving through the respiratory passages, travel through the body as sound waves. Sound is better and more rapidly conducted in liquids than in gases. Thus bronchial breath sounds are better heard when the bronchi are surrounded by lung consolidation. When sound waves reach a sudden change in density,

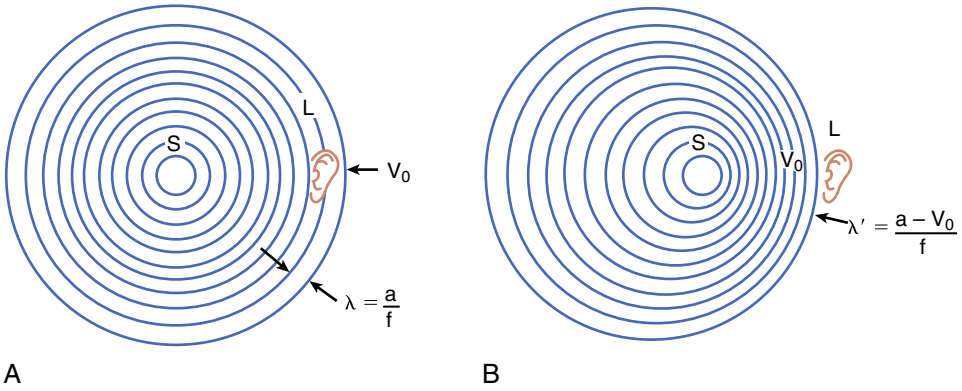

Figure 44-18. Doppler effect. **A,** When a listener is moving toward a stationary sound source, the frequency increases because the listener transverses more waves per unit time than a stationary listener. **B,** When a sound source is moving toward a stationary listener, the wavefronts "stack up," causing an apparent increased frequency.

for example a liquid-gas interface, some of the energy is reflected.

Some simple facts about sound waves can facilitate an understanding of the reflection and scattering process in the body. First, all sound waves can be represented as a summation of sinusoidal waves of various frequencies and amplitudes. (The process of Fourier or power spectral analysis is discussed earlier in this chapter.) A note from a musical instrument thus consists of a sine wave at the fundamental frequency plus many harmonics at multiples of this frequency. The fundamental frequency describes the pitch of the tone—middle C is standardized at 256 Hz, for example.

Fortunately for our ears, all of these many frequencies propagate at the same speed, the speed of sound, called *a*. For ideal gases, the speed of sound is proportional to the square root of temperature. The speed of sound in air at room temperature is 344 m/sec, or 1129 feet per second (ft/sec), or 770 miles per hour (mph). At an altitude of 13,000 m (40,000 ft), where the standard air temperature is –57° C, the speed of sound is only 295 m/sec or 661 mph. The speed of sound is significantly faster in liquids than it is in gases. For example, the speed of sound through water at 15° C is 1450 m/sec. This value also approximates the speed of sound through most of the solid parts of the human body. In other solids, the speed of sound greatly varies, with a range of 54 m/sec in rubber to 6000 m/sec in granite. Reflection of sound occurs at interfaces where the product of the density and the speed of sound ($\rho \times a$) suddenly changes. Larger changes in this acoustic impedance result in greater reflection and less transmission. In the human body, the largest changes in acoustic impedance occur at gas-tissue boundaries: the lungs and the gastrointestinal tract. Reflection of sound by the lungs thus makes it difficult to auscultate heart tones through an air-filled, emphysematous chest. For the same reason, a transthoracic echocardiograph provides less detail than the transesophageal technique; in the former case, the lungs are in the way.

The first attempts to gather information about the inside of the patient by using sound involved placing one's ear directly on the patient. Although this procedure had many limitations, it led to the development of the modern stethoscope, which is based on the physical principles of sound transmission. The stethoscope uses a large diaphragm to transmit and concentrate the sound energy. The bell acts as both an amplifier and a low-pass filter to transmit low-frequency diastolic rumbles. Rappaport and Sprague describe the physics of stethoscopy in depth.[8]

In a simple stethoscopic examination, errors are introduced by signal processing; that is, a lack of experience or appropriate knowledge on the part of the listener. Because it is a nonpowered, nontechnologic device (the energy levels come from the phenomena themselves), an esophageal or precordial stethoscope has unique value in being a continuous monitor during power outages. Physical limits to the technique include air space disease (in itself an informational finding), an inability to place the monitor appropriately, and a lack of quantifiable data.

Active Sound Examination (Percussion, Echo, Doppler)

The earliest active acoustic diagnostic technique was percussion of the chest wall. A skilled clinician can use this method to detect consolidation of the lungs, pleural effusion, and a few other chest pathologic conditions. Although based on transmission and the reflection of sound, percussion is purely qualitative and is unable to localize pathologic changes accurately. Modern ultrasound improves on percussion by using shorter-wavelength sound waves and quantitative detection of their reflections (echoes). The wavelength of the sound used limits the spatial resolution of an examination (see Fig. 44-11). Using ultrasound at frequencies in the megahertz (MHz) range (10^6 cycles/sec) allows resolution of much smaller objects. The wavelength of 1-MHz sound waves in solid tissue is approximately 1.5 mm, whereas the wavelength of a 256-Hz tone (middle C) in tissue is 5.7 m.

With the use of esophageal transducers, echocardiography has become a popular intraoperative monitoring technique. Sound waves in the 2- to 10-MHz range are transmitted toward the heart in short bursts or pulses. After each pulse, the transducer passively listens to the reflected echoes from various tissues. The ability to place the transducer in the esophagus is advantageous because sound does not then have to pass through air spaces or bone on its way to and from the heart. The speed of sound through the heart and surrounding soft tissues is a nearly constant 1540 m/sec. Thus the exact measurement of the elapsed time between transmission of the pulse and receipt of the echo provides the distance to the reflecting structure. The sound beam from the transducer

is projected in a narrow searchlight pattern; therefore the exact direction of reflecting structures is also known.

The Doppler effect is used in echocardiography to determine the presence and degree of valvular regurgitation by converting the Doppler shift of sound waves reflected from erythrocytes into a color display (see Appendix 44-7). Cardiac output can also be estimated from descending thoracic aortic blood velocity by using a Doppler technique. These devices estimate the blood flow in the descending aorta and ignore flow to the head and arms. They calibrate descending aortic flow to cardiac output by assuming a constant proportional relationship between the two flows.[9]

MEASUREMENTS USING ELECTRICAL ENERGY (TRANSVERSE WAVE)

Principles of Electricity

Most of our monitors and other anesthesiology apparatuses use the basic principles of electricity and magnetism. Nearly all transducers use some form of electrical energy as their output, and the subsequent data processing and display are entirely electrical. Some basic electromagnetic principles are reviewed in this section using examples from medical equipment. Electromagnetic waves, including light, are transverse waves, meaning that the electric and magnetic field vectors are oriented perpendicular to the direction of wave propagation. Unlike sound, these waves require no media in which to propagate.

Static Electricity

Electricity is a manifestation of a property called *charge* that is inherent in matter. The charge can be negative, positive, or neutral. Static electricity involves charges at rest; like charges repel one another, whereas opposite charges attract. Usually the meaning of the word *electricity* involves the flow of charges, or electrical current. Current flows in one direction in direct current (DC) electronic devices and alternates back and forth in alternating current (AC) devices.

The *coulomb* is the SI unit of charge , and the charge of an electron is the smallest quantum of charge (1.6×10^{-19} coulomb), which is equal but opposite to the charge of a proton. (Recently discovered subatomic particles called *quarks* actually have smaller charges, but this is beyond the scope of this chapter and not particularly relevant to medicine.) An electrostatic force is exerted between two charged objects and is directly proportional to the product of the two charges and inversely proportional to the square of the distance between them (Coulomb's law):

$$F = k \times q_1 \times q_2 / r^2 \quad (1)$$

This force is attractive when the charges are of opposite sign and repulsive when they are of the same sign. In a Nobel Prize–winning experiment, Robert Millikan determined the charge of an electron by suspending charged oil drops between two horizontal charged plates such that the electrostatic force balanced the gravitational force and the drops were held in midair (Fig. 44-19). Approximately 20 years later in 1940, his son, Glen Allen Millikan, developed one of the earliest infrared ear oximeters, the forerunner of the pulse oximeter (see "Processed Absorbance Monitors" on the pulse oximeter).

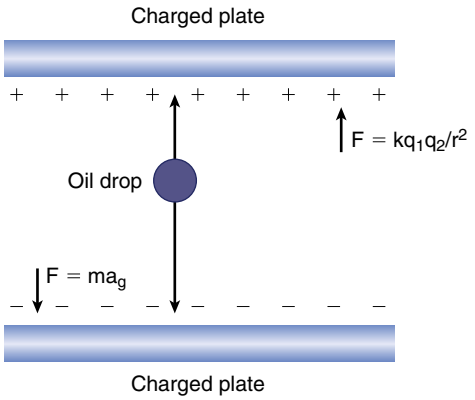

Figure 44-19. Electric force. The quantity of charge on an electron is determined by balancing the electric force on an oil drop against the gravitational force on the same drop. $F_1 = kq_1\, q_2 / r^2 = F_2 = m_1\, a_g$.

Direct Current

Just as mechanical energy may be stored as potential energy, electrical energy can be stored as a *potential difference*. A common analogy is to compare electrical potential difference with water pressure (Fig. 44-20 and Table 44-2). The potential difference between points A and B is defined as the work required to move a unit charge from A to B. The SI unit of potential difference is the volt (V); hence, the term *voltage* is often used for potential difference. Charges can easily move through conductors, but they do not move well through insulators, also called *dielectrics*. If a potential difference (V) exists between A and B and a conductor connects these two points, then charges will flow between them and produce an electrical current (I).

The SI unit of current is the coulomb per second, called the *ampere*. If an insulator separates points A and B, then no current will flow until the potential difference becomes so great that a breakdown of the insulator occurs. For example, if dry air separates A and B, then no current will flow until the potential difference reaches 3000 V/mm. At this very large potential gradient, air will ionize and become a conductor, and a current flows in the form of a visible (and audible) spark. To generate a spark between two electrodes 1 cm apart, a potential difference of 30,000 V must be created. The spark plugs in an automobile have an electrode gap of approximately 0.8 mm, thus requiring at least 2400 V from the ignition coil to generate a spark. Lightning is a larger manifestation of the same phenomenon.

A battery is a chemical cell that produces a nearly constant potential difference between two electrodes, which is called *electromotive force* (EMF). The battery can provide a continuous source of electrons, or current, to flow through any conducting circuit connected between its electrodes. Flow of electricity is opposed by resistance, analogous to resistance in water pipes. In most materials, resistance (R) is related to voltage (V) and current flow (I) in the following manner:

$$V = IR \quad (2)$$

This relationship is called Ohm's law, and the materials that follow this behavior are called *ohmic materials*.

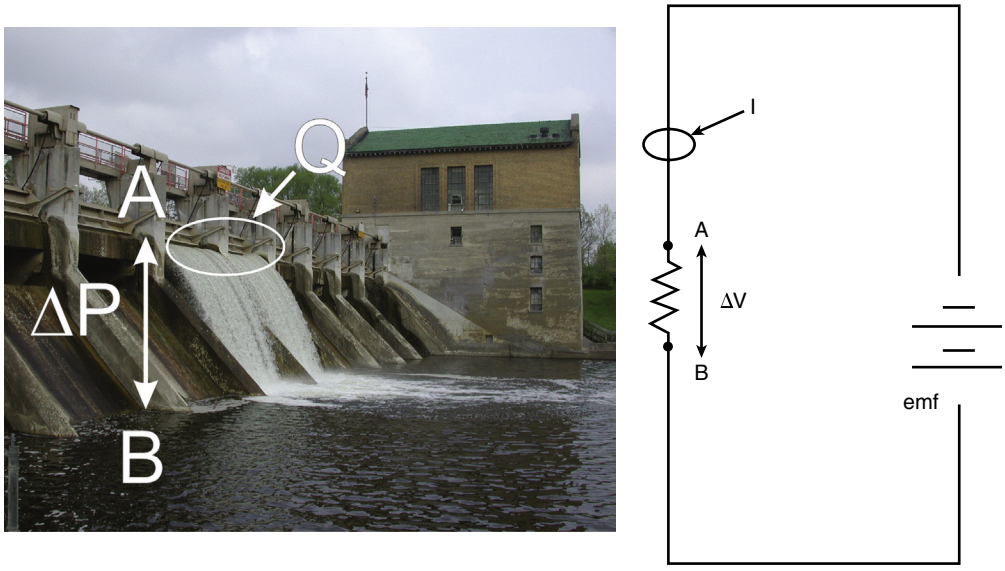

Figure 44-20. Water and electricity. The pressure drop over the dam (A to B) is analogous to the voltage drop over the resistance (A to B) (e.g., light bulb). The amount of flow (width of water) (Q) is analogous to the current (I). Both falling water and electrical potential can do work, as evidenced by the use of dams to generate electricity and electricity to pump water.

TABLE 44-2 **COMPARISON OF HYDRODYNAMIC AND ELECTRICAL ENERGY COMMONLY ENCOUNTERED**

Water	Electricity	Energy
Squirt gun	Static electric spark	High pressure, low flow, low energy
Garden hose	House current	Moderate pressure, moderate flow, moderate energy
	Car battery	Low pressure, moderate flow, moderate energy
River flood		Low pressure, huge flow, huge energy
Fire hose	High tension wires	High pressure, high flows
	Lightning	High pressure, high flow

This example is analogous to hemodynamic flow, in which the pressure drops across the systemic vasculature (mean arterial pressure – central venous pressure) (ΔP) equals cardiac output (CO) times systemic vascular resistance (SVR):

$$\Delta P = CO \times SVR \quad (3)$$

The power (i.e., rate of work) required to produce an electric current is the product of voltage and current: P = VI. By combining this formula with Ohm's law (V = IR), $P = I^2R = V^2/R$ is the result. Thus if the current is doubled through a fixed resistance (R), then four times the original power is used. This power loss in resistors is dissipated as heat, which is the reason why nearly all electrical devices become warm during use. The filament in an incandescent light bulb is merely a resistor that becomes so hot from ohmic heating that it glows or radiates light.

A capacitor is a device that stores charge (Q) in direct proportion to the potential difference (V) between its two electrodes: Q = CV. The proportionality constant (C) is called *capacitance*, which is measured in SI units of farads (1 farad = 1 coulomb/volt). When a capacitor is connected to a battery, current flows until the capacitor is charged to the point that the potential across the capacitor equals the EMF of the battery: V = Q/C = EMF (Fig. 44-21). When the charge button of a cardiac defibrillator is pushed, this kind of circuit is activated to charge a capacitor to the desired level. As shown in Figure 44-21, *B*, time is required to charge a capacitor. For a large capacitor, more time is required. Hence, it takes longer to charge a defibrillator to 200 J than to 50 J.

Alternating Current

In an AC circuit, the current and the voltage rapidly fluctuate (Fig. 44-22). Many important differences exist between AC and DC power. The voltage in common AC house power fluctuates sinusoidally at a frequency of 60 Hz (50 Hz in Europe). The amplitude of such a fluctuating voltage is characterized by its root mean square (RMS); that is, the square root of the time average of V^2. Thus for AC house power, V_{RMS} = 115 V (230 V in Europe). Current in an AC system is also constantly changing and is likewise measured as an RMS value.

AC circuits have three forms of impedance: resistance (R), capacitance (C), and inductance (L). An inductor is a circuit element whose impedance, called *inductive reactance*, increases with the frequency (f) of the current fluctuations ($R_L = 2\pi fL$). Conversely, the impedance of a capacitor, called *capacitive reactance*, decreases with increasing frequency ($R_C = {}^1/_{2\pi fC}$). Inductors thus tend to block high frequencies, whereas capacitors tend to block low frequencies (Fig. 44-23). This principle is used in stereo systems to direct the signal to either the woofer (low-frequency speaker) or the tweeter (high-frequency speaker). In medical instruments, inductance and capacitance circuits can be used to filter the signal, for example, decreasing the amount of 60-Hz interference from AC wiring.

Passive Electrical Examination (Electrocardiograph, Electroencephalograph)

With the basics of electricity discussed, the electrocardiograph (ECG) and the electroencephalograph (EEG)

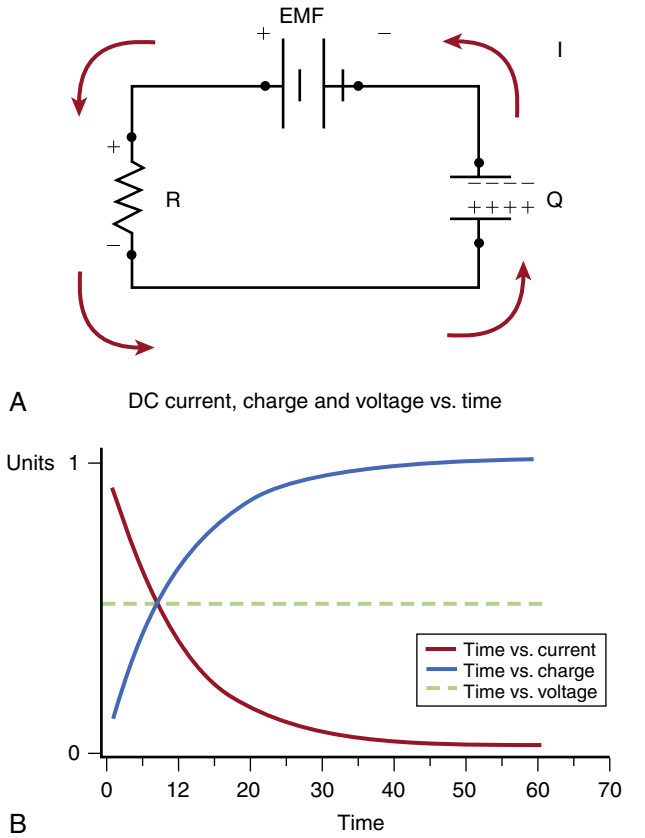

Figure 44-21. Resistance and capacitance in a direct current (DC) circuit. **A,** Under DC, the resistance impedes flow, developing a voltage drop across the resistance. The capacitor allows current to flow until the charge builds on the capacitor. **B,** Under DC, the voltage is constant over time, and the current flow decreases as the charge on the capacitor increases. This type of circuit is used to charge a defibrillator.

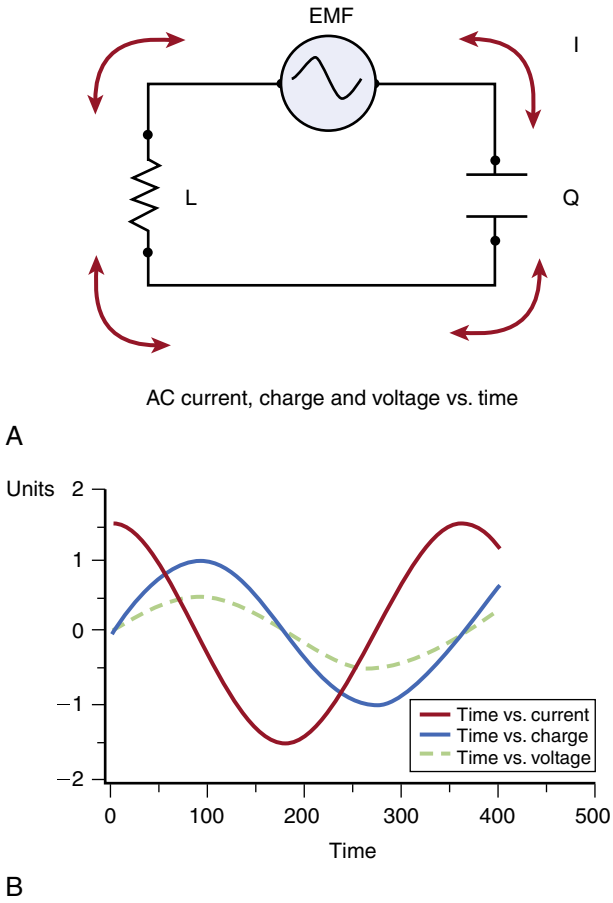

Figure 44-22. Resistance and capacitance in an alternating current (AC) circuit. **A,** In an AC circuit, unlike a DC circuit, the capacitor does not block current flow. **B,** The capacitor and resistance act to shift the phase of the AC current. Current changes lag behind voltage changes. *EMF,* Electromotive force.

are described, where the sources of the EMF are the heart and the brain, respectively (see also Chapters 47 and 49). Electrical potentials on biologic surfaces are too small to observe directly and must be amplified and processed before displaying. ECG potentials on the skin are in the 1-mV range, and EEG potentials are near 0.1 mV.

Figure 44-24 illustrates why electrical potentials on biologic surfaces are so small. The heart generates an electrical signal as a result of the synchronous depolarization and repolarization of multiple cells. The electrical potentials generated by the heart are measured between two skin electrodes, A and B. As this figure shows, multiple effective resistances and capacitances exist in the tissues between the EMF source and the measuring electrodes. These impedances lower the magnitude of the voltage signal at the skin. The shunt resistors R_3, R_4, and R_5, combined with the series resistors R_1, R_2, and R_3, form what is called a *voltage divider network*. Lower values of shunt resistance or higher values of series resistance result in smaller voltages at the skin. The capacitance of the skin (C_s) also acts to attenuate the low-frequency components and distort the waveform. Skin resistance, which may be a megaohm (10^6 ohms) for dry skin, can be reduced to a few hundred ohms by conductive gels.

If a DC voltage is applied between two body surface electrodes, then current flows through the tissues between them. Although the electrical current in metals consists entirely of electron flow, both positive and negative ions migrate in tissues. Negative ions tend to accumulate at the positive electrode (the anode), and positive ions accumulate at the negative electrode (the cathode). This collection of anions and cations near each electrode creates its own EMF, which opposes the EMF that set up the original current. The current therefore decreases and the effective impedance between the electrodes increases. This phenomenon, *called polarization of electrodes*, has two harmful effects. First, the increased impedance from polarization can attenuate the ECG signal for several seconds after defibrillation or DC cardioversion. Such attenuation could be misinterpreted as a lack of electrical activity and result in inappropriate administration of a second shock. The second consequence of prolonged application of DC voltage is the accumulation of a local concentration of toxic ions near electrode sites, a condition that can cause burns or tissue necrosis. A partial solution to the problem is the use of a nonpolarizable electrode, such as a silver and silver chloride combination. This electrode can act as a source of or *sink* for both anions and cations, thereby

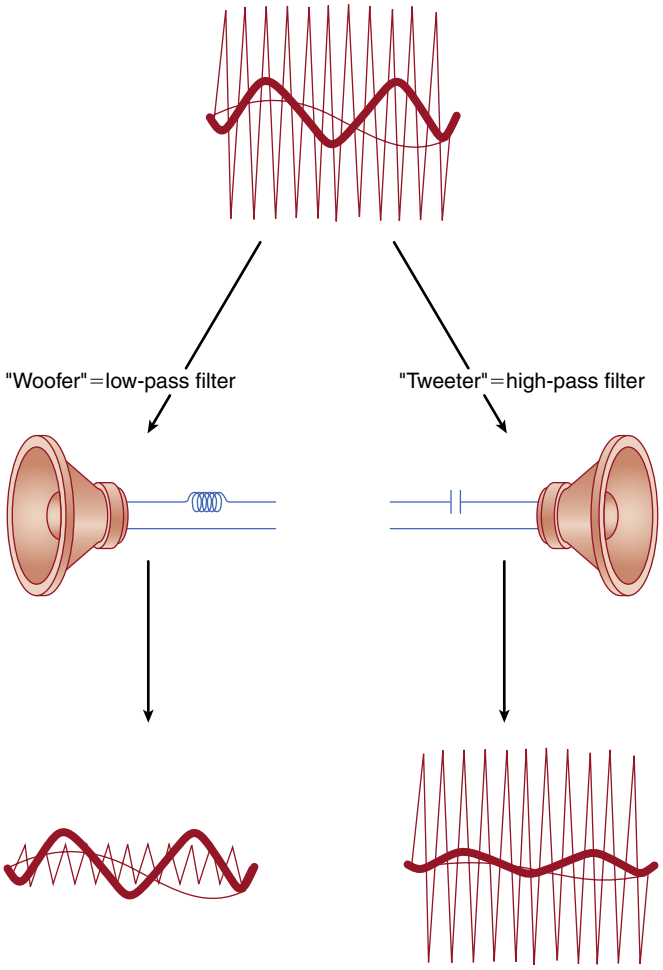

Figure 44-23. Woofer and tweeter. Stereo speakers use resistors to act as an impedance to high-frequency components of sound, allowing only the bass frequencies to pass to the woofer speaker. Capacitors are used as a high-pass filter to allow only the high frequencies to get to the tweeter speaker. A similar process can decrease 60-Hz interference from electrical appliances. *(From Hecht E:* Physics: algebra/trig. *Pacific Grove, Calif, 1994, Brooks/Cole.)*

minimizing the accumulation of ions. Most disposable ECG electrodes now use such materials. Even these electrodes, however, are nonpolarizable for only a limited time, and the application of prolonged DC voltage between any tissue electrodes must be avoided.

Similar problems complicate the measurements of the EEG; but in this case, the raw signal is one tenth the amplitude of the ECG: 100 μV versus 1 mV. The spontaneous EEG provides eight or more channels of surface voltage versus time data, which is of limited use for monitoring in the surgical unit. For rapid interpretation and diagnosis, the amplitude versus time data are usually transformed into plots of amplitude (or power) versus frequency. (This process of power spectral analysis is discussed in "Data Processing" earlier in this chapter.) The EEG power spectrum facilitates rapid diagnosis of hemisphere asymmetries and changes in frequency content that accompany either deep anesthesia or cerebral hypoxia. *Bispectral density* is another method of analyzing the raw EEG that determines the levels of correlation (or degree of phase-locking) between

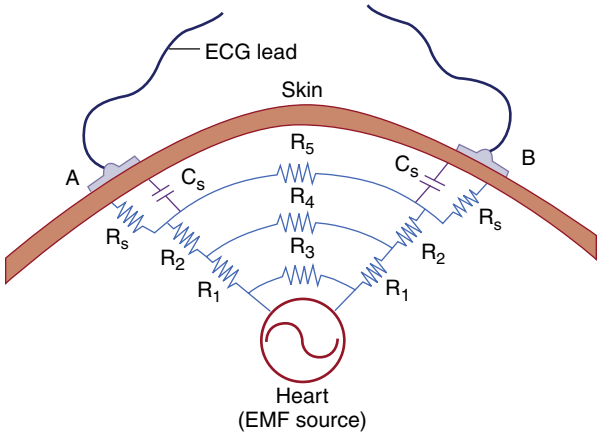

Figure 44-24. Why the electrocardiograph (ECG) is so small. Multiple resistances and capacitances in the body decrease the potential and distort the waveform before the electromotive force (EMF) reaches the surface.

various frequency components in the power spectrum. Yet another derived parameter is the *burst-suppression ratio*, which is the percentage of time during which the EEG amplitude is less than +5 microvolt (μV). Both of these last two derived quantities have been related to the depth of anesthesia in clinical studies (see Chapter 49 for a discussion on EEG monitoring).

Active Electrical Examination (Neuromuscular Block Monitor, Somatosensory Evoked Potentials)

A muscle twitch can be elicited by generating a 0.2- to 0.3-msec pulse of current to depolarize a peripheral motor nerve. This motor nerve then conducts the impulse to the muscle, where a twitch is generated. We can understand the in-use failings of this device by following the path of the signal. Clearly, we must start with an adequate power source (no power = no twitch). If the coupling of the electrodes to the patient is poor, that is, if the electrodes are dry or good skin contact is not made, then the circuit will have high resistance and little current will flow (see earlier discussion on direct current and equation 2), resulting in a diminished twitch. In summary, the simplest way to be certain that this monitor is properly functioning is to perform both a positive control (see the desired response of the thumb twitch before the chosen drug is administered) and a negative control (see the twitch disappear in response to administered drug) (see Chapters 49 and 53).

Evoked-potential (evoked-response) monitors can determine the status of multiple parts of the sensory nervous system by measuring the central nervous system response to a discrete sensory stimulus. The stimulus can be auditory, optical, or peripheral somatosensory. The amplitude of the evoked response measured at the skin can be small—less than 1 μV in the case of acoustic cortical potentials. This small signal is in a sea of spontaneous EEG signals (greater than 100-μV amplitude). We therefore resort to a signal enhancement technique called *ensemble averaging*. Rather than trying to measure the small response to a single stimulus, we average the responses from hundreds (or thousands) of stimuli.

Because we seek the evoked responses that consistently occur at the same time after the known stimulus, this averaging process reinforces the signal from the evoked response, and the random noise tends to cancel itself. In this way, we commonly measure signals whose amplitude is approximately 1% the amplitude of the background noise (see Fig. 44-9).

Whenever charged particles are moving, a magnetic field is generated in a direction perpendicular to the motion. *Paramagnetism* is a form of magnetism exhibited only in specific substances in the presence of an external magnetic field. Oxygen is a paramagnetic gas. This property is used to measure both inspired and expired oxygen concentrations; chemical methods similar to fuel cell amperometric sensors and polarographic electrodes are too slow to respond. In a fast-responding paramagnetic oxygen sensor, 100% oxygen can exert a pressure of 3 Pa in a 2.4 tesla magnetic field.

MEASUREMENT USING LIGHT ENERGY

PRINCIPLES OF LIGHT

What we commonly refer to as *light* is electromagnetic radiation in the visible range of wavelengths. Every substance with a temperature above absolute zero emits electromagnetic radiation, called *black body radiation*. This radiation is characterized by a frequency and wavelength that are related by the speed of light: frequency = speed of light ÷ wave length (c = speed of light = 3×10^8 m/sec or 186,400 miles/sec or 7.5 times around the earth's circumference in 1 second in a vacuum). High energies or temperatures are associated with high frequencies and short wavelengths, such as those of gamma rays and x-rays. As wavelength increases to the micron range, ultraviolet radiation proceeds to visible light (approximately 0.5 to 0.8 micron), and at larger wavelengths, infrared is then followed by microwaves and radio waves with wavelengths in the kilometer range.

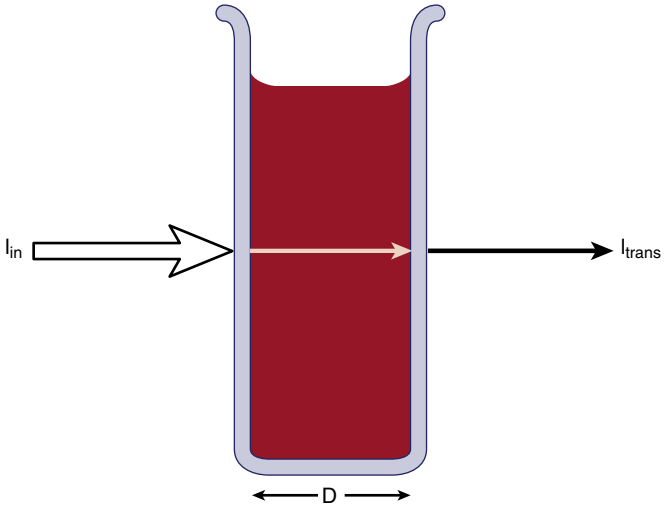
Electromagnetic waves and sound waves have some important differences. The particles in motion in sound waves are in the same direction as the propagation (longitudinal waves), whereas in electromagnetic waves, the electric and magnetic fields are perpendicular to the direction of propagation (transverse waves). Sound waves can propagate only through matter, whereas electromagnetic waves propagate through a vacuum without attenuation. The speed of light is approximately 1 million times faster than the speed of sound in sea-level air. If an observer is moving relative to a sound source, then the measurement of the speed of sound depends on the observer's own motion, but the speed of light is the same to any observer in any frame of reference. This last statement is the basic premise of Einstein's "Special Theory of Relativity." In the high-frequency range of the electromagnetic spectrum, two forms of ionizing radiation are found: x-rays and gamma rays. These high-frequency waves are capable of knocking electrons out of their orbits and can thereby cause cell injury and death or ontogenesis. Gamma rays are commonly emitted by decaying radioactive nuclei.

Visible light and infrared light demonstrate several properties common to all electromagnetic radiation. Light represents a form of energy that, when passing through matter, may be reflected, transmitted, or absorbed. Although light itself cannot be stored, it can be converted into some other form of energy such as electricity, chemical energy, and heat. In addition, light can be generated from other forms of energy, including heat (incandescent), electrical (gas discharge), and chemical (photoluminescent) energy.

LIGHT AS A MULTIFUNCTIONAL TOOL: THE BEER-LAMBERT LAW

When light passes through matter, it is transmitted, absorbed, or reflected. The relative absorption or reflection of light at different wavelengths is used in several monitoring devices to estimate the concentrations of dissolved substances, for example, carbon dioxide (CO_2) in respiratory gas and Hb in plasma. This type of measurement is called *spectrophotometry* and is based on the Beer-Lambert law of absorption, which states that if a known intensity of light illuminates a chamber of known dimensions, then the concentration of a dissolved substance can be determined if the incident and transmitted light intensity is measured:

$$I_t = I_i e^{-dC\alpha} \quad (4)$$



Solved for C,

$$C = (1/d\alpha) \ln [I_i/I_t] \quad (5)$$

where C is the concentration of the dissolved substance, d is the path length of the light a, and α is an absorption constant for the dissolved substance at the light wavelength used. I_i and I_t are the incident and transmitted light intensity, respectively. The unknown concentration C is thus inversely proportional to the light path length d and directly proportional to the log of the ratio of incident to transmitted light intensity (Fig. 44-25). Red and infrared light (wavelength 0.6 to 1.0 micron) are generally used because the constituents of interest to anesthesiologists (volatile anesthetics, CO_2, and Hb) absorb light within that range. Fortunately, both red and infrared light can penetrate soft tissues and may therefore be used to measure the concentrations of Hb species in vivo (see the section on "Processed Absorbance Monitors"). Small molecules absorb infrared light only if they have bonds and are asymmetric; in other words, their molecules have a dipole moment. Therefore nitrogen, oxygen, and helium cannot be measured by infrared light. Another limitation of infrared light is that ordinary glass absorbs it; therefore the measurement chambers for these devices must be made of sapphire or other infrared-permeable materials.

SIMPLE ABSORBANCE MONITORS (CAPNOMETER, ANESTHETIC ANALYZER)

Capnometers, capnographs, and anesthetic gas analyzers all use the Beer-Lambert law of absorption to analyze the constituents of the respiratory gas stream. A capnometer measures and displays only discrete values of partial

$I_{trans} = I_{in}e^{-(D \times C \times a_\lambda)}$

I_{trans} = intensity of light transmitted

I_{in} = intensity of incident light

D = distance light is transmitted through the liquid

C = concentration of solute (oxyhemoglobin)

a_λ = extinction coefficient of the solute (a constant)

Figure 44-25. Cuvette. Light entering the cuvette is reflected and absorbed. Measuring the amount of light entering and exiting the system can determine the concentration of substances absorbing and reflecting light.

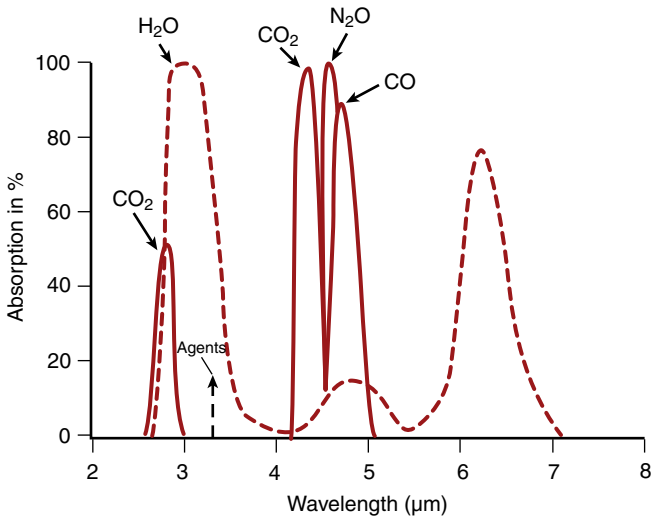


Figure 44-26. Absorption spectra. Absorption spectra of some gases and materials important to anesthesia. Note that the absorption is not constant over wavelengths. Therefore choosing the proper wavelength to measure is important. In addition, when multiple substances are present, measuring their concentrations is still possible, provided enough wavelengths are available. The solution becomes one of multiple equations with multiple unknowns. *(From Gravenstein JS, Paulus DA, Hayes TJ:* Capnography in clinical practice. *Boston, 1989, Butterworths.)*

pressure of CO_2 (P_{CO_2}), for example, the end-tidal value. A capnograph provides a continuous plot of P_{CO_2} in the airway versus time. The physical design of capnometers is divided into two categories: mainstream and sidestream. In mainstream capnometers, the light absorption chamber is placed directly in the airway and the light source shines through the chamber, with CO_2 being directly measured during inspiration and expiration. Advantages of this technique are an extremely fast response time and no problems with clogging of the sampling tubes, which is a disadvantage of sidestream capnometers. Disadvantages of the mainstream geometry include the necessity of having a potentially heavy, expensive infrared measurement device placed directly in the airway at the endotracheal tube and the unavailability of devices that can measure anesthetic agents, as well as CO_2. The most commonly used devices in the surgical unit are sidestream capnometers. A thin sampling tube is attached to the airway near the endotracheal tube, and samples are aspirated at 200 to 400 mL/min into the measurement chamber, which is located in the monitor itself. The advantages of this method are the opposite of the disadvantages of the mainstream capnometers; that is, the sampling tube is lightweight, and the device can be used to measure both CO_2 and anesthetic agents. Disadvantages of sidestream relate mostly to the delayed response time and potential clogging of the aspiration tubing.

Volatile anesthetic analyzers and capnographs function by the same physical principles but use different wavelengths of light (Fig. 44-26). The light absorbances of a mixture of gases can interfere with each other; consequently, compensations are built into current devices.

PROCESSED ABSORBANCE MONITORS (PULSE OXIMETER)

Oximeters are devices that use light absorbance measurements to determine the concentration of various species of Hb. One of the first in vivo oximeters was a noninvasive monitor used in aviation research during World War II. This device transilluminated tissue (the earlobe) with light of two wavelengths. One wavelength was sensitive to changes in oxyhemoglobin (HbO_2), and the other was not. In effect, the earlobe acted as a test tube containing the suspended Hb. For a review of the development of pulse oximetry, the reader is referred to the excellent article by Severinghaus and Astrup.[10]

One issue is the form of Hb being measured. Adult blood usually contains four species of Hb: HbO_2, reduced Hb, methemoglobin (metHb), and carboxyhemoglobin (COHb). The latter two are abnormal Hb, called *dyshemoglobins* and are normally present in only small amounts. Each of these Hb species has a different light absorption profile. Figure 44-27 illustrates the different absorption constants for each Hb species over a range of light from red to infrared. Fractional Hb saturation ($O_2Hb\%$) is defined as the *ratio of HbO_2 to total Hb*:

$$O_2Hb\% = HbO_2/(HbO_2 + Hb + metHb + COHb)$$

Measuring this quantity in the presence of metHb and COHb requires at least four wavelengths of light, which

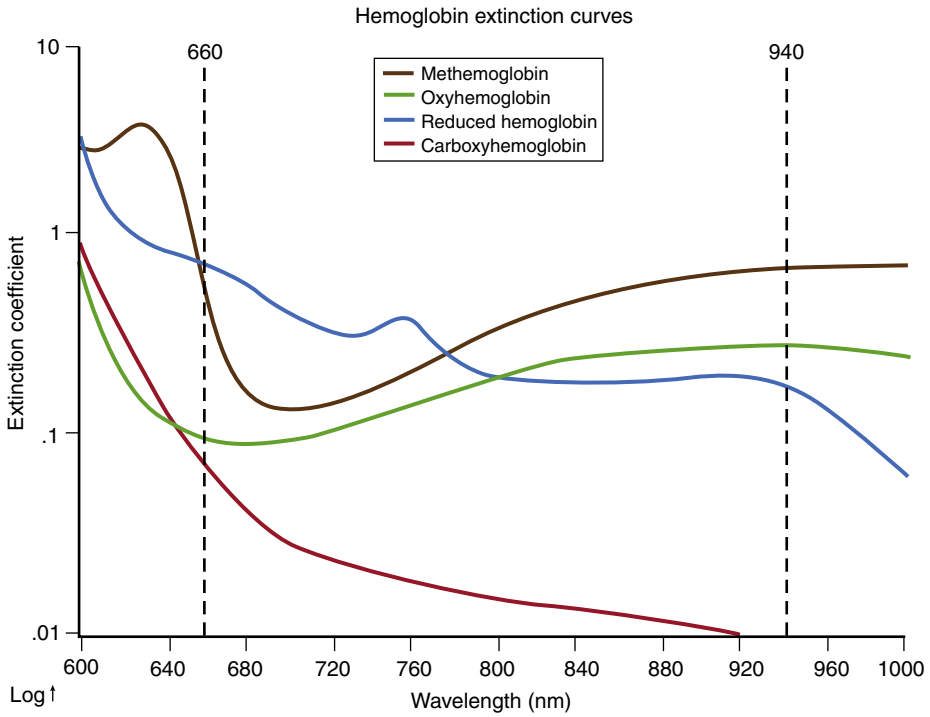

Figure 44-27. Hemoglobin extinction curves. Pulse oximetry uses the wavelengths of 660 nm and 940 nm because these wavelengths are available in solid-state emitters (not all wavelengths are able to be emitted from diodes). Unfortunately, carboxyhemoglobin (HbCO) and oxyhemoglobin (HbO_2) absorb equally at 660 nm. Therefore HbCO and HbO_2 both read as arterial oxygen saturation (Sa_{O_2}) to a conventional pulse oximeter. In addition, methemoglobin (Hbmet) and reduced hemoglobin (Hb) share absorption at 660 nm and interfere with correct Sa_{O_2} measurement. *(Courtesy Susan Manson, Boulder, Colorado, 1986, Biox/Ohmeda.)*

yield four simultaneous Beer-Lambert equations to solve for the four Hb species. Because metHb and COHb do not contribute to oxygen transport, functional saturation is defined as the ratio of HbO_2 to HbO_2 plus reduced Hb:

$$SaO_2 = HbO_2 / (HbO_2 + Hb).$$

Although functional saturation depends explicitly on only HbO_2 and Hb, four light wavelengths are still required to measure it in the presence of significant concentrations of COHb and metHb.[11] If the concentrations of both metHb and COHb are zero, then $O_2Hb\%$ and Sa_{O_2} become identical.

The pulse oximeter performs substantial signal processing of optically transduced physiologic data. Although the physical principle governing pulse oximetry is straightforward, application of this principle to produce a clinically useful device involves significant engineering problems. The remainder of this section describes the physical and physiologic problems of pulse oximeter design and the engineering solutions to these problems. The discussion is divided into basic design and management of signal artifacts.

BASIC DESIGN OF PULSE OXIMETERS

Noninvasive in vivo oximeters measure red and infrared light transmitted through and reflected by a tissue bed. Accurate estimation of Sa_{O_2} by this method entails several technical problems. First, many light absorbers other than arterial Hb are in the transmitted light path (e.g., skin, soft tissue, venous and capillary blood). The pulse oximeter accounts for the effects of absorption of light by tissue and venous blood by assuming that only arterial blood pulsates. Figure 44-28 schematically illustrates the series of absorbers in a typical sample of living

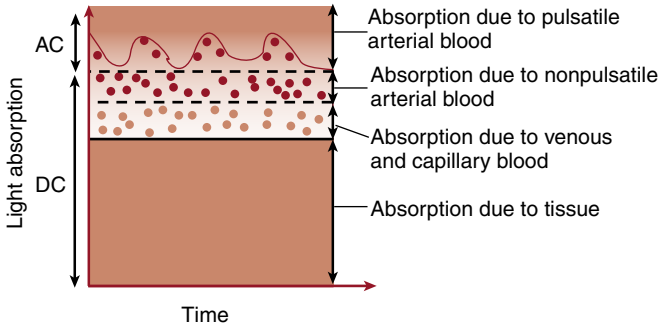

Figure 44-28. Pulse oximetry signals. A primary difficulty with pulse oximetry is that the pulsatile signal is small, compared with the total absorbance of the ear or finger being examined. Pulsatile flow is needed to determine the Sa_{O_2}. *(Modified from Ohmeda Pulse Oximeter model 3700 Service Manual.)*

tissue. At the top of the figure is the AC component, which represents absorption of light by the pulsating arterial blood. The DC (baseline) component represents absorption of light by the tissue bed, including venous, capillary, and nonpulsatile arterial blood. Pulsatile expansion of the arteriolar bed increases the light path length (see equations 4 and 5), thereby increasing absorbency. Conventional pulse oximeters (including all commercial pulse oximeters until 2005) use only two wavelengths of light, typically 660 nm (red light) and 940 nm (near-infrared light). The pulse oximeter first determines the fluctuating or AC component of absorbance at each wavelength and then divides this value by the nonfluctuating or DC component to obtain the pulse-added absorbance, which is independent of the incident light intensity. The oximeter then calculates

the ratio (R) of the two pulse-added absorbances (one for each wavelength)[11]:

$$R = (AC\ 660 / DC\ 660) / (AC\ 940/DC\ 940) \quad (6)$$

Finally, the value of R (often called the *ratio of ratios*) is related to the displayed estimate of saturation of peripheral oxygen (SpO_2) by a "look-up table" programmed into the oximeter's software. The tables used in all commercial pulse oximeters are based on experimental studies in healthy human volunteers. Although each manufacturer's exact calibration curve is proprietary, these curves are similar. For instance, when the ratio of red-to-infrared pulse-added absorbance is 1.0, the displayed SpO_2 is approximately 85%. This fact has clinical implications, which are discussed in the next section.

SIGNAL ARTIFACT MANAGEMENT

One of the most difficult engineering problems in pulse oximetry is the identification of the fluctuating absorbance pattern of arterial blood in a sea of electromagnetic and other artifacts. Artifacts have four major sources: ambient light, low perfusion (weak pulse, low AC-to-DC signal ratio), venous blood pulsations (caused by patient motion, among other things) and additional light absorbers in the blood (e.g., dyshemoglobins, intravenous dyes). All these sources of artifacts produce a low signal-to-noise ratio, resulting in either erroneous SpO_2 values or no value at all.

The photodiodes used in the sensor to detect light cannot differentiate one wavelength of light from another. Therefore the detector does not know whether the light received originates from the red (660 nm) light-emitting diode (LED), the infrared (940 nm) LED, or the room lights. This problem is solved in most pulse oximeters by alternating the red and infrared LED sources. The red LED is turned on first, and the photodiode detector produces a current resulting from the red LED plus the room lights. Next, the red LED is turned off and the infrared LED is turned on. The photodiode signal then represents the infrared LED plus the room lights. Finally, both LEDs are turned off, and the photodiode generates a signal from the room lights alone. This sequence is repeated hundreds of times per second. In this way, the oximeter attempts to eliminate light interference even in a quickly changing background of room light.[10] Some sources of fluctuating light can cause problems, despite this clever design. Simply covering the sensor with an opaque shield can minimize artifacts from ambient light.

Another engineering problem is that of a low AC-to-DC signal ratio or low perfusion. When a small pulsatile absorbance signal is detected, the conventional pulse oximeter amplifies the signal and estimates the saturation from the ratio of the amplified absorbances. In this way, the pulse oximeter can estimate saturation values of SpO_2 for a wide range of patients who generate different amplitudes for pulsatile absorbance. Unfortunately, as with a radio receiver, when a weak signal is amplified, the background noise, or static, is also amplified. At the highest amplifications (which can be up to 1 million times), some pulse oximeters may analyze this noise signal and generate an SpO_2 value from it. Because the noise is usually equal in the red and infrared signals, the ratio of the two is often near unity (1.0), which yields a displayed saturation of approximately 85%. This problem could be demonstrated in early pulse oximeters by placing a piece of paper in the sensor between the photodiode and the LED. Some early models amplified the background noise while searching for a pulse until they eventually displayed a pulse and saturation value for the piece of paper. To prevent this type of artifact, many manufacturers have now incorporated minimum values for the signal-to-noise ratio, below which the device displays no value for SpO_2. Some oximeters also display a low–signal strength error message; in addition, many display a plethysmographic wave for a visual identification of noise.

Patient motion, causing venous pulsations with a high AC-to-DC signal ratio, may be the most difficult artifact to eliminate. Engineers have tried several approaches to this problem, beginning with simply increasing the signal averaging time. If the device averages its measurements over a longer period, then the effect of an intermittent artifact is usually less. However, this longer averaging period also slows the response time to an acute change in Sao_2, and it may result in "frozen" SpO_2 values being displayed when the true saturation is rapidly changing. Most pulse oximeters now allow the user to select one of several time-averaging modes. In addition, some manufacturers use more sophisticated algorithms to identify and reject spurious signals.

One innovation aimed at reducing motion artifact is based on the premise that motion causes pulsations of venous blood within the tissue bed. Conventional pulse oximetry cannot distinguish venous pulsations from those of arterial blood; hence, large low-reading errors or loss of signal can result. In a new signal-processing algorithm developed by Masimo, Inc., the oximeter actually computes a venous *noise reference signal*, which is common to both light wavelengths. The noise reference is then subtracted from the total signal, and a *true* arterial signal is left. This is one of five "parallel engine" algorithms that Masimo SET (Signal Extraction Technology) simultaneously uses to find the most reliable SpO_2 value for the current signal conditions. Tests in human volunteers, as well as preliminary clinical studies, indicate that this new technology represents an improvement in pulse oximeter performance in low signal-to-noise ratio situations.[12,13]

More recently, the first multiwavelength pulse oximeter, the Rainbow Rad-57 Pulse CO-oximeter, has been introduced. This device uses eight light wavelengths rather than the usual two, making it capable of measuring both COHb and MetHb, in addition to the conventional SpO_2 value and pulse rate. The first human volunteer study of this instrument demonstrated that it can measure COHb with an uncertainty of ±2%, and MetHb with an uncertainty of ±0.5%.[14]

Over the past decade, other in vivo oximeters have been developed to measure light reflected by living tissue in an attempt to determine Hb saturation in specific organs. Using reflected rather than transmitted light adds complexity because the path lengths of the light through the tissue may be varied and tortuous, making calibration difficult. Nevertheless, a signal reflected from living tissue may produce useful information regarding the average

saturation of the Hb within that tissue. For example, a cerebral oximeter may be able to measure mean brain Hb saturation, which reflects the intracerebral balance among venous, arterial, and capillary blood, as well as the oxygenation of all three.

MEASUREMENT OF TEMPERATURE

PRINCIPLES OF TEMPERATURE

Moving matter contains energy. Even stationary objects are moving at the atomic level. This kinetic energy of molecules and atoms is described as temperature. When all molecular motion (translational, vibrational, and rotational) ceases, the substance is said to be at a temperature of absolute zero—the lowest possible temperature. This temperature is equivalent to –273° C and is defined as 0° Kelvin. This state provides a reference point for all temperature measurements, which in all thermodynamic calculations must be expressed in degrees Kelvin (see also Chapter 54).

Heat is a form of internal kinetic energy that can flow between two contacting bodies that are at different temperatures. The amount of heat required to raise the temperature of 1 g of a given substance by 1° C is called the *specific heat of that substance*. The *calorie*, a common heat unit, is the amount of heat required to raise the temperature of 1 g of water from 14.5° C to 15.5° C. One calorie is equivalent to 4.184 joules of energy. When we refer to calories in terms of the calories in the food that we eat or the calories that we expend while exercising, we are actually referring to kilocalories (thousands of calories and also called "kitchen calories"). Thus the total amount of heat energy in an object depends on its specific heat, its temperature, and its mass. For example, although a cup of 60° C coffee is much hotter than a 30° C swimming pool, the coffee contains significantly less total thermal energy than the pool. The same is true for potential energy stored as pressure potential or electrical potential. A small container at high pressure may have less potential energy than a larger container at lower pressure.

TEMPERATURE MONITORS (THERMOMETER, THERMISTOR, THERMOPILE, LIQUID CRYSTAL)

Three techniques are commonly used for measuring temperature: (1) those based on expansion of a material as its temperature increases, (2) those based on changes in electrical properties with temperature, and (3) those based on optical properties of a material. As heat is added to most substances (e.g., gases, liquids, solids), motion of the molecules increases, and the volume of the material increases at constant pressure. Depending on the material, this expansion can be directly calibrated to changes in temperature. Liquids are most commonly used, for example, mercury, because its effective range extends from its freezing point of –39° C to approximately 250° C. Mercury thermometers have two disadvantages. They require 2 to 3 minutes for complete thermal equilibration (mercury is a liquid metal with a high specific heat). In addition, they are enclosed in a glass tube, which may break and cause injuries. Thermometers based on the expansion of gas (Bourdon tube) or metal (bimetallic strip) are frequently used in thermostats because they also slowly respond to transient changes in temperature.

Electrical techniques for measuring temperature can be subdivided into three categories: resistance thermometers, thermistors, and thermocouples. Resistance thermometers operate on the principle that the electrical resistance of metals increases with temperature. These devices most frequently use a platinum wire as the temperature-sensitive resistor, a battery, and a galvanometer to measure current, which can be calibrated to temperature. The platinum wire is incorporated into a Wheatstone bridge circuit, which accurately measures very small changes in resistance (see Fig. 44-5).

When compared with a platinum thermometer, a thermistor is a semiconductor that displays the opposite behavior with regard to electrical resistance; that is, as the thermistor is heated, its resistance decreases. Thermistors, being solid-state devices, can be manufactured in extremely small sizes and therefore have a fast response to changes in temperature (i.e., little heat is needed to increase their temperature). Most of the temperature probes used in anesthesia, from the ones at the end of pulmonary artery catheters to esophageal probes, are thermistors. Physical problems with thermistors are few: cracked or broken wires lead to high resistance and incorrect temperature readings. More common are poor probe placement and a misinterpretation of the resulting value, for example, placing an esophageal probe in the oropharynx and measuring airway temperature rather than core temperature. Thermocouples are conductors that generate a voltage in response to a temperature gradient.

The optical properties of materials can be used to measure temperature in two ways: (1) a device known as a *thermopile* can measure the infrared *black-body emissions* of an object, and the emission is then converted to temperature; and (2) a liquid crystal matrix can be placed in direct contact with the desired zone, and an optical change in color can be observed. The most commonly encountered example of infrared temperature measurement involves the tympanic membrane temperature monitor used in recovery rooms, pediatrics, and hospital wards. The infrared detector produces an electrical signal that is proportional to the fourth power of the difference in absolute temperatures of the objects. The following formula describes this phenomenon:

$$Q_{1,2} = K\,(T_1^4 - T_2^4) \qquad (7)$$

where $Q_{1,2}$ is net heat transfer (W/cm^2), K is the Stefan-Boltzmann constant, and T_1 and T_2 are the absolute temperatures of the two objects (degrees K). In theory, this method of measuring the core temperature should be accurate. However, in practice, improper placement and lack of calibration, but not ear canal cerumen, contribute to real-world errors.[15] Additionally, the probe is rather large for intraoperative use.

Liquid crystal measures of temperature (found in "mood rings") are often used for skin temperature monitoring. Just as the molecules in a liquid crystal watch display change their optical properties with a small electric

current and become polarized and dark, the molecules in a liquid crystal temperature device change their optical properties with temperature, resulting in a rainbow of colors. The crystal matrix is sensitive to pressure and temperature. (By touching an LCD display panel, the visual rainbow of changing colors can be seen.) The reported clinical accuracy of liquid crystal devices varies.[16]

MEASUREMENT OF FLOW

PRINCIPLES OF FLOW

Although conceptually one of the easier measurements to understand as volume or mass movement over time, flow is actually not easy to measure. We must clearly distinguish between fluid flow and fluid velocity, which are often confused. Flow (Q) refers to the volume of fluid passing a particular surface area per unit of time; its SI units are cubic meters per second (m^3/sec); in medicine, however, flow is more commonly measured in milliliters per second (mL/sec) or liters per minute (L/min). Fluid velocity (U) is simply the speed of the fluid at a particular point in space, measured in meters per second (m/sec). By analogy, imagine a multilane freeway: the speed (velocity) of individual cars may vary depending on the lane; the flow is the number of cars passing a point per minute.

MASS AND VOLUME FLOWMETERS (UROMETER, VOLUMETER)

Flow can be directly measured by diverting the flow into a measuring chamber. We can measure the mass or volume of fluid flowing per unit time by catching the fluid in a container and either weighing it or measuring its volume. The common urometer for measuring urine volume is an example. The volumeter used in North American Drager anesthesia machines also measures aliquots of volume integrated over time to measure tidal and minute volumes (Fig. 44-29).[17]

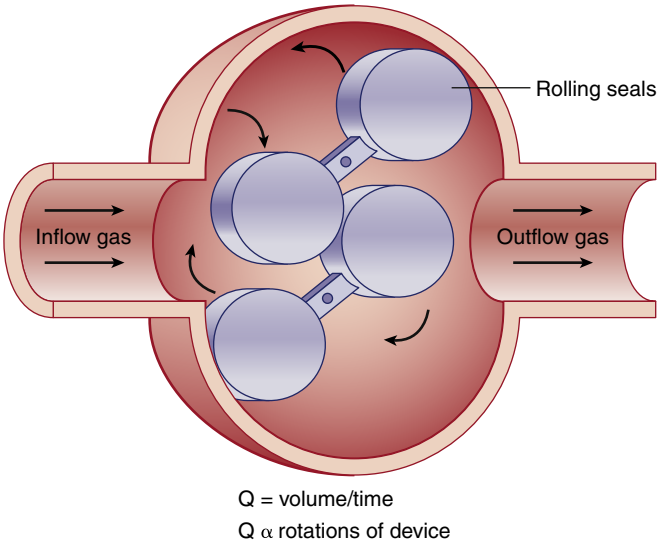

Figure 44-29. Volumeter. Flow can be described as volume over time. This design of flowmeter allows gas to pass in only little aliquots, each of which turns a counter to measure the amount flowing past. When divided by time, this results in a flow measurement. *(Modified from Ehrenwerth J, Eisenkraft J:* Anesthesia equipment: principles and applications. *St. Louis, 1993, Mosby.)*

DILUTIONAL FLOWMETERS (THERMODILUTION, FICK PRINCIPLE)

Dilutional techniques can also measure both volume and mass flow. If some measurable indicator (e.g., bolus of dye, thermal pulse, oxygen consumption, CO_2 production) is injected into a flow and its concentration is measured as a function of time at a point downstream, then the volume flow (Q) can be calculated by integration. The most common medical application is determining cardiac output by the pulmonary artery thermodilution method (see Appendix 44-6). Errors associated with these methods involve using the wrong injectate volume (too small a volume resulting in an overestimate of flow) or an error in temperature measurement (see "Measurement of Temperature" earlier in this chapter).

Continuous thermodilution cardiac output using an electric heating coil to warm the pulmonary artery blood removes errors associated with fluid injectate techniques but introduces the need to average the smaller signal over a longer time interval. Additionally, there is an upper limit to warming the blood without cellular damage; therefore signal quality is reduced in patients who are febrile. Measuring the electric current required to maintain a constant temperature at the catheter tip is a slightly different approach. Variable current is the principle behind a constant temperature hot wire anemometer (used to measure gas flows in wind tunnels and in some anesthesia machines) applied to cardiac output.

The rate of CO_2 production or oxygen consumption can be used to measure cardiac output by modifications of the Fick formula (see Appendix 44-6). When using these variables, a change in metabolic rate can lead to errors in cardiac output measurement.

VELOCITY AND PRESSURE FLOWMETERS (VENTURI, PITOT)

Flowing fluids in tubes generate both velocity and pressure, which can be used to measure the flow indirectly. As described earlier, pressure in fluids can be thought of as a form of potential energy. Kinetic energy in fluids is expressed in terms of flow, the bulk movement of fluid with a given direction and magnitude. The potential energy of pressure can be converted into the kinetic energy of flow; for example, the hydrostatic pressure generated by gravity acting on a vertical column of liquid can be transformed into flow by opening a valve at the bottom of the column. Pressure and flow can also change independently. With the human circulatory system used as an example, a healthy young trauma patient in hypovolemic shock can have relatively normal blood pressure but low blood flow with high SVR. On the other hand, a patient with sepsis can have very low blood pressure accompanied by high blood flow and low SVR (high-output septic

shock). The total mechanical energy of a moving fluid is the sum of the kinetic (flow) energy and the potential (pressure) energy (see Table 44-2).

A pressure gradient (changing pressure in a particular spatial direction) exerts a force on the fluid, and the fluid tends to accelerate in the direction of decreasing pressure. Pressure gradient is only one of the forces that commonly act on fluids; other forces include gravity (see earlier discussion in "Pressure Measurement") and viscous force or friction. If these other forces are negligible and the fluid is incompressible (i.e., a liquid with constant density), then the equation of motion (F = ma) can be integrated to yield:

$$P + {}^{1}/_{2}\rho U^2 = P_0 \qquad (8)$$

where P is pressure, ϱ is fluid density, U is the magnitude of the fluid velocity, and P_0 is a constant called the *stagnation pressure* (see Appendix 44-5). This form of the Bernoulli theorem tells us that pressure decreases as velocity increases in a frictionless flow, and vice versa. This principle dispels the common misconception that pressure always decreases in the direction of flow. For example, in the flow inside a tube (e.g., pipe, large vein) of gradually increasing diameter, fluid velocity (U) decreases in the downstream direction as the diameter and cross-sectional area of the tube increase. As U decreases, equation 8 tells us that P increases in the direction of flow. This example again shows the relationship of potential and kinetic energy in fluids: as the kinetic energy of this tube flow decreases (U^2 falls) in the flow direction, the potential energy increases (P rises) by an equal amount. The total energy remains constant because we have assumed no friction.

Measuring the average velocity of the fluid across the tube can determine flow. In laminar tube flow (Figure 44-30, *A*), the velocity profile has a parabolic shape, with the highest velocity at the centerline and the fluid at the walls being stationary. In turbulent tube flow, the velocity profile is flattened (Figure 44-30, *B*).

The Bernoulli theorem applies to a specific subset of frictionless flows, as described earlier. Many flows important to anesthesiologists do not follow the Bernoulli theorem. Most commonly, the flow that we desire to measure is not laminar but turbulent. The transition from laminar to turbulent flow depends on the type of fluid, the speed of the flow, and the shape of the flow. The fluid factors are combined in a dimensionless ratio called the *Reynolds number* (Re):

$$Re = \rho UL/\mu \qquad (9)$$

where ρ is the density of the fluid, U is the mean flow velocity, L is a characteristic dimension (length) of the flow, and μ is the viscosity of the fluid. For a given flow geometry (e.g., flow through a tube of circular cross section), transition from laminar to turbulent flow will occur at a critical value of Re. In straight, smooth, circular tubes, transition from laminar to turbulent flow occurs at Re of approximately 2100 (see Appendix 44-5).

A Venturi tube is circular tube with a gradual contraction and expansion in diameter, in contrast to the sudden contraction-expansion of an orifice flowmeter (Fig. 44-31). Because the contraction is smooth and gradual,

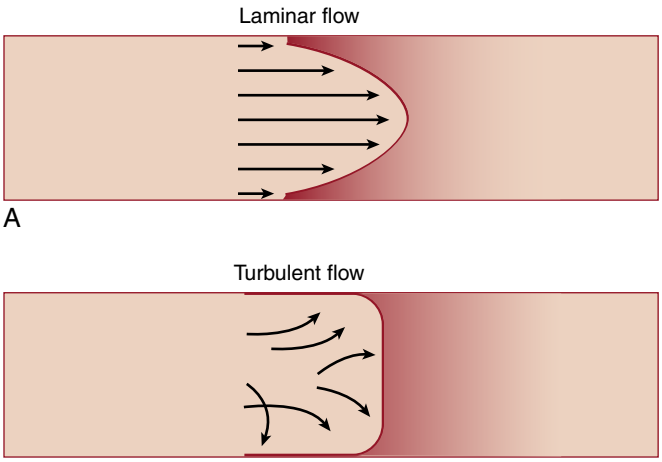

Figure 44-30. Laminar and turbulent flow. **A,** In a smooth-walled tube at low flow rates (i.e., small pressure gradients), the flow rate is laminar; that is, flow moves smoothly in concentric circles with the centermost area having the greatest flow velocity and the area nearest the wall of the tube being virtually stationary. **B,** As flow rate and pressure gradient increase, the flow transitions from laminar to turbulent. Instead of a neatly ordered flow, the velocities are more randomly distributed, energy is dissipated as heat, and the energy needed for a given flow rate increases. Many factors govern this transition, including the size of the tube, the viscosity of the fluid, and the flow rate and pressure gradient. These factors are combined in determining the Reynolds number (see Appendix 44-5).

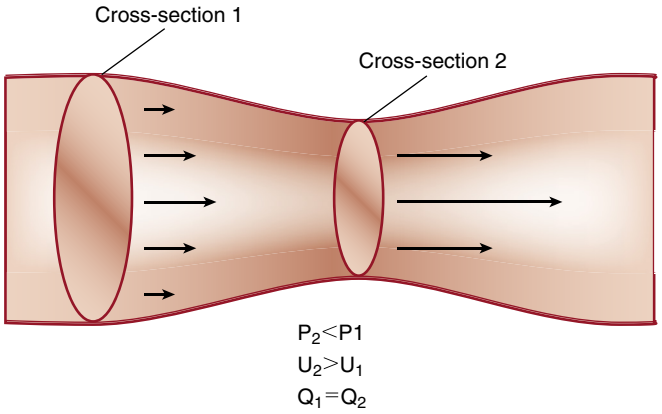

Figure 44-31. Venturi tube. By measuring the pressure difference between two points in a laminar flow, the average flow velocity can be determined because the mass flow and total energy (minus frictional losses) must be the same (see Appendix 44-5).

the Bernoulli theorem (equation 7) applies to this geometry. For conservation of mass and energy to apply, as we restrict the flow by narrowing the tube, the speed *increases*; therefore the pressure on the walls *decreases* to keep the total energy (the stagnation pressure of the Bernoulli theorem) constant. The total mass flow on both sides of the contraction must be equal (we have not created or lost any matter). If we measure the pressure difference between the widest and the narrowest parts of the Venturi tube, then we can solve the Bernoulli theorem for velocity (see Appendix 44-5). The Venturi tube derives fluid velocity (U) from the pressure difference, not volume flow (Q).

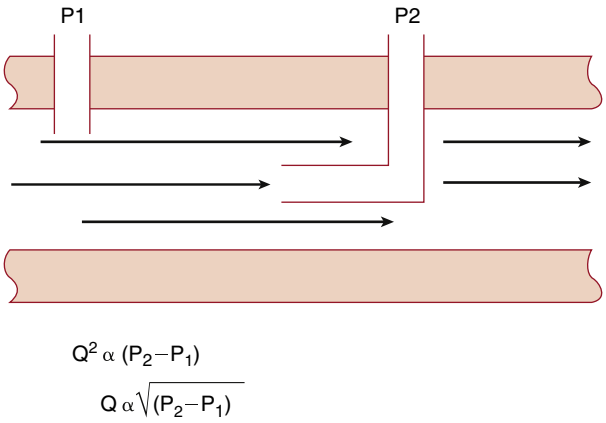

Figure 44-32. Pitot tube. As flows increase, wall pressure decreases as a result of the Bernoulli principle. The Pitot tube measures the difference in pressure from the middle of the flow to the wall and converts this to a flow measurement (see Appendix 44-5). *(Modified from Ehrenwerth J, Eisenkraft J:* Anesthesia equipment: principles and applications. *St. Louis, 1993, Mosby.)*

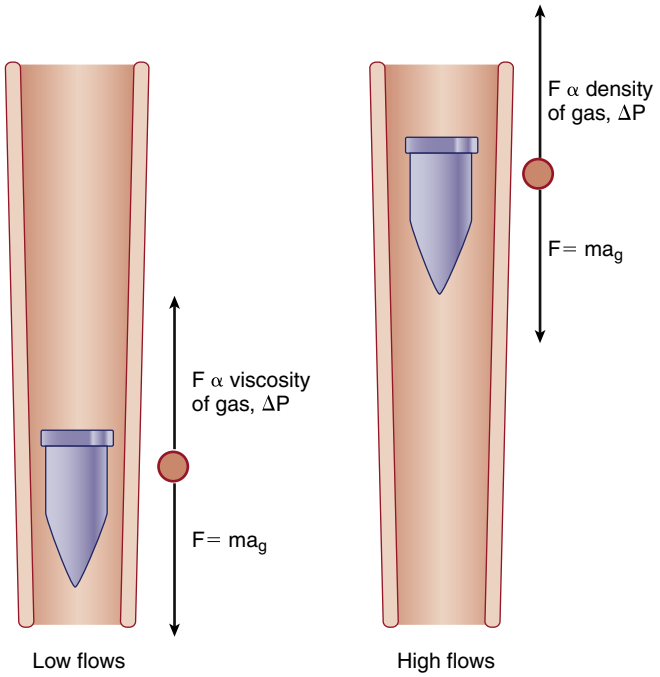

Figure 44-33. Thorpe tube flowmeter. At low flows, viscosity of gas predominates, and the flows balance when the gravitational attraction equals the pressure gradient across the equivalent orifice. At higher flows, density takes over, and the balance is the same, except for the formula determining pressure (acts like an orifice) (see Appendix 44-5).

The Venturi tube is used in many industrial applications and is also used on some aircraft to measure speed.

To ensure a measureable pressure gradient, some resistance must be present in the fluid path. The lower the rate of flow, the greater the resistance must be to generate the same pressure gradient. Therefore in respiratory applications, pediatric flowmeters have too much resistance (as a result of lower flows) to use in adults, and adult flowmeters do not generate enough resistance to give an adequate signal (pressure change) in pediatric patients. A variable resistance flowmeter has been devised (Ohmeda 7900/Aisys) in which the orifice is actually a flap that moves as the flow increases. No simple equation or relationship exists between the pressure above and below the restriction; therefore this flowmeter must be empirically calibrated and the calibration curve for each sensor electronically stored.

A Pitot tube is a cylindric tube whose open end is pointed directly into the flow, that is, *upstream* (Fig. 44-32). The pressure measured in the Pitot tube approximates the stagnation pressure given earlier in equation 7. If we independently measure the static pressure (p) (the p_1 side port in Fig. 44-32) at the same location and if we know the fluid density (ϱ), we can then easily solve equation 7 for the fluid velocity (U). Note, again, that the Pitot tube derives velocity (U), not volume flow (Q). The Pitot tube is simple and reliable and is used on most aircraft to measure speed. In anesthesia, the Pitot tube is used in Datex Ultima monitors. To measure gas flow in two directions, the Datex monitor incorporates two Pitot tubes, one facing in each direction. Additionally, the monitor samples gas composition to correct for the density and viscosity of the gas mixture.

BALANCE-OF-PRESSURE FLOWMETERS (THORPE TUBE, BOURDON TUBE)

If flow in a tube passes through a sudden restriction such as an orifice, then the volume flow (Q) is proportional to the area of the orifice and the square root of the pressure drop through the orifice. (The Bernoulli theorem does not apply to this flow geometry.) This is the principle of all orifice flowmeters, including the rotameter of an anesthesia machine (see Appendix 44-5).

The most common flowmeter used in anesthesia is the floating bobbin rotameter on the anesthesia machine (Thorpe tube, Fig. 44-33). This variable-orifice flowmeter uses a balance of forces to determine pressure change and to measure flow. When the flowmeter valve is opened, the flow of gases through the annular orifice between the bobbin and the tapered glass tube provides a force to raise the bobbin. As the bobbin rises, the area of the annular gap between the bobbin and the tube increases as a result of the taper of the tube. As the area of this gap (orifice) increases, the pressure change across the bobbin decreases; the pressure change across an orifice is inversely proportional to the square of the orifice area. The bobbin ceases its upward motion at an equilibrium point where the upward pressure force balances the downward force of gravity (weight of the bobbin). Thus the height of the bobbin in the tube is directly related to the gas flow. Although this flowmeter is simple in principle, its application becomes more complex when the flow in the tube changes from laminar to turbulent as velocity and diameter increase. (For mathematical derivations, see Appendix 44-5.)

Another flowmeter (Bourdon tube, Fig. 44-34) keeps the orifice constant and allows the pressure to vary. As flow (Q) increases, the gradient of P_1 to P_2 increases and causes the flattened metal tube to uncoil and move the pointer.

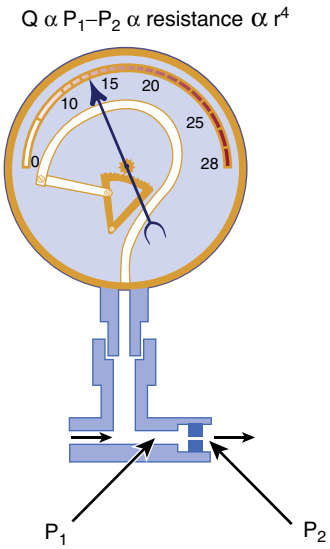

Figure 44-34. Bourdon tube flowmeter. Unlike the Thorpe tube, which has a constant pressure but a variable orifice, the Bourdon tube has a constant orifice but a variable pressure. The tube uncoils under the high backpressure. This drawback makes it unsuitable for use in low-pressure respiratory systems. However, it receives much use in portable oxygen tanks. Of note, if the orifice is increased in radius, then the flowmeter will under-read the actual flow. If the orifice is dirty (i.e., decreased radius), then the flow will be overestimated. *(From Mushin WW, Jones PL:* Physics for the anaesthetist*, ed 4. Oxford, 1987, Blackwell.)*

KINETIC ENERGY FLOWMETERS (WRIGHT SPIROMETER)

Vanes or propellers placed in a confined flow turn at a rate proportional to the volume flow if there is no friction in the propeller bearings. Various vane spirometers, such as the Wright spirometer, work by this principle (Fig. 44-35). These devices tend to be less accurate at both very high and very low flow rates because of frictional forces.

SUMMARY OF FLOW MEASUREMENT

Every method of measuring flow has its particular limitations and uncertainties. Because gases are not always pure with a known, constant density, flowmeters based on the Bernoulli theorem (equation 7) are subject to errors. Furthermore, any device inserted into a fluid flow can disturb the flow by its presence. For example, a rotating vane spirometer may reduce the gas flow at high flow rates because of internal friction. Several methods of flow or fluid velocity measurement are dependent on a pressure measurement (Pitot tube, Venturi tube, orifice

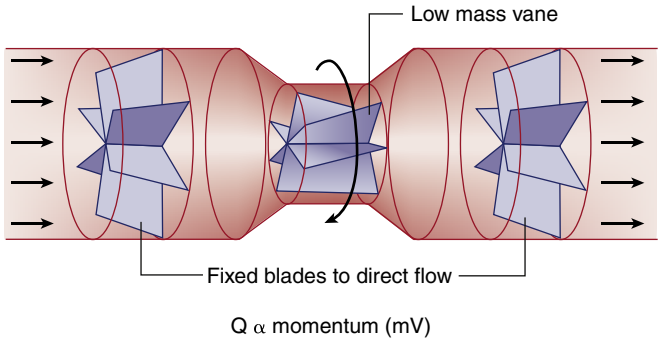

Figure 44-35. Vane spirometer. Moving gases contain kinetic energy, which can be sampled by a rotating "windmill" in the gas stream. *(Modified from Ehrenwerth J, Eisenkraft J:* Anesthesia equipment: principles and applications*. St. Louis, 1993, Mosby.)*

flowmeter); hence, the flow measurement is no more accurate than the pressure measurement.

In conclusion, new monitors are being developed almost continuously, but new physical principles are revealed only rarely. The science of physics is a constant effort to understand, simplify, and predict the behavior of our universe in quantitative terms. The terms and principles outlined in this chapter are referred to multiple times in subsequent chapters.

APPENDIX 44-1 *Distance Versus Time Under Constant Acceleration: Equivalence of Potential and Kinetic Energy*

Velocity (v) is the rate at which distance is changing; that is, it is the time derivative of distance:

$$\mathbf{v} = d\mathbf{x}/dt \quad (1)$$

The variable **v** is written in boldface type to indicate that it is a vector: it has both magnitude and direction. Distance **x** is a vector pointing from the origin to the present location of the particle or object; it is called the *position vector*. Time (t) is a scalar; it has magnitude but no direction and is therefore written in plain type.

Acceleration (**a**) is the time rate of change of velocity. Thus it is the time derivative of the velocity vector or the second derivative of distance with respect to time.

$$\mathbf{a} = d\mathbf{v}/dt = (d/dt)(d\mathbf{x}/dt) = d^2\mathbf{x}/dt^2 \quad (2)$$

If an object starts with zero velocity (**v** = 0) at time zero (t = 0) and then accelerates with constant acceleration (**a**), its velocity at time t will be simply **v** = at. To calculate the distance traveled by the object between time t = 0 and time t, we must divide the time interval 0 to t into a series of very small intervals, each of time length dt. The distance traveled during the interval dt is simply the velocity at that time multiplied by the time interval:

$$d\mathbf{x} = \mathbf{v}dt = (\mathbf{a}t)\,dt \quad (3)$$

In the second step, we have substituted the constant acceleration relationship **v** = **a**t from above. Now to compute the total distance traveled, we must sum the distance from all of the small dt time intervals that occur between 0 and t.

$$\mathbf{x} = \sum(\mathbf{a}t)dt \quad (4)$$

If we allow the length of the time interval dt to approach zero, the summation process becomes the integral with respect to time from time zero to time t.

$$x = \int v dt = \int (at)dt = \frac{1}{2}at^2 \quad (5)$$

Thus an object starting from rest at t = 0 and moving with constant acceleration (**a**) will move a distance $^1/_2$ **a**t^2 in time t. If this is a falling object (in a vacuum, where there is no air resistance), then **a** = g = 9.8 m/sec^2, and the distance formula becomes:

$$\mathbf{x} = \frac{1}{2}gt^2 = (4.9)\,t^2 \quad (6)$$

In the first second, the object falls 4.9 m; at the end of 2 seconds, it has fallen 19.6 m; after 3 seconds, 44.1 m; and so on.

The kinetic energy (KE) of a moving object is:

$$KE = \frac{1}{2}mv^2 \quad (7)$$

where m is the mass of the object and v is the magnitude of its velocity (also called *speed*). Note that v used in this sense is in plain type, not boldface. Consider, again, the falling object that started at position x = 0 at time t = 0 and falls a distance h:

$$h = \frac{1}{2}gt^2, \text{ or}$$

$$t = \sqrt{(2h/g)} \quad (8)$$

Because velocity v = at = gt, we have by substitution from equation 8

$$v = gt = g\sqrt{(2h/g)} = \sqrt{(2gh)} \quad (9)$$

The kinetic energy is given by

$$KE = \frac{1}{2}mv^2 = \frac{1}{2}m(2gh) = mgh \quad (10)$$

Now, let us consider the work required to lift the fallen object back to its original height of h. Recall that work is defined as the force exerted times the distance over which the force acts: W = Fd. The force of gravity acting on our object is F_g = mg, so the work required to lift it the distance (h) back to x = 0 is

$$W = Fd = (mg)d = mgh \quad (11)$$

Thus the work required to restore the object equals the kinetic energy possessed by the object at the bottom of its fall, KE = W = mgh. When we lift the object from x = h back to x = 0, we have increased its potential energy (PE) by the amount mgh. This PE can be converted to kinetic energy by allowing the object to fall the distance h. This type of PE is called *gravitational potential* and has a value that clearly depends on where we locate the origin of our coordinates, x = 0. However, it is the change in PE, not its absolute value, that the PE and kinetic energy balances:

$$\Delta KE = -\Delta PE \quad (12)$$

The change in kinetic energy is equal to and of opposite sign to the change in potential energy.

APPENDIX 44-2 *Physics of Hydrostatic Pressure*

A liquid manometer is a simple and reliable means of monitoring pressures that do not rapidly change. It simply uses the weight of a measured vertical column of liquid to balance the pressure exerted against the bottom of the column. We have defined weight as the force exerted by gravity on a mass (m): F_g = mg. To determine the weight of a column of liquid of known dimensions (in a manometer, see Fig. 44-4), we must first know the density (mass per unit volume) of the liquid. Density has dimensions of m/L^3, and the SI units are kilograms per cubic meter (kg/m^3). Because liquids are almost incompressible, their density is little influenced by pressure (but affected by temperature). The density of water at room temperature is 997.8 kg/m^3 or 1.0 g/cm^3.

The pressure (p) exerted by the bottom of the vertical column of liquid in a manometer (see Fig. 44-4) is determined as follows: if the cross-sectional area of the liquid cylinder is A and the height of the cylinder is z, then its volume is V = Az. If the liquid has a density of ρ, the mass of the column is:

$$m = \rho V = \rho Az \quad (1)$$

and its weight is

$$W = mg = \rho Azg \quad (2)$$

The liquid column exerts a force equal to its weight on its base, whose surface area is A, thus creating the following pressure on the surface:

$$p = \text{force/area} = \rho Azg/A = \rho gz \quad (3)$$

The pressure exerted by the manometer is therefore independent of its cross-sectional area (A); it depends only on the density of the working fluid and the vertical height of the column. If we know the liquid density, then the measurement of the column height (z) allows us to calculate the pressure (p). For example, if the working fluid is mercury (e.g., sphygmomanometers), then the density is 13,680 kg/m^3 (13.68 g/cm^3 or 13.68 times the density of water). The relationship of pressure to height of the column is then:

$$\begin{aligned} p = \rho gz &= (13{,}600\ \text{kg/m}^3)(9.8\ \text{N/kg})\,(z) \\ p[\text{N/m}^2] &= 133{,}300(z) \end{aligned} \quad (4)$$

The unit of pressure newton/meter^2 (N/m^2) is called the *pascal* (Pa). Because a Pa is a small unit of pressure, we usually use kilopascals (kPa or 10^3 Pa). If we express p in kPa and z in millimeters of mercury (rather than meters), equation 4 becomes:

$$p\ [\text{kPa}] = 0.1333\ (z)\ \ [\text{mm Hg}] \quad (5)$$

APPENDIX 44-3 *Wheatstone Bridge*

The Wheatstone bridge is a network of four resistors connected as shown in Figure 44-5, with a battery or DC voltage source (electromotive force) connected between A and C and a voltmeter (V) connected between B and D. The bridge is said to be "balanced" when the voltmeter reads zero potential difference between points B and D. From Ohm's law (V = IR), it is easy to show that balance occurs when $R_x = R_s \times (R_2/R_1)$. If R_s is an adjustable standard resistor and R_1 and R_2 are fixed known resistors, then the balanced bridge provides a very precise means of determining R_x, the unknown resistance. This principle has many applications in biomedical engineering, including strain gauge pressure transducer measurements. In this case, the transducer, itself, is the unknown resistance R_x.

APPENDIX 44-4 *Amplification Artifact of a Fluid Tube/Transducer Pressure Waveform*

The amplification artifact of a fluid tube/transducer pressure waveform can be calculated if a few properties of the system are known. The most relevant part of this solution is the response amplitude, which is plotted against the driving frequency (f) in Figure 44-16. This figure shows some important properties of fluid-coupled transducers and other harmonic oscillators. One of these properties is the existence of a resonant frequency, f_0, which is defined as follows:

$$f_0 = \frac{1}{2}\,\pi\,\sqrt{k/m} \quad (1)$$

Remember, m is the mass of the system and k is the elasticity or spring constant.

As we increase the amount of damping (i.e., friction; c is the friction constant), we observe a decrease in the peak amplitude at resonance, and the frequency at which the peak occurs decreases slightly. The damping coefficient (z) is defined as follows:

$$z = c/\sqrt{2km} \quad (2)$$

Although the arterial pressure waveform is not actually sinusoidal, Figure 44-15 shows the most important characteristics of the pressure transducer response. Any combination of catheter, tubing, and transducer can be characterized by two quantities: a resonant frequency (f_0) and a damping coefficient (z). Gardner measured these quantities for many transducer and tubing systems and found that most systems have resonant frequencies of 10 to 20 cycles/sec or hertz (Hz) and damping coefficients of 0.2 to 0.3. For clinical systems, the maximum amplification factor (the ratio of transducer output to input waveform amplitude) at resonance is near 2.5.

If the resonant frequency is 10 Hz (600 cycles/min), then one might conclude that amplification plays little role in the clinical range of pulse rates, which are 5 to 10 times smaller. However, the arterial pressure waveform is not a sine wave. It can be represented as a summation of sine waves (a Fourier series) with frequencies up to many times the pulse rate. It is these higher harmonic frequencies that are amplified most and that yield the spiked appearance of a poorly processed arterial waveform. Depending on the shape of the actual arterial pressure wave, this distortion can introduce a 20% to 40% "overshoot" error in systolic blood pressure readings. Even worse, this error is dependent on the pulse rate; therefore an error determined for a particular patient at the beginning of administration of an anesthetic may not remain constant.

From this discussion, we can easily predict how to optimize the performance of a pressure transducer system. First, the resonant frequency (f_0) should be as high as possible. Therefore the value for k in equation 1 should be large (i.e., the spring should be "stiff") and the value for m should be small (i.e., the cannula and pressure tubing should be as stiff and inelastic as possible). To minimize the mass of the moving fluid, the tubing should be short in length and small in diameter. Judging from plots of amplitude versus frequency/resonant frequency at different damping coefficients, the optimal damping coefficient would be 0.4 to 0.5. In addition, air bubbles should be carefully eliminated from the system because they add elasticity and friction, thereby lowering the resonant frequency. In a clinical system, the approximate f_0 and z of a transducer system can be determined if graphic output is available. If the high-pressure flush is turned on and then quickly off at a high chart speed (50 mm/sec), then the tracing oscillates through several cycles at a frequency near f_0. The damping coefficient can be found by determining the ratio of amplitudes of successive peaks on the tracing. This is a practical example of how fundamental principles of mechanics can be used to predict and optimize the performance of monitoring systems. These concepts of mechanics recur in later sections of this chapter.

APPENDIX 44-5 *Flowmeters, Bernoulli Principle, Laminar and Turbulent Flow*

The equations governing the motion of fluids are expressions of Newton's second law, F = ma. Forces associated with fluids fall into three major categories: (1) gravity, (2) pressure, and (3) friction. In the example using manometers, the gravitational force per unit volume of fluid is simply ϱg, acting in the vertical direction. Pressure forces are actually the result of differences in pressure from one point to another and are mathematically expressed as the negative of the pressure gradient. (A pressure gradient is a vector in the direction of the maximal rate of pressure increase, with a magnitude equal to the pressure derivative in that direction.) Friction is proportional to viscosity, the physical property of a fluid that relates shear stress to the rate of strain.

$$P_0 = p + \frac{1}{2}\rho U^2 + \rho g z \quad (1)$$

Equation 1 shows the relationship between velocity and pressure of a fluid in a flow that meets the conditions described. For flows in tubes, the manometer technique provides an easy method of measuring mean pressure. Therefore the simplest flowmeters apply a combination of these two principles to a tube of changing cross-sectional diameter. For example, the Venturi flowmeter shown in Figure 44-31 consists of a tube of varying cross-sectional area that has two ports for measurement of pressure. The Bernoulli theorem for points 1 and 2 in the figure becomes:

$$P_1 + \frac{1}{2}\rho U_1^2 = P_2 + \frac{1}{2}\rho U_2^2 \quad (2)$$

Here, the gravity terms have canceled out because the tube is horizontal, but these terms are usually negligible for gas flows in any direction.

The volume of the fluid flow (Q) (also called *flux*) at both locations must be the same because no fluid is entering or leaving through the tube walls. The dimensions and SI units for the volume of fluid flow are l^3/t and m^3/sec, respectively. This volume is determined at each cross section of the tube by multiplying the average velocity (U) by the cross-sectional area (A):

$$Q = U_1 A_1 = U_2 A_2 \quad (3)$$

Assuming that A_1, A_2, P_1, and P_2 are known, we now have two equations for the two unknowns U_1 and U_2. Solving these for the velocity U_1 produces

$$U_1 = \sqrt{\left[2(P_1 - P_2)/\rho\left(1 - A_1^2 - A_2^2\right)\right]} \quad (4)$$

To find the volume of the flow (Q), we merely multiply this result by A_1. Note that velocity is proportional to the square root of the pressure drop or that the pressure change varies as velocity squared. For a given U_1 or the magnitude of flow velocity, the pressure drop varies as the square of the ratio of the areas, or the fourth power of the ratio of the diameters. If we choose an A_2 greater than A_1, then equation 4 implies that P_2 is greater than P_1. In this case, the pressure increases in the direction of flow, a change that initially seems contrary to intuition.

The bobbin flowmeters (also called *variable-orifice flowmeters*) in anesthesia machines use a similar principle. These devices consist of a slightly tapered vertical tube and a bobbin or ball that fits inside the tube (see Fig. 44-33). The cross-sectional area of the ring-shaped gap between the bobbin and the tube wall is proportional to the height of the bobbin. Because changes in the cross-sectional area of flow are abrupt rather than gradual (see Fig. 44-31), the Bernoulli theorem does not accurately describe this type of flow. The flow above the bobbin (i.e., downstream) is highly turbulent, and turbulence is a condition that dissipates kinetic energy into heat. However, the introduction of the empirical constant C_d enables one to use the same formulation as in equation 4:

$$Q = C_d A\sqrt{[2(P_1 - P_2)]/\rho} \quad (5)$$

and

$$P_1 - P_2 = \left(\frac{1}{2}\rho Q^2\right) / \left(C_d^2 A^2\right) \quad (6)$$

where C_d is a dimensionless constant called the *discharge coefficient*. This constant varies with the shape of the orifice and with the value for another dimensionless parameter, the Reynolds number (Re). The Reynolds number, the overall ratio of inertial forces to viscous forces in a particular flow, is determined as follows:

$$Re = \rho UL/\mu \quad (7)$$

where U is mean flow velocity, L is a characteristic length for the flow (in our flowmeter, L is the diameter of the tube), and μ is the viscosity of the fluid. The dimension for viscosity is M/LT. The value for the Re is important to any fluid flow because it determines some of the most important characteristics of the flow. For example, the transition from laminar or "smooth" flow to turbulent flow is determined by the shape of the flow and the Re. Flow in a long, straight, smooth-walled tube becomes turbulent at an Re value of approximately 2100. On the other hand, flow through an abrupt orifice, such as that of the flowmeter in Figure 44-34, becomes turbulent at an Re value of less than 100.

Returning now to the function of the flowmeter, one can see that as gas flows upward through the tapered tube, the bobbin begins to rise. As the bobbin rises, the cross-sectional area of the orifice (A) increases because of the taper of the tube; therefore, the drop in pressure (P_1–P_2) decreases. The bobbin reaches an equilibrium position for a given volume of flow (Q) when the pressure lifting the bobbin is exactly equal to the weight of the bobbin. In this type of flowmeter, the pressure difference is fixed by the bobbin weight, and the area of the orifice varies with the volume of the flow, hence the name variable-orifice flowmeter. Equations 5 and 6 show that calibration of these flowmeters depends on both the density and the viscosity of the gas: density (ϱ) appears explicitly, and viscosity (μ) appears in the dependence of C_d on the Re. If we use the wrong gas in a particular flowmeter, then equations 5 and 6 and the viscosity and density of the new gas enable us to predict the change in calibration.

APPENDIX 44-6 *Measurement of Cardiac Output by the Thermal Dilution and Mass Flow Technique*

A commonly used method of measuring blood flow is dilutional calculation, that is, dye or thermal dilution. These methods are simply mass or energy balances that determine the volume of fluid that has been diluted by adding a volume of dye or a given thermal energy. If you have a bucket of water at room temperature (25° C) and you want to determine the volume of water in the bucket, then you could add a known volume of water at a known temperature. If 100 mL of water at 35° C is added to the bucket and the final temperature is 27° C, then the unknown volume can be calculated by balancing the heat energy associated with the dilutional process, assuming that no heat is lost to the environment. This dilutional process can be used to measure blood flow

by completing this same heat balance measured over time. Thermodilution cardiac output measurements can have significant error as a result of the many assumptions associated with the technique, such as rapid injection of the thermodilution injectate; accurate temperature and volume of the injected fluid; constant known heat capacity of blood, which, in reality, is a function of the hematocrit value; and little heat loss to the lung; among others.

Thermistor probes are most commonly used for clinical monitoring of patient temperature because they are inexpensive, small, and flexible. For these reasons, the thermistor probe is also used to measure cardiac output determined by the thermodilution technique. Computation of cardiac output performed in this manner is, in effect, a heat balance for the right side of the heart. (Heat balance is a method of accounting for all heat in a process or change involving the transfer of heat.) The technique consists of quick injection of a known volume of a sterile solution (usually 10 mL of 5% dextrose in water) into the right side of the heart while a sensor notes the temperature of the blood in the pulmonary artery. It is assumed that the cold injected solution thermally equilibrates with the blood as it perfuses the pulmonary artery but that the solution does not acquire heat from other tissues. The following equation is the solution of this heat balance:

$$CO = [\rho i Ci Vi\,(T_b - T_i)(60Cr)]/\left[(\rho_b C_b)\int_0^{\infty} T_b\,(t)\,dt\right] \quad (1)$$

where CO is cardiac output (L/min); ϱ_i and ϱ_b are the densities of the injectate and blood, respectively; C_i and C_b are the heat capacities of the injectate and blood, respectively; V_i is the volume of the injectate; T_b and T_i are the temperature of the blood and the injectate, respectively; Cr is a computational constant that corrects for the rising temperature of the injectate; and the integration is the area under the thermodilution curve. Because the injectate warms as it is injected through the catheter before mixing with the blood, the correction factor Cr is applied to the equation.

The same principle of balance used for temperature determination of cardiac output can be applied to oxygen (O_2) or carbon dioxide (CO_2) balance as well. Classically, O_2 balance is used as described by Fick. Measurement of O_2 consumption and content is cumbersome, and a modification of the Fick equation using CO_2 production is also used. Noninvasive cardiac output (NICO) is a new partial rebreathing method using the following equation:

$$Q = \dot{V}_{CO_2} / (C\overline{V}_{CO_2} - Ca_{CO_2}) \quad (2)$$

Cardiac output (Q) is simply the expired CO_2 divided by the arterial-venous difference in CO_2. Assuming that Q does not change, the equations for CO_2 elimination must be the same with or without rebreathing, where N indicates normal breathing and R indicates rebreathing. By rearranging the equations, cardiac output is the ratio of the change in the elimination of CO_2 divided by the change in arterial CO_2 content. Arterial CO_2 content is derived from the slope of partial pressure of end-tidal CO_2 ($Petco_2$).

$$Q = \dot{V}_{CO_{2N}} / \left(C\overline{V}_{CO_{2N}} - Ca_{CO_{2N}}\right) = \dot{V}_{CO_{2R}} / \left(C\overline{V}_{CO_{2R}} - Ca_{CO_{2R}}\right) = \frac{\Delta \dot{V}CO_2}{\Delta CaCO_2} \quad (3)$$

Therefore we can see that potential errors are induced by violations of the following assumptions: (1) change in Q during the measurement period, (2) change in metabolic rate and, hence, the production of CO_2, and (3) change in ventilation.

As a trend analysis, patients with chronic obstructive lung disease, in which the absolute value of arterial partial pressure of CO_2 ($Paco_2$) is widely different from $Petco_2$, may have an absolute error in Q determination by this method, but the relative changes should track.

APPENDIX 44-7 *Ultrasound*

The simplest sound wave to represent mathematically is a sinusoidal wave propagating in one dimension:

$$p' = p_0 \sin[(2\pi/\lambda)(x - at)] \quad (1)$$

where p′ is the pressure fluctuation, λ is the wavelength (distance between waves), x is the coordinate in the direction of propagation, and a is the speed of propagation, or the speed of sound.

The amplitude of a sound wave is measured by the root mean square value of the pressure fluctuations. This value is called the *sound pressure level* (SPL). Because the range of SPL values is often very wide, a logarithmic scale is used:

$$SPL = 20 \log (p^*/P_0) \quad (2)$$

where p* is the root mean square pressure fluctuation and P_0 is a reference pressure chosen as the lowest sound pressure detectable by the human ear. This pressure representing the threshold of hearing is 2×10^{-8} kPa at a sound frequency of 2 kHz (2000 cycles/sec). The units in this SPL scale are called *decibels* (dB). Thus a sound pressure of 2×10^{-8} kPa corresponds to an SPL of 0 dB, the lowest audible sound level [$(p^*/P_0 = 1$; log (1) = 0)]. Quiet conversation has an SPL of approximately 40 to 50 dB or a pressure 10 to 300 times that of the threshold of hearing.

When sound waves encounter a sudden change in the properties of the conducting medium, some of the sound is transmitted through the new medium and some of it is reflected or "scattered," in many directions. Although the mathematics of this process is complex, one conclusion is readily apparent: the greater the mismatch in density and compressibility between the two media, the more sound that is reflected. The quantity that best determines the degree of reflection at an interface between two media is the ratio (R) of the products of density (ϱ) and the speed of sound (a) through the two media:

$$R = (\rho_1 a_1)/(\rho_2 a_2) \quad (3)$$

We can easily see that the greatest acoustic mismatch in the body occurs between solid tissues and the lungs. Both the density and the speed of sound are much lower in the air-filled lungs than in solid tissues. Therefore ultrasonography cannot "look" through the lungs at tissues or organs on the other side. The second greatest mismatch occurs between soft tissues and bone, the latter having a much higher ϱa than the former. In 1842, Christian Johann Doppler first described the apparent change in pitch of a sound that occurred when either the source of the sound or the listener was moving. This Doppler effect now has several applications in patient monitoring, including precordial and esophageal Doppler ultrasound devices that measure local blood velocities or cardiac output. If a sound source radiating a frequency (f) is stationary and the listener is moving (see Fig. 44-18, *A*), the wavelength of the waves can be determined by the following equation:

$$\lambda = a/f \quad (4)$$

Continued on following page

APPENDIX 44-7 *Ultrasound (Continued)*

because the time between wave fronts is 1/f and the waves are moving at the speed of sound (a). If the listener moves toward the source at speed V_0, then the velocity of the listener relative to the moving wave fronts is $(a + V_0)$. The number of wave fronts that the listener encounters per unit time is therefore:

$$f' = \text{velocity/distance between waves} = (a + V_0)/\lambda \quad (5)$$

Because the sound frequency for a stationary listener is $f = a/\lambda$ (equation 4), the frequency f' heard by the moving listener becomes:

$$f' = (a + V_0)/\lambda = f + (V_0/\lambda) = f + (V_0 f/a) = f[1 + (V_0/a)] \quad (6)$$

The apparent frequency of the listener is thus increased by the factor $[1 + (V_0/a)]$. A listener moving toward the source at half the speed of sound hears a frequency 1.5 times that of a stationary listener.

Now consider a stationary listener and a source moving at speed V_0, as shown in Figure 44-18, *B*. The wave fronts are no longer concentric circles; they are more closely spaced in the direction that the source is moving. If the frequency of the sound emitted at the source is f, then the source moves a distance V_0/f during each vibration. The wavelength in the direction of motion is thus shortened by V_0/f and becomes $l = (a - V_0)/f$. The waves themselves are traveling at speed a; therefore the frequency heard by the stationary listener is:

$$f' = a/\lambda' = af/(a - V_0) = f[1/(1 - V_0/a)] \quad (7)$$

Now, if the source is moving at one half the speed of sound toward the listener, the apparent frequency doubles. Compare this situation with the preceding one in which the listener is moving and the apparent frequency increases by only 50%. Doppler ultrasound systems combine the two situations shown in Figure 44-18. The initial acoustic source is a stationary transducer, and the sound from this device is scattered from a moving target (e.g., red blood cells). The scattered sound then returns to a stationary listener—the receiving transducer. In effect, the target is a moving listener hearing a stationary source; the target then reradiates the sound as a moving source toward a stationary listener. The frequency heard by the receiving transducer is obtained by combining equations 6 and 7:

$$f' = f\left[\frac{1 + V/a}{1 - V/a}\right] \quad (8)$$

In this example, we have assumed that the target is moving toward the ultrasound transducers at speed V. If the target is moving at one half the speed of sound, then the observed frequency is increased by a factor of 3! Because changes in the frequency of sine waves can be precisely measured, the Doppler principle provides an accurate method of measuring the velocity of moving sound reflectors. At the high frequencies often used (≥5 MHz), objects as small as red corpuscles can scatter enough sound for detection.

Ultrasound imaging is exceptionally complex. For simplicity's sake, recall the submarine movies in which the sonar operator calls out "range 2000 yards, bearing 36 degrees." These two parameters are critical in describing some of the mathematics of ultrasound.

The first factor to consider is the maximal range of the ultrasound, which is described by the following relationship:

$$r_{max} = cT/2 \quad (9)$$

that is, the maximal range equals the speed of sound in tissue (≈1540 m/sec), multiplied by the time T between pulses divided by 2. A further limitation is the fact that the energy dissipates in the tissue. (You need to tap harder when percussing to detect deeper structures). For deeper penetration into tissues, higher energies and slower pulse rates are required. Wavelength and frequency are related in the following manner:

$$\lambda = c/f \quad (10)$$

where f is the frequency, λ is the wavelength, and c is the speed of sound.

Next, we need to consider both the axial resolution (Is the enemy destroyer 2000 or 2005 yards distant?) and the annular resolution (Is its bearing 36 or 38 degrees?). Sound in tissue spreads out in a bandwidth around a fundamental frequency. Therefore to determine the necessary bandwidth for an axial resolution of 2 mm, the following approximation holds:

$$B = 2c/\Delta r \quad (11)$$

where Δr is the axial resolution. Therefore we need a bandwidth of 1.54 MHz to get an axial resolution of 2 mm.

For annular resolution ($\Delta\theta$), remember that the beam spreads out the further it goes from the source. Without deriving the mathematics, two factors determine annular resolution—frequency and aperture. Aperture size is limited to a size that will fit into or onto a human. Remember that a 1-degree error at a 1-cm range will increase at a 10-cm range: circumference = $2\pi r$: $1/360 \times 2 \times \pi \times 1 = 0.17$ mm; thus, at 10 cm, circumference = 1.7 mm.

Chapter 45

Cardiovascular Monitoring

BECKY SCHROEDER • ATILIO BARBEITO • SHAHAR BAR-YOSEF • JONATHAN B. MARK

Key Points

- Most automated noninvasive arterial blood pressure measuring devices use an oscillometric measurement technique and rarely cause complications. Caution should be exercised in patients who cannot complain of arm pain, those with irregular rhythms that force repeated cuff inflation, and those receiving anticoagulant therapy.
- The Allen test for palmar arch collateral arterial flow is not a reliable method to predict complications from radial artery cannulation. Despite the absence of anatomic collateral flow at the elbow, brachial artery catheterization for perioperative blood pressure monitoring is a safe alternative to radial or femoral arterial catheterization.
- The accuracy of a directly recorded arterial pressure waveform is determined by the natural frequency and damping coefficient of the pressure monitoring system. Optimal dynamic response of the system will be achieved when the natural frequency is frequent, thereby allowing accurate pressure recording across a wide range of damping coefficients.
- Rather than the common placement at the midaxillary line, the preferred position for alignment (or "leveling") of external pressure transducers is approximately 5 cm posterior to the sternomanubrial junction. When using external transducers and fluid-filled monitoring systems, this transducer location will eliminate confounding hydrostatic pressure measurement artifacts.
- Because of wave reflection and other physical phenomena, the arterial blood pressure recorded from peripheral sites has a wider pulse pressure than when measured more centrally.
- Dynamic measures of cardiac preload, such as stroke volume and pulse pressure variation, are better predictors of intravascular volume responsiveness than static indicators, such as central venous pressure (CVP) and pulmonary capillary wedge pressure.
- Selecting the best site, catheter, and method for safe and effective central venous cannulation requires that the physician consider the purpose of catheterization, the patient's underlying medical condition, the intended operation, and the skill and experience of the physician performing the procedure. Right internal jugular vein cannulation is preferred due to its consistent, predictable anatomic location and its relative ease of access intraoperatively.
- Mechanical complications from central venous catheters can be decreased by the use of ultrasound vessel localization, venous pressure measurement before large catheter insertion, and radiographic confirmation that the catheter tip lies outside the pericardium and parallel to the walls of the superior vena cava.
- CVP is the result of a complex and diverse interplay among many different physiologic variables, the main ones being venous return and cardiac function. No simple relationship exists between CVP and circulating blood volume. Despite this, important pathophysiologic information can be obtained by careful assessment of the CVP waveform morphology.
- Catheter misuse and data misinterpretation are among the most common complications of central venous and pulmonary artery catheters.

KEY POINTS—cont'd

- Pulmonary artery wedge pressure is a delayed and damped reflection of left atrial pressure. The wedge pressure provides a close estimate for pulmonary capillary pressure in many cases, but it may underestimate capillary pressure when postcapillary pulmonary vascular resistance is increased, as in patients with sepsis.
- Use of central venous, pulmonary artery diastolic, or pulmonary artery wedge pressures as estimates of left ventricular preload is subject to many confounding factors, including changes in diastolic ventricular compliance and juxtacardiac pressure.
- Pulmonary artery catheter monitoring has not been shown to improve patient outcome. Reasons cited for these results include misinterpretation of catheter-derived data and failure of hemodynamic therapies that are guided by specific hemodynamic indices.
- Thermodilution cardiac output monitoring, the most widely used clinical technique, is subject to measurement errors introduced by rapid intravenous fluid administration, intracardiac shunts, and tricuspid valve regurgitation.
- Mixed venous hemoglobin oxygen saturation is a measure of the adequacy of cardiac output relative to bodily oxygen requirements. This measurement is also dependent on the arterial hemoglobin oxygen saturation and hemoglobin concentration.

INTRODUCTION TO CARDIOVASCULAR MONITORING: FOCUSED PHYSICAL EXAMINATION

Although electronic devices constitute crucially important cardiovascular monitors, the physician's senses offer an integrated, panoramic view of the patient's condition, enhanced further by an understanding of the specific clinical context. Whereas electronic instruments accurately and reliably collect massive volumes of data, the clinician plays a vital role by evaluating, and interpreting these data.[1] Just as inspection, palpation, and auscultation are the cornerstones of physical examination, they are also fundamental to perioperative cardiovascular monitoring. For example, direct palpation of a pulse can differentiate true asystole from monitoring artifact more efficiently than troubleshooting an electrocardiogram (ECG) monitor, and direct observation of a beating heart during cardiac surgery or palpation of the aorta by the surgeon provide immediate and invaluable information about the potential causes of hemodynamic instability. However, the strengths and limitations of all monitoring techniques must be understood.

Given that the cardiovascular system is responsible for the transport of substrates and by-products to and from all organ systems, end-organ function is routinely substituted for cardiovascular performance. Inspection of mucous membranes, skin color, and skin turgor often yields important information about hydration, oxygenation, and perfusion. Empiric estimation of intravascular fluid deficits and blood loss, urine output, and changes in mental status is also helpful. Unfortunately, interpretation of these clinical signs and symptoms is often confounded by anesthetic drugs and preexisting organ dysfunction.

STETHOSCOPY

Although Laennec is credited with introducing the stethoscope into general medical practice in 1818, nearly a century elapsed before Harvey Cushing proposed its routine use during surgery.[2] Stethoscopy provides a simple and reliable means of continuous monitoring of heart and breath sounds. Precordial stethoscopy consists of a heavy metal bell or accumulator attached to a length of rubber or plastic extension tubing and a custom-molded monaural plastic earpiece. The esophageal stethoscope facilitates temperature, clear breath, and heart sound monitoring, but it is only practical during general anesthesia.[3] Although generally considered very low risk, rare cases of pharyngeal or esophageal trauma or hypoxemia from tracheobronchial compression can occur.

Despite its purported value, widespread use of continuous stethoscopy has decreased in recent years, possibly related to routine use of pulse oximetry or capnography.[4-6] As a practical matter, clinicians may no longer be as adept at recognizing changes in heart or breath sounds owing to the increasing reliance on electronic monitoring devices, distraction, or operating room noise. As a result, intraoperative stethoscopy has primarily become limited to specialized clinical settings (e.g., pediatric anesthesia, remote locations).

HEART RATE MONITORING

The ability to estimate the heart rate quickly with a "finger on the pulse" is a skill as important as this expression is common, even though electronic devices are most often used to continuously monitor this crucial vital sign as an important guide to anesthetic depth and surgical stimulation. The ECG is the most common method used in the operating room, even though any device measuring the

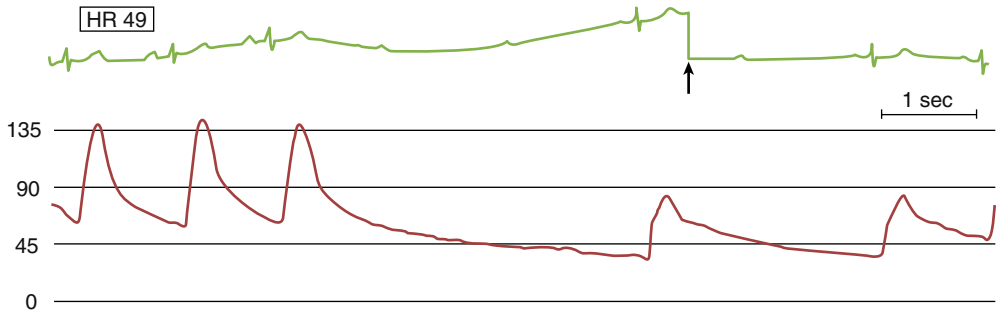

Figure 45-1. Digital heart rate (HR) displays may fail to warn of dangerous bradyarrhythmias. Direct observation of the electrocardiogram (ECG) and the arterial blood pressure traces reveals complete heart block and a 4-second period of asystole, whereas the digital display reports a HR of 49 beats/min. Note that the ECG filter (*arrow*) corrects the baseline drift so that the trace remains on the recording screen. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

period of the cardiac cycle will suffice. Accurate detection of the R wave and measurement of the R wave–R wave interval serve as the basis from which digitally displayed values are derived and periodically updated (e.g., at 5- to 15-second intervals)[7] (Fig. 45-1).

Electrical interference in the ECG trace most often arises from the electrosurgical unit but other sources may also be problematic. Power line noise appears as a 60-Hz artifact and may be eliminated by selecting narrower-bandpass ECG filters, including a 60-Hz notch filter. Problems can also be caused by random twitching and fasciculations, as well as by medical devices such as lithotripsy machines, cardiopulmonary bypass equipment, and fluid warmers.[8] High-amplitude pacing spikes may be misinterpreted as R waves and confound heart rate measurement, as can tall T waves. Decreasing the ECG gain, adjusting R-wave detection sensitivity, changing the ECG lead to one with a smaller pacing spike or T-wave amplitude, or selecting pacing detection modes may improve R-wave detection and heart rate measurement.

PULSE RATE MONITORING

The distinction between heart rate and pulse rate is the difference between electrical depolarization with systolic contraction of the heart (heart rate) and a detectable peripheral arterial pulsation (pulse rate). Pulse deficit describes the extent to which the pulse rate is less than the heart rate and may arise in conditions such as atrial fibrillation in which, intermittently, a very short R wave–to–R wave interval compromises the stroke volume to such an extent that no corresponding arterial pulse is detectable for that systolic ejection. The most extreme example of a pulse deficit is electrical-mechanical dissociation or pulseless electrical activity, seen in patients with cardiac tamponade, extreme hypovolemia, and other conditions in which cardiac contraction does not generate a palpable peripheral pulse.

Many monitors report heart rate and pulse rate separately, the former from the ECG trace and the latter from the pulse oximeter plethysmograph or arterial blood pressure monitor. In addition to indicating the pulse rate, this waveform may also provide supplementary diagnostic clues to cardiovascular function.[9,10] Although monitoring both heart rate and pulse rate may seem redundant, such redundancy is intentional, improves accuracy, and reduces measurement errors and false alarms.[11]

ARTERIAL BLOOD PRESSURE MONITORING

Like heart rate, arterial blood pressure is a fundamental cardiovascular vital sign included in the mandated standards for basic anesthetic monitoring.[12] Blood pressure is usually measured either by indirect cuff devices or direct arterial cannulation with pressure transduction. These techniques measure different physical signals and differ in their degree of invasiveness. However, both are subject to numerous confounding factors that often result in significantly discrepant results, even with simultaneous measurements.[13]

INDIRECT MEASUREMENT OF ARTERIAL BLOOD PRESSURE

Manual Intermittent Techniques

Most indirect methods of arterial blood pressure measurement use a sphygmomanometer, first described by Riva-Rocci in 1896.[14] Using an arm-encircling inflatable elastic cuff, a rubber bulb to inflate the cuff, and a mercury manometer to measure cuff pressure, the radial arterial pulse was palpated as the pressure in the cuff was increased (or later on rapid cuff deflation), identifying the systolic blood pressure (SBP). Detecting both systolic and diastolic pressure became possible with the description of the auscultatory method of blood pressure measurement by Korotkoff in 1905.[15] The Korotkoff sounds are a complex series of audible frequencies produced by turbulent flow beyond the partially occluding cuff. The pressure at which the first Korotkoff sound is heard is considered the systolic pressure (phase I). The sound character progressively changes (phases II and III), becomes muffled (phase IV), and is finally absent (phase V). Diastolic blood pressure (DBP) is recorded at phase IV or V (i.e., significant muffling or disappearance of the sounds altogether).

A fundamental shortcoming of the auscultatory method is its reliance on blood flow to generate Korotkoff sounds. Decreased peripheral blood flow from any

etiology, including shock or intense vasoconstriction, can attenuate or obscure sound generation or detection.[16] In contrast, changes in vessel or tissue compliance underlying the cuff (such as in severe edema, shivering, or calcific arteriosclerosis) require excessively high cuff-occluding pressures and may yield completely inaccurate readings.[17]

Other common sources of error during intermittent manual blood pressure measurement include selection of an inappropriate cuff size and excessively rapid cuff deflation. A well-fitted cuff has a bladder that extends to 40% of arm circumference and 80% of length of the upper arm.[17] The cuff should be applied snugly and contain no residual air, with the bladder centered over the artery. Although too large a cuff often provides acceptable results, the use of a cuff that is too small usually results in falsely high readings.[17] The cuff pressure should decrease slowly enough for the changes in Korotkoff sounds to be detected and properly interpreted. An excessively rapid deflation would cause changes in the sounds to be missed and yield a falsely low pressure reading.

Automated Intermittent Techniques

Automated noninvasive blood pressure (NIBP) devices are standard equipment in most critical care settings because they provide frequent, regular pressure measurements, free the operator to perform other vital clinical duties, provide audible alarms, and can transfer data to a computerized information system. Most NIBP devices are based on oscillometry, a technique first described by Marey in 1876.[17] In this method, small changes in cuff pressure with arterial pulsation during cuff deflation are used to estimate mean arterial blood pressure (MAP). In contrast to the auscultatory method, in this case, the maximal degree of detectable pulsation is determined to be the MAP. SBP and DBP pressures are calculated according to proprietary algorithms that vary by manufacturer; they are thus less reliable than the values for MAP.[17-19] Systolic pressure is typically identified as the pressure at which escalating pulsations reach 25% to 50% of maximum. Diastolic pressure is the most unreliable oscillometric measurement and is commonly recorded when the pulse amplitude has declined to a small fraction of its peak value. In clinical practice, oscillometric automated NIBP measurement is from the upper arm.

In general, automated NIBP measurements closely approximate directly measured arterial pressure, especially at mean pressures of 75 mm Hg and lower.[17,20] However, significant shortcomings have been identified in clinical studies and are important to recognize. Standards for performance of automated NIBP devices have been established by the Association for the Advancement of Medical Instrumentation (AAMI) and the British Hypertension Society (BHS); however, given the ethical conflict that is posed by a requirement for validation of noninvasive devices against invasive direct arterial measurements, auscultation remains the standard against which all devices are evaluated. Consequently, the minimum performance standards that all NIPB devices are required to meet are significantly affected by the fundamental nature of the auscultatory method and the specific protocols used during each validation procedure.[21] At present, in a pool of 85 subjects, new automatic devices must demonstrate average differences no more than ± 5 mm Hg, with standard deviations no greater than 8 mm Hg. This implies that some values may deviate up to 20 mm Hg from the true pressure and still achieve "acceptable performance" as defined by the AAMI.[22] However, attempts to reproduce these validation procedures in clinical situations indicate that with at least one very commonly used device, only 74% of diastolic and 60% of mean and systolic measurements were within 10% of direct measured values. Although the device did meet the minimum performance standards, (MAP ≤ 5 mm Hg difference from the standard), the variances were large.[23]

Clinical studies comparing NIPB with direct arterial pressure measurements also reflect the problematic nature of NIBP monitoring. Oscillometric methods often underestimate systolic and overestimate diastolic measurements, significantly underestimating pulse pressure calculations.[24] These devices also tend to underestimate mean values during periods of hypertension and overestimate during hypotension, potentially biasing clinical decisions in unstable patients.[25] Ankle, calf, and thigh cuffs have never been validated at all, although there is sometimes no choice but to use a cuff in such a manner. Several well-conducted studies in critically ill patients have shown that NIBP measurements show acceptable agreement when a well-fitted cuff is used on the upper arm. The devices can also be reliably used in unstable patients or in alternative locations to identify patients who are hypotensive (MAP ≤ 65 mm Hg), and to differentiate those who have responded to a therapeutic intervention from those who have not (e.g., MAP ≤ 65 mm Hg versus MAP > 65 mm Hg). However, they *cannot* be reliably used to titrate therapy outside of these variables, and averaging of several measurements is necessary for a measurement to be considered reliable.[20,26]

NIBP devices are validated against a technique that measures something slightly different—and in a fundamentally different manner. The auscultatory method measures the systolic and diastolic pressures, estimating the mean, whereas oscillometric devices measure the mean and calculate (in different ways) the systolic and diastolic. Furthermore, directly measured arterial pressure measurements use another technique altogether. It has been stated that "current protocols for validating blood pressure monitors give no guarantee of accuracy in clinical practice."[21] Perhaps expecting these techniques to yield identical or even similar values is unrealistic, especially in complex and unstable clinical situations.

Complications of Noninvasive Blood Pressure Measurement

Although automated, noninvasive blood pressure measurement is generally safe, severe complications, though rare, do occur[27] (Box 45-1). Compartment syndromes have developed after prolonged periods of frequent cuff cycling, likely related to trauma or impaired distal limb perfusion. Other contributing factors include cuff placement over a joint or other vulnerable tissue, or repeated use in the face of a significant confounding factor such as muscle tremors, significant dysrhythmias, or a kinked

cable. Also, patients with peripheral neuropathies, arterial or venous insufficiency, severe coagulopathies, or recent use of thrombolytic therapy may be vulnerable to complications from a noninvasive blood pressure monitor.

Automated Continuous Techniques

Advances in microprocessor and servomechanical control technology have enabled noninvasive techniques to provide a reasonable representation of the arterial pressure waveform and a nearly continuous assessment of blood pressure without resorting to direct arterial cannulation. One such device measures finger blood pressure with an arterial volume-clamp method designed and first reported by Penaz in 1973.[28] Although reasonable accuracy of finger blood pressure as a surrogate for intraarterial pressure measurements are possible, many factors have precluded more widespread application of this technology.[29] Under many circumstances, finger blood pressure monitoring will not reflect brachial arterial pressure. In addition, finger arteries are prone to spasm with the potential for distal ischemia, hand position will influence pressure values, and blood sampling cannot be performed without indwelling catheters. Changes in finger physiology also influence noninvasive hemoglobin (SpHb) monitoring (also see Chapter 61).

Other automatic continuous noninvasive techniques are available to measure arterial blood pressure, using technologies based on arterial wall displacement, pulse transit time, arterial tonometry, and other methods. All techniques have limitations, including need for calibration, sensitivity to motion artifact, and limited applicability in critically ill patients.[17,30,31] It is not clear whether any noninvasive technique will reduce the need for direct arterial pressure monitoring or whether these methods will replace automated intermittent oscillometry as the standard NIBP monitoring method in anesthesia and critical care.

DIRECT MEASUREMENT OF ARTERIAL BLOOD PRESSURE

Arterial cannulation with continuous pressure transduction remains the accepted reference standard for arterial blood pressure monitoring. Despite its increased risk, cost, and need for technical expertise for placement and management, its utility in providing crucial and timely information outweighs its risks in many cases (Box 45-2). The Australian Incident Monitoring Study of 1993 confirmed the superiority of direct arterial pressure monitoring over indirect monitoring techniques for the early detection of intraoperative hypotension.[26,32]

Perhaps the most underemphasized value of direct arterial pressure monitoring is the potential for arterial pressure waveform analysis to provide diagnostic information regarding changes in the patient's condition. This was directly proposed more than a half century ago by Eather and associates, who advocated monitoring of "arterial pressure and pressure pulse contours" in anesthetized patients.[33] Some aspects are readily apparent and routinely used, such as identification of the dicrotic notch to guide proper timing for intraaortic balloon counterpulsation. Others, such as recognition of excessive variation in arterial blood pressure variables as a sign of preload reserve, have only gained significant attention more recently.[34]

Percutaneous Radial Artery Cannulation

The radial artery is the most common site for invasive blood pressure monitoring because it is technically easy to cannulate and complications are uncommon.[35,36] Slogoff and coauthors described 1700 cardiovascular surgical patients who underwent radial artery cannulation without ischemic complications despite evidence of radial artery occlusion after decannulation in more than 25% of patients.[37] Furthermore, most investigations of hand perfusion, in both the early and late postoperative periods following radial artery harvest for coronary artery bypass and flap transfer procedures, have reported no significant decrease relative to the contralateral hand.[38-43]

Before attempting radial artery cannulation, many clinicians assess the adequacy of collateral flow to the hand by performing a modified Allen test. This bedside examination is a variation on a technique originally described in 1929 to assess arterial stenosis in the hands of patients with thromboangiitis obliterans.[44] The examiner compresses both the radial and ulnar arteries and asks the patient to make a tight fist, exsanguinating the palm. The patient then opens the hand, avoiding hyperextension of the wrist or fingers. As occlusion of the ulnar artery is released, the color of the open palm is observed. Normally, the color will return to the palm within several seconds; severely reduced ulnar collateral flow is present when the palm remains pale for more than 6 to 10 seconds.

Although the Allen test is often used to identify patients at increased risk for ischemic complications from radial artery cannulation, the predictive value of this test is poor. Numerous reports of permanent ischemic sequelae note that a normal Allen test result was present before vessel cannulation.[38,45] In contrast, there are many descriptions of uncomplicated radial artery monitoring in the face of a

documented abnormal Allen test.[37,46] In recent years, the radial artery has been used safely as an access site for coronary catheterization and stenting or harvested for use in coronary bypass grafting, even in individuals who have an abnormal Allen test.[46,47] Although most patients show radial artery dominance with respect to overall hand perfusion, total radial artery occlusion does not compromise distal perfusion, perhaps as the result of collateral recruitment.[47] Overall, the diagnostic accuracy of the modified Allen test with a 5-second threshold is only 80% with 76% sensitivity and 82% specificity. It appears that the test is unable to provide a cutoff point below which perfusion can be deemed vulnerable.[48] Unfortunately, use of pulse oximetry, plethysmography, or Doppler ultrasound as adjuncts to visual inspection of the palm for return of circulation does not seem to improve its accuracy. Oximetry is able to detect blood flow at extremely low flows, leading to poor specificity, whereas no established ultrasound criteria are available by which to evaluate radial or ulnar blood flow and identify abnormalities.[38,49,50] In general, although a normal modified Allen test may be useful in identifying patients acceptable for radial artery harvest or use for coronary angiography, it does not predict clinical outcomes following cannulation for arterial blood pressure monitoring as currently practiced.[38]

In preparation for cannulation of the radial artery, the wrist and hand are immobilized and secured with the wrist resting across a soft pad. Dorsiflexion of the wrist should be mild at most to avoid attenuating the pulse by stretch or extrinsic tissue pressure. The course of the radial artery proximal to the wrist is identified by gentle palpation, the skin is prepared with an antiseptic, and a local anesthetic is injected intradermally and subcutaneously beside the artery. Arterial catheterization can be performed with a standard IV catheter or an integrated guidewire-catheter assembly designed for this purpose. A recent educational video provides great detail about this standard procedure.[50-52]

Once the catheter is fully advanced into the vessel lumen, the radial artery is occluded by applying proximal pressure, the needle is removed, the monitoring system pressure tubing is fastened to the catheter, an appropriate sterile dressing is applied, and the apparatus is taped and secured to the wrist. Although a soft arm board can be used to maintain the wrist in an anatomically neutral position during arterial pressure monitoring, extreme wrist dorsiflexion should be avoided to prevent injury to the median nerve.[53,54]

Some clinicians choose the "transfixion" technique for arterial cannulation, in which the front and back walls of the artery are punctured intentionally, the needle is removed from the catheter, the catheter is withdrawn until pulsatile blood flow appears, and then advanced into the vessel lumen either directly or over a wire using the Seldinger technique. Although it is unnecessary to place an additional hole in the back wall of the radial artery for successful cannulation, the technique *per se* is not associated with a more frequent rate of complications or failure.[55]

Other aids to arterial cannulation include the use of ultrasound imaging to guide catheter insertion, especially as a rescue method following a failed attempt.[56] Although ultrasound techniques improve first-pass cannulation success rates, improved clinical outcomes and shorter times required to place have not been documented as a justification for routine use.[57-60]

Alternative Arterial Pressure Monitoring Sites

If the radial arteries are unsuitable or unavailable, multiple alternatives exist. The ulnar artery is cannulated in a manner similar to that for the radial and has been used safely even following failed attempts to access the ipsilateral radial artery.[37,61] Similarly, the brachial artery, although lacking collateral branches to protect the hand, has a long track record of safe use. Bazaral and associates reported more than 3000 brachial artery catheters in patients undergoing cardiac surgery, with only one significant thrombotic complication and no long-term sequelae.[62] The axillary artery has the advantages of patient comfort, mobility, and access to a central arterial pressure waveform, and complications are similar in incidence to those for use of radial and femoral arteries.[36] A slightly longer catheter is preferred for the brachial or axillary sites because of their relatively deeper location and position with respect to the shoulder and elbow joints. However, the risk of cerebral embolization is significantly increased when more centrally located vessels are used.

The femoral artery is the largest vessel in common use for monitoring, but its safety appears to be comparable to those for other sites.[36] As with axillary artery pressure monitoring, the femoral artery waveform more closely resembles aortic pressure than do waveforms recorded from peripheral sites. The risk of distal ischemia may be reduced because of the large diameter of the artery, but risk of atherosclerotic plaque embolization is significant during initial vessel manipulation. Catheterization of the femoral artery is best achieved with a guidewire technique, and the point of vessel entry must be distal to the inguinal ligament to minimize the risk of arterial injury, hidden hematoma formation, or even uncontrolled hemorrhage into the pelvis or peritoneum.[63]

Less commonly used alternatives include the dorsalis pedis, posterior tibial, and superficial temporal arteries, with the pedal vessels being more popular for pediatric patients.

Complications of Direct Arterial Pressure Monitoring

Large clinical investigations confirm the infrequent incidence of long-term complications after radial arterial monitoring.[35-37] Although vascular complications from radial artery cannulation are uncommon, factors that may increase risk include vasospastic arterial disease, previous arterial injury, thrombocytosis, protracted shock, high-dose vasopressor administration, prolonged cannulation, and infection.[38,64,65] Catheter diameter and composition as well as artery size and patient gender may be associated with arterial injury.[38]

Rare complications can occur after arterial cannulation at any location (Box 45-3). In most cases, catheter placement was technically difficult or there were contributory factors such as shock or coagulopathy. In a large observational study of 2000 untoward clinical events resulting

from vascular access of all kinds, only 13 were related to peripheral arterial cannulation, fewer than those associated with central venous[18] or peripheral venous cannulation.[33] Of these cases, 5 involved problems with equipment; in 3 cases the arterial line was used inadvertently for drug injection, and in the remainder, the arterial line was either disrupted or kinked. In only 1 case did transient vasospasm follow radial artery cannulation.[32,66] A second report from this study noted that direct pressure monitoring was problematic in 10 cases, resulting from incorrect calibration or interpretation of the pressure display or unrecognized subclavian artery stenosis. Furthermore, the anesthesia closed claims study reported claims related to arterial pressure monitoring at any site constitute only 8% of all claims related to any vascular access (2% of total claims). Of these, almost 54% were related to radial artery use (ischemic injury, median or radial nerve injury, or retained wire fragment), less than 8% were associated with use of the brachial artery, and the remainder followed severe thrombotic or hemorrhagic complications after femoral artery monitoring.[67] Although patient physiology is important, equipment misuse, careful placement technique and catheter care, as well as improper data interpretation are primary issues in many complications related to arterial pressure monitoring.

Technical Aspects of Direct Blood Pressure Measurement

Direct measurement of arterial blood pressure requires that an accurate and appropriate pressure waveform be reproduced on the monitor. Unfortunately, several factors, including extension tubing, stopcocks, flush devices, recorders, amplifiers, and transducers, influence this process and may introduce significant error.[68]

Most invasive blood pressure monitoring systems are underdamped second-order dynamic systems modeled after mass-spring systems that demonstrate simple harmonic motion dependent on elasticity, mass, and friction.[68-70] These three properties determine the system operating characteristics (i.e., frequency response or dynamic response), which in turn are characterized by critical system parameters, natural frequency (f_n, ω) and damping coefficient (τ, Z, α, D). The natural frequency of a system determines how rapidly the system oscillates after a stimulus, whereas the damping coefficient reflects frictional forces acting on the system and determines how rapidly it returns to rest after a stimulus. Both variables may be estimated or measured at the bedside and dramatically influence the appearance of the displayed pressure waveform.

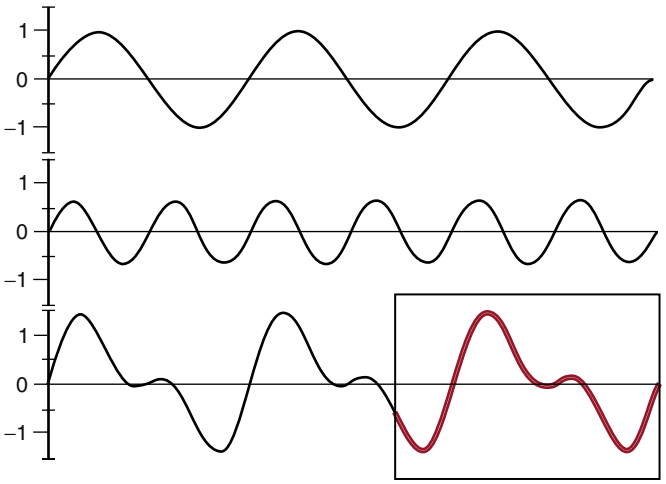

Figure 45-2. Arterial blood pressure waveform produced by summation of sine waves. The fundamental wave (*top*) added to 63% of the second harmonic wave (*middle*) results in a pressure wave (*bottom*) resembling a typical arterial blood pressure waveform (*box*). *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

Natural Frequency, Damping Coefficient, and Dynamic Response of Pressure Monitoring Systems. The displayed arterial blood pressure waveform is a periodic complex wave produced via Fourier analysis of a summation of a series of simpler but diverse propagated and reflected pressure waves. As such, it is a mathematic re-creation of the original complex pressure wave created by stroke volume ejection.[71,72] The original pressure wave is characterized by its fundamental frequency, manifested clinically as the pulse rate. Although the pulse rate is measured in beats per minute, fundamental frequency is expressed as cycles per second or Hertz (Hz).

The sine waves that sum to produce the final complex wave have frequencies that are multiples or harmonics of the fundamental frequency. A crude arterial waveform depicting a systolic upstroke and peak, dicrotic notch, and so forth can be reconstructed with reasonable accuracy from only two sine waves, the fundamental frequency and the second harmonic (Fig. 45-2). If the original arterial pressure waveform contains high-frequency components such as a steep systolic upstroke, higher-frequency sine waves (and more harmonics) are needed to provide a faithful reconstruction of the original pressure waveform. As a general rule, 6 to 10 harmonics are required to provide distortion-free reproductions of most arterial pressure waveforms.[71,73] Hence, accurate arterial blood pressure measurement in a patient with a pulse rate of 120 beats/min (2 cycles/sec or 2 Hz) requires a monitoring system dynamic response of 12 to 20 Hz (i.e., 6 to 10 waveforms × 2 Hz). The faster the heart rate and the steeper the systolic pressure upstroke, the greater the dynamic response demands on the monitoring system.

All monitoring systems have an intrinsic natural frequency and damping coefficient. If the natural frequency is too low, frequencies in the monitored pressure waveform will overlap that of the measurement system, the system will resonate, and pressure waveforms recorded on the monitor will be exaggerated or amplified versions

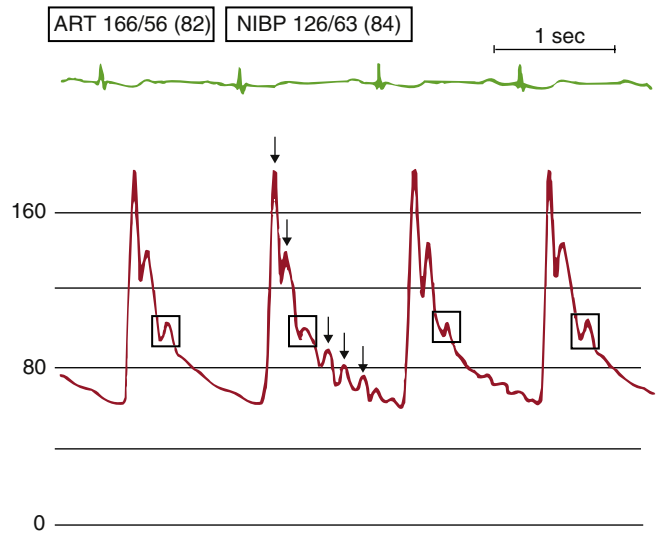

Figure 45-3. Underdamped arterial pressure waveform. Systolic pressure overshoot and additional small, nonphysiologic pressure waves (*arrows*) distort the waveform and make it hard to discern the dicrotic notch (*boxes*). Digital values displayed for direct arterial blood pressure (ART 166/56, mean 82 mm Hg) and noninvasive blood pressure (NIBP 126/63, mean 84 mm Hg) show the characteristic relationship between the two measurement techniques in the presence of an underdamped system. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

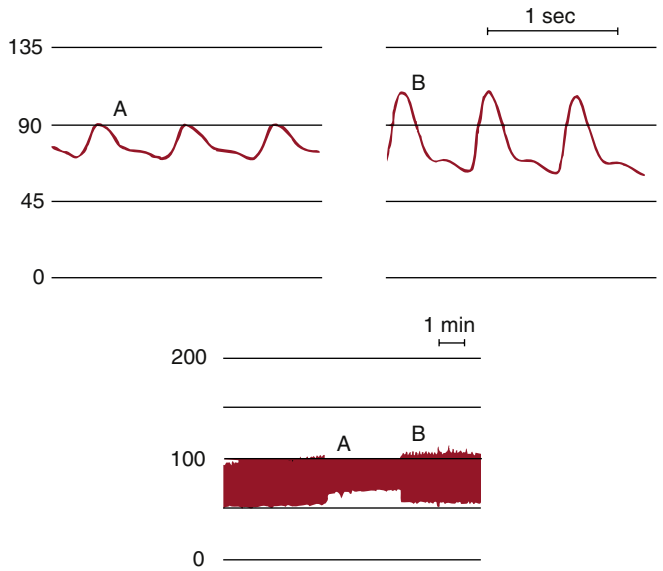

Figure 45-4. Overdamped arterial pressure waveform. The overdamped pressure waveform (**A**) shows a diminished pulse pressure compared with the normal waveform (**B**). The slow-speed recording *(bottom)* demonstrates a 3-minute period of damped arterial pressure. Note that despite the damped system, mean arterial pressure remains unchanged. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

of true intraarterial pressure. An underdamped pressure waveform displays systolic pressure overshoot and may contain elements produced by the measurement system itself rather than the original propagated pressure wave (Fig. 45-3). In contrast, an overdamped waveform is recognizable by its slurred upstroke, absent dicrotic notch, and loss of fine detail. Such waves display a falsely narrowed pulse pressure, although MAP may remain reasonably accurate (Fig. 45-4).

Catheter-tubing transducer systems in routine clinical use tend to be underdamped but have an acceptable natural frequency that exceeds 12 Hz[68] (Fig. 45-5). In general, the lower the natural frequency of the monitoring system, the more narrow the range of damping coefficients necessary to ensure faithful reproduction of the pressure wave. For example, if the monitoring system's natural frequency is 10 Hz, the damping coefficient must be between 0.45 and 0.6 for accurate pressure waveform monitoring. If the damping coefficient is too low, the monitoring system will be underdamped, resonate, and display factitiously elevated systolic blood pressure; if the damping coefficient is too high, the system will be overdamped, systolic pressure will be falsely decreased, and fine detail in the pressure trace will be lost.

For any specific system, the most rapid possible natural frequency facilitates an optimal dynamic response.[72] In theory, this is achieved best by using short lengths of stiff pressure tubing and limiting the number of stopcocks and other monitoring system appliances. Blood clots and air bubbles concealed in stopcocks and other connections have a similar impact on system dynamic response. As a general rule, adding air bubbles to a monitoring system will not improve its dynamic response because any

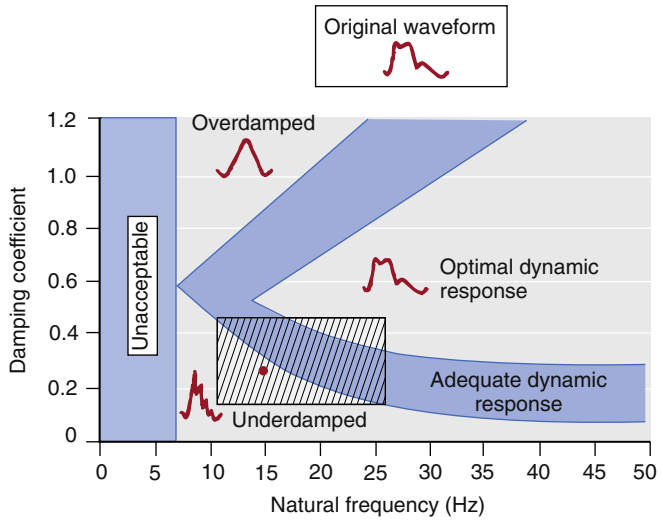

Figure 45-5. Interaction between damping coefficient and natural frequency. Depending on these two parameters, catheter tubing-transducer systems may be classified by their dynamic response range. Systems with an optimal or adequate dynamic response will record and display all or most pressure waveforms encountered in clinical practice. Overdamped and underdamped systems skew measurements in predictable ways, with those having a natural frequency <7 Hz proving unacceptable. The *rectangular crosshatched box* indicates the ranges of damping coefficients and natural frequencies commonly encountered in clinical pressure measurement systems. The *red dot* within the box marks the mean values of 30 such systems.[74] *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

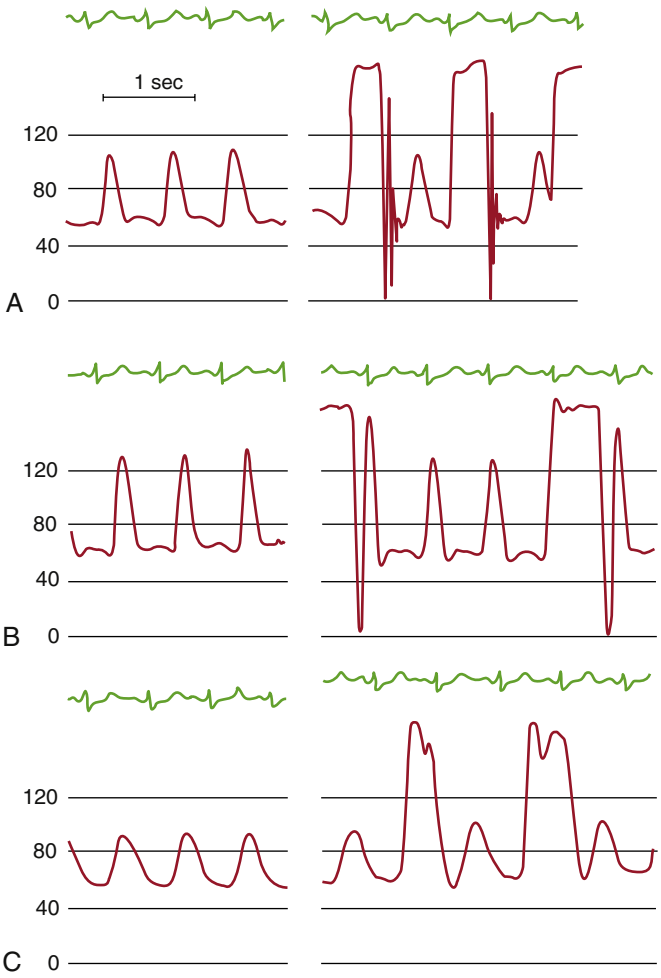

Figure 45-6. Effect of small air bubbles within arterial pressure monitoring systems. Arterial pressure waveforms are displayed, along with superimposed fast-flush square-wave artifacts. **A,** Original monitoring system has an adequate dynamic response (natural frequency 17 Hz, damping coefficient 0.2). **B,** A small 0.1-mL air bubble added to the monitoring system produces a paradoxical increase in arterial blood pressure. Note decreased natural frequency of the system. **C,** A larger 0.5-mL air bubble further degrades dynamic response and produces spurious arterial hypotension. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

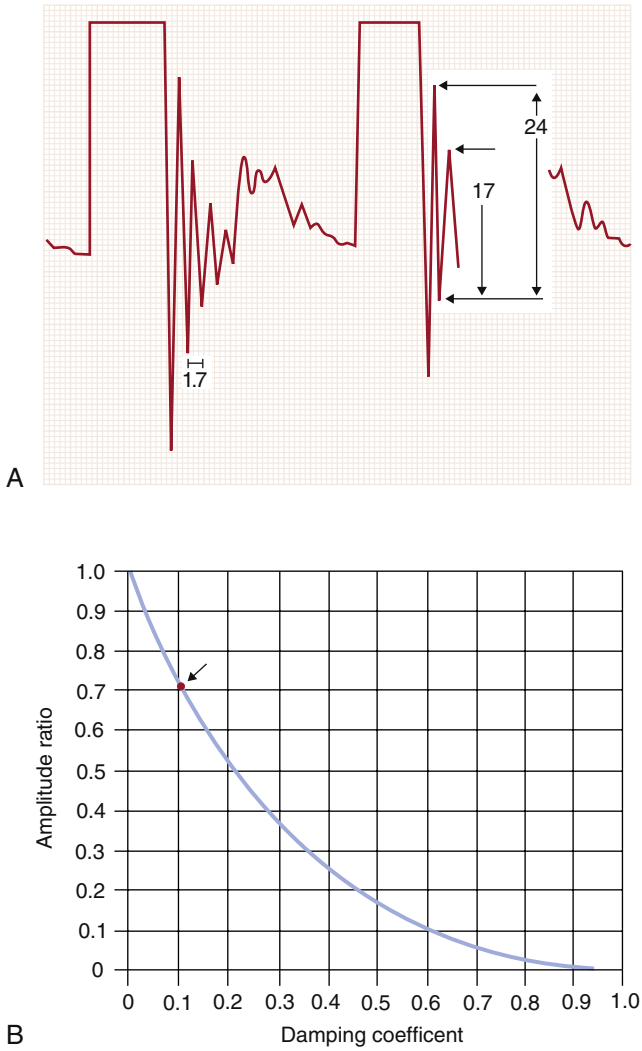

Figure 45-7. Clinical measurement of natural frequency and damping coefficient. **A,** Two square-wave fast-flush artifacts interrupt an arterial pressure waveform recorded on standard 1-mm grid paper at a speed of 25 mm/second. Natural frequency is determined by measuring the period of one cycle of adjacent oscillation peaks (1.7 mm). Damping coefficient is determined by measuring the heights of adjacent oscillation peaks (17 and 24 mm). From these measurements, a natural frequency of 14.7 Hz and an amplitude ratio of 0.71 may be calculated. **B,** Relation between amplitude ratio and damping coefficient. The amplitude ratio determined in the fast-flush test in (**A**) corresponds to a damping coefficient of 0.11. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

increase in system damping is necessarily accompanied by a decrease in natural frequency. Somewhat paradoxically, monitoring system resonance may increase and cause even greater systolic pressure overshoot (Fig. 45-6).

The fast-flush test provides a convenient bedside method for determining dynamic response of the system and assessing signal distortion.[68,70,72] The nature and duration of the flush artifact following a brief opening of the fast-flush valve are noted. Natural frequency is inversely proportional to the time between adjacent oscillation peaks, calculated as 1 cycle/1.7 mm × 25 mm/sec = 14.7 cycles/sec (14.7 Hz) (Fig. 45-7, *A*). Shorter oscillation cycles indicate a more rapid natural frequency.[72] Alternatively, the damping coefficient is related to the amplitudes of successive oscillation peaks. The amplitude ratio thus derived indicates how quickly the measuring system returns to a resting state. The damping coefficient can be calculated mathematically, but it is usually determined graphically from the amplitude ratio.[68,72] For example, the amplitudes of two successive oscillation cycles are 24 and 17 mm, giving an amplitude ratio of 17/24 or 0.71. This corresponds to a damping coefficient of 0.11 based on the graphic solution (Fig. 45-7, *B*). Note that the monitoring system illustrated has an adequate natural frequency (approximately 15 Hz) but is underdamped (damping coefficient 0.11, optimal range 0.45 to 0.6, see earlier). One would expect to find systolic pressure overshoot in such a system.

Although the technical requirements for accurate arterial blood pressure measurement are well known, these

conditions are often lacking in routine clinical practice. Examination of the frequency response of 30 radial artery catheter-transducer systems used in routine intensive care monitoring showed natural frequency (mean 14.7 ± 3.7 Hz) and damping coefficient (mean 0.24 ± 0.07) values that fell within the range of underdamped systems.[68,74] Furthermore, the range of frequency responses (10.2 to 25.3 Hz) and damping coefficients (0.15 to 0.44) measured in this setting suggests that distortion of the arterial waveform is common in clinical practice, particularly systolic arterial pressure overshoot resulting from underdamped systems (see Fig. 45-5).

Pressure Monitoring System Components. Arterial pressure monitoring systems have a number of components, beginning with the intraarterial catheter and including extension tubing, stopcocks, inline blood sampling set, pressure transducer, continuous-flush device, and electronic cable connecting the bedside monitor and waveform display screen. The stopcocks in the system provide sites for blood sampling and allow the transducer to be exposed to atmospheric pressure to establish a zero reference value. Needleless blood sampling ports and inline aspiration systems permit blood drawing without use of sharp needles and allow aspirated waste blood to be returned to the patient within a convenient closed system. Modifications such as these are intended to reduce the risk of needle injury and decrease waste of the patient's blood during sampling. However, these additional features may degrade the dynamic response of the monitoring system and further exacerbate systolic arterial pressure overshoot.

The flush device provides a continuous, slow (1 to 3 mL/hr) infusion of saline to purge the monitoring system and prevent thrombus formation within the arterial catheter. Dextrose solutions should not be used, because flush contamination of sampled blood may cause serious errors in blood glucose measurement.[75] A dilute concentration of heparin (1 to 2 units heparin/mL saline) has been added to the flush solution to reduce further the incidence of catheter thrombosis, but this practice increases the risk of heparin-induced thrombocytopenia and should be avoided. The flush device not only ensures continuous slow flushing of the line and catheter but also includes a spring-loaded valve for periodic, high-pressure flushing. This rapid flushing is used to purge the extension line of blood after an arterial sample has been taken or to restore the dynamic response characteristics of the pressure monitoring system, which otherwise slowly deteriorate over time.[76]

Transducer Setup: Zeroing and Leveling. Before use, pressure transducers must be zeroed, calibrated, and leveled to the appropriate position relative to the patient. A zero pressure reference value must be established by opening the appropriate stopcock and exposing the transducer to atmospheric pressure and executing the zero-command, a specific maneuver that may vary with each manufacturer. This underscores the fact that all pressures displayed on the monitor are referenced to local atmospheric pressure. To be precise, it is the air-fluid interface at the level of the stopcock that is the zero pressure locus. This point must be specifically positioned relative to the patient to ensure correct transducer level. When a significant or unexpected change in pressure occurs, the zero reference value can be rechecked quickly by opening the stopcock and noting that the pressure value on the bedside monitor is still zero.[72] Occasionally, a faulty transducer, cable, or monitor will cause the zero baseline to drift introducing significant error into all subsequent pressure measurements until the zero reference is reestablished.[77,78]

Historically, transducer calibration closely followed zeroing. Calibration is an adjustment in system gain to ensure accurate transducer measurement relative to a known reference. Although traditionally calibrated against a mercury manometer, current disposable pressure transducers meet accuracy standards established by the AAMI and the American National Standards Institute.[77] As such, formal bedside transducer calibration is no longer performed. However, it is good practice to routinely compare pressures obtained via a newly placed arterial catheter with a blood pressure obtained via other means as a more informal but useful calibration. On occasion, despite successful transducer zeroing, the measured blood pressure values seem erroneous, and a malfunctioning pressure transducer, cable, or monitor is identified and replaced.[78]

The final step in transducer setup is to adjust the pressure monitoring zero point to the appropriate level relative to the patient. Note that transducer zeroing and leveling are two distinct procedures. Zeroing established the zero reference point for the transducer system, whereas leveling matches this reference point to a specific point on the patient's body. That is, it determines where the value 0 will be and, hence, from where measurements will begin. Although the precise location for the zero reference level is important for accurate blood pressure monitoring, it is even more critical when the physiologic range of values is smaller, such as for cardiac filling pressures. In such cases, a small absolute error would have a large influence on the displayed pressures.

Arterial pressure transducers should be placed to best estimate aortic root pressure. Although the midchest position is often used in supine patients, several investigators have shown that cardiac filling pressures are significantly overestimated when transducers are leveled to the midchest rather than a position approximately 5 cm posterior to the sternal border.[79,80] This preferred (more anterior) transducer location obviates the confounding effect of hydrostatic pressure on cardiac filling pressure measurements.

The position of the pressure transducer relative to the patient must be considered in interpreting blood pressure measurements. In some circumstances, the clinician may choose to place the arterial transducer at a level different from the standard. In such a case, the displayed pressure is the pressure measured at that level and, important to note, is not the same at the aortic root. For example, when the arterial pressure transducer is elevated to the level of the patient's ear to approximate the location of the circle of Willis during a sitting neurosurgical procedure, arterial blood pressure at the level of the brain is being measured and displayed, and that at the aortic

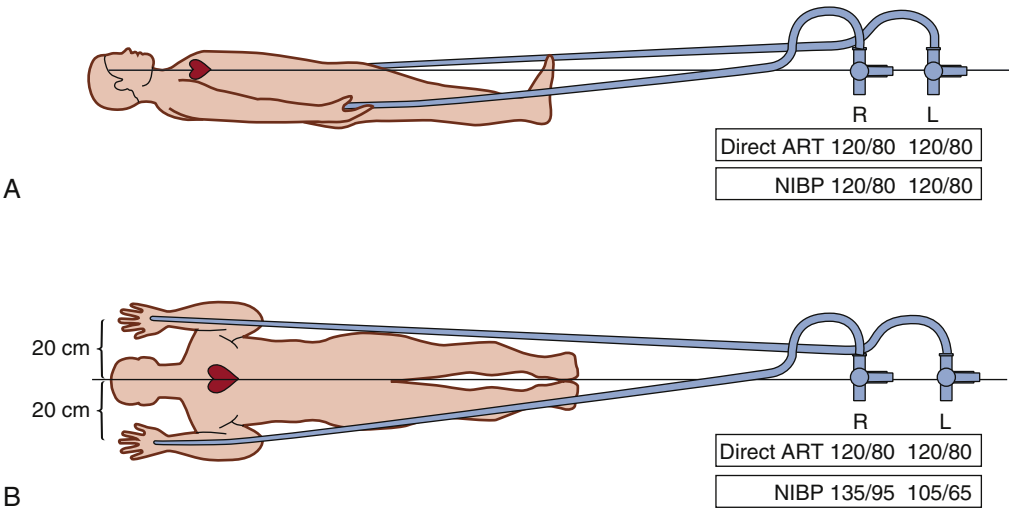

Figure 45-8. Effect of patient position on the relation between direct arterial blood pressure (ART) and indirect noninvasive blood pressure (NIBP) measurements. **A,** In the supine patient, pressures measured from the right (R) or left (L) arms by either technique will be the same. **B,** In the right lateral decubitus position, ART pressures recorded directly from the right and left radial arteries will remain unchanged so long as the respective pressure transducers remain at heart level. However, NIBP will be higher in the dependent right arm and lower in the nondependent left arm. Differences in NIBP are determined by the positions of the arms above and below the level of the heart and are equal to the hydrostatic pressure differences between the level of the heart and the respective arm. A 20-cm difference in height produces a 15-mm Hg difference in pressure. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

root is higher (by an amount equal to the vertical height difference between the two points). There is no need to re-zero the transducer when it is moved, as atmospheric pressure changes very little over the few inches of height adjustment. Errors are also common when pressure transducers are fixed to an intravenous pole and the patient's bed height is adjusted. Raising the height of the bed relative to the transducer will cause overestimation of arterial blood pressure, whereas lowering the patient below the transducer will lead to underestimation.

For proper interpretation of blood pressure measurements from a patient in the lateral decubitus position, it is helpful to differentiate zeroing and leveling pressure transducers and to appreciate the differences between noninvasive and invasive blood pressure measurement. In this position, although the aortic root remains stationary, one arm is necessarily higher than the other. However, as long as the pressure transducer remains *fixed at the level of the heart,* the location of the arms or in which vessel the catheter resides has no influence on the measured arterial pressure. On the other hand, noninvasive cuff blood pressure measurements will be different in the two arms—higher in the dependent (down) arm and lower in the nondependent (up) arm (Fig. 45-8). As a result, to check the accuracy of a cuff measurement, it may be necessary to temporarily move the pressure transducer to the level of the blood pressure cuff in question.

Normal Arterial Pressure Waveforms

In the early era of arterial pressure monitoring, significant diagnostic information was gleaned from waveform analysis.[33] Unfortunately, this practice declined, possibly because of increasing reliance on cuff sphygmomanometry, which provides "numbers which came to be linked in a simplistic way to cardiac strength (systolic pressure) and arteriolar tone (diastolic pressure). Pseudoscience had arrived with (these) numbers …"[81] With the advent of automated graphic analysis and high-resolution, multicolored displays, renewed interest in waveform analysis is attracting new attention.[34] However, full appreciation of the diagnostic clues provided by the direct arterial pressure waveform requires understanding of normal waveform components, their relationship to the cardiac cycle, and the implications of waveform variations when recorded from different arterial sites.

The systemic arterial pressure waveform results from ejection of blood from the left ventricle into the aorta during systole, followed by peripheral runoff during diastole. The systolic waveform components consist of a steep pressure upstroke, peak, and ensuing decline, and immediately follow the ECG R wave. The downslope of the arterial pressure waveform is interrupted by the dicrotic notch, continues its decline during diastole after the ECG T wave, and reaches its nadir at end-diastole (Fig. 45-9). The dicrotic notch, known as the incisura when recorded at the central aorta (from the Latin, meaning "a cutting into") is sharply defined and thought to result from aortic valve closure.[82] In contrast, more peripheral arterial waveforms generally display a later, more blunted dicrotic notch that is more dependent on properties of the arterial wall. Note that the systolic upstroke starts 120 to 180 milliseconds after beginning of the R wave (see Fig. 45-9). This interval reflects total time required for depolarization of the ventricular myocardium, isovolumic left ventricular contraction, opening of the aortic valve, left ventricular ejection, propagation of the aortic pressure wave, and finally, transmission of the signal to the pressure transducer.

The bedside monitor displays values for the peak systolic and end-diastolic nadir pressures. MAP is dependent on the algorithm used by the monitor. In simplest terms, MAP is equal to the area beneath the arterial pressure

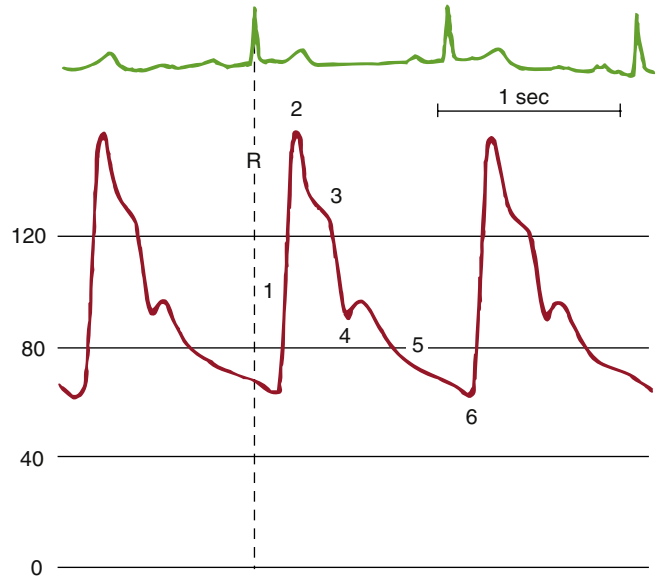

Figure 45-9. Normal arterial blood pressure waveform and its relation to the electrocardiographic R wave. (*1*) Systolic upstroke, (*2*) systolic peak pressure, (*3*) systolic decline, (*4*) dicrotic notch, (*5*) diastolic runoff, and (*6*) end-diastolic pressure. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

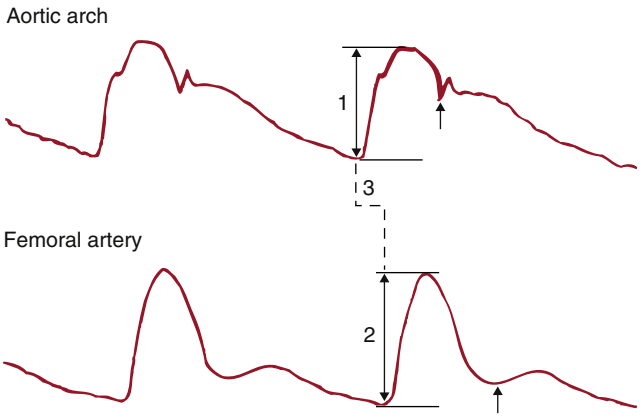

Figure 45-10. Distal pulse wave amplification of the arterial pressure waveform. Compared with pressure in the aortic arch, the more peripherally recorded femoral artery pressure waveform demonstrates a wider pulse pressure (compare *1* and *2*), a delayed start to the systolic upstroke (*3*), a delayed, slurred dicrotic notch (compare *arrows*), and a more prominent diastolic wave. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

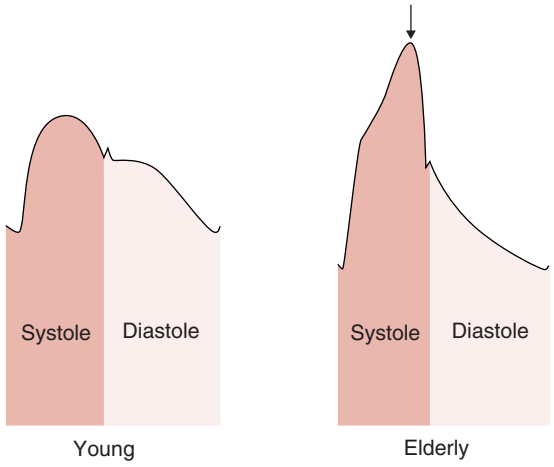

Figure 45-11. Impact of pressure wave reflection on arterial pressure waveforms. In older individuals with reduced arterial compliance, early return of peripherally reflected waves increases pulse pressure, produces a late systolic pressure peak (*arrow*), attenuates the diastolic pressure wave, and at times, distorts the smooth upstroke with an early systolic hump.

curve divided by the beat period, averaged over multiple cardiac cycles. Although MAP is often estimated as diastolic pressure plus one third times pulse pressure, this estimate is only valid at slower heart rates, because the proportion of the cardiac cycle spent in diastole decreases as the heart rate increases.[83]

An important feature of the arterial pressure waveform is distal pulse amplification. Pressure waveforms recorded simultaneously from different sites have different morphologies due to the physical characteristics of the vascular tree, namely, impedance and harmonic resonance[31,81] (Fig. 45-10). As the pressure wave travels from the central aorta to the periphery, the arterial upstroke becomes steeper, the systolic peak increases, the dicrotic notch appears later, the diastolic wave becomes more prominent, and end-diastolic pressure decreases. As a result, compared with central aortic pressure, peripheral arterial waveforms have higher systolic, lower diastolic, and wider pulse pressures. Furthermore, as the signal is delayed in arriving at the peripheral site, the systolic pressure upstroke begins approximately 60 milliseconds later in the radial artery than in the aorta. MAP in the aorta is only slightly higher than that in the periphery.

Reflection of pressure waves within the arterial tree has a great impact on changes to the arterial pressure waveform as it travels peripherally.[81] As blood flows from the aorta to the radial artery, mean pressure decreases only slightly because there is little resistance to flow in the major conducting arteries. At the arteriolar level, though, mean blood pressure decreases markedly as a result of a dramatic increase in vascular resistance. This resistance to flow diminishes pressure pulsations in smaller downstream vessels but augments upstream arterial pressure pulses by way of pressure wave reflection.[84] The summation of these antegrade and reflected waves determine the shape of the arterial pulse wave recorded from different arterial sites. For example, reduced arterial compliance causes premature return of reflected pressure waves, resulting in arterial pressure waveforms with increased pulse pressure, a late systolic pressure peak, attenuated diastolic pressure waves, and at times, an early systolic hump distorting the smooth upstroke (Fig. 45-11).

From these considerations, the morphology of the arterial waveform and the precise values of systolic and diastolic blood pressure vary throughout the arterial system under normal conditions in otherwise healthy individuals. These variations are augmented and at times greatly exaggerated by various factors, including but not limited to age, pathologic processes, and pharmacologic interventions.

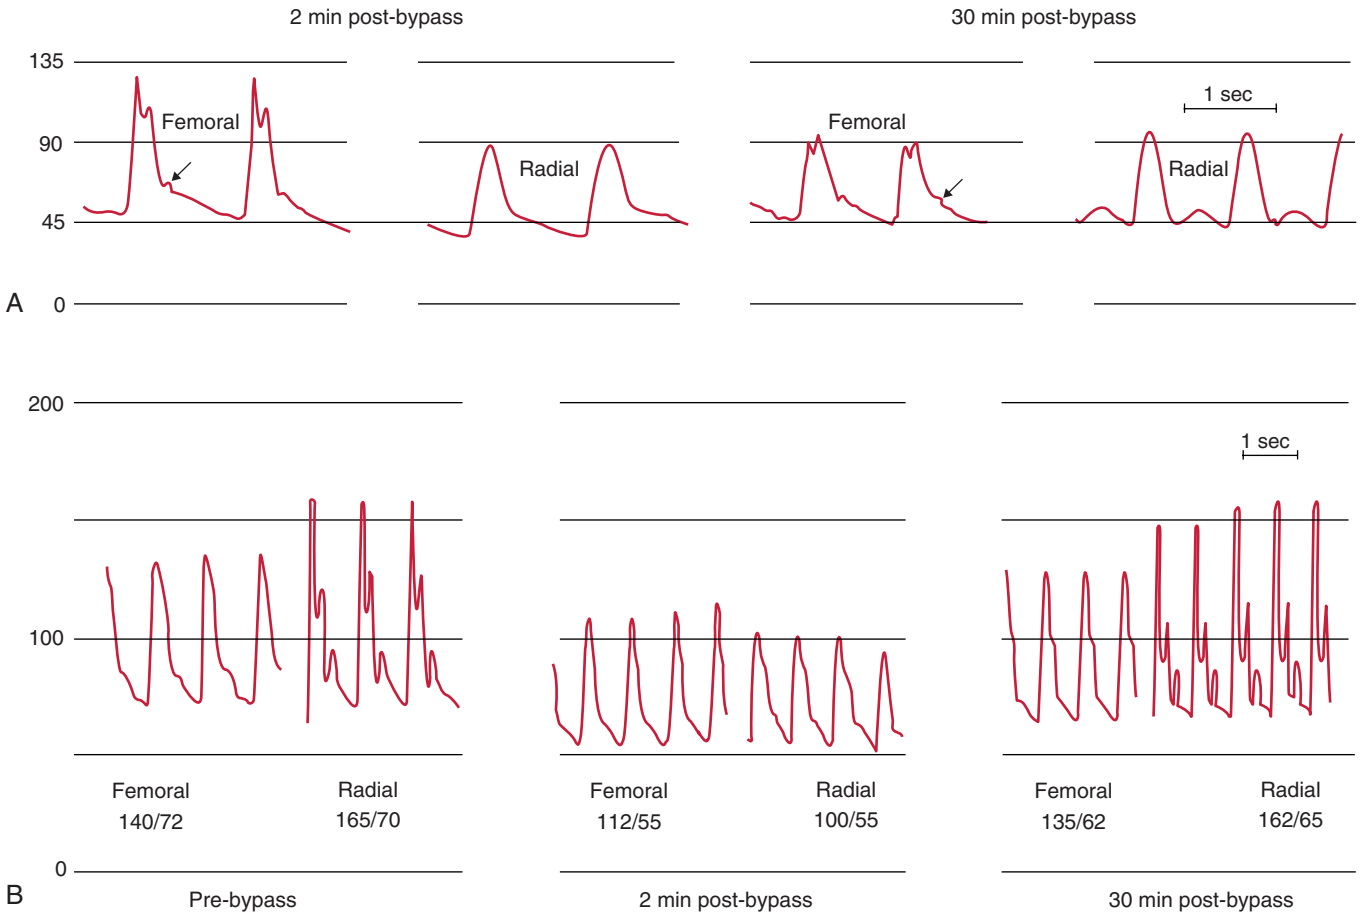

Figure 45-12. Arterial pressure gradients following cardiopulmonary bypass. **A,** Femoral and radial artery pressure traces recorded 2 minutes after bypass (2 min post-bypass), when radial artery pressure underestimates the more centrally measured femoral artery pressure and 30 minutes later (30-min post-bypass), when radial and femoral arterial pressures have equalized and radial pressure has resumed a more typical morphology. Note that dicrotic notch (*arrows*) is visible in the femoral pressure trace immediately after bypass, but is delayed in the radial pressure trace. **B,** Femoral and radial artery pressure traces recorded before cardiopulmonary bypass (pre-bypass), 2 minutes following bypass (2 min post-bypass), and 30 minutes following bypass (30 min post-bypass). Note changing relationship between femoral and radial artery pressure measurements at these different times.

Arterial Blood Pressure Gradients

A number of pathophysiologic conditions cause exaggerated arterial pressure gradients between monitoring sites, be they real, iatrogenic, or artifactual. Frank and co-workers demonstrated that 21% of patients undergoing peripheral vascular surgery had a blood pressure difference between the two arms that exceeded 20 mm Hg.[85] Clearly, monitoring blood pressure in an arm that has yielded a lower NIBP measurement or has a weaker palpable pulse will likely lead to errors in measurement and perhaps management. Atherosclerosis or pathologic conditions such as arterial dissection, stenosis, or embolism may preclude accurate pressure monitoring from affected sites. In addition, unusual patient positions during surgery may produce regional arterial compression, whereas surgical retraction can compromise perfusion and monitoring to a more localized area.[86,87]

The nature of the operative procedure is important when choosing the appropriate site for arterial pressure monitoring. Procedures requiring placement of a descending thoracic aortic cross-clamp may interrupt arterial flow to the left subclavian artery, perfusion to the left arm, and all vessels distal to the clamp unless some form of bypass is used. In such cases, blood pressure monitored in the right arm provides the best estimate of aortic root and carotid arterial pressure. Femoral artery pressure may be monitored simultaneously to estimate perfusion pressure distal to the aortic cross-clamp.

Significant physiologic disturbances, such as sepsis or shock, may produce generalized arterial pressure gradients that can affect the choice of site for arterial pressure monitoring. In patients receiving vasopressor infusions for septic shock, the femoral arterial pressure was noted to exceed the radial pressure by more than 50 mm Hg.[88] Such gradients, albeit less severe, have been noted with anesthetics, neuraxial blocks, and changes in patient temperature.[31] During hypothermia, thermoregulatory vasoconstriction causes systolic pressure in the radial artery to exceed that in the femoral artery, whereas during rewarming, vasodilation reverses the gradient.[89]

Characteristic gradients between central and peripheral sites have been described in cardiac surgery patients undergoing cardiopulmonary bypass (Fig. 45-12) (see Chapter 67). The mean radial artery pressure decreases on initiation

of bypass and remains less than mean femoral artery pressure throughout the bypass period.[90] Notably, this pattern persists in the first few minutes following separation from bypass, often by more than 20 mm Hg.[91] In most patients, this gradient resolves within the first hour, but occasionally, it remains well into the postoperative period.

Abnormal Arterial Pressure Waveforms

Detailed examination of the morphologic features of individual arterial pressure waveforms can provide important diagnostic information (Table 45-1) (Fig. 45-13, *A* to *D*). Aortic stenosis produces a fixed obstruction to ejection resulting in reduced stroke volume and a slowed rate of ejection. As a result, the waveform is small in amplitude (pulsus parvus), and has a slowly rising systolic upstroke on the arterial pressure waveform and a delayed peak in systole (pulsus tardus) (see Fig. 45-13, *B*). A distinct shoulder, termed the anacrotic notch, often distorts the pressure upstroke and even the dicrotic notch may not be discernible. These features may make the arterial pressure waveform appear overdamped.

In aortic regurgitation, the arterial pressure wave displays a sharp increase, wide pulse pressure, and decreased diastolic pressure owing to the runoff of blood into both the left ventricle and the periphery during diastole. The arterial waveform may have two systolic peaks (bisferiens pulse), with the first peak resulting from antegrade ejection and the second from a reflected wave originating in the periphery (see Fig. 45-13, *C*). In hypertrophic cardiomyopathy, the arterial pressure waveform assumes a peculiar bifid shape termed a spike-and-dome configuration. After an initial sharp blood pressure increase resulting from rapid, early systolic ejection, arterial pressure plummets as left ventricular outflow obstruction in mid-systole impedes ejection. This is finally followed by a second, late-systolic increase associated with arrival of reflected waves from the periphery (see Fig. 45-13, *D*).

Observation of how arterial waveform patterns change over time is another source of useful information. Pulsus alternans is a pattern of alternating beats of larger and

TABLE 45-1 ARTERIAL BLOOD PRESSURE WAVEFORM ABNORMALITIES

Condition	Characteristics
Aortic stenosis	Pulsus parvus (narrow pulse pressure) Pulsus tardus (delayed upstroke)
Aortic regurgitation	Bisferiens pulse (double peak) Wide pulse pressure
Hypertrophic cardiomyopathy	Spike and dome (mid-systolic obstruction)
Systolic left ventricular failure	Pulsus alternans (alternating pulse pressure amplitude)
Cardiac tamponade	Pulsus paradoxus (exaggerated decrease in systolic blood pressure during spontaneous inspiration)

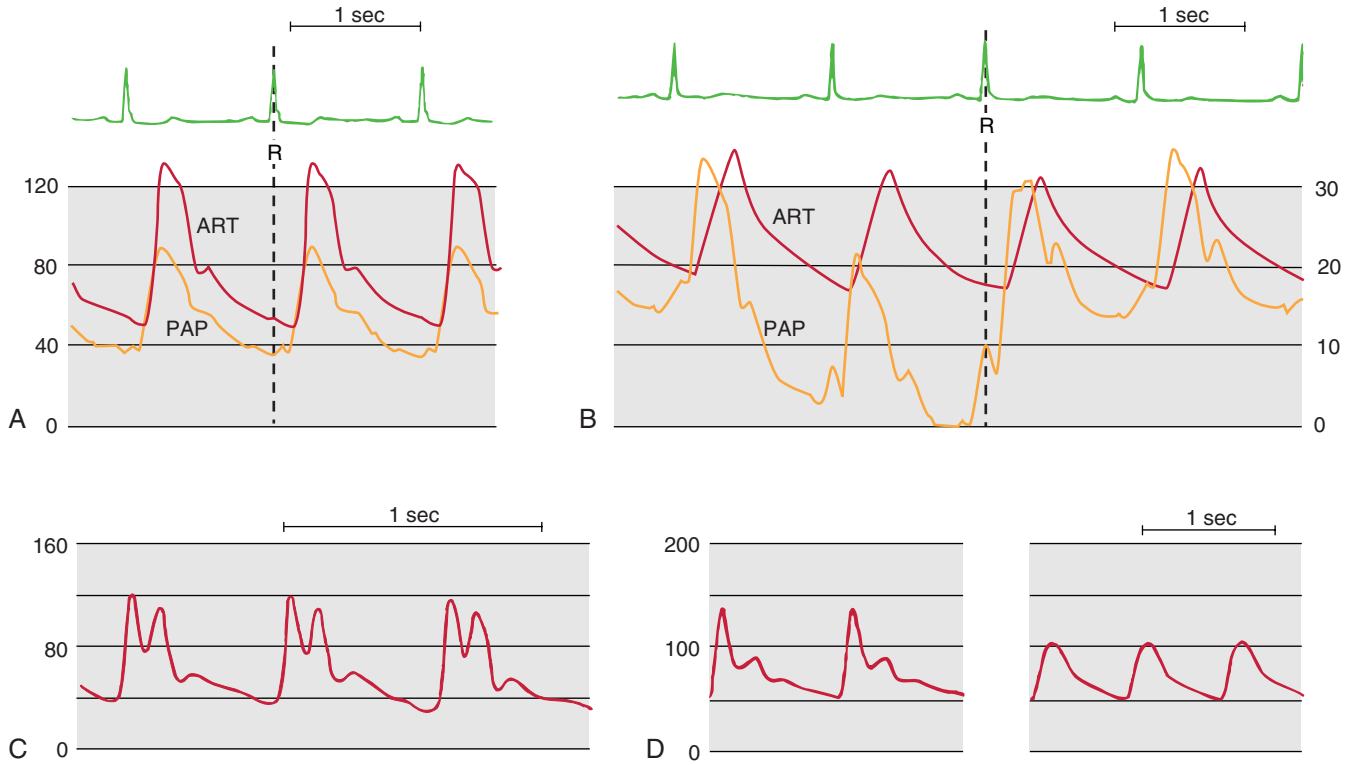

Figure 45-13. Influence of pathologic conditions on arterial pressure (ART) waveform morphology. **A,** Normal ART and pulmonary artery pressure (PAP) waveform morphologies demonstrating the similar timing of these waveforms relative to the electrocardiographic R wave. **B,** In aortic stenosis, the ART waveform is distorted with a slurred upstroke and delayed systolic peak. These changes are particularly striking in comparison with the normal PAP waveform. Note the beat-to-beat respiratory variation in the PAP waveform. For **A** and **B,** the ART scale is on the left and the PAP scale is on the right. **C,** Aortic regurgitation produces a bisferiens pulse and a wide pulse pressure. **D,** Arterial pressure waveform in hypertrophic cardiomyopathy shows a peculiar spike-and-dome configuration. The waveform assumes a more normal morphology following surgical correction of this condition. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

smaller pulse pressures that also vary with the respiratory cycle although its underlying mechanism remains poorly understood (Fig. 45-14, *A*). It may be a sign of severe left ventricular systolic dysfunction but can also be seen in patients with advanced aortic stenosis. Pulsus alternans should be distinguished from bigeminal rhythms, which are usually ventricular in origin. Although both appear as alternating pulse pressures in the arterial pressure waveform, pulsus alternans presents a regular rhythm.

Pulsus paradoxus is exaggerated variation in arterial pressure (<10 to 12 mm Hg) during quiet breathing[92,93] (Fig. 45-14, *B*). Pulsus paradoxus is not truly paradoxical, but rather an exaggeration of a normal variation in blood pressure that accompanies spontaneous ventilation. Pulsus paradoxus is highly characteristic, almost universal, in patients with cardiac tamponade but may also develop with pericardial constriction, severe airway obstruction, bronchospasm, dyspnea, or any condition that involves large swings in intrathoracic pressure. It is important to note, though, that in cases of cardiac tamponade, the pulse pressure and left ventricular stroke volume decrease during inspiration, in contrast to the arterial blood pressure changes observed in patients with forced breathing patterns and exaggerated changes in intrathoracic pressure in which pulse pressure remains constant.[94]

ARTERIAL PRESSURE MONITORING AND WAVEFORM ANALYSIS FOR PREDICTION OF INTRAVASCULAR VOLUME RESPONSIVENESSS

The starting point for hemodynamic resuscitation begins with optimizing cardiac preload, or more precisely, determining whether a specific patient has sufficient residual preload reserve. The limitations of static indicators of preload such as central venous pressure are well documented, as are the array of factors that confound their interpretation.[95] Newer dynamic markers of preload reserve and intravascular volume responsiveness have been studied for their ability to discriminate between those who would and those who would not benefit from volume expansion. Variations in arterial blood pressure observed during positive pressure ventilation, as well as a variety of derived indices, are the most widely studied of these dynamic indicators. Such changes in blood pressure may be visible on the bedside monitor in patients who are receiving direct arterial blood pressure monitoring, and they result from changes in intrathoracic pressure and lung volume that occur during the respiratory cycle.

During positive pressure ventilation, increases in lung volume compress lung tissue and displace blood contained within the pulmonary venous reservoir into the left heart chambers, thereby increasing left ventricular preload. Simultaneously, the increase in intrathoracic pressure reduces left ventricular afterload. The increase in left ventricular preload and decrease in afterload produce an increase in left ventricular stroke volume, an increase in cardiac output, and in the absence of changes in peripheral resistance, an increase in systemic arterial pressure. In most patients the preload effects are more prominent, but in patients with severe left ventricular systolic failure, the reduction in afterload plays an important role in increasing ventricular ejection. Simultaneously with increasing left heart filling during early inspiration, rising intrathoracic pressure causes a decrease in systemic venous return and right ventricular preload. The increased lung volume

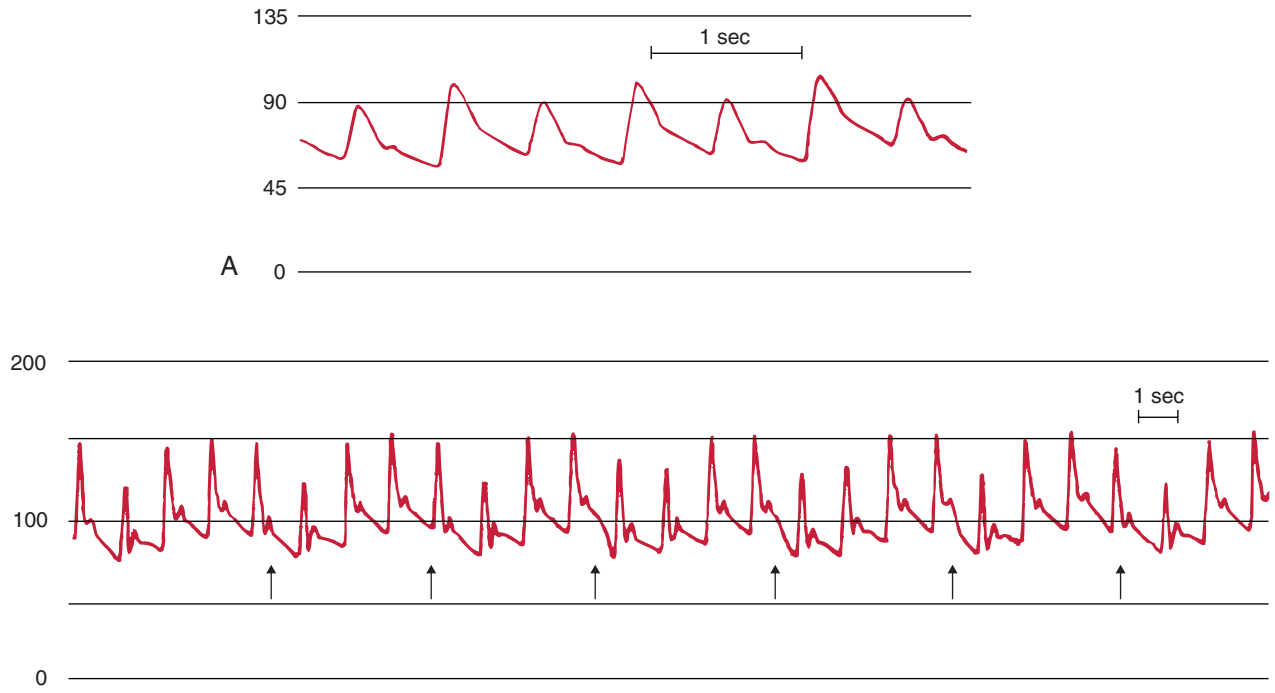

Figure 45-14. Beat-to-beat variability in arterial pressure waveform morphologies. **A,** Pulsus alternans. **B,** Pulsus paradoxus. The marked decline in both systolic blood pressure and pulse pressure during spontaneous inspiration (*arrows*) is characteristic of cardiac tamponade. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

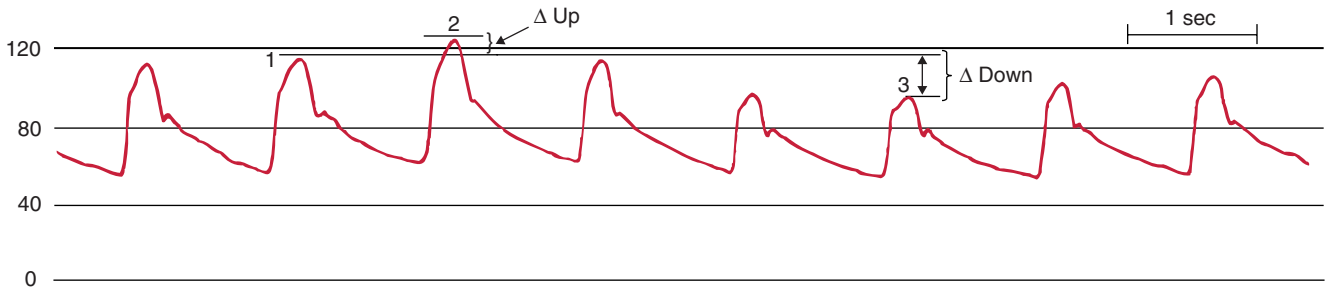

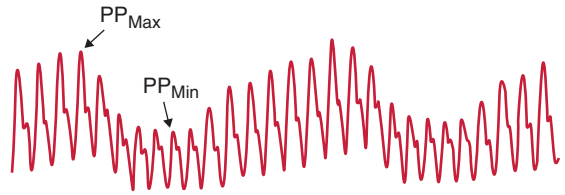

Figure 45-15. Systolic pressure variation. Compared with systolic blood pressure recorded at end expiration (*1*) a small increase occurs during positive-pressure inspiration (*2*, Δ Up) followed by a decrease (*3*, Δ Down). Normally, systolic pressure variation does not exceed 10 mm Hg. In this instance, the large Δ Down indicates hypovolemia even though systolic arterial pressure and heart rate are relatively normal. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

may also increase pulmonary vascular resistance slightly and thereby increase right ventricular afterload. These effects combine to reduce right ventricular ejection during early inspiration. During early expiration, the situation is reversed. The smaller amount of blood ejected from the right ventricle during inspiration traverses the pulmonary vascular bed and enters the left heart, resulting in reduced left ventricular filling. Left ventricular stroke volume falls, and systemic arterial blood pressure decreases. This cyclic variation in systemic arterial pressure is known as the systolic pressure variation (SPV).

SPV is often subdivided into inspiratory and expiratory components by measuring the increase (Δ Up) and decrease (Δ Down) in systolic pressure relative to the end-expiratory, apneic baseline pressure (Fig. 45-15). In a mechanically ventilated patient, normal SPV is 7 to 10 mm Hg, with Δ Up being 2 to 4 mm Hg and Δ Down being 5 to 6 mm Hg.[96] This observation has been used clinically in attempts to identify hypovolemic patients.[97] Both in experimental animals and critically ill patients, hypovolemia causes a dramatic increase in SPV, particularly the Δ Down component. However, it may be more accurate to describe the patients identified by increased SPV as having residual preload reserve. Although not identical to hypovolemia, preload reserve describes a physiologic state in which intravascular volume expansion or fluid challenge shifts the patient upward on the Frank-Starling curve, resulting in increased stroke volume, and increased cardiac output as long as systemic vascular resistance remains unchanged.

In a heterogeneous group of intensive care patients, Marik demonstrated that a large SPV (>15 mm Hg) was highly predictive of a low pulmonary artery wedge pressure (PAWP) (<10 mm Hg).[98] Using echocardiography to measure the left ventricular cross-sectional area as a surrogate for preload, Coriat and colleagues found Δ Down to be a better predictor of preload than wedge pressure.[99] Using receiver-operator curve analysis, Tavernier and coworkers showed that compared with PAWP or left ventricular end-diastolic area, Δ Down was a far better indicator of volume responsiveness.[100]

Another dynamic marker of preload reserve is pulse pressure variation (PPV). Many automated devices are now available that provide real-time PPV, and although calculated according to slightly different and proprietary algorithms, PPV should not exceed 13% to 17%[101-105]

Note: The arterial blood pressure tracing is not drawn to scale

PP_{Max} =150–70=80
PP_{Min} =120–60=60
PPV =(PP_{Max}–PP_{Min})/([PP_{Max}+PP_{Min}]/2)
PPV =80–60/([80+60]/2)=29%

Figure 45-16. Pulse pressure variation. Pulse pressure variation (PPV) is calculated as the difference between maximal (PP_{Max}) and minimal (PP_{Min}) pulse pressure values during a single mechanical respiratory cycle, divided by the average of these two values. (Note that the arterial blood pressure trace is drawn for illustrative purposes and not to scale.)

(Fig. 45-16). In addition to SPV and PPV, more sophisticated pulse contour methods for measurement of cardiac output (see later) allow online measurement of variations in stroke volume variation (SVV). As with other dynamic indicators of preload reserve, normal SVV is approximately 10% to 13%, whereas greater variability predicts a positive response to volume expansion.[104,106] Although SVV may be theoretically superior to PPV, clinical studies have not borne this out.[104]

Devices based on respiratory cycle–induced variation in the pulse plethysmogram have been developed as a less invasive but similar alternative. Measures such as photoplethysmography variation (ΔPOP) or the plethysmography variability index (PVI) appear to be useful when conditions are good, but this particular physiologic signal is even more subject to confounding influences than arterial blood pressure waveform.[103,107,108] Both numeric pulse oximetry and the photoplethysmography waveform are sensitive to sympathetic variations in regional circulation, especially in the skin and extremities in critically ill patients. Tidal volume, core and peripheral temperature, ambient light, and cardiac dysrhythmias pose significant impediments to valid and reproducible data collection and interpretation. There is no consensus regarding meaningful threshold values, and validity seems especially poor in children, under conditions of

mechanical ventilation in a sedated but not paralyzed patient, and in the setting of an open abdomen.[108] Furthermore, there are sophisticated autogaining features incorporated in most commercially available monitoring systems to optimize signal display. As such, the degree of variation visible to the naked eye may not correlate with true signal variation, resulting in erroneous clinical decisions.

Dynamic measures are significantly superior to static indices of intravascular volume and are more valuable for making informed clinical decisions, especially in critically ill patients. Both PVV and SVV are accurate following cardiac surgery (also see Chapter 67) in patients with normal and reduced ventricular function, whereas PPV was proved accurate in assessing intravascular fluid responsiveness in patients with septic shock.[109,110] Intraoperative use has also been examined with similar results.[111,112] Indeed, the ability of clinicians to "eyeball" respiratory variation in the arterial blood pressure waveform as displayed on the monitor seems reasonably accurate. Subjective estimates of such pressure variation were incorrect only 4.4% of the time, a rate that would have resulted in only 1% of treatments being erroneous.[105]

Newer automated monitors have obviated the need to interrupt mechanical ventilation and establish an apneic baseline in order to differentiate Δ Up from Δ Down and are able to continuously display PPV or SVV.[96,113,114] However, the automated nature of these monitors makes it important to recognize clinical conditions under which their use was validated. The magnitude of arterial blood pressure variation observed is influenced by positive-pressure ventilation variables, and most patients are no longer routinely ventilated in a manner similar to that in the supporting clinical studies. In general, mechanical ventilation with tidal volumes of 8 to 10 mL/kg, positive end-expiratory pressure of 5 mm Hg or greater, regular cardiac rhythm, normal intraabdominal pressure, and a closed chest are necessary to duplicate the experimental conditions. Also, effects of changes in patient position such as steep Trendelenberg or the lateral position are not clear.[104] In addition, patients with pulmonary hypertension or reduced right ventricular ejection fraction may not have reliable responses to changes in intrathoracic pressure, resulting in overhydration and worsening right heart failure.[115] Increased respiratory rates, especially when coupled with respiratory failure or significant bradycardia, may disrupt the relationship between respiratory cycle–induced changes in intrathoracic pressure and cardiac chamber volume, thus invalidating the theoretic basis for blood pressure variation analysis completely in these patients.[104]

As noted earlier, respiratory cycle–induced arterial pressure variations are not solely related to changes in left ventricular preload, but also depend in part on changes in afterload. Indeed, decreased arterial compliance and increased baseline pulse pressure seen with both normal and pathologic vascular aging results in an exaggerated PPV response to changes in stroke volume due to any stimulus. As such, PPV thresholds should be higher in such patients than in those with more elastance in their vascular tree.[116,117]

There is disagreement on precise threshold values that differentiate responders from nonresponders, and the variety of techniques, devices, and approaches have not been standardized.[103] In a recent systematic review, mean discriminatory thresholds for PVV and SVV were found to be 12.5% ± 1.6% and 11.6% ± 1.9%, respectively, with acceptable sensitivities and specificities (89%, 88% and 82%, 86%, respectively).[118] However, simply differentiating patients into responders and nonresponders does not take into account the nature of the clinical intervention at issue. Intravascular volume expansion does not result in a dichotomous outcome; it does not yield a simple positive or negative result with an equivalent range of values on each side. The asymmetric nature of the Frank-Starling curve dictates that the cost-benefit ratio of acting in one direction will be different from acting in the other. Any particular change in preload will result in a different change in stroke volume in one direction than in the other, with the differential change being dependent on how close to the peak of the curve the patient begins. Consequently, the concept of the "gray zone" has been proposed, in which two cutoffs are identified, two values between which evidence-based decision making is not possible.[119] For PPV, this zone has been described as 9% to 13%, such that those below 9% should receive intravascular volume expansion, whereas those above 13% should not. For those between the two values, the measurement is not able to provide meaningful information and the decision should be made on other criteria.[104,120]

CENTRAL VENOUS PRESSURE MONITORING

Cannulation of a central vein and direct measurement of central venous pressure (CVP) are frequently performed in hemodynamically unstable patients and those undergoing major operations. A central venous catheter may be inserted to provide secure vascular access for many reasons, including administration of vasoactive drugs or fluids, CVP monitoring, transvenous cardiac pacing, temporary hemodialysis, pulmonary artery catheterization, or aspiration of entrained air. A central venous catheter may also be inserted when no peripheral access can be obtained or when repeated blood sampling is required (Box 45-4).

CENTRAL VENOUS CANNULATION

When intraoperative cannulation is required, the decision to perform central venous cannulation before or after induction of anesthesia is guided most often by individual patient and physician preferences or institutional practice. Preoperative central venous cannulation should be terminated in any patient who becomes overly sedated or uncooperative during the procedure. The need for central venous cannulation can be reevaluated after induction of anesthesia and intubation of the trachea.

Choosing the Catheter, Site, and Method for Central Venous Cannulation

Choosing the Catheter. Central venous catheters come in a variety of lengths, diameter, composition, and lumen

BOX 45-4 ***Indications for Central Venous Cannulation***

Central venous pressure monitoring
Pulmonary artery catheterization and monitoring
Transvenous cardiac pacing
Temporary hemodialysis
Drug administration
- Concentrated vasoactive drugs
- Hyperalimentation
- Chemotherapy
- Agents irritating to peripheral veins
- Prolonged antibiotic therapy (e.g., endocarditis)

Rapid infusion of fluids (via large cannulas)
- Trauma
- Major surgery

Aspiration of air emboli
Inadequate peripheral intravenous access
Sampling site for repeated blood testing

configuration.[121,122] Different catheters are chosen according to the purpose of catheterization, whether for CVP monitoring or other therapeutic indication, and whether intended for short- or long-term use. The most commonly used catheter is a 7-Fr, 20-cm multiport catheter that allows simultaneous CVP monitoring and infusion of drugs and fluids.[123] Rapid intravascular fluid resuscitation is most efficient with short, large-bore, peripheral intravenous catheters, because central venous catheters are longer and have narrower individual lumina, significantly increasing resistance to flow. For example, according to the manufacturer's product specifications, the maximal flow rate of the 16-gauge lumen of a standard 7-Fr 20-cm central venous catheter is one quarter that of a 16-gauge, 3-cm intravenous catheter.

A popular alternative method for multilumen central venous access uses a large introducer sheath with one or two integrated ports for multiple drug infusions, combined with a single-lumen catheter inserted through the hemostasis valve for continuous CVP monitoring. Although use of these larger introducer sheaths is not free from complications, they do allow rapid placement of a pacing wire or pulmonary artery catheter should the need arise.

Choosing the Insertion Site. Selecting the best site for central venous cannulation requires consideration of the indication for catheterization (pressure monitoring versus drug or fluid administration), the patient's underlying medical condition, the clinical setting, and the skill and experience of the clinician performing the procedure. In patients with severe bleeding diatheses, a puncture site should be selected where bleeding from the vein or adjacent artery is easily detected and controlled with local compression. In such a patient, an internal or external jugular approach would be preferable to a subclavian site. Likewise, patients with severe emphysema or others who would be severely compromised by a pneumothorax would be better candidates for internal jugular than subclavian cannulation, owing to the more frequent pneumothorax risk with the latter approach. If transvenous cardiac pacing is required in an emergency situation, catheterization of the right internal jugular vein is recommended, because it provides the most direct route to the right ventricle. Trauma patients, with their necks immobilized in a hard cervical collar, are best resuscitated using a femoral or subclavian catheter; the latter may be placed even more safely if the risk of pneumothorax is obviated by prior placement of a thoracostomy tube. The physician must recognize that the length of catheter inserted to position the catheter tip properly in the superior vena cava will vary according to puncture site, being slightly (3 to 5 cm) greater when the left internal or external jugular veins are chosen, compared with the right internal jugular vein.[124] Finally, a physician's personal experience undoubtedly plays a significant role in determining the safest site for central venous cannulation, particularly when the procedure is performed under urgent or emergent circumstances.

Since its introduction into clinical practice in the late 1960s, percutaneous puncture of the right internal jugular vein has been the method preferred by anesthesiologists for central venous cannulation.[125-127] Reasons for this preference include the consistent, predictable anatomic location of the internal jugular vein, readily identifiable and palpable surface landmarks, and a short straight course to the superior vena cava. An internal jugular vein catheter is highly accessible during most surgical procedures and has a high rate of successful placement (90% to 99%).[126,128]

Left internal jugular vein cannulation may be accomplished reliably and safely, although several anatomic details make the left side less attractive than the right. The cupola of the pleura is higher on the left, theoretically increasing the risk of pneumothorax. The thoracic duct may be injured during the procedure as it enters the venous system at the junction of the left internal jugular and subclavian veins.[129] The left internal jugular vein is often smaller than the right and demonstrates a greater degree of overlap of the adjacent carotid artery.[130] Most important, any catheter inserted from the left side of the patient must traverse the innominate (left brachiocephalic) vein and enter the superior vena cava perpendicularly. As a result, the catheter tip may impinge on the right lateral wall of the superior vena cava, increasing the risk of vascular injury. This anatomic disadvantage pertains to all left-sided catheterization sites and highlights the need for radiographic confirmation of proper catheter tip location. Finally, most operators have less experience performing left internal jugular vein cannulation, which leads to more adverse events and morbidity.[131,132]

The subclavian vein is an important site for central venous cannulation and is particularly popular among surgeons and other physicians who place central venous catheters for emergency volume resuscitation and long-term intravenous therapy or dialysis, rather than for shorter-term monitoring purposes.[133,134] Advantages of subclavian venous cannulation include a less frequent risk of infection compared with femoral sites, ease of insertion in trauma patients who may be immobilized in a cervical collar, and increased patient comfort, especially for long-term intravenous therapy, such as hyperalimentation and chemotherapy.[135,136]

Both the right and left external jugular veins provide safe, albeit somewhat technically challenging, alternatives to internal jugular or subclavian vein cannulation. Because the external jugular veins are superficial, they allow central venous cannulation with essentially no risk of pneumothorax or unintended arterial puncture. In most instances, it is best to use an 18-gauge catheter rather than the thin-wall needle to introduce the guidewire (i.e., the *modified* Seldinger, as opposed to the Seldinger technique), because of the tortuous course of the external jugular vein and the frequent need to manipulate the guidewire repeatedly to guide it into the superior vena cava. A J-tip guidewire should always be used, because it may be advanced under the clavicle and into the central circulation more successfully than a straight-tip wire.[137,138] When the guidewire does not advance as desired and appears to be moving peripherally into the subclavian vein, abducting the ipsilateral shoulder beyond 90 degrees before advancing the wire may facilitate central venous passage. Alternatively, the patient's ipsilateral arm is placed at the side, and an assistant applies mild caudad traction on the shoulder to straighten the course of the external jugular vein while the wire is advanced. Essentially, the only factors that preclude use of the external jugular veins for CVP monitoring are an inability to visualize and cannulate the vessel in the neck and to advance a catheter into the central circulation. Advancing catheters and stiff dilators into the external jugular vein requires extreme caution. The catheter needs to travel around the sharp angle in the vein as it enters the subclavian vein. This may be the site for venous injury if undue force is used during insertion of the catheter. Not surprisingly, approximately 20% of the problems occur in attempted external jugular central venous catheterizations, thus limiting more widespread application of this technique.[139,140]

Femoral vein cannulation is useful when the more common jugular and subclavian sites are not accessible, as is commonly the case in patients with burns, with trauma, during surgical procedures that involve the head, neck, and upper thorax, or during cardiopulmonary resuscitation (also see Chapters 85, 66, and 108). Use of the femoral vein obviates many of the common complications of central venous catheterization, particularly pneumothorax, but it also carries the risk of injury to the femoral artery and, more rarely, the femoral nerve. Femoral venipuncture using the landmark technique is performed below the inguinal ligament just medial to the palpated femoral arterial pulse. Central venous pressure measurements may be made using longer (40 to 70 cm) catheters that reside in the inferior vena or with shorter (15 to 20 cm) catheters that terminate in the common iliac vein. Both provide CVP measurements that correlate with right atrial pressure, although the shorter more distally located catheters appear to provide wider variations in CVP values.[141,142] This holds true in both mechanically and spontaneously ventilated patients.[142,143] Disadvantages of the femoral venous route include increased risk of thromboembolic complications, as well as vascular injury that may lead to intraabdominal or retroperitoneal hemorrhage.[144] In addition, patients with femoral vascular catheters are generally unable to ambulate, which can delay and complicate postoperative recovery.

In patients with extensive, severe burn injuries, the axillary region is often spared and provides a useful site for either arterial or venous pressure monitoring.[145] Standard 20-cm CVP catheters placed in the axillary vein, approximately 1 cm medial to the palpated axillary artery, allow pressure measurement from the superior vena cava. Even more distal pressures measured from peripheral veins in the hand and forearm may provide a reasonably accurate estimate of CVP in selected surgical patients.[146] Modified volumetric infusion pumps can even measure in-line peripheral venous pressures without the need for additional transducers and monitoring equipment.[147] Although this method of measuring CVP incurs no risk beyond that associated with placing any standard peripheral intravenous catheter, it has not been validated widely and cannot replace central venous cannulation in most circumstances.

Peripherally inserted central venous catheters (PICC) have become a popular alternative to centrally inserted catheters in patients requiring long-term intravenous therapy. Advantages of the PICC include bedside placement under local anesthesia, extremely low risk of major insertion-related complications, and safe placement by non-physicians (i.e., registered nurses and physician assistants). This technique may be particularly cost-effective, because it eliminates the need for a minor operative procedure in those patients who require a Hickman or Broviac central venous catheter.[148] Venous access for a PICC is obtained through an antecubital vein, preferably the basilic vein, which is generally more successfully catheterized than the cephalic vein due to its more linear course. Early reports described only modest success with positioning PICCs in an appropriate central location as well as a considerable risk of venous thrombosis, but improvements in catheter design and insertion technique now result in successful placement with few complications in most patients.[148-150] Most PICCs are inserted for long-term therapeutic indications (chemotherapy or parenteral nutrition), using very flexible, nonthrombogenic silicone catheters. Less commonly, a standard polyurethane 40-cm intravenous catheter is inserted peripherally and advanced to a central location for short-term infusion of vasoactive drugs or monitoring CVP or PAP. Central venous pressure recorded via PICCs is slightly higher than the pressure measured using centrally inserted catheters, but this difference is clinically insignificant.[151] When these standard long venous catheters are inserted from an antecubital vein, the catheter tip may advance into the heart as the arm is abducted, thereby increasing the risk of cardiac perforation or arrhythmias.[152,153] Whenever a PICC line is in place, the clinician should cautiously place any additional central venous catheters because of the risk of shearing the PICC line within the central venous circulation.

Choosing the Central Venous Cannulation Method. A central vein may be cannulated using either a landmark technique or ultrasound guidance. Ultrasound technology is rapidly gaining acceptance, and numerous specialty groups and governmental agencies have issued practice recommendations for its use during central line placement.[154-156] See other sources for detailed descriptions

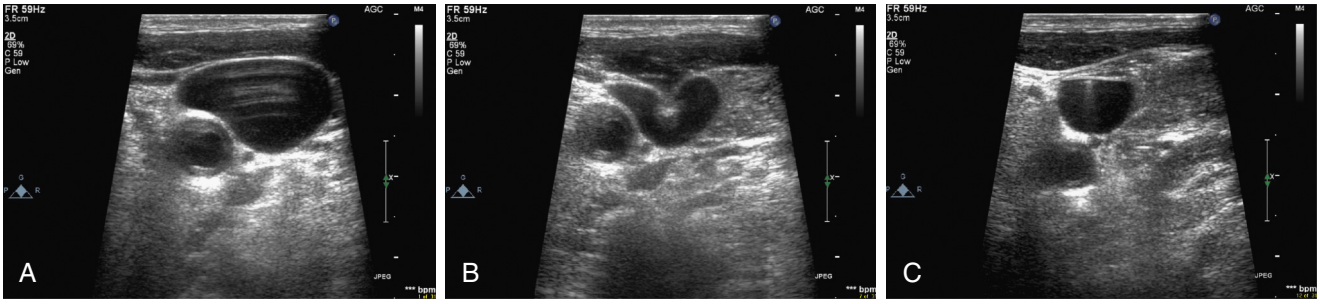

Figure 45-17. A, Transverse plane ultrasound image showing the right internal jugular vein and its typical anatomic position anterior and lateral to the right common carotid artery. **B,** Needle entering the right internal jugular vein. It is essential that the operator directly visualize the needle entering the vessel lumen, as shown here, to avoid inadvertent puncture of the posterior wall of the vein. **C,** The wire is seen as an echodense structure within the vessel lumen. Confirmation of the location of the wire should always precede the use of the vessel dilator.

and tutorials on the various insertion techniques for different access sites using surface landmarks.[123,157]

Regardless of the insertion technique used or the cannulation site chosen, certain general principles should be emphasized for all central line placements. Ideally, a protocol or checklist describing the basic procedural steps for central line insertion should be in place at every institution, and all staff members should feel empowered to speak up when they witness a protocol violation. Standardized equipment, routine use of an assistant, hand washing and maximal barrier precautions all contribute to the sterility of the procedure.[154] The use of real-time ultrasound guidance for vessel localization and venipuncture should be strongly considered, especially when the internal jugular vein site is selected. Pressure manometry or waveform measurement should be used to confirm venous placement of the catheter before use. Finally, the position of the catheter tip should be verified as soon as clinically appropriate to avoid delayed complications (see later).

Ultrasound-Guided Central Venous Cannulation

First described in 1984, ultrasound-guided central venous catheter placement has proved beneficial in most settings, including the intensive care unit and the operating room[156,158] (also see Chapter 58). Fewer needle passes are required for successful venous cannulation when real-time two-dimensional ultrasound guidance is used. In addition, ultrasound guidance reduces the time required for catheterization, increases overall success rates, and results in fewer immediate complications.[159,160] The benefits of ultrasound-guided catheterization are clear for internal jugular vein catheters, when inexperienced operators perform the procedure, and for adult rather than pediatric patients. Based on this evidence, the Agency for Healthcare Research and Quality has listed the use of real-time ultrasound guidance for central venous catheterization as one of 11 practices to improve health care.[155] It is unknown whether the additional equipment and manipulation associated with real-time ultrasound guidance may increase the rate of catheter-related infections or whether the increased dependence on this technology by trainees will prove detrimental in those clinical settings.

As an alternative to real-time ultrasound-guided catheterization, ultrasound can be used to confirm vessel location and patency, provide a clear target to mark the skin, and then allow venipuncture to proceed in the usual fashion.[154,161]

Real-time, two-dimensional ultrasound guidance for internal jugular vein cannulation requires a 7.5- to 10-MHz transducer. A rapid ultrasound scan should be performed once the patient is placed in the Trendelenburg position and before the skin is cleansed to identify the target vein location, confirm its patency, and rule out anatomic abnormalities. This simple step is aimed at avoiding futile insertion attempts when the patient has a thrombosed, narrowed, or anomalous central vein.

Once the site is prepped and draped, the operator holds the ultrasound probe protected by a sterile sheath with the nondominant hand to obtain a view of the target vessel. The vein and artery appear as two circular black structures on the ultrasound image. The vein is identified by anatomic location and by its compressibility. The artery appears mildly pulsatile, is generally smaller, and has a thicker wall (Fig. 45-17, *A*). When using ultrasound guidance, either the transverse (short axis) or longitudinal (long axis) view is adequate. In general, the transverse view is easier to learn and allows simultaneous identification of the artery and vein, whereas the longitudinal view allows visualization of the needle tip at all times, which may reduce perforation of the posterior wall of the vein.[162] After positioning the vein in the center of the ultrasound screen, the vessel is punctured under direct vision using an 18-gauge needle (see Fig. 45-17, *B*) and then proceeds as a standard Seldinger (wire through needle) or modified Seldinger (wire through catheter) technique. An additional recommended safety stop is to confirm intravenous location of the guidewire before proceeding with vessel dilation (see Fig. 45-17, *C*).

Ultrasound imaging of the subclavian vessels is more difficult and often hampered by the patient's body habitus and ultrasound probe size and shape. When using ultrasound to guide subclavian vein cannulation, the transducer is placed in the infraclavicular groove at the level of the middle or lateral third of the clavicle and the axillary vein and artery are imaged as they exit the bony canal formed by the clavicle and the first rib.[163] The artery is usually identified by its location cephalad to the vein, its noncompressibility, and its not varying size with respirations. Either a transverse or longitudinal view can be obtained and used to guide needle insertion.[164] Another

approach has been described for children in whom the probe is placed in the supraclavicular space to obtain a longitudinal view of the subclavian vein while cannulation is performed via the usual infraclavicular route[165] (also see Chapter 93).

Confirming Catheter Position

Central venous catheters placed in the operating room are commonly used for the duration of the surgical procedure without radiologic confirmation of the location of the catheter tip. Before monitoring or infusion commences, aspiration of blood should confirm intravenous location of each lumen of a multilumen catheter and remove any residual air from the catheter-tubing system. Following surgery, however, the position of the catheter tip must be confirmed radiographically. Catheter tips located within the heart or below the pericardial reflection of the superior vena cava increase the risk of cardiac perforation and fatal cardiac tamponade. Ideally, the catheter tip should lie within the superior vena cava, parallel to the vessel walls, and be positioned *below* the inferior border of the clavicles and *above* the level of the third rib, the T4 to T5 interspace, the azygos vein, the tracheal carina, or the takeoff of the right mainstem bronchus.[166,167] Using fresh human cadavers, Albrecht and colleagues confirmed that the tracheal carina was always more cephalad than the pericardial reflection on the superior vena cava, suggesting that a central venous catheter tip should always be located superior to this radiographic landmark.[168]

COMPLICATIONS OF CENTRAL VENOUS PRESSURE MONITORING

Complications of central venous cannulation are becoming increasingly recognized as major sources of morbidity, with more than 15% of patients experiencing some sort of related adverse event.[144] Although serious immediate complications are infrequent when these procedures are performed by well-trained, experienced clinicians, infectious complications are common, and use of central venous catheters continues to result in significant morbidity and mortality. Complications are often divided into mechanical, thromboembolic, and infectious etiologies (Box 45-5).

Mechanical Complications of Central Venous Catheterization

The incidence of complications depends on a number of factors, including the catheter insertion site and the patient's medical condition. Large retrospective and observational studies provide the best estimates of incidence for these types of complications.

Vascular injuries from central venous catheterization have a range of clinical consequences. The most common minor complications are localized hematoma or injury to the venous valves.[169] More serious complications include perforation into the pleural space or mediastinum, resulting in hydrothorax, hemothorax, hydromediastinum, hemomediastinum, and/or chylothorax.[129,170-173]

In general, unintended arterial puncture is the most common acute mechanical complication, with incidence ranging from 1.9% to 15%.[174] Many of these injuries result in localized hematoma formation, but in rare occasions even small-gauge needle punctures may lead to serious complications such as arterial thromboembolism.[175] If arterial puncture with a small needle occurs during central venous cannulation, the needle should be removed and external pressure applied for several minutes to prevent hematoma formation. When unintentional carotid artery cannulation with a dilator or large-bore catheter occurs, the dilator or catheter should be left in place and a vascular surgeon consulted promptly regarding removal. Immediate removal of the catheter has resulted in severe complications such as hemothorax, arteriovenous fistula, pseudoaneurysm, and cerebral infarction.[176,177] Open or endovascular repair followed by careful neurologic monitoring (and hence postponement of any elective surgical procedure) is usually required.[176]

Other catastrophic but rare vascular injuries have been reported, including aortic perforation and avulsion of the facial vein.[178,179] Delayed vascular complications following central venous catheterization are uncommon but should be considered as consequences of this procedure. A number of these have been described in the literature, including aortoatrial fistula, venobronchial fistula, carotid artery–internal jugular vein fistula, and pseudoaneurysm formation.[180-183]

The most important life-threatening vascular complication of central venous catheterization is cardiac tamponade resulting from perforation of the intrapericardial superior vena cava, right atrium, or right ventricle. These vascular injuries may cause hemopericardium or unintentional pericardial instillation of intravenous fluid leading to cardiac compression.[184] This injury was the second-most common complication related to central catheters reported in the American Society of Anesthesiologists Closed Claims Project in 2004.[185] Cardiac tamponade resulted in death in 81% of the cases in this report, and

- Misinterpretation of data
- Misuse of equipment

often had a delayed presentation (1 to 5 days), indicating that this complication is related to catheter maintenance and use more often than to the vascular access procedure itself. Most reports document the avoidable nature of this catastrophic event and highlight that patients are predisposed to this complication when central venous catheter tips are malpositioned within the heart chambers or abutting the wall of the superior vena cava at a steep angle. This latter position can be recognized radiographically as a gentle curvature of the catheter tip within the superior vena cava.[186] These observations emphasize that objective confirmation of proper catheter tip location is mandatory, regardless of whether the catheter is inserted from a central or peripheral site. In fact, many early reports of catheter-related cardiovascular perforation suggested that peripheral catheters may present an unusually high risk for this complication because arm abduction may cause the catheter tip to advance into a dangerous location within the heart.[152,187] When cardiac tamponade is caused by catheter-induced cardiac perforation, symptoms develop suddenly, requiring a high index of suspicion if severe hypotension occurs in any patient with a central venous catheter in place. Cardiac arrhythmias may provide an early clue to the intracardiac location of the catheter tip.[153] Occasionally, both posteroanterior and lateral chest radiographs, as well as injection of radiopaque contrast, are required to locate the catheter tip precisely.[188]

Pneumothorax is the most common complication of subclavian vein cannulation, although unintended arterial puncture may actually be more frequent.[66,189] Mansfield and associates reported 821 patients who underwent attempted subclavian venous cannulation, with a 1.5% incidence of pneumothorax and a 3.7% incidence of arterial puncture when using the landmark technique.[189] Pneumothorax is even less frequent with the internal jugular approach. Shah and colleagues reported an incidence of pneumothorax of 0.5% in their series of nearly 6000 internal jugular catheterizations.[174] This is most likely a larger-than-expected estimate, because these patients had undergone sternotomy for cardiac surgery, a procedure that may have been responsible for the pneumothorax in many cases. Small pneumothoraces may be managed conservatively, whereas tube thoracostomy is the best treatment for larger air collections or for patients receiving positive-pressure mechanical ventilation or scheduled for major surgery. The physician must always be prepared for the possibility of tension pneumothorax and its adverse hemodynamic sequelae. In addition to pneumothorax, other respiratory tract injuries occur following central venous catheterization, including subcutaneous and mediastinal emphysema, tracheal perforation, and rupture of an endotracheal tube cuff.[190]

Nerve injury is another potential complication of central venous cannulation. Damage may occur to the brachial plexus, stellate ganglion, phrenic nerve, or vocal cords.[191,192] In addition, chronic pain syndromes have been attributed to this procedure.[193]

Thromboembolic Complications of Central Venous Catheterization

Catheter-related thrombosis varies according to the site of central venous catheterization, occurring in as many as 21.5% of patients with femoral venous catheters and 1.9% of those with subclavian venous catheters.[135] Catheters that are positioned low in the right atrium may be more prone to thrombus formation, possibly due to mechanical irritation of the right atrial endocardium by the catheter.[194] Thrombi that form at the catheter tip or adhere to the endocardium have the potential to become a nidus for infection, cause superior vena cava syndrome, or embolize into the pulmonary circulation.[195-197] Occasionally, surgical removal is required.[198]

In addition to thromboembolism, other reported embolic complications of central venous catheterization include embolism of portions of the catheter or guidewire, and air embolism.[199,200] Almost invariably, these are the result of equipment misuse, highlighting the need for proper education and training of nurses and physicians responsible for the use of these devices.

Infectious Complications of Central Venous Catheterization

By far, the most common major late complication of central venous cannulation is infection. Central line–associated bloodstream infections (CLABSI) have decreased in incidence, likely because of a focus on evidence-based best practices for catheter insertion and maintenance. Despite this, in 2009, CLABSI still represented 14% of all health care–related infections in the United States.[201] Although most of these cases occurred in non-ICU patients (inpatient wards and outpatients receiving hemodialysis), many were diagnosed in ICU patients[201-203] (also see Chapters 101 and 102).

As previously noted, the starting point for prevention of infection is meticulous attention to aseptic technique.[204] A recent review showed, in addition to a declining CLABSI rate, equal rates of infection for internal jugular, femoral, and subclavian insertion sites.[205] Multilumen catheters may create a more frequent risk of infection than single-lumen catheters, although the added clinical functionality of such catheters often mandates their use.[136,144] Catheters are made from a wide variety of materials, including silicone, polyvinyl chloride, Teflon, and polyurethane. Furthermore, catheters of the same material may be manufactured differently, which influences their surfaces and the frequency of bacterial adherence to the surface.[206] Heparin-bonded central venous catheters have been shown to reduce the incidence of catheter-related thrombosis and infection in children and adults.[207,208] The incorporation of antimicrobial treatments such as silver (this metal has broad antimicrobial activity and is nontoxic), combinations of the antiseptics chlorhexidine and silver sulfadiazine, or the antibiotics monocycline and rifampin onto the catheter surfaces reduces rates of catheter colonization and in some cases bloodstream infection.[208-210] The added expense has prevented more widespread adoption of these catheters, although an analysis has suggested their cost-effectiveness in settings in which the rate of catheter-related infections remains frequent, such as immunocompromised patients (more than 3.3/1000 catheter days).[211]

A chlorhexidine gluconate–impregnated sponge dressing reduces catheter colonization in infants and children, but it does not reduce the rate of catheter-associated

bloodstream infections[212,213] (also see Chapter 93). Current guidelines from the Centers for Disease Control and Prevention (CDC) do not support routine catheter site changes or scheduled changes over a guidewire. CDC guidelines provide other detailed recommendations for catheter management to reduce the risk of infectious complications.[136]

Other Complications of Central Venous Catheterization

Miscellaneous other adverse sequelae of central venous cannulation have been reported, and although their incidence is not clearly known, most appear to be uncommon (see Box 45-5). All physicians performing these procedures should be familiar with them, particularly since many of these complications are related to operator error.[66,214]

Use of guidewires, vessel dilators, and large-bore catheters carries certain additional risks that mandate meticulous attention to technique. The proximal tip of the guidewire must remain under the physician's control at all times to avoid inserting the wire too far into the heart, thus causing arrhythmias, or potentially losing the guidewire within the circulation.[199,215] By design, vessel dilators are stiffer than catheters and may cause significant trauma if inserted forcefully or further than necessary to dilate the subcutaneous tissue tract from skin to vein.[216] Large-bore introducer sheaths and multilumen catheters are popular because of their clinical utility, yet their size may increase the risk of cannulation-associated trauma, hemorrhage from unrecognized line disconnections, and major venous air embolism. Not only may air be entrained during initial cannulation, but improperly connected large-bore cannulas may pose an additional risk because of the large site for air entry directly into the central venous circulation.[200,217]

Although many complications of CVP monitoring relate to equipment misuse, the impact of data misinterpretation is unknown. It is extremely likely, though, that clinicians have a poor understanding of CVP monitoring and are thus more prone to misinterpretation of measured values. A similar phenomenon has been repeatedly demonstrated for pulmonary artery catheter monitoring (see discussion later). Safe and effective use of CVP monitoring requires a detailed understanding of cardiovascular physiology, normal CVP waveforms, and common pathologic abnormalities in these measurements.

PHYSIOLOGIC CONSIDERATIONS FOR CENTRAL VENOUS PRESSURE MONITORING

Cardiac filling pressures are measured directly from a number of sites in the vascular system. Central venous pressure monitoring is the least invasive method, followed by pulmonary artery and left atrial pressure monitoring. Proper interpretation of all cardiac filling pressures requires knowledge of normal values for pressures within the cardiac chambers, great vessels, and other measured and derived hemodynamic variables (Table 45-2).

CVP is the result of a complex interplay among a diverse array of physiologic variables, many of which are impossible to measure in the operating room or intensive care unit. Not surprisingly, CVP sometimes fails as a predictor of intravascular volume status or fluid responsiveness. There is, fundamentally, no simple relationship between CVP and circulating blood volume.[95,218,219] Despite this, the CVP waveform is important, so its components and potential pitfalls must be understood.

TABLE 45-2 NORMAL CARDIOVASCULAR PRESSURES

Pressures	Average (mm Hg)	Range (mm Hg)
Right Atrium		
a wave	6	2-7
v wave	5	2-7
Mean	3	1-5
Right Ventricle		
Peak systolic	25	15-30
End-diastolic	6	1-7

Peak systolic	130	90-140
End-diastolic	70	60-90
Mean	90	70-105

NORMAL CENTRAL VENOUS PRESSURE WAVEFORMS

Mechanical events during the cardiac cycle are responsible for the sequence of waves seen in a typical CVP trace. The CVP waveform consists of five phasic events: three peaks (a, c, v) and two descents (x, y) (Table 45-3) (Fig. 45-18).[220,221] The most prominent wave is the *a wave* of atrial contraction, which occurs at end-diastole following the ECG P wave. Atrial contraction increases atrial pressure and provides the atrial kick to fill the right ventricle through the open tricuspid valve. Atrial pressure decreases following the a wave, as the atrium relaxes. This smooth decline in pressure is interrupted by the *c wave*. This wave is a transient increase in atrial pressure produced by isovolumic ventricular contraction, which closes the tricuspid valve and displaces it toward the atrium. The c wave always follows the ECG R wave because it is generated during onset of ventricular systole. Note that the c wave observed in a jugular venous pressure trace might have a slightly more complex origin. This wave is due to early systolic pressure transmission from the adjacent carotid artery and may be termed a carotid impact wave. [222] Because the jugular venous pressure also reflects right atrial pressure, however, this c wave likely represents both arterial (carotid impact) and venous (tricuspid motion) origins. Atrial pressure

TABLE 45-3 CENTRAL VENOUS PRESSURE WAVEFORM COMPONENTS

Waveform Component	Phase of Cardiac Cycle	Mechanical Event
a wave	End-diastole	Atrial contraction
c wave	Early systole	Isovolumic ventricular contraction, tricuspid motion toward right atrium
v wave	Late systole	Systolic filling of atrium
h wave	Mid- to late diastole	Diastolic plateau
x descent	Mid-systole	Atrial relaxation, descent of the base, systolic collapse
y descent	Early diastole	Early ventricular filling, diastolic collapse

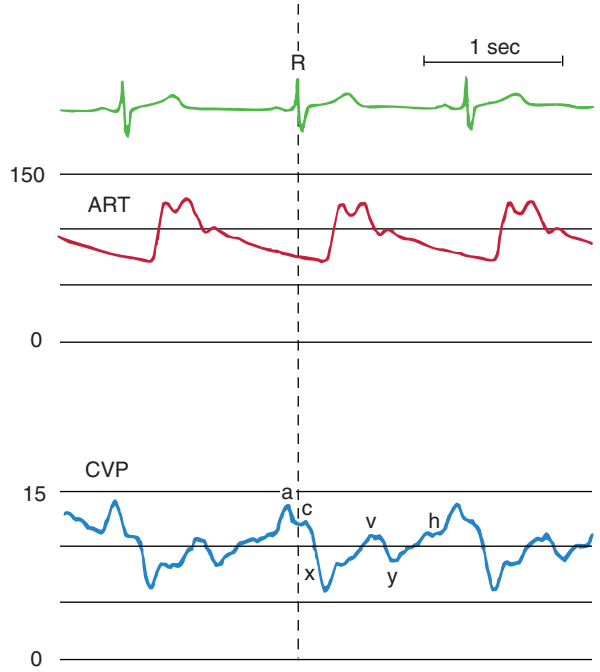

Figure 45-18. Normal central venous pressure (CVP) waveform. The diastolic components (y descent, end-diastolic a wave) and the systolic components (c wave, x descent, end-systolic v wave) are all clearly delineated. A mid-diastolic plateau wave, the h wave, is also seen because heart rate is slow. Waveform identification is aided by timing the relation between individual waveform components and the electrocardiographic R wave. Waveform timing using the arterial (ART) pressure trace is more confusing, owing to the relative delay in the systolic arterial pressure upstroke. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

continues its decline during ventricular systole, owing to continued atrial relaxation and changes in atrial geometry produced by ventricular contraction and ejection. This is the *x descent,* or systolic collapse in atrial pressure. The x descent can be divided into two portions, x and x′, corresponding to the segments before and after the c wave. The last atrial pressure peak is the *v wave*, which is caused by venous filling of the atrium during late systole while the tricuspid valve remains closed. The v wave usually peaks just after the ECG T wave. Atrial pressure then decreases, inscribing the *y descent,* or diastolic collapse, as the tricuspid valve opens and blood flows from atrium to ventricle. A final component of the CVP waveform, the *h wave,* occasionally appears as a pressure plateau in mid- to late diastole. The h wave is not normally seen unless the heart rate is slow and venous pressure is increased.[222,223] In summary, the normal venous waveform components may be remembered as follows: the a wave results from atrial contraction; the c wave results from tricuspid valve closure and isovolumic right ventricular contraction; the x descent is the systolic decrease in atrial pressure due to atrial relaxation; the v wave results from ventricular ejection, which drives venous filling of the atrium; and the y descent is the diastolic decrease in atrial pressure due to flow across the open tricuspid valve.

In relation to the cardiac cycle and ventricular mechanical actions, the CVP waveform can be considered to have three systolic components (c wave, x descent, v wave) and two diastolic components (y descent, a wave). By recalling the mechanical actions that generate the pressure peaks and troughs, these waveform components can be identified properly by aligning the CVP waveform and the ECG trace and using the ECG R wave to mark end-diastole and onset of systole. When the radial artery pressure trace is used for CVP waveform timing instead of the ECG, confusion may arise because the arterial pressure upstroke occurs nearly 200 milliseconds after the ECG R wave (see Fig. 45-18). This normal physiologic delay reflects the times required for the spread of the electrical depolarization through the ventricle (≈60 milliseconds), isovolumic left ventricular contraction (≈60 milliseconds), transmission of aortic pressure rise to the radial artery (≈50 milliseconds), and transmission of the radial artery pressure rise through fluid-filled tubing to the transducer (≈10 milliseconds).[82,224]

The normal CVP peaks are designated systolic (c, v) or diastolic (a) according to the phase of the cardiac cycle in which the wave begins. However, one generally identifies these waves not by their onset or upstroke, but rather by the location of their peaks. For instance, the a wave generally begins and peaks in end-diastole, but the peak may appear delayed to coincide with the ECG R wave, especially in a patient with a short PR interval. In this instance, a and c waves merge, and this composite wave is termed an a-c wave. Designation of the CVP v wave as a systolic event may be even more confusing. Although the ascent of the v wave begins during late systole, the peak of the v wave occurs during isovolumic ventricular relaxation, immediately before atrioventricular valve opening and the y descent. Consequently, the most precise description would be that the v wave begins in late systole, but peaks during isovolumic ventricular relaxation, the earliest portion of diastole. For clinical purposes, it is simplest to consider the v wave to be a systolic wave.

Although three distinct CVP peaks (a, c, v) and two troughs (x, y) are discernible in the normal venous pressure trace, heart rate changes and conduction abnormalities alter this pattern. A short ECG PR interval causes fusion of a and c waves, and tachycardia reduces the length of diastole and the duration of the y descent, causing v and a waves to merge. In contrast, bradycardia causes each wave to become more distinct with separate

TABLE 45-4 CENTRAL VENOUS PRESSURE WAVEFORM ABNORMALITIES

Condition	Characteristics
Atrial fibrillation	Loss of a wave Prominent c wave
Atrioventricular dissociation	Cannon a wave
Tricuspid regurgitation	Tall systolic c-v wave Loss of x descent
Tricuspid stenosis	Tall a wave Attenuation of y descent
Right ventricular ischemia	Tall a and v waves Steep x and y descents M or W configuration
Pericardial constriction	Tall a and v waves Steep x and y descents M or W configuration
Cardiac tamponade	Dominant x descent Attenuated y descent
Respiratory variation during spontaneous or positive-pressure ventilation	Measure pressures at end-expiration

x and x′ descents visible and a more prominent h wave. Although there are circumstances in which other pathologic waves may be evident in the CVP trace, one should resist the temptation to assign physiologic significance to each small pressure peak, because many will arise as artifacts of fluid-filled tubing-transducer monitoring systems. It is more useful to search for the expected waveform components, including those waveforms that are characteristic of the pathologic conditions suspected.

ABNORMAL CENTRAL VENOUS PRESSURE WAVEFORMS

Various pathophysiologic conditions may be diagnosed or confirmed by examination of the CVP waveform (Table 45-4). One of the most common applications is the rapid diagnosis of cardiac arrhythmias.[225] In atrial fibrillation, the a wave disappears and the c wave becomes more prominent because atrial volume is larger at end-diastole and onset of systole, owing to the absence of effective atrial contraction (Fig. 45-19, *A*). Occasionally, atrial fibrillation or flutter waves may be seen in the CVP trace when the ventricular rate is slow. Isorhythmic atrioventricular dissociation or junctional (nodal) rhythm alters the normal sequence of atrial contraction before ventricular contraction (see Fig. 45-19, *B*). Instead, retrograde conduction of the nodal impulse throughout the atrium causes atrial contraction to occur during ventricular systole while the tricuspid valve is closed, resulting in a tall "cannon" a wave in the CVP waveform. Absence of normal atrioventricular synchrony during ventricular pacing can be identified in a similar fashion by searching for cannon waves in the venous pressure trace (see Fig. 45-19, *C*). In these instances, the CVP helps diagnose the cause of arterial hypotension; loss of the P wave may not be as evident in the ECG trace as are the changes in the CVP waveform.

Right-sided valvular heart diseases alter the CVP waveform in different ways.[226] Tricuspid regurgitation

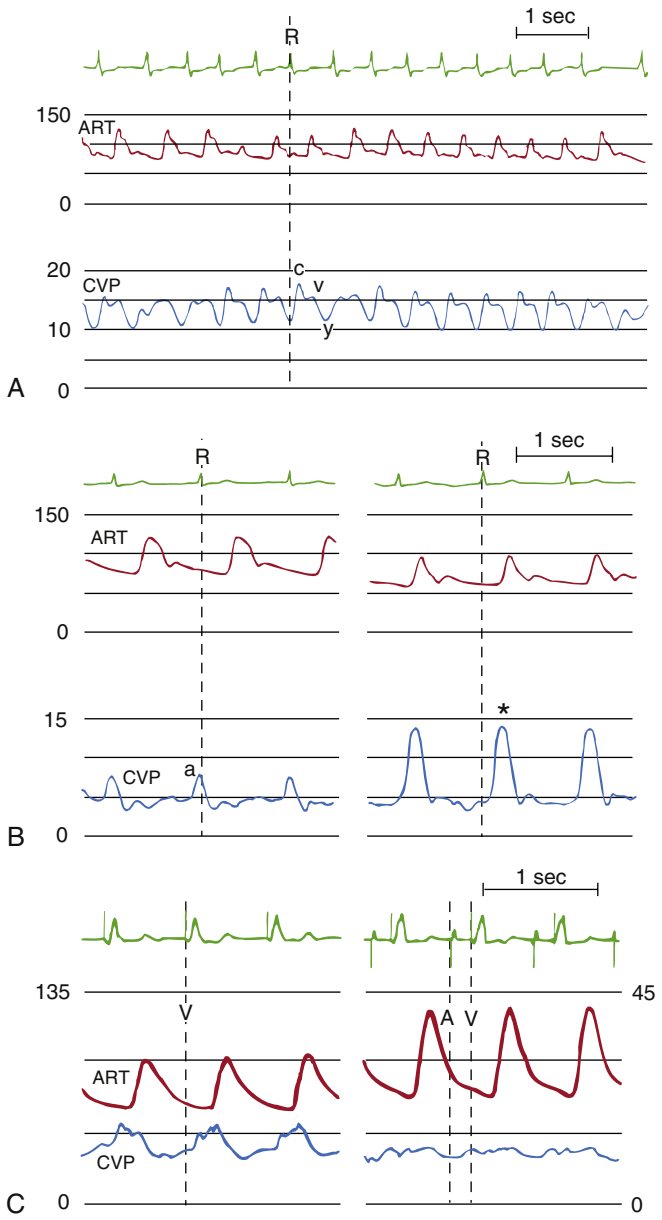

Figure 45-19. Central venous pressure (CVP) changes caused by cardiac arrhythmias. **A,** Atrial fibrillation. Note absence of the a wave, a prominent c wave, and a preserved v wave and y descent. This arrhythmia also causes variation in the electrocardiographic (ECG) R-R interval and left ventricular stroke volume, which can be seen in the ECG and arterial (ART) pressure traces. **B,** Isorhythmic atrioventricular dissociation. In contrast to the normal end-diastolic a wave in the CVP trace (*left panel*), an early systolic cannon wave is inscribed (*, *right panel*). Reduced ventricular filling accompanying this arrhythmia causes a decreased arterial blood pressure. **C,** Ventricular pacing. Systolic cannon waves are evident in the CVP trace during ventricular pacing (*left panel*). Atrioventricular sequential pacing restores the normal venous waveform and increases arterial blood pressure (*right panel*). ART scale left, CVP scale right. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

produces abnormal systolic filling of the right atrium through the incompetent valve. This results in a broad, tall systolic c-v wave, beginning in early systole and obliterating the systolic x descent in atrial pressure (Fig. 45-20, *A*). The CVP trace is said to be ventricularized, resembling

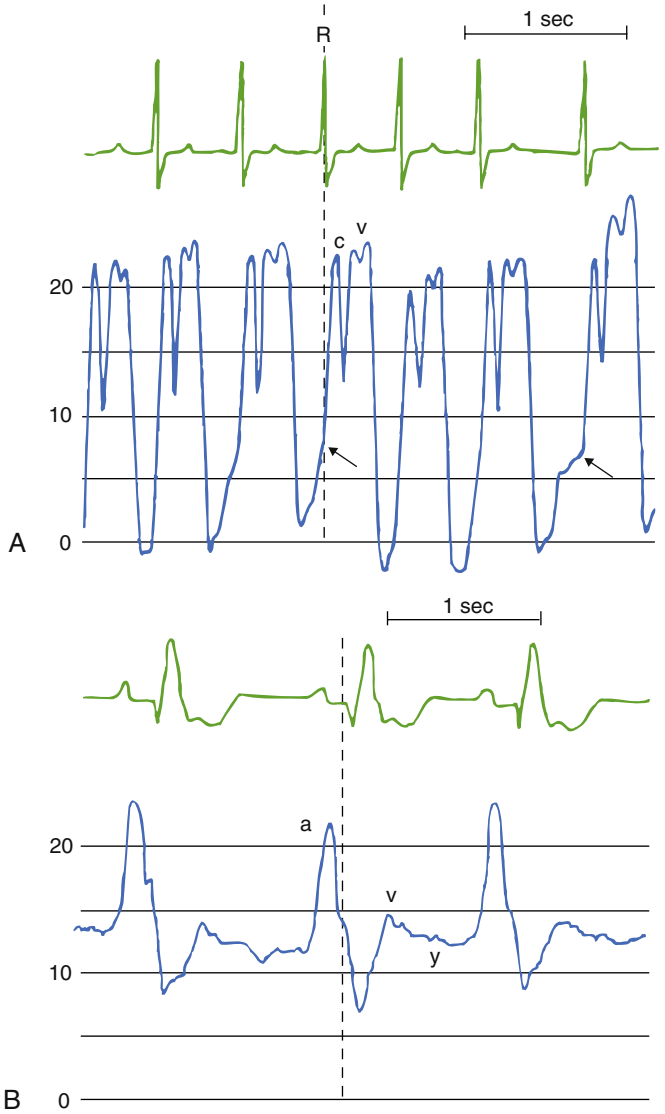

Figure 45-20. Central venous pressure (CVP) changes in tricuspid valve disease. **A,** Tricuspid regurgitation increases mean CVP, and the waveform displays a tall systolic c-v wave that obliterates the x descent. In this example, the a wave is not seen because of atrial fibrillation. Right ventricular end-diastolic pressure is estimated best at the time of the electrocardiographic R wave (*arrows*) and is lower than mean CVP. **B,** Tricuspid stenosis increases mean CVP, the diastolic y descent is attenuated, and the end-diastolic a wave is prominent. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

right ventricular pressure. Note that this regurgitant wave differs in onset, duration, and magnitude from a normal v wave caused by end-systolic atrial filling from the vena cavae. In patients with tricuspid regurgitation, right ventricular end-diastolic pressure is overestimated by the numeric display on the bedside monitor, which reports a single mean value for CVP. Instead, right ventricular end-diastolic pressure is estimated best by measuring the CVP value at the time of the ECG R wave, before the regurgitant systolic wave (see Fig. 45-20, *A*). Unlike tricuspid regurgitation, tricuspid stenosis produces a diastolic defect in atrial emptying and ventricular filling (see Fig. 45-20, *B*). Mean CVP is elevated, and a pressure gradient exists throughout diastole between right atrium and ventricle. The a wave is unusually prominent and the y descent is attenuated, owing to the impaired diastolic egress of blood from the atrium. Other conditions that reduce right ventricular compliance, such as right ventricular ischemia, pulmonary hypertension, or pulmonic valve stenosis, may produce a prominent end-diastolic a wave in the CVP trace but do not attenuate the early diastolic y descent. CVP waveform morphology changes in other characteristic ways in the presence of pericardial diseases and right ventricular infarction. These patterns are interpreted best in conjunction with pulmonary artery pressure monitoring, which is discussed later.

Perhaps the most important traditional application of CVP monitoring is to provide an estimate of the adequacy of the circulating blood volume. Several randomized trials and systematic reviews have demonstrated a very poor relationship between CVP and circulating blood volume, as well as the inability of a static CVP value to predict the hemodynamic response to a fluid challenge.[227-229] This is not surprising given the complexity of the interactions among the many variables that affect CVP. Perhaps the important clinical question with regard to intravascular volume responsiveness should be phrased in the negative—that is, whether a patient is *unlikely* to respond to an intravenous fluid challenge. The subset of patients that will suffer all the deleterious effects of fluid administration (capillary leak and tissue edema) and no benefit (increased cardiac output) is in most instances the group of clinical interest.

PULMONARY ARTERY CATHETER MONITORING

In 1970, Swan, Ganz, and colleagues introduced pulmonary artery catheterization into clinical practice for the hemodynamic assessment of patients with acute myocardial infarction.[230] These catheters allowed accurate measurement of important cardiovascular physiologic variables at the bedside, and their popularity soared. By the mid-1990s, estimated annual pulmonary artery catheter (PAC) sales in the United States approached 2 million catheters, with an estimated cost associated with their use in excess of 2 billion dollars each year.[231]

The PAC provides measurements of several hemodynamic variables that many clinicians, including experts in intensive care, cannot predict accurately from standard clinical signs and symptoms.[232] However, it remains uncertain whether PAC monitoring improves patient outcome.[233]

PULMONARY ARTERY CATHETERIZATION

The standard PAC has a 7.0- to 9.0-Fr circumference, is 110 cm in length marked at 10-cm intervals, and contains four internal lumina. The distal port at the catheter tip is used for pulmonary artery pressure monitoring, whereas the second port is 30 cm more proximal and is used for CVP monitoring. The third lumen leads to a balloon near the tip, and the fourth houses wires for a temperature thermistor, the end of which lies just proximal to the balloon.

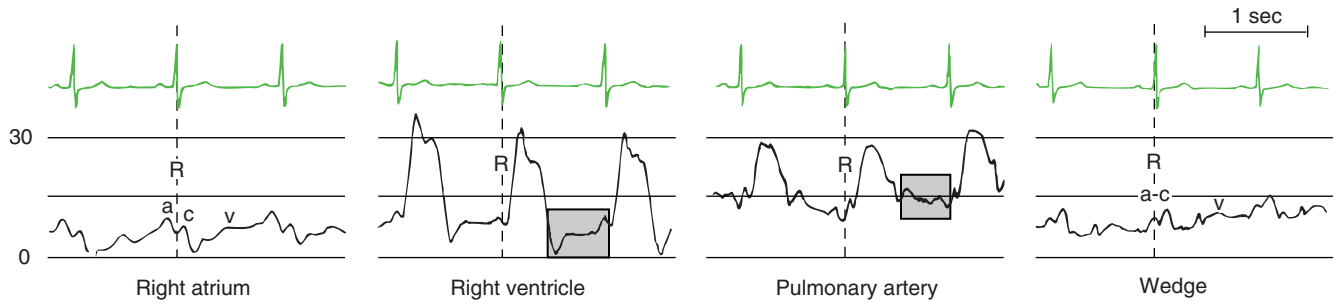

Figure 45-21. Characteristic waveforms recorded during passage of the pulmonary artery catheter. The right atrial pressure resembles a central venous pressure waveform and displays a, c, and v waves. Right ventricular pressure shows a higher systolic pressure than seen in the right atrium, although the end-diastolic pressures are equal in these two chambers. Pulmonary artery pressure shows a diastolic step-up compared with ventricular pressure. Note also that right ventricular pressure increases during diastole, whereas pulmonary artery pressure decreases during diastole (*shaded boxes*). Pulmonary artery wedge pressure has a similar morphology to right atrial pressure, although the a-c and v waves appear later in the cardiac cycle relative to the electrocardiogram. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

PACs can be inserted from any of the central venous cannulation sites described earlier, but the right internal jugular vein provides the most direct route to the right heart chambers. A large-bore introducer sheath with a hemostasis valve at its outer end is inserted in a manner similar to that for central venous cannulation. The PAC is passed through a sterile sheath to allow for later sterile manipulation of the PAC position, its distal lumen is connected to a pressure transducer, and then the catheter is inserted through the introducer's hemostatic valve to a depth of 20 cm. The gentle curvature of the PAC should be oriented to point just leftward of the sagittal plane (the 11-o'clock position, as viewed from the patient's head) to facilitate passage through the anteromedially located tricuspid valve. The balloon at the tip of the catheter is inflated with air, and the catheter is advanced into the right atrium, through the tricuspid valve, the right ventricle, the pulmonic valve, into the pulmonary artery, and finally into the wedge position. Characteristic waveforms from each of these locations confirm proper catheter passage and placement (Fig. 45-21).

After the pulmonary artery wedge pressure is measured, the balloon is deflated, and the pulmonary artery pressure waveform should reappear. Wedge pressure may be obtained as needed by reinflating the balloon and allowing the catheter to float distally until pulmonary artery occlusion again occurs.

Additional Guidelines for Pulmonary Artery Catheter Insertion

From a right internal jugular vein puncture site, the right atrium should be reached when the PAC is inserted 20 to 25 cm, the right ventricle at 30 to 35 cm, the pulmonary artery at 40 to 45 cm, and the wedge position at 45 to 55 cm. When other sites are chosen for catheter placement, additional distance is required, typically an additional 5 to 10 cm from the left internal jugular and left and right external jugular veins, 15 cm from the femoral veins, and 30 to 35 cm from the antecubital veins.[234] These distances serve only as a rough guide; waveform morphology must always be verified and catheter position confirmed with a chest radiograph as soon as practical. The tip of the PAC should be within 2 cm of the cardiac silhouette on a standard anteroposterior chest film.[235]

Use of these typical distances helps avoid complications caused by unintended catheter loops and knots within the heart. If a right ventricular waveform is not observed after inserting the catheter 40 cm, coiling in the right atrium is likely. Similarly, if a pulmonary artery waveform is not observed after inserting the catheter 50 cm, coiling in the right ventricle has probably occurred. The balloon should be deflated, the catheter withdrawn to 20 cm, and the PAC floating sequence repeated.

If repeated attempts to advance the PAC to the right ventricle prove difficult, an abnormal venous anatomy may exist. The most common abnormality of the systemic veins is persistence of the left superior vena cava (LSVC), which is present in approximately 0.1% to 0.2% of the general population and 2% to 9% of patients with other forms of congenital heart disease.[236,237] The persistent LSVC descends along the left mediastinum and empties into a dilated coronary sinus. Because of the benign nature of LSVC, virtually all cases are asymptomatic and discovered incidentally at the time of failed central venous or pulmonary artery catheterization. Because a normal right superior vena cava is present in most of these patients, the anomaly is recognized only when attempted PAC placement proceeds from a left-sided vein. More rarely, difficult PAC placement is encountered during attempted right-sided venous cannulation because the right superior vena cava is absent as well. In these cases, the right internal jugular vein joins the persistent left superior vena cava by a bridging innominate vein. A rare form of atrial septal defect, termed *unroofed coronary sinus*, may also be encountered in these patients providing coronary sinus–left atrial communication and the potential for a PAC to enter the left atrium and systemic circulation.[237] With any of these venous anomalies, PAC advancement into the coronary sinus may disclose an unexpected pressure waveform, coronary sinus pressure.

A few additional points might aid successful positioning of the PAC. The air-filled balloon tends to float to nondependent regions as it passes through the heart into the pulmonary vasculature. Consequently, positioning the patient head down will aid flotation past the tricuspid valve, and tilting the patient onto the right side and placing the head up will encourage flotation out of the right ventricle, as well as reduce the incidence of arrhythmias

during insertion.[238,239] Deep inspiration during spontaneous ventilation will increase venous return and right ventricular output transiently and may facilitate catheter flotation in a patient with low cardiac output. On occasion, a catheter may be floated to proper position when stiffened by injecting 10 to 20 mL of ice-cold solution through the distal lumen. Finally, a catheter that is initially difficult to place may be positioned easily when hemodynamic conditions change, as commonly occurs after induction of general anesthesia and initiation of positive-pressure ventilation.

COMPLICATIONS OF PULMONARY ARTERY CATHETER MONITORING

Complications of PAC use may be divided into those resulting from catheter placement, those associated with the in vivo presence of the catheter, and those resulting from catheter use and misuse. For the most part, problems encountered during catheter placement are the same for both PAC and CVP monitoring (see Box 45-5). However, catheterization of the right ventricle and pulmonary artery causes complications uniquely associated with PACs (Box 45-6).[240]

When all adverse effects from PAC use are considered, including self-limited arrhythmias observed during catheter insertion, minor complications occur in more than 50% of catheterized patients.[231] However, major morbidity specifically attributable to PAC use is uncommon.[241] In 2003, the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization emphasized that the reported incidence of complications from PAC monitoring varies widely, although serious complications occur in 0.1% to 0.5% of PAC-monitored surgical patients.[231] In 1984, Shah and colleagues reported use of PACs in 6245 patients undergoing cardiac and noncardiac operations.[174] Quite remarkably, only 10 patients (0.16%) had serious complications resulting in morbidity and only 1 patient (0.016%) died as a result of pulmonary artery catheterization. Furthermore, a 1998 European report of PAC use in 5306 patients undergoing cardiac surgery confirms this infrequent incidence of major morbidity, with injury of the right ventricle or PA occurring in only 4 patients (0.07%).[242] Finally, only 1 of 2000 adverse events reported in the Australian Incident Monitoring Study of 1993 involved use of a PAC, in contrast to 64 adverse events involving access to the arterial or venous systems.[66] However, although these large studies indicate an infrequent incidence of serious complications attributable to the use of PACs, the frequency of complications in a particular clinical setting or patient group remains unknown.

Arrhythmias are the primary complication observed during pulmonary artery catheterization. In fact, self-limited atrial or ventricular arrhythmias are so common during PAC passage through the heart that most clinicians do not consider them complications, but rather confirmation that the PAC is traversing the cardiac chambers appropriately. Shah and associates observed transient premature ventricular contractions in 68% and atrial dysrhythmias in 1.3% of their catheterized patients.[174] Of more clinical significance, persistent ventricular dysrhythmias requiring treatment occurred in only 3.1% of patients, none of whom suffered prolonged hemodynamic instability. Although the balloon-tipped PAC is less arrhythmogenic when it strikes the endocardium than a standard intravenous catheter or transvenous pacing wire, PACs have been reported to induce sustained atrial fibrillation, ventricular tachycardia, and even ventricular fibrillation.[242-244]

Prophylactic use of IV lidocaine before pulmonary artery catheterization is not effective in reducing ventricular ectopy.[245] When such problems arise, the balloon should be deflated and the catheter withdrawn to the right atrium. When hemodynamically significant dysrhythmias develop hours or even days after placement, it is unlikely that the PAC is responsible. However, the position of the catheter tip should always be checked by observation of the pressure waveform and chest radiograph to identify catheters that have migrated back into the right ventricle.

As the PAC passes through the right ventricle and strikes the interventricular septum, transient right bundle branch block occurs in up to 5% of patients.[246,247] This is important only in patients with preexisting left bundle branch block. In these patients, complete heart block may be precipitated, although this is rare. Shah and associates catheterized 113 patients with preexisting left bundle branch block; only 1 patient developing complete heart block (0.9%).[174] In a different population of 47 high-risk patients with left bundle branch block, many of whom had acute myocardial infarction or heart failure, Morris and colleagues inserted 82 PACs without a single episode of complete heart block for the initial 24 hour period. [246] However, transcutaneous pacing equipment, an external pulse generator, and a temporary transvenous pacing wire or pacing PAC should be readily available as a precaution, especially as the onset of heart block in this setting may be delayed.

Many mechanical problems have been reported with PACs or introducer sheaths. In the setting of cardiac surgery, PACs may be damaged by surgical instruments or become entrapped in sutures or bypass cannulas.[174,248-250] Whenever right heart structures are involved in surgery, free movement of the PAC should be ensured before chest closure. Sternal retraction during cardiac surgery

BOX 45-6 *Complications of Pulmonary Artery Catheter Monitoring*

- Catheterization
  - Arrhythmias, ventricular fibrillation
  - Right bundle branch block, complete heart block

  - Pulmonary infarction
  - Infection, endocarditis
  - Endocardial damage, cardiac valve injury
  - Pulmonary artery rupture
  - Pulmonary artery pseudoaneurysm
- Misinterpretation of data
- Misuse of equipment

may pose other problems, particularly when the PAC is inserted through the external jugular or subclavian route. The PAC may kink as it exits the introducer sheath and makes an acute angle between the sheath and vessel wall.[251,252] These mechanical difficulties should be suspected whenever there is a damped appearance of the monitored pressure trace or difficulty in either infusing fluids or withdrawing blood through one of the catheter lumina.

Although gross structural defects in the catheter itself should be recognized by inspection of the catheter before insertion, more subtle manufacturing problems may escape detection. Some, such as communications between the PAP, CVP, and balloon inflation lumina may be suspected only when data are contradictory or inconsistent.[253,254]

PACs may dislodge temporary transvenous pacing wires, become entangled with other cardiac catheters, or form knots within the heart.[255,256] Arnaout and colleagues reported a PAC knot around the tricuspid valve chordae tendinae, which resulted in severe tricuspid valve regurgitation following catheter removal.[255] Catheter knots should be suspected when there is difficulty withdrawing a PAC and the diagnosis may be confirmed by chest radiography. Knots may be untied by radiologists using intravascular snares and fluoroscopic guidance.[257] If the knot has already been drawn tight, surgical exploration and removal are usually required.

Although both severe tricuspid regurgitation and severe pulmonic regurgitation have been reported, these are rare complications of PAC use.[255,258,259] Using color flow Doppler echocardiography, Sherman and associates demonstrated that placement of a PAC caused a slight increase in the magnitude of tricuspid regurgitation, but in no instance did the PAC lead to severe right-sided valvular insufficiency.[260]

Although the incidence of thromboembolic complications is increased in patients who require PAC monitoring for longer periods of time, thrombi have been detected on PACs within hours of placement.[261] When administration of drugs such as aprotinin and aminocaproic acid reduce perioperative bleeding, the risk of thrombus formation on the PAC may be increased.[262,263] Although external surface heparin bonding unquestionably has reduced thrombogenicity of PACs, it does not entirely eliminate the possibility.[261,264] Fortunately, major pulmonary embolism is a rare occurrence.[265]

The incidence of PAC-related infection increases after 3 days of continuous monitoring and in patients with preexisting sepsis.[266] The most catastrophic of these infections is endocarditis, most often of the right-sided valves.[259,267] Using sophisticated microbiologic techniques in 297 critically ill patients, Mermel and colleagues demonstrated a 22% incidence of local infection of the introducer sheath, but only 0.7% incidence of bacteremia related to the PAC.[268] Changes of PACs do not reduce the risk of bloodstream infection, particularly when the catheter is changed over a guidewire.[269] However, cannulation at a new site carries a significant risk of vascular complications. The specific risks and benefits must be weighed in each patient. Although heparin-bonded PACs carry an infection risk similar to central venous catheters, non–heparin-bonded catheters have double the risk.[136]

Pulmonary artery rupture, the most deadly but also most preventable of complications, occurs in approximately 0.02% to 0.2% of catheterized patients and carries a mortality rate of 50%.[174,270] Several factors increase the risk of this catastrophic event, including hypothermia, anticoagulation, and advanced age, although many reported cases involve heart transplant procedures.[270-272] Pulmonary hypertension also may predispose patients to arterial injury during balloon inflation owing to the increased gradient between the proximal arterial and distal wedge pressures or because pulmonary hypertension distends the pulmonary vasculature and causes the PAC to wedge in a distal, less compliant vessel.[273]

Several mechanisms exist for pulmonary artery injury. These include forceful inflation of the PAC balloon and chronic erosion by the catheter tip abutting the vessel wall or eccentric balloon inflation forcing the noncushioned catheter tip through the vessel wall.[272,274] Regardless of the precise mechanism by which pulmonary arterial injury occurs, case reports highlight that this complication often results from suboptimal catheter insertion and management techniques. Procedural errors include unnecessary catheter manipulation, excessive insertion depth, unrecognized persistent wedge pressure, prolonged balloon inflation, or improper balloon inflation with liquid rather than air.[273-275] It is critical that the clinician recognize artifactual "over-wedged" pressure recordings that indicate peripheral migration of the PAC tip or impaction against the vessel wall and correct this problem immediately by withdrawing the catheter into the proximal pulmonary artery. This problem is more common during cardiopulmonary bypass, owing to the repeated cardiac manipulations and temperature changes that alter the stiffness of the catheter.[276]

The hallmark of catheter-induced pulmonary artery rupture is hemoptysis, which may cause life-threatening exsanguination or hypoxemia. Less commonly, occult hypotension or respiratory compromise may develop. If the visceral pleura fails to contain the bleeding, free rupture into the pleural space produces a large hemothorax. When time allows, a chest radiograph helps determine the diagnosis by revealing the hemothorax or a new infiltrate near the tip of a distally positioned PAC. Although its initial appearance may be confused with catheter-related pulmonary infarction, the pattern of resolution and clinical course differentiate these diagnoses. In confusing cases, the diagnosis may be confirmed by performing a wedge angiogram, in which radiopaque dye injected through the wedged PAC will extravasate into the pulmonary parenchyma to identify the site of arterial disruption.[271]

Treatment of pulmonary artery rupture focuses on resuscitation and immediate control of the hemorrhage. Specific therapeutic steps are highly individualized, depending on the setting. The first priority is ensuring adequate oxygenation and ventilation and may require endobronchial intubation with either a single- or double-lumen endotracheal tube to selectively ventilate and protect the unaffected lung. In addition, positive end-expiratory pressure applied to the affected lung may help

control hemorrhage.[277] Any anticoagulation should be reversed unless the patient must remain on cardiopulmonary bypass and bronchoscopy is performed to localize and control the site of bleeding. A bronchial blocker may be guided into the involved bronchus to tamponade the bleeding and prevent contamination of the uninvolved lung.[278] Management of the PAC itself is more controversial. Some experts recommend removing the catheter, but others suggest leaving the PAC in place to monitor pulmonary artery pressure and guide antihypertensive therapy targeted at decreasing this pressure and reducing bleeding.[279,280] The PAC balloon may be carefully reinflated and the catheter floated into the involved pulmonary artery to occlude the bleeding arterial segment as a temporizing measure.[278] Although these measures may be effective in some cases, many patients will require definitive surgical therapy, such as oversewing the involved pulmonary artery or resecting the involved segment, lobe, or lung.[271,278] In addition, angiography may be recommended to rule out pseudoaneurysm formation in those managed conservatively due to the high morbidity associated with secondary hemorrhage.[270,278,281,282]

A more insidious but possibly more common complication of PAC use is misinterpretation of data.[283,284] Although the magnitude of the problem is not clear, widespread knowledge deficits likely exist among practitioners who use PACs. In 1990, Iberti and colleagues reported the results of a 31-question multiple-choice examination given to 496 resident and staff physicians in medicine, surgery, and anesthesiology departments, who practiced in 13 North American medical centers. The authors found a poor overall level of knowledge of PACs, as evidenced by a mean score of only 67% correct answers. Although higher scores were demonstrated by individuals with more training and more experience inserting and using PACs, none of these factors ensured a high level of knowledge.[285] These results have been duplicated in a variety of other specialty care groups.[286] It is especially concerning that pulmonary artery wedge pressure measurement was performed incorrectly by 30% to 50% of the clinicians in these studies and that educational programs failed to improve performance.[287,288] Taken together, these observations highlight the fact that effective use of PACs requires a great deal of expertise and clinical experience, and even measuring the most fundamental PAC-derived variable, namely wedge pressure, is a complicated endeavor.[289]

NORMAL PULMONARY ARTERY PRESSURES AND WAVEFORMS

As the balloon-tipped PAC is floated to its proper position in the pulmonary artery, characteristic pressure waveforms are recorded (see Fig. 45-21). In the superior vena cava or right atrium, a CVP waveform with characteristic a, c, and v waves and low mean pressure should be observed. At this point, the PAC balloon is inflated, and the catheter is advanced until it crosses the tricuspid valve to record right ventricular pressure, characterized by a rapid systolic upstroke, a wide pulse pressure, and low diastolic pressure. Next, the PAC enters the right ventricular outflow tract and floats past the pulmonic valve into the main pulmonary artery. Premature ventricular beats are common during this period as the balloon-tipped catheter strikes the right ventricular infundibular wall. Entry into the pulmonary artery is heralded by a step-up in diastolic pressure and a change in waveform morphology.

On occasion, it may be difficult to distinguish right ventricular pressure from PAP, particularly if only the numeric values for these pressures are examined. However, careful observation of the pressure waveforms, focusing on the diastolic pressure contours, allows differentiation. During diastole, the PAP will fall because of interruption of flow during pulmonic valve closure, whereas the pressure in the right ventricle will increase as a result of filling from the right atrium[234] (see Fig. 45-21).

Under normal conditions, the PAP upstroke slightly precedes the radial artery pressure upstroke as a result of the longer duration of left ventricular isovolumic contraction and the time required for pressure wave propagation to a distal monitoring site. As a practical matter, though, the pulmonary and systemic arterial pressure waveforms appear to overlap on the bedside monitor (Fig. 45-22). Understanding these temporal relations is critically

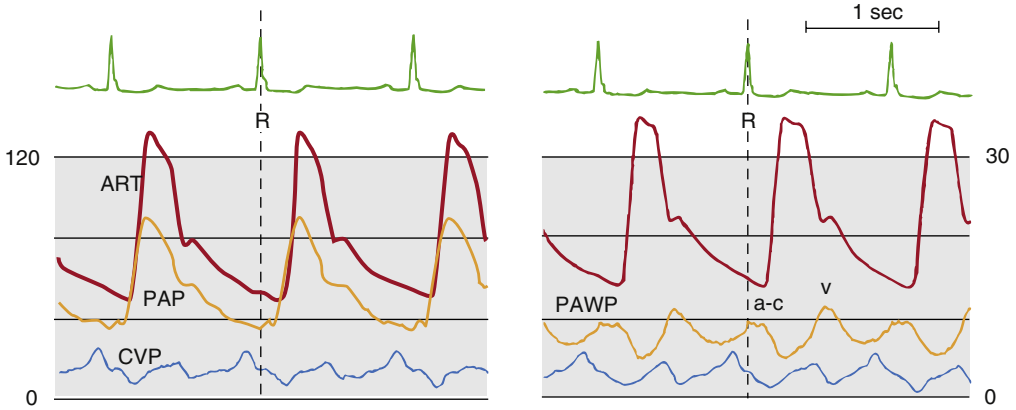

Figure 45-22. Temporal relations between normal systemic arterial pressure (ART), pulmonary artery pressure (PAP), central venous pressure (CVP), and pulmonary artery wedge pressure (PAWP). Note that the PAWP a-c and v waves appear to occur later in the cardiac cycle compared with their counterparts on the right side of the heart seen in the CVP trace. ART pressure scale on the left; PAP, CVP, and PAWP pressure scales on the right. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

important if one is to properly interpret abnormal pulmonary artery and wedge pressure waveforms, particularly when tall v waves are present (see later).

As noted earlier, the wedge pressure is an indirect measurement of pulmonary venous pressure and left atrial pressure and should therefore resemble these venous waveforms with characteristic a and v waves and x and y descents. However, owing to the pulmonary vascular bed interposed between the PAC tip and left atrium, wedge pressure is a delayed and damped representation of left atrial pressure.[290] On average, 160 milliseconds are required for the left atrial pressure pulse to traverse the pulmonary veins, capillaries, arterioles, and arteries. Additionally, atrial depolarization originates in the sinoatrial node located at the junction of the superior vena cava and the right atrium, and therefore the left-sided a wave appears slightly later than the right-sided a wave (Fig. 45-23). As a consequence of these two phenomena, the wedge pressure a wave appears to follow the ECG R wave in early ventricular systole, even though the a wave is an end-diastolic event (see Fig. 45-22). Although the a wave is the most prominent pressure peak in a normal CVP trace, the v wave is often taller than the a wave in a normal left atrial pressure waveform, suggesting that atrial contraction is stronger on the right than the left, and that the left atrium is less distensible than the right.[82] Finally, the interval between atrial and ventricular contraction is approximately 40 milliseconds longer on the right than on the left.[82] Consequently, a and c waves are seen as separate waves in a right atrial pressure trace, whereas on the left they merge into a composite a-c wave (see Fig. 45-22).

To recognize prominent a or v waves in the wedge pressure trace, it is not always necessary to inflate the PAC balloon. Because the PAWP trace reflects pressure waves transmitted in retrograde fashion from the left atrium, these waves will not normally be visible within the antegrade pulmonary artery pressure waves produced by right ventricular ejection. In the setting of prominent a or v waves, the PAP trace becomes a composite wave, reflecting both retrograde and antegrade components. Tall left atrial a or v waves will distort the normal pulmonary artery pressure waveform appearance, with the a wave inscribed at the onset of the systolic upstroke and the v wave distorting the dicrotic notch[290,291] (Fig. 45-24). Once these waves are identified by wedging the PAC and comparing the PAP and PAWP traces, it is wise to "follow" the wedge-pressure a and v waves in the unwedged PAP trace, rather than repeatedly inflating the balloon.

The terms *pulmonary artery wedge pressure* and *pulmonary artery occlusion pressure* are used interchangeably and refer to the same measurement obtained from the tip of a PAC following balloon inflation and flotation to the wedged position. However, pulmonary capillary pressure must not be confused with wedge pressure or left atrial pressure, nor should the term *pulmonary capillary wedge pressure* be used at all. The hydrostatic pressure in the pulmonary capillaries that causes edema formation according to the Starling equation is different from LAP. This is the pressure that must exceed left atrial pressure in order to maintain antegrade blood flow through the lungs. Although the magnitude of the difference between pulmonary capillary pressure and wedge pressure is generally small, it can increase markedly when resistance to flow in the pulmonary veins is elevated.[292] In most situations, the major component of pulmonary vascular resistance occurs at the precapillary, pulmonary arteriolar level. However, rare conditions like pulmonary venoocclusive disease may cause a marked increase in postcapillary resistance to flow. Similar situations arise in conditions that disproportionately increase pulmonary venous resistance, such as central nervous system injury, acute lung injury, hypovolemic shock, endotoxemia, and norepinephrine infusion.[291,293] Under these conditions, measurement of wedge pressure will underestimate pulmonary capillary pressure substantially and thereby underestimate the risk of hydrostatic pulmonary edema. Although pulmonary capillary pressure may be measured at the bedside by analyzing the decay in pulmonary artery pressure trace following PAC balloon inflation, these techniques have not been widely adopted in clinical practice.[294,295] To avoid confusion, the term *pulmonary capillary wedge pressure* should be abandoned because it is imprecise and misleading.

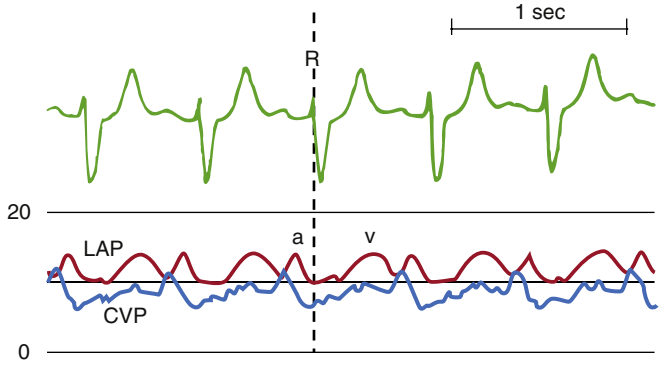

Figure 45-23. Normal temporal relations between the electrocardiographic, central venous pressure (CVP), and left atrial pressure (LAP) traces. The LAP and CVP waveforms have nearly identical morphologies, although the CVP a wave slightly precedes the LAP a wave. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

ABNORMAL PULMONARY ARTERY AND WEDGE PRESSURE WAVEFORMS

PAC monitoring is subject to the same technical artifacts inherent in all invasive pressure monitoring techniques,

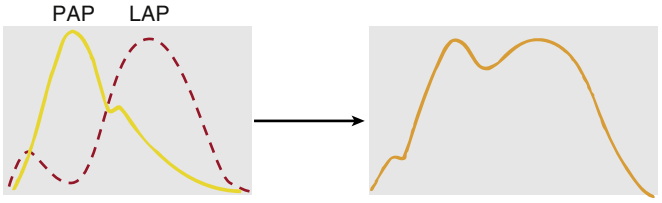

Figure 45-24. Tall left atrial pressure (LAP) a and v waves transmitted in a retrograde direction through the pulmonary vasculature distort the antegrade pulmonary artery pressure (PAP) waveform. The LAP a wave distorts the systolic upstroke, and the v wave distorts the dicrotic notch. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

as well as some additional problems unique to this method.[274,296,297] Because the PAC is longer and passes through the cardiac chambers, it is more prone to distortions from clot or air bubbles, and motion-related artifacts are more problematic. Artifactual pressure spikes may be distinguished from the underlying physiologic pressure waveform by their unique morphology and timing.

At the onset of systole, tricuspid valve closure accompanied by right ventricular contraction and ejection result in excessive catheter motion, causing the most common PAC trace artifact.[296,298] This pressure artifact is simultaneous with the CVP c wave and may produce either an artificially low pressure or a pressure peak. If the monitor detects this inappropriate pressure nadir, it may be erroneously designated as the pulmonary artery diastolic pressure (Fig. 45-25). Repositioning the PAC often solves the problem.

Another common artifact in PAC pressure measurement occurs when the balloon is overinflated and occludes the lumen orifice. This phenomenon is termed overwedging and usually is caused by distal catheter migration and eccentric balloon inflation that forces the catheter tip against the vessel wall. The catheter now records a gradually rising pressure as the continuous flush system builds up pressure against the obstructed distal opening (Fig. 45-26). For a catheter that has migrated to a more distal position, it is possible for overwedging to occur without balloon inflation. Note that the overwedged pressure is devoid of pulsatility, is higher than expected, and increases continuously because of the continuous flush pressure. This should be corrected by catheter withdrawal.

As emphasized earlier, with each PAC balloon inflation and wedge measurement, the catheter tip migrates distally. When a wedge pressure tracing appears during partial balloon inflation, it suggests that the PAC is inappropriately located in a smaller, distal branch of the pulmonary artery. The catheter should be withdrawn before overwedging results in vascular injury or pulmonary infarction.

Pathophysiologic conditions involving the left-sided cardiac chambers or valves produce characteristic changes in the pulmonary artery and wedge pressure waveforms. One of the most easily recognized patterns is the tall v wave of mitral regurgitation. Unlike a normal wedge pressure v wave produced by late systolic pulmonary venous inflow, the prominent v wave of mitral regurgitation begins in early systole. Mitral regurgitation causes fusion of c and v waves and obliteration of the systolic x descent, as the isovolumic phase of left ventricular systole is eliminated owing to the retrograde ejection of blood into the left atrium.[226] Because the prominent v wave of mitral regurgitation is generated during ventricular systole, the mean wedge pressure overestimates left ventricular end-diastolic filling pressure, which is better estimated by the pressure value before onset of the regurgitant v wave (Fig. 45-27). Although mean wedge pressure exceeds left ventricular end-diastolic pressure in patients with severe mitral regurgitation, it remains a good approximation for mean left atrial pressure and the subsequent risk of hydrostatic pulmonary edema.

When large v waves are present in the wedge pressure trace, it is critically important to recognize them and be able to distinguish the wedged from the unwedged pressure waveform. At first glance, a wedge trace with a tall

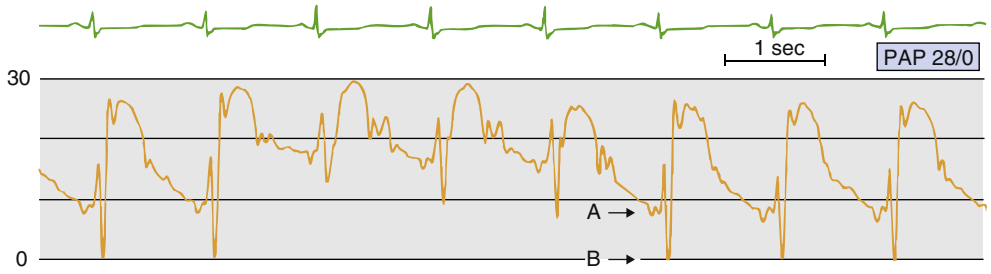

Figure 45-25. Artifactual pressure peaks and troughs in the pulmonary artery pressure (PAP) waveform caused by catheter motion. The correct value for pulmonary artery end-diastolic pressure is 8 mm Hg (A), although the monitor digital display erroneously reports the PAP as 28/0 mm Hg (B). *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

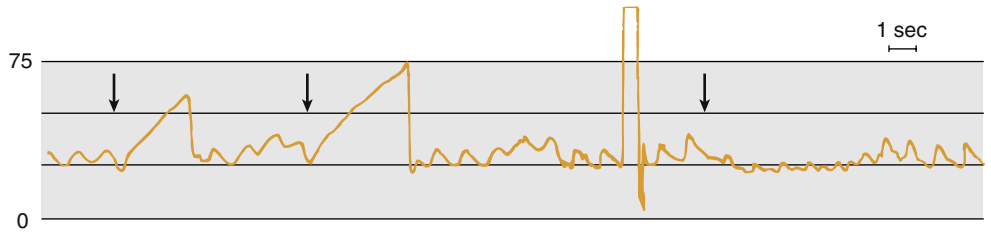

Figure 45-26. Overwedging of the pulmonary artery (PA) catheter causes artifactual waveform recordings. The first two attempts to inflate the PA catheter balloon (*first two arrows*) produce a nonpulsatile increasing pressure caused by an occluded catheter tip. After the catheter is withdrawn slightly, balloon inflation allows proper wedge pressure measurement (*third arrow*). Before the third attempt at balloon inflation, the PA pressure lumen is flushed. This restores the appropriate pulsatile nature to the PA and wedge pressure waveforms on the right side of the trace. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

systolic v wave resembles a typical unwedged pulmonary artery pressure trace, but closer observation reveals a number of discriminating details. The pulmonary artery pressure upstroke is steeper and slightly precedes the systemic arterial pressure upstroke, whereas a wedge tracing with a prominent v wave has a more gradual upstroke that begins after the radial artery pressure upstroke. Furthermore, the wedge pressure v wave reaches its peak later in the cardiac cycle, after the ECG T wave as opposed to the simultaneous peaks of the systemic and pulmonary arterial peaks[226,299] (see Fig. 45-27). Another distinguishing feature in patients with severe mitral regurgitation is the unusual morphology of the pulmonary artery waveform itself. The larger the regurgitant v wave, the more it distorts the pulmonary artery waveform, giving it a bifid appearance and obscuring the normal end-systolic dicrotic notch[291] (see Fig. 45-27).

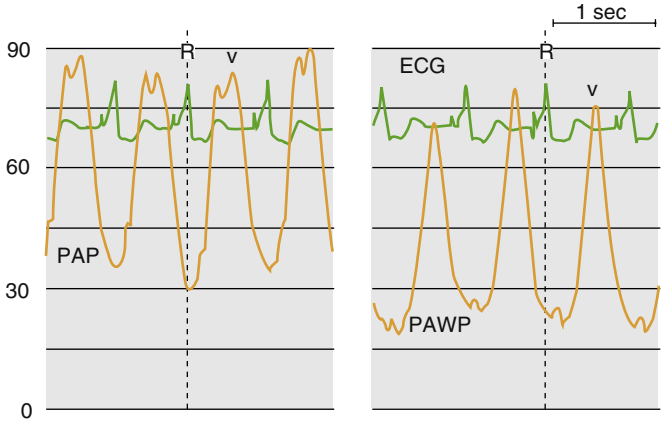

Figure 45-27. Severe mitral regurgitation. A tall systolic v wave (v) is inscribed in the pulmonary artery wedge pressure (PAWP) trace and also distorts the pulmonary artery pressure (PAP) trace, giving it a bifid appearance. The electrocardiogram (ECG) is abnormal owing to ventricular pacing. Left ventricular end-diastolic pressure is estimated best by measuring PAWP at the time of the electrocardiographic R wave, before onset of the regurgitant v wave. Note that mean PAWP exceeds left ventricular end-diastolic pressure in this condition. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

A close look at left atrial pressure-volume relations helps to explain the apparently paradoxical coexistence of severe mitral regurgitation and a normal pulmonary artery wedge pressure trace.[300,301] Three factors determine whether mitral regurgitation produces a prominent v wave in the left atrial or wedge pressure traces: left atrial volume, left atrial compliance, and regurgitant volume (Fig. 45-28). Given that the left atrial pressure-volume relation is not linear, the same volume of regurgitation will result in a variable increment in systolic pressure, depending on the preexisting atrial volume at onset of systole. Furthermore, the nature of that relationship is dependent on the compliance (i.e., stiffness) of the left atrium. Although the total regurgitant volume of blood entering the left atrium will influence the height of the v wave, this clearly is not the only determinant of v wave magnitude. This may explain why patients with acute mitral regurgitation tend to have tall wedge pressure v waves—they have smaller, stiffer left atria with poorer compliance compared with those of patients with long-standing disease. It is not surprising that wedge pressure v waves are neither sensitive nor specific indicators of mitral regurgitation severity, and the height of these waves should not be used in such a manner.[300] Prominent wedge pressure v waves may exist in the absence of mitral regurgitation when left atrial pressure is high, as might occur when the left atrium is compressed.[302] Tall v waves are also seen commonly in patients with hypervolemia, congestive heart failure, and ventricular septal defect.[300] Note that the giant v waves observed in patients with ventricular septal defect are not caused by retrograde flow, but rather by excessive antegrade systolic flow into the left atrium due to the intracardiac shunt.[303]

In contrast to mitral regurgitation, which distorts the systolic portion of the wedge pressure waveform, mitral stenosis alters its diastolic aspect. In this condition, the holodiastolic pressure gradient across the mitral valve results in an increased mean wedge pressure, a slurred early diastolic y descent, and a tall end-diastolic a wave. Similar hemodynamic abnormalities are seen in patients with left atrial myxoma or whenever mitral flow is obstructed. Diseases that increase left ventricular stiffness

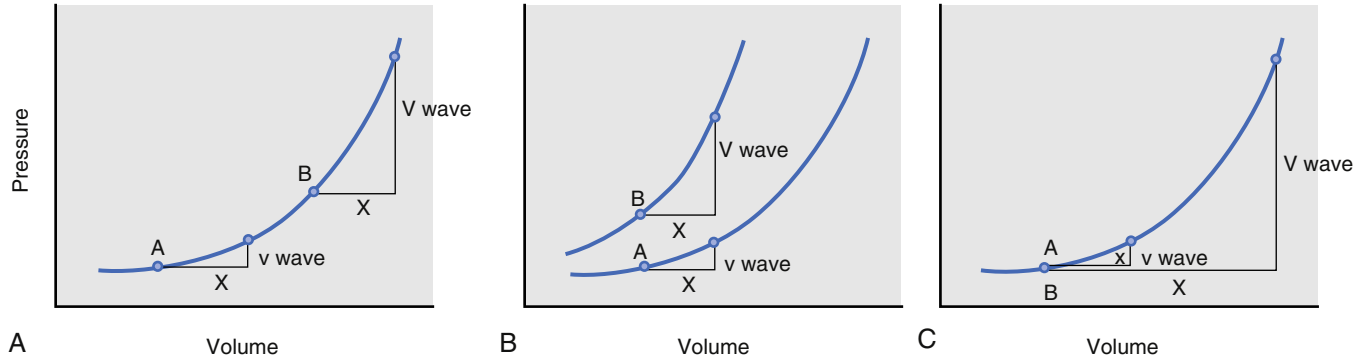

Figure 45-28. V wave height as an indicator of mitral regurgitation severity. Left atrial pressure-volume curves describe the three factors that determine v wave height. **A,** Influence of left atrial volume. For the same regurgitant volume (x), the left atrial v wave will be taller if baseline atrial volume is greater (point B versus point A). **B,** Influence of left atrial compliance. For the same regurgitant volume (x), the left atrial v wave will be taller if baseline atrial compliance is reduced (point B versus point A). **C,** Influence of regurgitant volume. Beginning at the same baseline left atrial volume (points A and B), if regurgitant volume increases (X versus x), the left atrial pressure v wave will increase (V versus v). *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

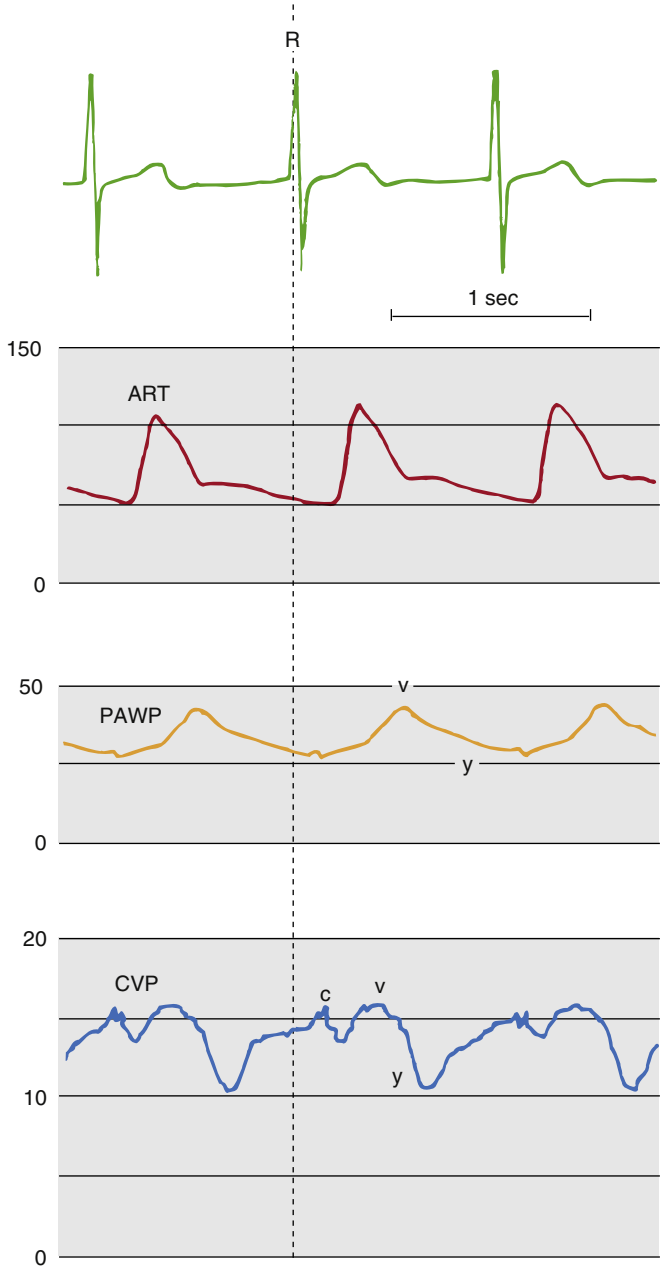

Figure 45-29. Mitral stenosis. Mean pulmonary artery wedge pressure (PAWP) is increased (35 mm Hg), and the diastolic y descent is markedly attenuated. Compare the slope of the y descent in the PAWP trace with the y descent in the central venous pressure (CVP) trace. In addition, compare this PAWP y descent with the PAWP y descent in mitral regurgitation (see Fig. 45-27); a waves are not seen in the PAWP or CVP traces, owing to atrial fibrillation. Arterial blood pressure (ART). *(From Mark JB: Atlas of cardiovascular monitoring, New York, 1998, Churchill Livingstone.)*

(e.g., left ventricular infarction, pericardial constriction, aortic stenosis, and systemic hypertension) produce changes in the wedge pressure that resemble in part those seen in mitral stenosis. In these conditions, mean wedge pressure is increased and the trace displays a prominent a wave, but the y descent remains steep, because there is no obstruction to flow across the mitral valve during diastole. Because patients with advanced mitral stenosis often have coexisting atrial fibrillation, the a wave will not be present in many of these cases[226] (Fig. 45-29).

Myocardial ischemia may be detected by PAC in several ways. Ischemia itself impairs left ventricular relaxation resulting in diastolic dysfunction, a pattern particularly characteristic of demand ischemia associated with tachycardia or induced by rapid atrial pacing.[304-306] Impaired ventricular relaxation results in a stiffer, less compliant left ventricle, resulting in an increased left ventricular end-diastolic pressure. Not only does this, in turn, increases left atrial and wedge pressures, but the morphology of these waveforms changes as well, with the phasic a and v wave components becoming more prominent as diastolic filling pressure increases.[307-309] Although myocardial ischemia will often be detectable as a rise in pulmonary artery diastolic, mean, or systolic pressures, these changes are generally less striking than the accompanying change in wedge pressure and new appearance of tall a and v waves (Fig. 45-30). In patients with left ventricular ischemia, the tall wedge pressure a wave is produced by end-diastolic atrial contraction into a stiff, incompletely relaxed left ventricle.[310] Although the diastolic dysfunction accompanying myocardial ischemia leads to an increase in left ventricular end-diastolic pressure, this pressure elevation often coexists with a decreased left ventricular end-diastolic volume or preload.[304] The dissociation between filling pressure and filling volume in this condition must be appreciated to avoid diagnostic and therapeutic errors.

Myocardial ischemia also produces a characteristic pattern of left ventricular systolic dysfunction. Systolic dysfunction is the hallmark of supply ischemia, caused by a sudden reduction or cessation of coronary blood flow to a region of the myocardium.[306,311] With severe systolic dysfunction, changes in global left ventricular contractile performance may be detected with hemodynamic monitoring. As ejection fraction falls significantly, left ventricular end-diastolic volume and pressure rise and systemic arterial hypotension and elevated pulmonary diastolic and wedge pressures develop.[312] A more common hemodynamic manifestation of myocardial ischemia occurs when left ventricular geometry is distorted or when the region of ischemic myocardium underlies a papillary muscle, resulting in acute mitral regurgitation.[313] This form of ischemic mitral regurgitation is often termed papillary muscle ischemia or functional mitral regurgitation. As noted earlier, PAC monitoring is particularly well suited to detect this event by revealing the onset of new regurgitant v waves in the pulmonary artery or wedge pressure traces (see Fig. 45-27).

Whether the PAC should be used in high-risk patients as a supplemental monitor for detection of myocardial ischemia remains controversial.[309,314-316] None of the current methods for detecting perioperative myocardial ischemia is perfectly sensitive or specific. Although patients with left ventricular ischemia are likely to have higher mean wedge pressures than those without ischemia, these differences are small and may be difficult to detect clinically.[309] Furthermore, clear quantitative threshold values for mean wedge pressure or a and v wave peak pressures that are diagnostic of ischemia have not been identified, perhaps owing to the wide variations in normal patients. Consequently, when a PAC is used to diagnose myocardial ischemia, the best approach is to integrate the PAC data with other clinical and monitored information.[317]

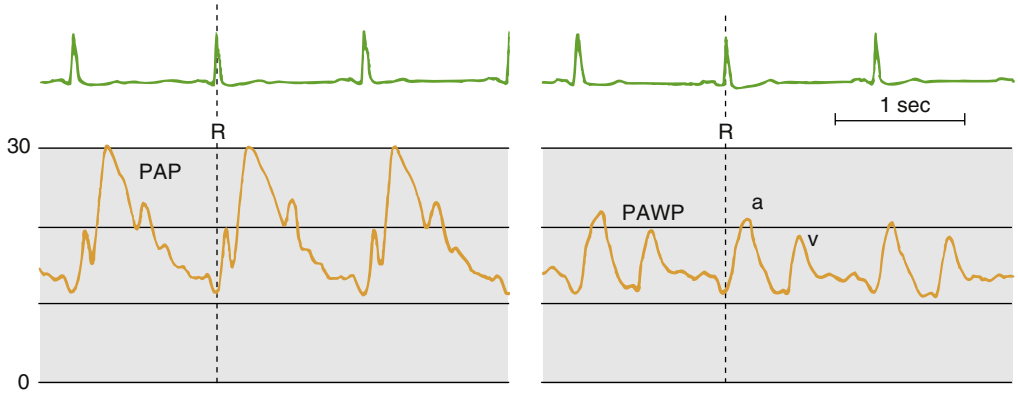

Figure 45-30. Myocardial ischemia. Pulmonary artery pressure (PAP) is relatively normal and mean pulmonary artery wedge pressure (PAWP) is only slightly elevated (15 mm Hg). However, PAWP morphology is markedly abnormal with tall a waves (21 mm Hg) resulting from the diastolic dysfunction seen in this condition. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

Right ventricular ischemia produces characteristic PAC waveform patterns that may be helpful in diagnosis and management. Just as left ventricular ischemia increases pulmonary artery wedge pressure, right ventricular ischemia increases CVP. In fact, this is one of the few situations in which CVP may be higher than wedge pressure. In addition, CVP waveforms may display a prominent a wave resulting from right ventricular diastolic dysfunction, and a prominent v wave resulting from ischemia-induced tricuspid regurgitation.[318,319] This particular CVP waveform is described as having an M or W configuration, referring to the tall a and v waves and interposed steep x and y descents. Severe pulmonary artery hypertension may also result in right ventricular ischemia and dysfunction as well as increased CVP, but this is distinguished from primary right ventricular dysfunction in that the pulmonary artery pressure and calculated pulmonary vascular resistance are normal in primary right ventricular failure.

The CVP waveform in right ventricular infarction is similar to that from a patient with restrictive cardiomyopathy or pericardial constriction, including elevated mean pressure, prominent a and v waves, and steep x and y descents.[320] The cardinal feature common to these conditions is impaired right ventricular diastolic compliance, often termed restrictive physiology. In restrictive cardiomyopathy and right ventricular infarction, diastolic dysfunction impairs ventricular relaxation and decreases chamber compliance, whereas in constrictive pericarditis cardiac filling is limited by the rigid, often calcified pericardial shell. Impaired venous return decreases end-diastolic volume, stroke volume, and cardiac output. Despite reduced cardiac volumes, cardiac filling pressures are markedly elevated and equal in all four chambers of the heart at end-diastole (Fig. 45-31). Although PAC monitoring reveals this pressure equalization, the characteristic M or W configuration is more apparent in the CVP trace, most likely because of the damping effect of the pulmonary vasculature on the left-sided filling pressures.[321-323]

Another hallmark of pericardial constriction is observed in the right and left ventricular pressure traces. These demonstrate rapid but short-lived early diastolic ventricular filling, which produces a diastolic dip-and-plateau

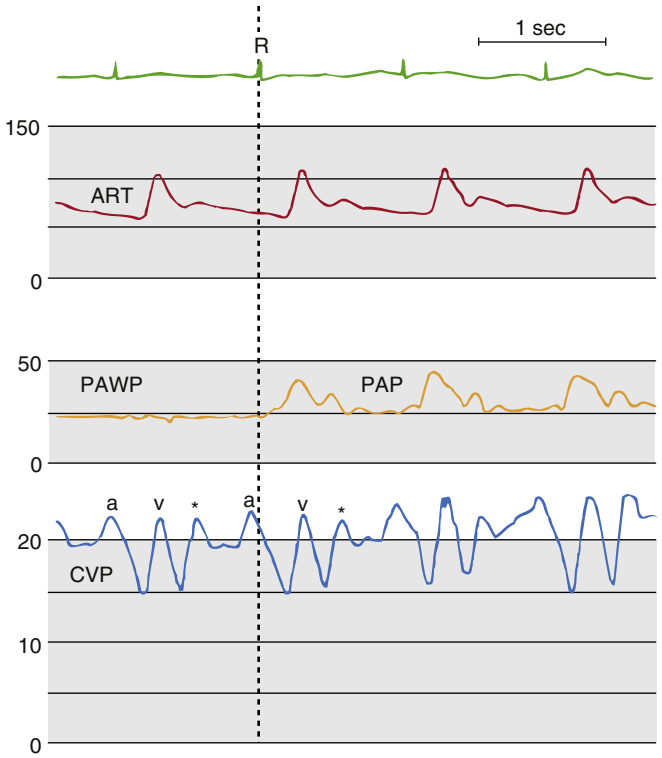

Figure 45-31. Pericardial constriction. This condition causes elevation and equalization of diastolic filling pressures in the pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), and central venous pressure (CVP) traces. The CVP waveform reveals tall a and v waves with steep x and y descents and a mid-diastolic plateau wave (*) or h wave. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

pattern or "square root sign."[93,324] In some cases, particularly when heart rate is slow, a similar waveform pattern may be noted in the CVP trace: a steep y descent (the diastolic dip) produced by rapid early diastolic flow from atrium to ventricle, followed by a mid-diastolic h wave (the plateau) from the interruption in flow imposed by the restrictive pericardial shell (see Fig. 45-31).

Like pericardial constriction, cardiac tamponade impairs cardiac filling, but in the case of tamponade, a

compressive pericardial fluid collection produces this effect. This results in a marked increase in CVP and a reduced diastolic volume, stroke volume, and cardiac output. Despite many similar hemodynamic features, tamponade and constriction may be distinguished by the different CVP waveforms seen in these two conditions. In tamponade, the venous pressure waveform appears more monophasic and is dominated by the systolic x pressure descent. The diastolic y pressure descent is attenuated or absent, because early diastolic flow from right atrium to right ventricle is impaired by the surrounding compressive pericardial fluid collection[321,325,326] (Fig. 45-32). Clearly, other clinical and hemodynamic clues help distinguish these diagnoses, such as the presence of pulsus paradoxus, an almost invariable finding in cardiac tamponade[327] (see Fig. 45-14). Coexisting abnormalities such as tachycardia, arrhythmias, and atrial contractile failure may complicate interpretation of these waveforms. On occasion, localized pericardial constriction may simulate valvular stenosis, and hypovolemia may lower cardiac filling pressures to within the normal range and confound the diagnosis.

Probably the single most important waveform abnormality or interpretive problem in PAC monitoring is discerning the correct pressure measurement in patients with large intrathoracic pressure swings like those receiving positive-pressure ventilation or those with labored spontaneous breathing. Just as in the case of CVP monitoring, all transmural cardiac filling pressures are estimated best when end-expiratory pressure values are recorded. During positive-pressure ventilation, inspiration increases pulmonary artery and wedge pressures. By measuring these pressures at end-expiration, the confounding effect of this inspiratory increase in intrathoracic pressure is minimized[328] (Fig. 45-33). Forceful inspiration during spontaneous ventilation has the opposite effect, but again, measurement of these pressures at end-expiration eliminates this confounding factor. Bedside monitors are designed with algorithms that aim to identify and report the numeric values for end-expiratory pressures but are often inaccurate.[329,330] The most reliable method for measuring central vascular pressures at end-expiration is examination of the waveforms on a calibrated monitor screen or paper recording.[330,331]

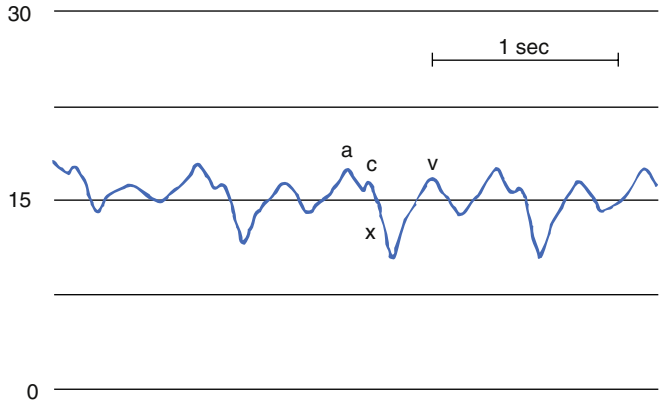

Figure 45-32. Cardiac tamponade. The central venous pressure waveform shows an increased mean pressure (16 mm Hg) and attenuation of the y descent. Compare with Figure 45-31. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

PHYSIOLOGIC CONSIDERATIONS FOR PULMONARY ARTERY CATHETER MONITORING: PREDICTION OF LEFT VENTRICULAR FILLING PRESSURE

One of the main reasons to measure pulmonary artery diastolic and wedge pressures is to be able to estimate left ventricular end-diastolic pressure, the closest surrogate to left ventricular end-diastolic volume, which is the true left ventricular preload (also see Chapter 46). When a PAC floats to the wedge position, the inflated balloon isolates the distal pressure-monitoring orifice from upstream pulmonary artery pressure. A continuous static column of blood now connects the wedged PAC tip to the junction of the pulmonary veins and left atrium. Thus, wedging the PAC, in effect, extends the catheter tip to measure the pressure at the point at which blood flow resumes on the venous side of the pulmonary circuit. Because resistance in the large pulmonary veins is negligible, pulmonary artery wedge pressure provides an indirect measurement of both pulmonary venous pressure and left atrial pressure.[71,332]

Pulmonary artery diastolic pressure (PAD) is often used as an alternative to PAWP to estimate left ventricular filling pressure. This is acceptable under normal circumstances because when pulmonary venous resistance is low, the pressure in the pulmonary artery at end of diastole will equilibrate with downstream pressure in the pulmonary veins and left atrium.[333,334] From a monitoring standpoint, PAD has the added advantage of being

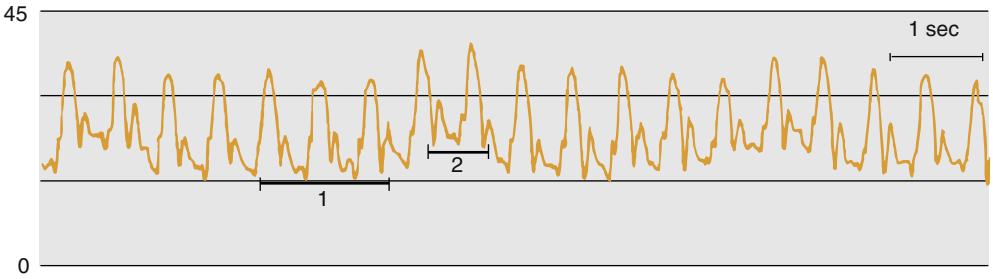

Figure 45-33. Influence of positive-pressure mechanical ventilation on pulmonary artery pressure. Pulmonary artery pressure should be measured at end expiration (*1*, 15 mm Hg) in order to obviate the artifact caused by positive-pressure inspiration (*2*, 22 mm Hg). *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

available for continuous monitoring, whereas PAWP is only measured intermittently.

For both PAD and PAWP to be valid estimates of left ventricular filling pressure, the column of blood connecting the tip of the wedged catheter and the draining pulmonary vein must be continuous and static. At the microcirculatory level, this channel consists of pulmonary capillaries that are subject to external compression by surrounding alveoli. West and associates described a three-zone model of the pulmonary vasculature based on the gravitationally determined relationships between relative pressures in the pulmonary arteries, pulmonary veins, and surrounding alveoli.[335] In West zone 1, alveolar pressure exceeds pressure in both the pulmonary artery and pulmonary veins, whereas in zone 2, it is intermediate between these two pressures (Fig. 45-34). A PAC positioned in both zone 1 and 2 will be highly susceptible to alveolar pressure, and measurements will reflect alveolar or airway pressure rather than left ventricular filling pressure. As such, the tip of the PAC must lie in zone 3 for PAWP measurements to be accurate. In most clinical settings, the supine position of the patient favors zone 3 conditions, a finding that has been confirmed by radiographic studies.[336] However, when patients are placed in the lateral or semi-upright position, zone 2 may expand significantly. In general, zones 1 and 2 become more extensive when left atrial pressure is low, when the PAC tip is located vertically above the left atrium, or when alveolar pressure is high. Clues to an incorrectly positioned catheter include absence of normal PAWP a and v waves, marked respiratory variation in PAWP, and a PAD that exceeds the PAWP measurement without excessively tall a or v waves visible on the trace.[71]

Assuming the PAC resides appropriately in West zone 3, the end-diastolic wedge pressure following atrial contraction is generally the best predictor of left ventricular end-diastolic filling pressure as measured at the Z-point. This is the point at which the slope of the left ventricular pressure upstroke changes, approximately 50 milliseconds after the ECG Q wave, and it generally coincides with the ECG R wave[82] (Fig. 45-35).

However, in many cases, the left ventricular end-diastolic pressure is either underestimated or overestimated by the PAWP and/or PAD. These situations are summarized in Figure 45-36 and Tables 45-5 and 45-6 (also see several excellent references for further discussion of this topic).[71,332,337]

USE OF CENTRAL FILLING PRESSURES TO ESTIMATE LEFT VENTRICULAR PRELOAD

A detailed understanding of the relationship between left ventricular filling pressure and preload is important for clinically meaningful interpretation of PAC-derived data. Even when surrogate pressures such as pulmonary artery diastolic pressure and wedge pressure accurately estimate left ventricular end-diastolic pressure, many factors can influence the relationship between end-diastolic pressure and end-diastolic chamber volume, which is the true preload. For example, a pulmonary artery wedge pressure of 20 mm Hg is somewhat higher than normal, but depending on its interpretation and the clinical setting, different treatments would be indicated. Proper interpretation of filling pressures requires assessment of juxtacardiac pressure and ventricular compliance. When juxtacardiac pressure and ventricular compliance are normal, a wedge pressure of 20 mm Hg is interpreted as hypervolemia, with an increased left ventricular end-diastolic volume causing the increased PAWP. However, different conclusions are reached if juxtacardiac pressure is increased, for example, as a result of cardiac tamponade, pericardial constriction, or positive-pressure ventilation. Furthermore, a wedge pressure of 20 mm Hg may mean that ventricular compliance is decreased, such as might occur with diastolic dysfunction from myocardial ischemia, hypertrophy, or

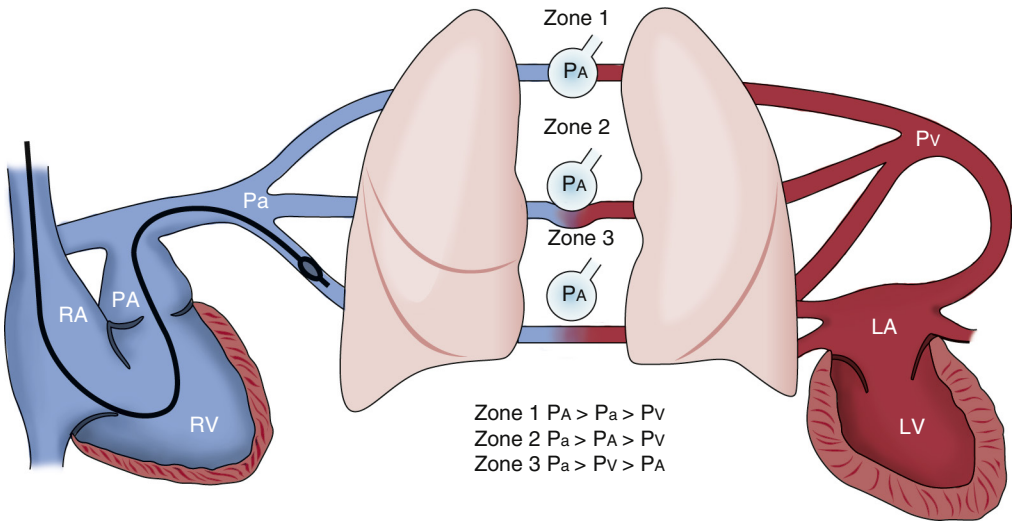

Figure 45-34. The pulmonary artery catheter tip must be wedged in lung zone 3 to provide an accurate measure of pulmonary venous (Pv) or left atrial (LA) pressure. When alveolar pressure (P_A) rises above Pv in lung zone 2, or above pulmonary arterial pressure (Pa) in lung zone 1, wedge pressure will reflect alveolar pressure rather than intravascular pressure. *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

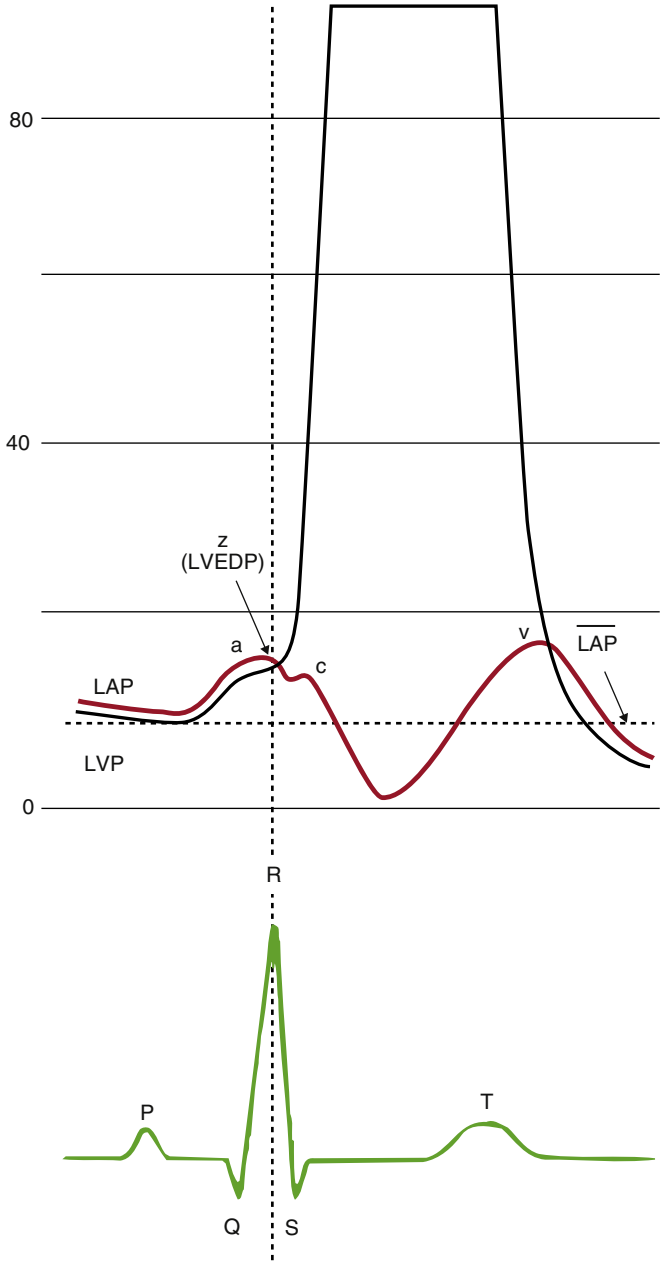

Figure 45-35. Relationship between left atrial pressure (LAP) and left ventricular end-diastolic pressure (LVEDP). LVEDP is measured at the Z-point on the left ventricular pressure (LVP) trace, at the time of the electrocardiographic R wave. Mean LAP (9 mm Hg) underestimates LVEDP (15 mm Hg), but the LAP a wave pressure peak closely estimates LVEDP.[456] *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

cardiomyopathy (Fig. 45-37). Under these two situations, a wedge pressure of 20 mm Hg can coexist with a small, hypovolemic left ventricle.

A fluid challenge may be useful in deciding whether hypovolemia exists. An intravenous bolus of crystalloid or colloid solution (250 to 500 mL) is given over 15 minutes, and the change in wedge pressure is measured. Small increases in wedge pressure following the fluid challenge (e.g., less than 3 mm Hg) suggest that the ventricle is operating on the flat portion of its diastolic filling curve, whereas large increases in wedge pressure (e.g., 7 mm Hg or greater) suggest that the steep portion of the curve has been reached and that little further increase in stroke volume and cardiac output can be achieved without a substantial risk of producing hydrostatic pulmonary edema.[71,330]

The shared septum of the left and right ventricles as well as the presence of the pericardium lead to further interpretive problems in the use of CVP for assessing ventricular preload. Ventricular interdependence and pericardial constraint couple changes in right and left ventricular function, such that a primary change in right ventricular filling may produce a secondary and opposite change in left ventricular filling by altering its diastolic pressure-volume relation.[338,339] For example, acute pulmonary artery hypertension increases right ventricular end-diastolic volume and pressure, shifts the ventricular septum leftward, and increases left ventricular end-diastolic pressure while simultaneously decreasing left ventricular end-diastolic volume, owing to a shift in the left ventricular pressure-volume relation to a steeper, stiffer curve. Conversely, primary changes on the left side can adversely affect the right heart structures in similar ways. Finally, numerous additional factors may alter the relationship between CVP and left ventricular preload[340] (see Fig. 45-37). With all these considerations in mind, both CVP and PAWP do not correlate with blood volume and do not predict the cardiac output response to an intravenous fluid challenge.[227,341]

PULMONARY ARTERY CATHETER–DERIVED HEMODYNAMIC VARIABLES

The cardiovascular system is often modeled as an electrical circuit, with the relationship between cardiac output, blood pressure, and resistance to flow related in a manner similar to Ohm's law:

$$SVR = \frac{MAP - CVP}{CO} \times 80$$

$$PVR = \frac{MPAP - PAWP}{CO} \times 80$$

where SVR = systemic vascular resistance (dyne·sec/cm^5)
PVR = pulmonary vascular resistance (dyne·sec/cm^5)
MAP = mean arterial pressure (mm Hg)
CVP = central venous pressure (mm Hg)
MPAP = mean pulmonary artery pressure (mm Hg)
PAWP = pulmonary artery wedge pressure (mm Hg)
CO = cardiac output (L/min)

Normal values for SVR and PVR are given in Table 45-7. When the numeric constant (80) in the above equations is not included, the units for SVR and PVR are termed Wood units rather than the derived metric unit values. Note that these calculations of systemic and pulmonary vascular resistance are based on a hydraulic fluid model that assumes continuous, laminar flow through a series of rigid pipes.[342] Atrial pressures are used as the downstream pressure for systemic or pulmonary flow, with CVP used for right atrial pressure in the SVR calculation and PAWP used for left atrial pressure in the PVR calculation.

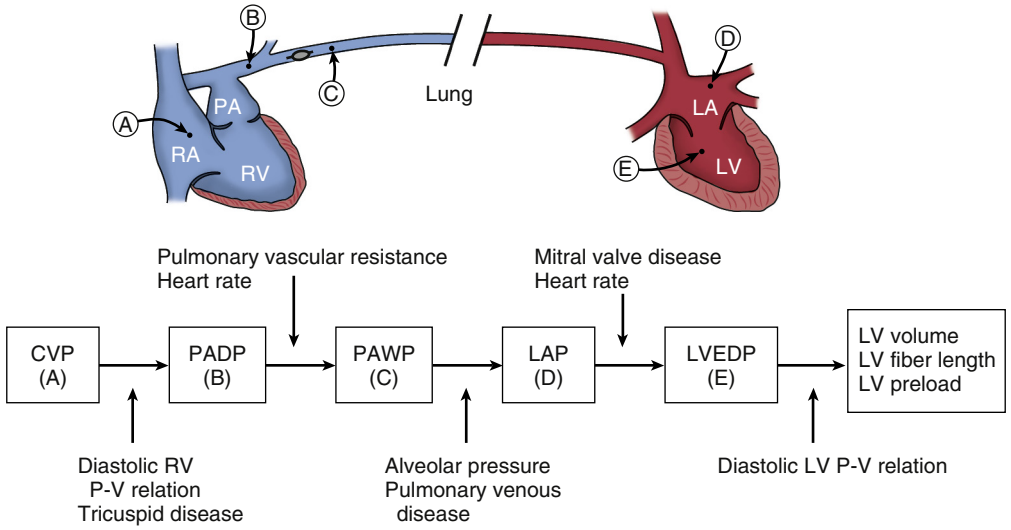

Figure 45-36. Anatomic and physiologic factors that influence the relations between various measures of left ventricular (LV) filling and true LV preload. The further upstream the filling pressure is measured, the more confounding factors may influence the relation between this measurement and LV preload. *CVP*, Central venous pressure; *LA*, left atrium; *LAP*, left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *PA*, pulmonary artery; *PADP*, pulmonary artery diastolic pressure; *PAWP*, pulmonary artery wedge pressure; *P-V*, pressure-volume; *RA*, right atrium; *RV*, right ventricle. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

TABLE 45-5 UNDERESTIMATION OF LEFT VENTRICULAR END-DIASTOLIC PRESSURE

Condition	Site of Discrepancy	Cause of Discrepancy
Diastolic dysfunction	Mean LAP <LVEDP	Increased end-diastolic a wave
Aortic regurgitation	LAP a wave <LVEDP	Mitral valve closure before end-diastole
Pulmonic regurgitation	PADP <LVEDP	Bidirectional runoff for pulmonary artery flow
Right bundle branch block	PADP <LVEDP	Delayed pulmonic valve opening
Post-pneumonectomy	PAWP <LAP or LVEDP	Obstruction of pulmonary blood flow

Modified from Mark JB: Predicting left ventricular end-diastolic pressure. In Mark JB, editor: Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone, p 59.*
LAP, Left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *PADP*, pulmonary artery diastolic pressure; *PAWP*, pulmonary artery wedge pressure.

TABLE 45-6 OVERESTIMATION OF LEFT VENTRICULAR END-DIASTOLIC PRESSURE

Condition	Site of Discrepancy	Cause of Discrepancy
Positive end-expiratory pressure	Mean PAWP >Mean LAP	Creation of lung zone 1 or 2, or pericardial pressure changes
Pulmonary arterial hypertension	PADP >Mean PAWP	Increased pulmonary vascular resistance
Pulmonary venoocclusive disease	Mean PAWP >Mean LAP	Obstruction to flow in large pulmonary veins
Mitral stenosis	Mean LAP >LVEDP	Obstruction to flow across mitral valve
Mitral regurgitation	Mean LAP >LVEDP	Retrograde systolic v wave raises mean atrial pressure
Ventricular septal defect	Mean LAP >LVEDP	Antegrade systolic v wave raises mean atrial pressure
Tachycardia	PADP >Mean LAP >LVEDP	Short diastole creates pulmonary vascular and mitral valve gradients

These formulas oversimplify the behavior of the cardiovascular system to a tremendous degree. A more physiologic model of the systemic circulation considers the vasculature to be a series of collapsible vessels with intrinsic tone. This model, also called the vascular waterfall, describes a critical closing pressure in the downstream end of the circuit that exceeds right atrial pressure and serves to limit flow—an effective downstream pressure that is higher than the right atrial pressure used in the SVR formula. A detailed consideration of these issues is beyond the scope of this discussion and is available in other sources.[343,344] The important point, though, for clinicians is that therapy focused on the fine adjustment of SVR may be very misleading and should be avoided.

Additional problems arise in considering the pulmonary vasculature and using the formulas as a measure of resistance to flow through the lung.[345] The pulmonary vasculature is more compliant than the systemic vasculature, and marked increases in pulmonary blood flow may not produce any significant increase in pulmonary artery

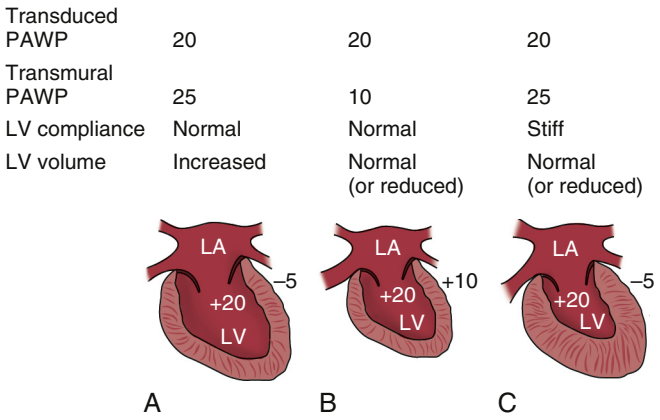

Figure 45-37. Influence of juxtacardiac pressure and ventricular compliance on left ventricular (LV) preload. Three interpretations of an increased transduced pulmonary artery wedge pressure (PAWP, 20 mm Hg) are possible. **A,** Juxtacardiac pressure (–5 mm Hg) and LV compliance are normal, transmural PAWP is increased (25 mm Hg), and LV volume is increased. **B,** Juxtacardiac pressure is increased (+10 mm Hg), LV compliance is normal, transmural PAWP is decreased (10 mm Hg), and LV volume is normal or decreased. **C,** Juxtacardiac pressure is normal, LV compliance is decreased, transmural PAWP is increased (25 mm Hg), and LV volume is normal or decreased. *(From Mark JB:* Atlas of cardiovascular monitoring, *New York, 1998, Churchill Livingstone.)*

TABLE 45-7 NORMAL HEMODYNAMIC VALUES

	Average	Range
Cardiac output (L/min)	5.0	4.0-6.5
Stroke volume (mL)	75	60-90
Systemic vascular resistance (Wood units)	15	10-20
(Dynes-sec-cm^{-5})	1200	800–1600
Pulmonary vascular resistance (Wood units)	1	0.5–3
(Dynes-sec-cm^{-5})	80	40–180
Arterial oxygen content (mL/dL)	18	16-20
Mixed venous oxygen content (mL/dL)	14	13-15
Mixed venous oxygen saturation (%)	75	70-80
Arteriovenous oxygen difference (mL/dL)	4	3-4
Oxygen consumption (mL/min)	225	200-250

pressure. In addition, flow usually ceases at end-diastole in the low resistance pulmonary circuit. Thus, changes in pulmonary vascular resistance may result from intrinsic alterations in pulmonary vascular tone (constriction or dilation), vascular recruitment, or rheologic changes. For the pulmonary circuit, a better approach to evaluating the changes in pulmonary vascular resistance may be to examine the end-diastolic gradient between the pulmonary artery diastolic and wedge pressures (Fig. 45-38).

Another set of common calculations derived from standard hemodynamic variables adjusts these measurements for the patient's body surface area (BSA) in an attempt to normalize these measurements for patients of different sizes. The BSA is generally determined from a standard nomogram based on height and weight. The most

Figure 45-38. Pulmonary hypertension. commonly indexed variables are the cardiac index (cardiac index = cardiac output/body surface area) and stroke volume index (stroke volume index = stroke volume/body surface area). On occasion, the systemic and pulmonary vascular resistances are indexed as well (systemic vascular resistance index = systemic vascular resistance × body surface area; pulmonary vascular resistance index = pulmonary vascular resistance × body surface area). In theory, normalizing hemodynamic values through "indexing" should help clinicians determine appropriate normal physiologic ranges to help guide therapy. Unfortunately, there is little evidence that these additional calculations provide valid normalizing adjustments. Body surface area is a biometric measurement with an obscure relationship to blood flow, and it does not adjust for variations between individuals based on age, sex, body habitus, or metabolic rate.[346] The patient's size and medical history is important in interpreting and treating changes in any of the measured or calculated hemodynamic variables. Therapy should not be solely directed towards achieving normal indexed values.

PULMONARY ARTERY CATHETERIZATION AND OUTCOME CONTROVERSIES

Pulmonary artery catheterization has stimulated much controversy. It is an expensive, invasive technique that is widely used but still not proven to improve patient outcome. The PAC controversy has been fueled in part by strongly worded editorials, written by prominent physicians, debating whether PAC use should be suspended pending scientific proof of its efficacy.[347-349] Although similar controversies have surrounded the use of other widely adopted, highly technical, clinical monitoring techniques such as electronic fetal monitoring,[350] physicians who use PACs should especially appreciate the uncertainties surrounding PAC monitoring and be fully informed of the evidence that must guide patient selection.[351,352]

The study published by Connors and colleagues in 1996 examining the association between PAC use during the first 24 hours of intensive care and subsequent survival marked a tipping point in the use of PACs for monitoring.[353] This prospective multicenter cohort study included 5735 patients with predicted 6-month

mortality in excess of 50%. Patients who were in the PAC-monitored group were judged to be sicker by every measurement recorded, although to the extent statistically possible, authors used case-matching analyses and applied a propensity score to adjust for these confounding medical covariates. After all adjustments, PAC-monitored patients had increased lengths of hospital stay and 20% increased mortality, and they incurred increased costs. Moreover, no subgroup of patients appeared to benefit from PAC monitoring. The publication of this study was accompanied by a strongly worded editorial calling for a moratorium on PAC use or a randomized controlled trial to define its efficacy.[347]

In the years since the study by Connors and colleagues, numerous studies have tried to determine whether patients are being helped or harmed by use of PACs. Many of these studies have been plagued by problems in study design (lack of randomization, small sample size), lack of standardization, and heterogeneity of both patients and clinical settings (medical versus surgical, cardiac surgery patients versus patients in acute congestive heart failure). In addition, little consensus exists regarding which hemodynamic variables are the most relevant to be obtained from catheter use. Furthermore, appropriate therapeutic interventions in response to specific findings are not clear.[283] Several large, randomized, adequately powered studies have been published regarding the use of the PAC in various settings: general noncardiac surgery,[233] vascular surgery,[354] CABG surgery,[338] nonsurgical patients with congestive heart failure,[355] patients with acute lung injury,[356] and critically ill patients in the intensive care unit.[357] Generally, these studies have shown no benefit to PAC use, but they also show no increase in mortality or in hospital or intensive care unit length of stay despite sometimes a more frequent incidence of adverse events, mainly infections or insertion-related events.

One common drawback to most of these large randomized studies is that they have necessarily examined the routine use of PAC and enrolled a sequential cohort of patients, most of them with a relatively moderate risk of death or complications. Also, not all of these studies have used a specific therapeutic intervention protocol.[358]

In especially high-risk patients, a clinical benefit from use of the PAC became evident. A review of 53,312 patients from the National Trauma Data Bank showed no mortality benefit to those treated with PACs in the group as a whole. However, in those with an injury severity scale greater than 25, those that arrived to the hospital in severe shock, or those older than 60 years of age, mortality was decreased significantly if PAC was used.[359] In another cohort study of 7300 mixed medical and surgical population, PAC use was associated with reduced mortality in patients with a high APACHE score (>31), but increased mortality in patients with a low APACHE score (<25).[360] Last, in a cohort of 280 older patients undergoing colon surgery, preoperative optimization with the use of PAC reduced mortality threefold in patients with a high Goldman's cardiac risk index but was not beneficial in those at a low cardiac risk (also see Chapter 80).[361]

PULMONARY ARTERY CATHETERIZATION: INDICATIONS

The most recent recommendation pertaining to the perioperative use of PACs is the American Society of Anesthesiologists practice guideline published in 2003.[231] The task force considered PAC monitoring to be appropriate in high-risk surgical patients undergoing high-risk procedures. Furthermore, the specific practice setting and the proficiency and experience of clinicians should be considered.

PAC use must be tailored to the degree of risk for the patient and the risk posed by the procedure itself. For example, a patient with advanced ischemic cardiomyopathy who needs lower extremity amputation under regional anesthesia would not warrant PAC monitoring whereas a patient with stable ischemic heart disease scheduled for extensive abdominal cancer resection may benefit from perioperative use. Furthermore, the individual practice setting must be considered.[231] Keats has termed this feature "the role of environment in the outcome of operation," by which he means important unmeasurable aspects of the clinical setting, including, but not limited to, technical skill and experience.[362] Clearly, all physicians and nurses using PAC must have the requisite knowledge and skills to use it safely and effectively.

The conclusion is that PAC use should be limited, although a moratorium on use is ill-advised. Indeed, data demonstrate a significant and continuing decrease in PAC usage.[316] Use should be reserved to centers with significant experience and expertise. PAC generally should be used to monitor and guide therapy in patients at high risk for hemodynamic instability, those who are judged more critically ill by a variety of clinical means, and those who are in shock, especially if they are older and suffer from other systemic diseases.

Much uncertainty and controversy continue to surround PAC use. Among the many measurements and calculations possible from PAC, little consensus exists regarding the most meaningful or the most useful. Obviously, PAC itself has no capacity to benefit unless it guides therapies that improve patient outcomes. Future research should focus on defining subgroups of patients who might benefit from the use of PAC, as well as defining effective therapeutic interventions based on the hemodynamic information gained from PAC.[351,358]

SPECIAL TYPES OF PULMONARY ARTERY CATHETERS

The popularity of PACs is largely due to the fact that they are multipurpose and provide a wide range of supplementary features for therapeutic and diagnostic applications. Some catheters have a third lumen, which is often used as an additional venous infusion line that opens 20 to 30 cm from the catheter tip. Specialized PACs allow temporary endocardial pacing or intracardiac ECG recording and may even have combinations of electrodes permanently implanted along its length to allow bipolar ventricular, atrial, or atrioventricular pacing.[363] These catheters can be especially useful for minimally invasive cardiac

surgery, where avoiding sternotomy hinders the placement of epicardial pacing leads.[364] Other models have a special lumen that opens into the right ventricle, through which a thin bipolar wire may be introduced for endocardial ventricular pacing, or separate atrial and ventricular lumina for passage of two pacing wires for dual-chamber sequential pacing.[365]

Specific PAC modifications were designed to allow for continuous cardiac output measurement, mixed venous oxygen saturation monitoring, or right heart function evaluation, vastly expanding the types of physiologic information available to those caring for critically ill patients.

Mixed Venous Oximetry Pulmonary Artery Catheter

Although the formal Fick cardiac output method is not widely applied in clinical practice outside the cardiac catheterization laboratory, the physiologic relations described by the Fick equation form the basis for another PAC-based monitoring technique termed *continuous mixed venous oximetry*. Rearrangement of the Fick equation reveals the four determinants of mixed venous hemoglobin saturation ($S\dot{v}O_2$):

$$S\bar{v}O_2 = SaO_2 - \frac{\dot{V}O_2}{\dot{Q} \times 1.36 \times Hgb}$$

where $S\bar{v}O_2$ = mixed venous hemoglobin saturation (%)
SaO_2 = arterial hemoglobin saturation (%)
$\dot{V}O_2$ = oxygen consumption (mL O_2/min)
$\dot{Q}$ = cardiac output (L/min)
Hgb = hemoglobin concentration (g/dL)

To the extent that arterial hemoglobin saturation, oxygen consumption, and hemoglobin concentration remain stable, mixed venous hemoglobin saturation may be used as an indirect indicator of cardiac output. For example, when cardiac output falls, tissue oxygen extraction increases and the mixed venous blood will have a lower oxygen content and lower hemoglobin oxygen saturation. However, as noted in this equation, mixed venous hemoglobin saturation also varies directly with arterial hemoglobin concentration and saturation, and varies inversely with oxygen consumption. When any of these other variables change significantly, one cannot assume that a change in mixed venous hemoglobin saturation results solely from a change in cardiac output. Although these considerations may confound the use of mixed venous hemoglobin saturation as an indicator of cardiac output, monitoring this variable provides more comprehensive information about the balance of oxygen delivery and consumption by the body—not just the cardiac output value, but also the adequacy of that cardiac output compared with tissue oxygen requirements.[366]

Although mixed venous hemoglobin saturation may be determined by intermittent blood sampling from the distal port of PAC, a specially designed PAC can provide this information reliably and continuously. Fiberoptic bundles incorporated into PAC determine the hemoglobin oxygen saturation in pulmonary artery blood based on the principles of reflectance oximetry using either a two- or three-wavelength system. A special computer connected to this PAC displays the mixed venous hemoglobin saturation continuously. The technology is typically incorporated into the standard PAC or the continuous cardiac output PAC (see later), in the latter case providing both continuous cardiac output and venous oximetry data.

Technical problems with continuous mixed venous oximetry are generally limited to improper PAC tip positioning against the vessel wall or inaccurate calibration.[367] Multi-wavelength fiberoptic technology and reflection intensity algorithms help to reduce wall artifacts caused by spurious reflections from a PAC thrombus or the pulmonary arterial walls. These catheters are calibrated at the bedside before use but may also be calibrated in vivo from a pulmonary artery blood gas sample. Recalibration every 24 hours is usually recommended because of a drift artifact. One note of caution is that a wedged PAC will read spuriously high oxygen saturation values corresponding to arterialized pulmonary blood. Most clinical trials comparing PAC-derived continuous venous oximetry values with laboratory analysis of pulmonary artery blood samples have shown good agreement between techniques.[368] Mixed venous hemoglobin saturation values reflect global, whole-body measurement. Therefore, regionally inadequate blood flow and tissue oxygen delivery (such as with limb or intestinal ischemia) can coexist with a normal or high mixed venous hemoglobin saturation.

Recently, the technology to continuously measure oxygen saturation has been incorporated into central venous catheters as well. These catheters measure central venous saturation, measured in the superior vena cava. Normally, this saturation is around 70% versus 75% in the pulmonary artery.[366] Low central venous saturation has been associated with increased complications both in trauma patients and in major surgery patients.[369,370]

The real value of measuring venous oxygen saturation lies in its ability to guide therapeutic interventions. Because one of the body's physiologic compensations for anemia is increased oxygen extraction, low venous hemoglobin saturation has been used to guide the need for blood transfusion.[371] Several studies have used venous hemoglobin saturation to guide interventions aimed at increasing cardiac output, a goal-directed approach. A recent randomized study in patients undergoing cardiac surgery has shown better outcome in patients randomized to protocol-driven interventions aimed at achieving mixed venous hemoglobin saturation above 70% (and blood lactate <2 mg/dL).[372] Similarly, optimizing the central venous oxygen saturation has been shown to improve outcome in patients with early sepsis[373] and in high-risk noncardiac and off-pump cardiac surgical patients.[374,375]

These studies have used strict protocol-driven therapeutic interventions. In contrast, a large Veterans Affairs observational trial of 3265 cardiac surgical patients noted that 49% of patients received continuous mixed venous oximetry PACs, and use of this catheter was associated with increased cost but no better outcome than the standard PAC group.[376] In this study, however, no protocol was used to guide therapeutic interventions based on monitoring results.

Right Ventricular Ejection Fraction Pulmonary Artery Catheter

Although cardiovascular monitoring has focused predominantly on left ventricular performance, in some instances right ventricular dysfunction may be the more important factor limiting circulation. Patient populations at increased risk for right ventricular dysfunction include those with chronic obstructive pulmonary disease, adult respiratory distress syndrome, pulmonary hypertension, and right ventricular ischemia and infarction.[377] Pulmonary artery catheter monitoring in patients with right ventricular infarction often reveals the characteristic hemodynamic patterns described earlier. However, accurate evaluation of right ventricular performance has proved more complicated. In patients with severe respiratory failure, for example, the confounding effects of mechanical ventilation with high levels of positive end-expiratory pressure (PEEP) have made interpretation of cardiac filling pressures difficult and, in some cases, misleading.[378]

Measurement of right ventricular ejection fraction (RVEF) with a specially designed PAC offers another method for evaluating right ventricular function. This method uses a standard PAC equipped with a rapid response thermistor that detects and quantifies the small changes in pulmonary artery blood temperature that occur with each heartbeat, in a manner somewhat analogous to a standard continuous cardiac output PAC. The cardiac output computer measures the residual fraction of thermal signal following each heart beat and derives the RVEF.[379] Clearly, all factors that confound standard thermodilution cardiac output measurement (described later) will also interfere with accurate determination of RVEF. In addition, because the temperature changes measured by the RVEF PAC are small beat-to-beat changes, the method will not work if the ECG R waves cannot be detected accurately, when the R-R interval is short owing to tachycardia, or if the cardiac rhythm is irregular.[367] Comparison of PAC-based RVEF measurements with angiographic or nuclear techniques has yielded mixed results in terms of accuracy, but this may reflect, in part, the absence of a widely accepted reference standard for this measurement.[379,380] Intraoperative use of the RVEF PAC has focused primarily on detection of right ventricular dysfunction in patients with coronary artery disease undergoing surgical revascularization. Reduced RVEF has been noted following cardiopulmonary bypass, particularly in patients with preexisting right coronary artery obstruction.[381] However, RVEF is an extremely load-dependent measurement of right ventricular performance, and the clinician must keep this fact in mind to interpret this measurement properly.[367,382] Clinical use of the RVEF PAC appears to have found its greatest application to date in critically ill patients, especially in those with respiratory failure.[382,383] In these applications, the measurement of greatest interest has been the right ventricular end-diastolic volume, which is derived mathematically from RVEF:

$$\text{RVEDV} = \frac{\text{SV}}{\text{RVEF}}$$

where RVEDV = right ventricular end-diastolic volume (mL)

SV = stroke volume (mL)

RVEF = right ventricular ejection fraction

The right ventricular end-diastolic volume appears to correlate better with volume status than standard preload measurements, such as CVP or PAWP.[383,384] These findings are not surprising given all the interpretive problems associated with cardiac filling pressure monitoring previously discussed. It should be kept in mind, however, that the better correlation between right ventricular end-diastolic volume and cardiac output may result from the mathematical coupling of measurements, because both are derivatives of stroke volume determined with PAC. Furthermore, as in the case of standard PAC monitoring, the benefit of RVEF PAC monitoring, in terms of patient outcomes, remains unproven.[231]

CARDIAC OUTPUT MONITORING

Cardiac output is the total blood flow generated by the heart, and in a normal adult at rest, it ranges from 4.0 to 6.5 L/min. Measurement of cardiac output provides a global assessment of the circulation, and in combination with other hemodynamic measurements (heart rate, arterial blood pressure, CVP, pulmonary artery pressure, and wedge pressure), it allows calculation of additional important circulatory variables, such as systemic and pulmonary vascular resistance and ventricular stroke work (see Table 45-7).

Three factors have driven efforts to measure cardiac output in clinical practice. The first is the recognition that in many critically ill patients, low cardiac output leads to significant morbidity and mortality.[385] Second, clinical assessment of cardiac output is often inaccurate; for example, seriously ill patients with decreased cardiac output might have normal systemic arterial blood pressures.[386] Finally, newer techniques for cardiac output measurement are becoming less invasive and thus might provide benefit to many patients without the attendant risks of invasive monitoring.[386,387] The advantages and disadvantages of each technique must be appreciated for proper clinical application.

THERMODILUTION CARDIAC OUTPUT MONITORING

The thermodilution technique has become the de facto clinical standard for measuring cardiac output because of its ease of implementation and the long clinical experience with its use in various settings. It is a variant of the indicator dilution method, described in more detail in Chapter 44, in which a known amount of a tracer substance is injected into the bloodstream and its concentration change is measured over time at a downstream site.[388] For thermodilution, a known volume of iced or room-temperature fluid is injected as a bolus into the proximal (right atrium) lumen of the PAC, and the resulting change in the pulmonary artery blood temperature is recorded by the thermistor at the catheter tip. As in all other forms of cardiovascular monitoring, it is important

to have a real-time display of the thermodilution curve resulting from each cardiac output measurement.[389] This allows the clinician to discern artifacts that would invalidate the cardiac output measurement, such as unstable blood temperature, recirculation, or incomplete indicator injection.

Because several groups have demonstrated equivalent accuracy in cardiac output determinations when either ice-cold or room-temperature injectates are used, it appears that room-temperature injectate is preferred for almost all clinical applications.[390] In adults, an injectate volume of 10 mL should be used, whereas in children, an injectate volume of 0.15 mL/kg is recommended.[389]

Usually, three cardiac output measurements performed in rapid succession are averaged to provide a more reliable result. When only a single injection was used to determine cardiac output, a difference between sequential cardiac output measurements of 22% was required to suggest a clinically significant change. In contrast, when three injections are averaged to determine the thermodilution measurement, a change greater than 13% indicates a clinically significant change in cardiac output.[391]

Even when carefully performed, some studies have found that thermodilution cardiac output measurements may not agree with other reference methods.[392,393] However, few complications are directly attributable to the technique itself, and following the trend in cardiac output is probably more clinically useful than emphasizing any absolute value.

Sources of Error in Thermodilution Cardiac Output Monitoring

Several important technical issues and potential sources of error must be considered to interpret thermodilution cardiac output measurements properly[388,389] (Box 45-7). The thermodilution technique measures right ventricular output. With intracardiac shunt, right ventricular and left ventricular outputs will not be equal. In patients with a left-to-right shunt, early recirculation of the thermal indicator can be seen to distort the downward slope of the thermodilution curve, and in patients with right-to-left shunt, some of the injected indicator will bypass the thermistor, resulting in overestimation of the left ventricular cardiac output.

Patients with tricuspid or pulmonic valve regurgitation pose additional problems for thermodilution cardiac output measurement owing to recirculation of the indicator across the incompetent valve. In patients with severe tricuspid regurgitation, the thermodilution curves have an abnormally prolonged decay time and the measured cardiac output is simply unreliable, either underestimated or overestimated, depending on the severity of valvular regurgitation and the magnitude of the cardiac output.[389,394]

Other technical problems with thermodilution cardiac output measurement are caused by inadequate delivery of the thermal indicator. Mishandling of an iced injectate syringe can warm the solution and reduce the signal-to-noise ratio of the thermal indicator administered. In addition, fibrin or blood clot on the PAC tip may lead to thermistor malfunction and result in spurious cardiac output values. Unrecognized fluctuation in blood temperature may also influence cardiac output measurement. In most patients, pulmonary artery blood temperature falls rapidly in the initial minutes following cardiopulmonary bypass when the rewarmed body core redistributes the heat gained at the end of bypass. Owing to this progressive decline in central core and pulmonary artery blood temperature, the thermal baseline is unstable. Thermodilution cardiac output measurements made in the minutes following bypass are notoriously unreliable, most often leading to marked underestimation of the true cardiac output.[395] Other inaccuracies in thermodilution cardiac output measurement occur when pulmonary artery blood temperature changes because of rapid fluid infusion.[396] Either overestimation or underestimation of cardiac output occurs, depending on the timing of the additional fluid bolus.

One controversy surrounding bolus thermodilution cardiac output monitoring is the proper timing of measurement in relation to the respiratory cycle, particularly in patients receiving positive-pressure mechanical ventilation, because right ventricular stroke output varies as much as 50% during the respiratory cycle. Although reproducibility of consecutive measurements improves markedly when the bolus injections are synchronized to the same phase of the respiratory cycle, an accurate measurement of average cardiac output is achieved more reliably by making multiple injections during the different phases of the respiratory cycle and then averaging the results.[389,397] Last, the measured thermodilution cardiac output can overestimate true cardiac output during low-flow states because of significant heat loss from slow injectate transit.[398]

BOX 45-7 *Factors Influencing Accuracy of Thermodilution Cardiac Output Measurement*

- Intracardiac shunts
- Tricuspid or pulmonic valve regurgitation
- Inadequate delivery of thermal indicator
  - Central venous injection site within catheter introducer sheath
  - Warming of iced injectate
- Thermistor malfunction from fibrin or clot
- Pulmonary artery blood temperature fluctuations
  - Following cardiopulmonary bypass
  - Rapid intravenous fluid administration
- Respiratory cycle influences

CONTINUOUS THERMODILUTION CARDIAC OUTPUT MONITORING

Newer technologies applied to PAC monitoring allow nearly continuous cardiac output (CCO) monitoring using a warm thermal indicator.[388,399] In brief, small quantities of heat are released from a 10-cm thermal filament incorporated into the right ventricular portion of a PAC, approximately 15 to 25 cm from the catheter tip, and the resulting thermal signal is measured by the thermistor at the tip of the catheter in the pulmonary artery. The heating filament is cycled on and off in a pseudorandom binary sequence, and the cardiac output is derived from cross correlation of the measured pulmonary artery temperature with the known sequence of heating filament activation.[399] Typically, the displayed value for cardiac

output is updated every 30 to 60 seconds and represents the average value for the cardiac output measured over the previous 3 to 6 minutes. In a laboratory investigation examining how CCO measurements responded to unstable hemodynamic conditions, such as hemorrhage and fluid resuscitation, Siegel and associates showed that CCO changes were markedly slower than changes detected by ultrasonic flow probe, blood pressure, or mixed venous oxygen saturation.[400] In view of these inherent time delays, the PAC CCO method should be considered a continual rather than a continuous real-time monitor.

In general, the CCO method has good agreement with standard bolus thermodilution cardiac output measurements or electromagnetic flow probe techniques.[388,401] The device performed well in patients with a wide range of cardiac outputs (1.6 to 10.6 L/min) and core temperatures (33.2° C to 39.8° C). Reproducibility and precision appear to be better with the CCO method compared with the standard bolus thermodilution technique, probably because the continuous method displays a time-weighted average cardiac output value, as opposed to a single instantaneous measurement.[402,403]

The CCO PAC has been widely accepted into clinical use for a number of practical reasons. Although these catheters are more expensive than standard PACs, obviating the need for bolus injections reduces nursing workload and the potential risk of fluid overload or infection. Furthermore, because the CCO PAC provides a cardiac output value that is an average derived over the previous several minutes, beat-to-beat variations in stroke volume that occur during a single respiratory cycle are all equally represented. As a result, a cardiac output measured by the CCO method may provide a more accurate measurement of global cardiac output for patients receiving positive-pressure mechanical ventilation.

However, like cold bolus thermodilution techniques, warm thermal CCO has certain methodologic pitfalls that must be recognized and avoided. The CCO computer and catheter require a significant amount of time to warm up and may work poorly in an environment with a great deal of thermal noise, such as the cardiac operating room. As already emphasized, CCO monitors have an inherent 5- to 15-minute delay in responding to abrupt changes in cardiac output, and the magnitude of this delay depends on the type of physiologic perturbation, as well as the CCO computer monitor algorithm.[400] Although modifications of CCO algorithms provide a "STAT mode" rapid response time, acute changes in cardiac output are still detected more slowly by CCO monitoring than by other methods, such as direct arterial pressure or mixed venous oximetry. In effect, the CCO technique involves a fundamental tradeoff between rapid response time and overall accuracy of measurement. The standards for these performance characteristics have not been defined, but must balance the response time against the stability of the displayed value and its immunity from thermal noise.[402]

TRANSPULMONARY THERMODILUTION CARDIAC OUTPUT

For transpulmonary thermodilution measurement, ice-cold saline is injected into a central venous line while the change in temperature is measured in a large peripheral artery (femoral, axillary, or brachial artery) via a special arterial catheter equipped with a thermistor.[404] Several studies have shown adequate agreement with standard thermodilution cardiac output.[405,406] Because the measurement lasts over several cardiac cycles, respiratory effects on stroke volume are averaged and eliminated, in contrast to standard thermodilution.[407]

Mathematic derivation from the transpulmonary thermodilution curve can produce several additional useful indices. Extravascular lung water is a measure of pulmonary edema and can be used to guide fluid therapy in patients with acute lung injury or sepsis.[408-410] Other derived indices are the global end-diastolic volume and intrathoracic blood volume. These indices are a better measure of cardiac preload than traditional measurements such as CVP or pulmonary artery wedge pressure.[411,412] However, these indices still cannot predict cardiac output response to intravenous fluid administration.[413] The last parameter derived from the transpulmonary thermodilution curve is called the cardiac function index, calculated using cardiac output and the intrathoracic blood volume. It correlates closely with echocardiography-derived left ventricular ejection fraction.[414]

LITHIUM DILUTION CARDIAC OUTPUT MONITORING

The lithium dilution technique is another cardiac output monitoring method that derives its fundamental basis from indicator dilution principles.[415] In brief, following an intravenous bolus injection of a small dose of lithium chloride, an ion-selective electrode attached to a peripheral arterial catheter measures the lithium dilution curve, from which the cardiac output is derived. This is an accurate technique compared with standard thermodilution or electromagnetic flowmetry.[416,417] The lithium indicator can be injected through a peripheral intravenous catheter with similar measurement accuracy, thus eliminating the need for a central venous line.[418] This technique can also be used in children.[419] Lithium dilution cannot be used in patients who are taking lithium or those who have just received nondepolarizing neuromuscular blockers (because these blockers also alter the lithium sensor electrode measurement).

OTHER METHODS FOR MONITORING CARDIAC OUTPUT AND PERFUSION

ESOPHAGEAL DOPPLER CARDIAC OUTPUT MONITORING

All of the ultrasound-based methods for cardiac output monitoring employ the Doppler principle (also see Chapters 44 and 46). Cardiac output can be intermittently measured by the Doppler technique during transthoracic or transesophageal echocardiography examinations (see Chapter 46). A special esophageal Doppler probe has been developed that could be positioned and left in place for continuous monitoring without the need for time-consuming measurements and calculations by the

physician or ultrasonographer. The transducer is incorporated into the tip of a probe resembling a standard esophageal stethoscope and allows continuous monitoring of cardiac output by measuring the Doppler shift of the interrogated blood flow in the descending thoracic aorta. The Doppler probe is inserted into the esophagus to a depth of approximately 35 cm from the incisor teeth and is adjusted to optimize the audible Doppler flow sound from the descending aorta. In most patients, optimal probe tip position is at the T5-T6 vertebral interspace or the third sternocostal junction, because the esophagus and the descending aorta lie in close proximity and run essentially parallel to each other at this location.[420] The ultrasound transducer is mounted at a fixed angle that is anatomically defined and known by the cardiac output computer. This angle is then used to correct the resulting Doppler shift frequency to provide an accurate velocity measurement.

Several limitations of the esophageal Doppler technique must be recognized to avoid incorrect data interpretation. This monitoring method interrogates blood flow in the descending thoracic aorta and therefore measures only a fraction of total cardiac output. To report total cardiac output, either the esophageal Doppler measurement must be "calibrated" by some alternative method, or an empirically determined correction constant of 1.4 is used.[421] This constant is accurate for most patients but does not apply universally, especially in the presence of conditions that redistribute blood flow (such as pregnancy), in aortic cross-clamping, and following cardiopulmonary bypass.[420,422] In addition, the descending thoracic aorta diameter is either measured using A-mode ultrasound or calculated from a nomogram based on the patient's age, sex, height, and weight.[423] When calculated, the aortic diameter is assumed not to change throughout the cardiac cycle.[424] In addition, the technique is likely to be inaccurate in the presence of aortic valve stenosis or regurgitation and in patients with thoracic aortic disease. It is not easily applied in nonintubated, nonsedated patients, and it cannot be used in individuals with esophageal pathology. Finally, like all ultrasound techniques, the acoustic window needed to acquire the Doppler signal may not be adequate in some individuals, thereby precluding use of this method.

Advantages of the esophageal Doppler monitoring technique include its ease of use, minimal invasiveness, and inherent safety. It appears that limited experience is needed for clinical success—as few as 10 to 12 cases for accurate application of the technique.[420] A recent review described 25 clinical trials comparing esophageal Doppler cardiac output measurement with PAC thermodilution measurements and noted that the Doppler cardiac output values correlated well with thermodilution measurements, showed minimal overall bias, and resulted in good tracking of directional changes in thermodilution cardiac output with low intra- and interobserver measurement variability.[420]

Recently, the esophageal Doppler method has seen renewed popularity.[425,426] Current devices provide a clear visual display of the spectral Doppler waveform and also calculate and display additional hemodynamic variables, including the peak blood flow velocity, flow acceleration,

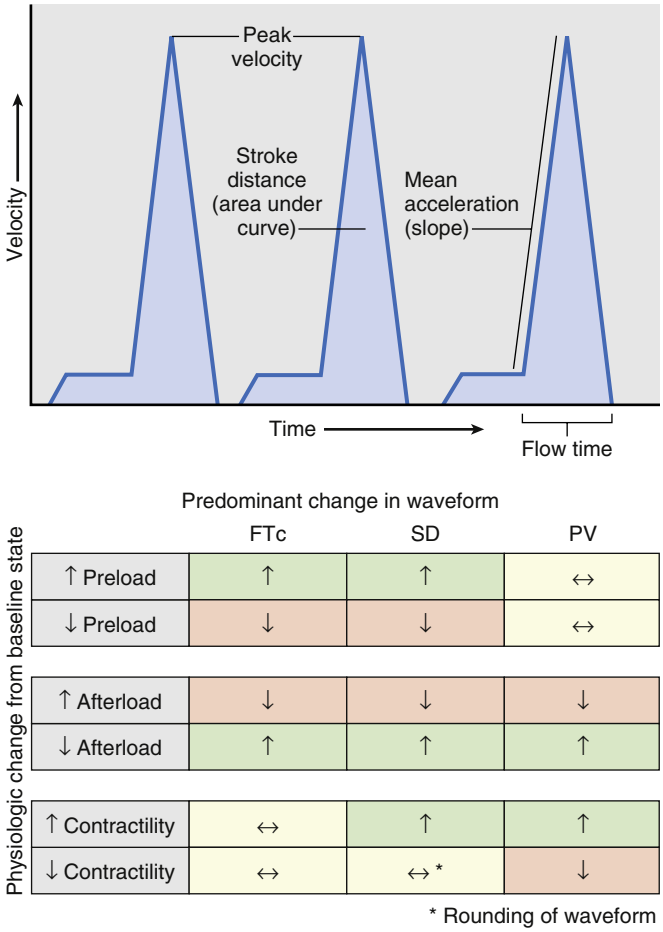

Figure 45-39. The velocity-time waveform displayed by esophageal Doppler cardiac output monitoring devices reflects alterations in contractility, preload, and afterload. Stroke distance (SD) is directly related to calculated stroke volume and provides a useful surrogate measure of cardiac output. *FTc*, Systolic flow time corrected for heart rate; *PV*, peak velocity.

and heart rate–corrected flow time (Fig. 45-39). Some studies have shown that these additional measures provide useful information about left ventricular preload, fluid responsiveness, contractility, and systemic vascular resistance.[421,427,428] One of the more important benefits of this monitor may be focusing clinical attention on optimizing stroke volume rather than total cardiac output. Indeed, in critically ill patients, complications may be better predicted by low stroke volume than by low cardiac output.[429] Several studies have shown that volume resuscitation, guided by maximizing esophageal Doppler-measured stroke volume in moderate risk surgical patients, reduces perioperative morbidity and shortens hospital stay.[425,426]

BIOIMPEDANCE CARDIAC OUTPUT MONITORING

The technique of bioimpedance cardiac output monitoring was first described by Kubicek and associates and is based on changes in electrical impedance of the thoracic cavity occurring with ejection of blood during cardiac

systole.[430] Their original formula relates these bioimpedance measurements to stroke volume:

$$SV = \rho L^2/Zo^2 \bullet VET \bullet \max\frac{dZ}{dt}$$

where SV = stroke volume
ϱ = specific resistivity of blood
L = thoracic length
Z_O = basal thoracic impedance
VET = ventricular ejection time

$\max\frac{dZ}{dt}$ = maximum rate of impedance change during systolic upstroke

For performing the measurements, disposable electrodes are applied to the skin surface along the sides of the neck and lateral aspect of the lower thorax, and a continuous small electrical current is applied across the chest. Patient height, weight, and gender are used to calculate the volume of the thoracic cavity. Bioimpedance cardiac output is computed for each cardiac cycle and continuously displayed as an average value over several heart beats.

Although the bioimpedance method is accurate in healthy volunteers, its reliability deteriorates in critically ill patients, including those with sepsis, pulmonary edema, aortic regurgitation, and cardiac pacing[431-433] (also see Chapters 47, 67, and 101). More recent changes in signal processing techniques have improved the accuracy of thoracic bioimpedance measurements and might increase its clinical acceptance.[434]

PARTIAL CO_2 REBREATHING CARDIAC OUTPUT MONITORING

Another method for cardiac output monitoring that does not require pulmonary artery catheterization is the partial CO_2 rebreathing technique.[435,436] Owing to the difficulty encountered in the standard Fick method involving measuring oxygen consumption and mixed venous hemoglobin saturation, this alternative technique is based on a restatement of the Fick equation for carbon dioxide elimination rather than oxygen uptake.

$$\dot{Q} = \dot{V}co_2/(C\bar{v}co_2 - Caco_2)$$

where $\dot{Q}$ = cardiac output
$\dot{V}co_2$ = rate of carbon dioxide elimination
$C\bar{v}co_2$ = carbon dioxide content of mixed venous blood
$Caco_2$ = carbon dioxide content of arterial blood

This method uses the change in CO_2 production and end-tidal CO_2 concentration in response to a brief, sudden change in minute ventilation. With a specially designed breathing system and monitoring computer, this measurement is easily performed in any tracheally intubated patient. Every 3 minutes, a computer-controlled pneumatic valve intermittently increases dead space for a 50-second period, thereby causing partial rebreathing of exhaled gases. Changes in end-tidal CO_2 in response to the rebreathing maneuver are used to calculate cardiac output by a differential version of the Fick equation for carbon dioxide. This method is entirely noninvasive, it can be performed every few minutes, and the brief episodes of rebreathing pose no substantial risk to most patients, with end-tidal CO_2 measurements increasing by less than 3 mm Hg. Unfortunately, accurate measurements with this technique require tracheal intubation for precise measurement of exhaled gases. Furthermore, changing patterns of ventilation may have an unpredictable influence on the measurement. As with all Fick-based techniques, the partial CO_2 rebreathing method measures pulmonary capillary blood flow as an indicator of total cardiac output and thus requires correction for pulmonary shunt.

There is good agreement between the partial rebreathing CO_2 cardiac output method and other techniques, such as thermodilution. However, the clinical trials were small (i.e., number of patients studied) and mainly focused on specific patient groups, particularly coronary artery bypass surgery patients.[437] The clinical role for this technique is mainly focused on short-term intraoperative applications or mechanically ventilated postoperative patients. Because of the mandatory increase in $Paco_2$, the technique is relatively contraindicated in patients with increased intracranial pressure.

PULSE CONTOUR CARDIAC OUTPUT MONITORING

Analysis of the arterial pulse pressure waveform is one of the most recent developments in the area of cardiac output monitoring. Basically continuous measurement of cardiac output is derived from the analysis of the arterial pulse pressure waveform. These methods, generally termed pulse contour cardiac output, determine stroke volume from computerized analysis of the area under the arterial pressure waveform recorded from an arterial catheter or even a noninvasive finger blood pressure waveform.[438-441] Pulse contour methods offer the potential for noninvasive, continuous, beat-to-beat cardiac output monitoring. Also, the change in stroke volume from beat to beat (termed *stroke volume variation*) can be used to evaluate volume status in ventilated patients.[118,442]

However, several shortcomings need to be considered.[443] First, a baseline calibration with a known cardiac output is required to account for individual differences in vascular resistance, impedance, and wave reflectance. Additionally, recalibration is required every 8 to 12 hours to account for changes in vascular characteristics over time. This need for external calibration might require the use of a more invasive technique, negating the noninvasiveness advantage of pulse contour methods. Recently, several systems were developed with the capability for an autocalibration based on patient's demographic variables. However, the accuracy of this autocalibration in various clinical situations is questionable.[444] A reasonably well-defined arterial pressure waveform with a discernible dicrotic notch is required for accurate identification of systole and diastole, a condition that might not exist under severe tachycardia or dysrhythmia, or other very low output states. Last, for a meaningful use of beat-to-beat variation in stroke volume (as well as systolic pressure or pulse pressure variation), the patient needs to be

on controlled mechanical ventilation with a tidal volume of at least 8 mL/kg body weight.[445]

Still, clinical trials in surgical patients have shown that the pulse contour cardiac output methods provide an acceptable level of accuracy with a bias of less than 0.5 L/minute compared with thermodilution cardiac output.[440,446,447] Stroke volume variation above 10% is a useful predictor of responsiveness to intravenous fluid administration.[106] Finally, goal-directed therapy based either on maximizing pulse contour–derived cardiac output or minimizing stroke volume variation results in improved perioperative outcome.[448,449]

GASTRIC TONOMETRY

Gastric tonometry aims at monitoring gastric circulation as an early indication of splanchnic hypoperfusion.[450] A balloon-tipped tube is inserted into the stomach, and the saline or air in the balloon is allowed to equilibrate with the CO_2 in the gastric lumen. Intermittently, the saline or air is aspirated and the CO_2 level is measured. With development of gastric hypoperfusion, CO_2 clearance from the gastric mucosa decreases, whereas CO_2 production increases from bicarbonate titration of acid released by anaerobic metabolism. The CO_2 from the mucosa diffuses freely to the gastric lumen and is detected by the tonometry device.

Gastric mucosal CO_2 and pH are predictors of post-trauma and perioperative complications or death.[451-453] Also, therapy guided by gastric tonometry can improve clinical outcome in critically ill or perioperative patients.[454,455] However, this somewhat cumbersome and time-consuming method for monitoring tissue perfusion has not been widely adopted.

Chapter 46

Perioperative Echocardiography

GEORGES DESJARDINS • DANIEL P. VEZINA • KEN B. JOHNSON • MICHAEL K. CAHALAN

Key Points

- The latest guidelines for perioperative transesophageal echocardiography (TEE) recommend TEE in all patients having open heart and thoracic aortic vascular procedures and in patients with unexplained life-threatening circulatory instability unless contraindicated by esophageal pathologic abnormalities.
- The higher the ultrasound transducer frequency, the better the image quality, but the more limited the depth of penetration.
- The modified Bernoulli theorem transforms velocities measured by Doppler echocardiography into transvalvular pressure gradients. Pressure gradient = $4V^2$, where V = velocity in meters per second.
- Tissue Doppler imaging measures myocardial velocities and is the primary tool for the assessment of ventricular systolic and diastolic functions.
- Three-dimensional TEE in real time is now widely available and proving to be of significant value in perioperative patients.
- The basic TEE examination is an abbreviated version of the comprehensive examination. It is significantly faster to complete than the comprehensive examination and will identify the majority of life-threatening perioperative cardiac pathologic complications.
- The basic transthoracic echocardiography (TTE) examination is performed from three standard windows and provides cross sections comparable with those produced with TEE.
- TEE provides highly reliable and reproducible methods to assess cardiac filling and ejection.
- TEE is more sensitive than the electrocardiogram for the detection of intraoperative myocardial ischemia. It is more predictive of postoperative outcome than preoperative cardiac stress testing.
- TEE is an essential tool in the cardiac surgical unit where it plays a vital role in assessing the need for management changes, as well as guiding those changes and evaluating the effectiveness of the surgical procedure.

INTRODUCTION

Echocardiography has transformed the practice of anesthesia. Transesophageal echocardiography (TEE) is the most powerful cardiovascular diagnostic technique available in the practice of perioperative medicine today. Thousands of published reports document its vital role in the determination of hemodynamics, the detection of myocardial ischemia, cardiovascular pathologic evaluation, and the assessment of cardiac surgical plans and results. With the information provided by TEE, anesthesiologists, surgeons, and intensivists can alter therapy to decrease morbidity and increase the survival of surgical patients. No other diagnostic technique has had such an impact on the practice of anesthesia and critical care. As a result, routine intraoperative TEE is an expectation in most cardiac surgical practices, and basic TEE is a resource in many noncardiac practices. In addition, transthoracic echocardiography (TTE) has emerged as a highly portable tool for cardiac assessment in the patient whose trachea is not intubated. This chapter reviews the published literature documenting echocardiography's role in perioperative care after presenting a brief summary of its history, its underlying physical principles, and the techniques required to perform it.

HISTORY

In 1976, Dr. Leon Frazin published the results of studies using an esophageal M-mode transducer, thereby introducing the concept of TEE.[1] Subsequently, Matsumoto

and associates used M-mode TEE to study left ventricular (LV) function during cardiovascular surgery.[2] However, M-mode echocardiography provides too limited a view of spatial relationships to be practical for intraoperative monitoring or real-time decision making. In the early 1980s, Hanrath and associates introduced a two-dimensional (2-D), phased-array transducer mounted on the tip of a flexible gastroscope, and TEE's intraoperative potential became apparent.[3] However, wide adoption of TEE did not occur until the mid-1980s, when the TEE transducer design was refined and color-flow Doppler (CFD) became commercially available. With these advances, TEE could provide the high-resolution, real-time images of structure and blood flow used today on a daily basis. However, the original single-plane and subsequent biplane TEE probes limited the potential imaging planes. Multiplane TEE imaging uses a rotatable 2-D transducer within the probe tip that has substantially resolved those limitations and remains the current standard of practice.

Along with advances in probe technology, ultrasound manufacturers improved image compression algorithms, high-density digital storage, and broadband communication networks that have revolutionized the storage and processing of TEE images. Secure digital servers have replaced videotape libraries of clinical studies, resulting in vastly faster access to and fidelity of stored images. In addition, after decades of work on real-time three-dimensional (3-D) imaging, it is finally a reality. The impact of 3-D imaging on clinical practice continues to evolve but has already become a highly valuable tool in valvular pathologic assessment and repair.[4]

TRANSESOPHAGEAL ECHOCARDIOGRAPHY PRACTICE GUIDELINES

In 1992, the American Society of Echocardiography (ASE) Committee for Physician Training in Echocardiography published its guidelines for training in TEE.[5] These are based on the prior recommendations for training in TTE and are directed at training for TEE in both operative and nonoperative applications. These guidelines require the trainee to attain at least an intermediate level of training in echocardiography and to perform and interpret at least 50 supervised TEE examinations. In 1996, a joint taskforce of the American Society of Anesthesiologists (ASA) and the Society of Cardiovascular Anesthesiologists (SCA) published guidelines for perioperative TEE that defined two levels of practice: basic and advanced.[6] Anesthesiologists with basic training in perioperative TEE "should be able to use TEE for indications that lie within the customary practice of anesthesiology" and "must be able to recognize their limitations in this setting and request assistance, in a timely manner, from a physician with advanced training." Anesthesiologists with advanced training in perioperative TEE "should, in addition to the above, be able to exploit the full diagnostic potential of TEE in the perioperative period." In 2010, the ASA House of Delegates approved updated guidelines for TEE, which delineated the following three subsets of recommendations.[7]

Cardiac and thoracic aortic surgery: "For adult patients without contraindications, TEE should be used in all open heart (e.g., valvular procedures) and thoracic aortic surgical procedures and should be considered in coronary artery bypass graft surgeries to: (1) confirm and refine the preoperative diagnosis, (2) detect new or unsuspected pathology, (3) adjust the anesthetic and surgical plan accordingly, and (4) assess the results of surgical intervention. In small children, the use of TEE should be considered on a case-by-case basis because of risks unique to these patients (e.g., bronchial obstruction)" (also see Chapter 94).

Noncardiac surgery: "TEE may be used when the nature of the planned surgery or the patient's known or suspected cardiovascular pathology might result in severe hemodynamic, pulmonary, or neurologic compromise. If equipment and expertise are available, TEE should be used when unexplained life-threatening circulatory instability persists despite corrective therapy."

Critical care patients: "TEE should be used when diagnostic information that is expected to alter management cannot be obtained by transthoracic echocardiography or other modalities in a timely manner" (also see Chapter 102).

In 1999, a joint taskforce of the ASE and SCA published recommendations for a comprehensive TEE examination.[8] These recommendations described in detail the 20 TEE cross sections that make up the comprehensive examination. In addition, in 2002, a joint taskforce of the ASE and SCA used the principles and recommendations published in the aforementioned guidelines to formulate guidelines for training in perioperative TEE, including the prerequisite medical knowledge and training, echocardiographic knowledge and skills, training components and duration, training environment and supervision, and equivalence requirements for postgraduate physicians already in practice.[9] Minimum numbers of cases are delineated; however, these numbers are less important than the depth and diversity of the clinical experience and quality of training. Similar to prior published guidelines, these guidelines provide training recommendations for a basic level and an advanced level of perioperative echocardiography. Unlike prior guidelines, these guidelines do not specify the duration of training; rather, they emphasize the goals of training and the number and diversity of cases required to meet these goals (Table 46-1). The time required for perioperative training will vary significantly, depending on the patient volume and diversity of the affiliated cardiac surgical program.

The American Heart Association, the American College of Cardiology, the European Association of Echocardiography, and other professional organizations have issued other guidelines that involve TEE.[10-12] In 2011, the ASE and other societies published updated appropriateness criteria for echocardiography, including perioperative applications. More than 200 indications were classified as appropriate, uncertain, or inappropriate. Unstable coronary syndromes, decompensated heart failure, significant arrhythmias, and severe valvular diseases were listed as appropriate indications for the perioperative use of echocardiography.[13] Recent retrospective reviews performed

TABLE 46-1 RECOMMENDATIONS FOR BASIC AND ADVANCED PERIOPERATIVE ECHOCARDIOGRAPHY

	Basic*	Advanced*
Minimum number of examinations†	150	300
Minimum number of examinations personally performed‡	50	150
Program director qualifications	Advanced perioperative echocardiography training	Advanced perioperative echocardiography training plus at least 150 additional perioperative transesophageal echocardiographic examinations
Program qualifications	Wide variety of perioperative applications of echocardiography	Full spectrum of perioperative applications of echocardiography

Adapted from Cahalan MK, Abel M, Goldman M, et al: American Society of Echocardiography and Society of Cardiovascular Anesthesiologists task force guidelines for training in perioperative echocardiography, Anesth Analg *94:1384-1388, 2002.*

*Totals for basic training may be counted toward advanced training, provided the basic training was completed in an advanced training environment.

†Complete echocardiographic examinations interpreted and reported by the trainee under appropriate supervision. May include transthoracic studies recorded by qualified individuals other than the trainee.

‡Comprehensive intraoperative echocardiographic examinations personally performed, interpreted, and reported by the trainee under appropriate supervision.

on more than 2500 patients showed that echocardiography is appropriately used in 80% of the cases and inappropriately used in less than 15%.[14,15] Published audits specifically addressing perioperative echocardiography services showed that using appropriate indications leads to the identification of significant cardiac pathologic complications in 26% of the cases and significant changes 60% of the time in medical and surgical management.[16,17] The ever-expanding uses of perioperative echocardiography will require ongoing outcome-based studies and quality assessment programs. The ASE recently published recommended components of such programs.[18] When these guidelines address perioperative TEE, their recommendations are consistent with those previously noted. Finally, a section on perioperative TEE for this indication will be included in the new Guidelines on Perioperative Cardiovascular Evaluation before Noncardiac Surgery to be published in 2014.

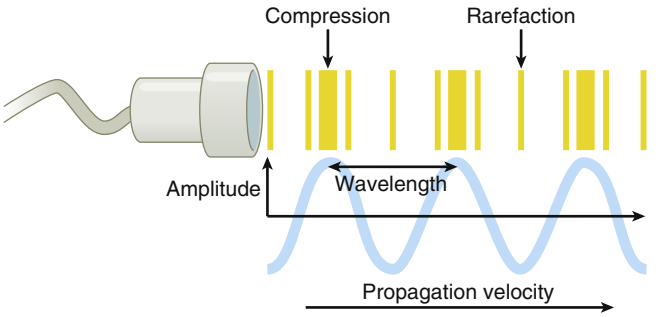

Figure 46-1. Illustration of terms used to describe ultrasound energy transmission from a transducer into adjacent tissue. As ultrasound vibrations enter surrounding tissue, particles within the tissue compress *(compression)* and then spread apart *(rarefaction)*. Sine waves are used to characterize the sequence of compression and rarefaction. The *wavelength* is the distance between two peaks of the sine wave. The *amplitude* is a measure of tissue compression. The *propagation velocity* is the speed of the ultrasound wave within tissue.

PROPERTIES OF ULTRASOUND

To noninvasively visualize structures inside the body, ultrasound machines generate an imperceptible vibration within a transducer that, when placed next to tissue surfaces, vibrates the surrounding tissue (muscle, blood, fat, or bone). During vibration, particles within the tissue compress and then spread apart. This process is called *compression* and *rarefaction*. The sequence of compression and rarefaction is described using sine waves and is characterized in terms of wavelength, frequency, amplitude, and propagation velocity (Figure 46-1).

The *wavelength* is the distance between two peaks of the sine wave. Wavelengths used in ultrasound are measured in millimeters (mm). Frequency is the number of cycles that occur in one second. One cycle per second is defined as 1 hertz (Hz). Ultrasound is sound with frequencies higher than the audible range for humans or greater than 20,000 cycles per second (20 KHz). Frequencies typically used for sonographic imaging are 2 to 10 million hertz (MHz). The wavelength is inversely related to the frequency.

The *amplitude* is a measure of tissue compression. Amplitude represents how loud an ultrasound wave is. The amplitude can vary over a large range and is described using decibels (dB). Decibels is a logarithmic transformation that allows the presentation of large amplitudes next to small amplitudes (i.e., 1000 and 0.001) on the same display. A rule of thumb is that a change of 6 dB is equivalent to a doubling or halving of the amplitude.

The *propagation velocity* describes the speed of an ultrasound wave traveling through tissue. In blood, it is 1540 meters per second (m/sec). The relationship between propagation velocity, frequency, and wavelength is described by Equation 1:

$$c = f \times \lambda \quad (1)$$

where c is the propagation velocity, f is the frequency (Hz) and λ is the wavelength (mm). Assuming the propagation velocity is constant, the wavelength for any frequency can be calculated using the relationship shown in Equations 2 and 3:

$$\lambda\,(\text{mm}) = 1,540,000\,(\text{mm/sec}) \div f\,(\text{Hz}) \quad (2)$$

or

$$\lambda\,(\text{mm}) = 1.54\,(\text{km/sec}) \div f\,(\text{MHz}) \quad (3)$$

TABLE 46-2 **RELATIONSHIP BETWEEN FREQUENCY, WAVELENGTH, AND DEPTH OF PENETRATION**

Frequency	Wavelength	Depth of Penetration (200 to 400 × Wavelength)	Approximate Resolution (2 × Wavelength)
3.5 MHz	0.44 mm	9-18 cm	0.9 mm
5.0 MHz	0.31 mm	6-12 cm	0.6 mm
6.0 MHz	0.26 mm	5-10 cm	0.5 mm
7.5 MHz	0.21 mm	4-8 cm	0.4 mm

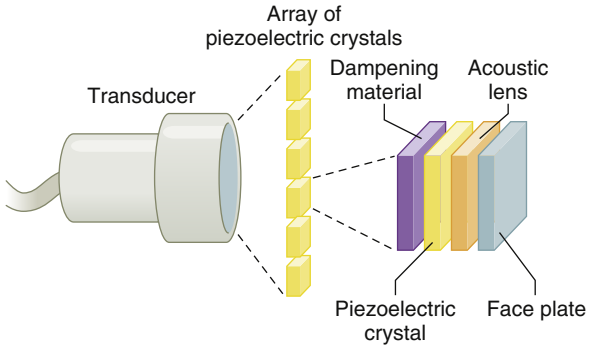

Figure 46-2. Illustration of an array of piezoelectric crystals contained within an ultrasound transducer. When pulsed with alternating current, piezoelectric crystals "ring" much like a bell. The crystal continues to vibrate after an electrical pulse has ended. To achieve a crisper pulse, a backing material is applied to the crystal to *dampen* the ring after the pulse has ended. To optimize transmission from the crystal into tissue, an *acoustic lens* focuses the ultrasound beam and an *impedance matching face plate* improves the conductance of ultrasound from the transducer into tissue.

Wavelengths associated with commonly used transducer frequencies range from 0.1 to 0.6 mm. Examples of commonly used transducer frequencies are presented in Table 46-2.

Transducers use crystals that exhibit the piezoelectric effect and are typically made out of quartz or titanate ceramic. With electricity, the crystal vibrates and emits ultrasound. The reverse also holds; when ultrasound waves strike a piezoelectric crystal and make it vibrate, the crystal generates electricity. Thus the same crystals can serve as emitters and receivers of ultrasound. The *frequency* of vibration is determined by the thickness of the piezoelectric crystal. To refine and control the emitted ultrasound beam, several layers of material are placed adjacent to the crystal (Figure 46-2).

TRANSDUCER FREQUENCY, IMAGE RESOLUTION, AND DEPTH OF PENETRATION

Echocardiography uses ultrasound waves with frequencies of 2.5 to 7.5 million cycles per second (MHz). Frequencies greater than 7.5 MHz are not used because they produce wavelengths too short for adequate penetration into tissues. Penetration is limited to between 200 and 400 times the wavelength. Frequencies less than 2.5 MHz are not used because they produce wavelengths too long for the resolution of small objects (resolution is limited to approximately twice the wavelength). Thus ultrasound transducers in the range of 2.5 to 7.5 MHz resolve objects 0.4 to 1.2 mm in size and penetrate tissues up to 24 cm.

Image resolution is characterized in terms of axial, lateral, elevational, and temporal resolution. Axial resolution is resolution along the length of an ultrasound beam. It is a function of transducer frequency and pulse width. Longer wavelengths have deeper tissue penetration but are unable to resolve objects that are close together. Shorter wavelengths do the opposite. Similarly, short-duration ultrasound pulses improve axial resolution.

Lateral resolution is resolution from side to side across a 2-D image and is a function of beam formation. The initial segment (near field) of an ultrasound beam is columnar, and the length is dependent on transducer width and wavelength (Figure 46-3, *A*). Beyond the near field, the beam diverges (far field). Divergence is also a function of transducer frequency (Figure 46-3, *B*). As the frequency goes up, the near field gets longer and the divergence angle decreases. As the width gets smaller, the angle of divergence gets larger. The lack of lateral resolution at greater depths accounts for the blurring of the image in the far field.

Another feature of ultrasound beam formation that influences lateral resolution is the grating lobes (Figure 46-4). A grating lobe is a diverging ultrasound beam that emerges from the transducer along with the main ultrasound beam. The angle of the diverging grating lobe is determined by the spacing between the crystals in the transducer array. A grating lobe is formed at the angles where the path length of an ultrasound wave between the two adjacent transducer crystals differs by one wavelength. An example of a grating lobe artifact is when a properly positioned pulmonary artery catheter appears to go through the aorta. The artifact appears as an echo-dense, archlike object that traverses structures within the heart and is at equal distance from the transducer throughout the image. In this example, a diverging ultrasound beam from a grating lobe is reflected back to the transducer. The ultrasound machine cannot differentiate between reflected ultrasound from the main beam and the grating lobe beam.

Elevational resolution refers to the thickness of the wedge-shaped ultrasound image. The thickness is typically 10 mm. Temporal resolution is the ability to locate moving structures accurately at a particular instant in time. The more images displayed per second (frame rate), the better the temporal resolution. A typical frame has 128 lines in a 90-degree 2-D image. If the depth is set at 20 cm, then the time required for sampling one line is 0.3 microseconds. To scan all 128 lines requires 33 microseconds. In one second, the sector is scanned 30 times. For cardiac applications, imaging moving structures at a frame rate of at least 30 frames per second is optimal. Decreasing the image depth will improve the temporal resolution. Ultrasound machines allow the sonographer to *zoom* in on a region of interest within the 2-D display. This function redistributes the number of scan lines used to generate a full 2-D image into a smaller region of interest, therefore improving the temporal resolution.

As ultrasound waves penetrate tissue, the signal strength is attenuated. *Attenuation* is a function of tissue *absorption* (ultrasound energy converted to heat),

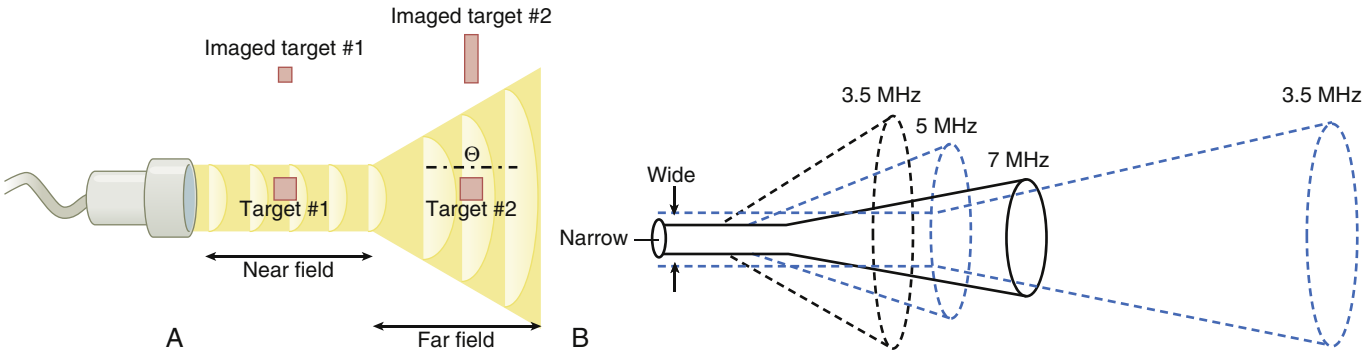

Figure 46-3. A, Near- and far-field beam formation. The near field is the columnar portion of the beam, and the far field is the diverging segment of the beam. Theta (Θ) represents the angle of divergence. Structures within the near field (Target #1) are imaged with crisp lateral resolution, whereas structures in the far field (Target #2) are imaged with blurred lateral resolution. **B,** Relationship between the near-field length and the transducer frequency and width. The length of the near field is a function of transducer width and frequency. As the frequency increases, the near field lengthens. The angle of divergence is also a function of transducer frequency. With increasing transducer frequency, the angle of divergence decreases. The *black dashed, dotted,* and *solid lines* represent the beam divergence for a 3.5-, 5.0-, and 7.0-MHz transducer, respectively. With wider transducers, the near field increases in length. The *blue dashed* lines represent the near and far field for a 3.5-MHz transducer that is twice as wide as the narrow transducer.

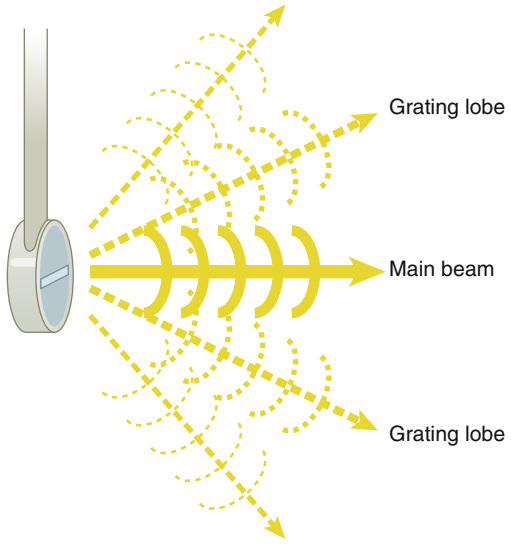

Figure 46-4. The main ultrasound beam *(solid line)* emitted from a transducer is accompanied by a series of grating lobes *(dotted lines)*. The grating lobes are a phenomenon of beam formation that is a function of the array of piezoelectric crystals within the transducer. At certain angles from the main beam, the ultrasound wave from each crystal within the array is exactly one wavelength behind the wavelength from the adjacent crystal. which generates a grating lobe. The clinical implications of grating lobes are that highly echogenic objects such as a Swan-Ganz catheter or a mitral valve prosthesis can "appear" to be locations within the heart (e.g., the aorta) that are incorrect.

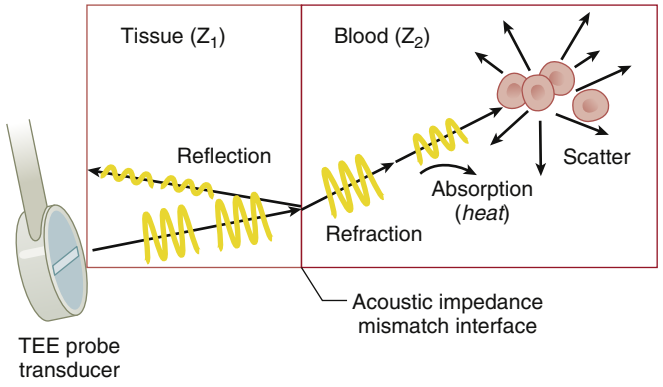

Figure 46-5. Diagram of specular reflection, refraction, absorption, scatter, and acoustic impedance. As ultrasound waves strike an interface between two different tissue types, some of it is reflected and the remainder passes through. The reflected ultrasound wave has a trajectory angle equal to the incident angle. Refraction refers to a deflection of the ultrasound beam as it travels from one tissue type to another. Scattering occurs when an ultrasound wave strikes a structure that is less than one wavelength in lateral dimension (e.g., a red blood cell). Absorption represents the amount of ultrasound energy that dissipates as heat. Acoustic impedance refers to the resistance an ultrasound wave meets when traveling through tissue. Acoustic impedance *(Z)* is defined as the product of tissue density multiplied by the propagation velocity. *TEE,* Transesophageal echocardiography.

divergence of ultrasound energy as it moves away from the transducer, *reflection*, and *scattering* (Figure 46-5). Absorption is dependent on tissue type. For example, air absorbs more ultrasound energy than bone, but bone absorbs more than blood or water. A term used to describe absorption is *half-power distance*, which is the distance required to decrease the ultrasound energy by 50%. The half-power distance for air, bone, blood, and water are 0.08, 0.8, 15, 380 cm, respectively.

As ultrasound waves strike an interface between two different tissue types, some of it is reflected and the remainder passes through (see Figure 46-5). As light is reflected from a mirror, the reflected ultrasound wave has a trajectory angle equal to the incident angle. The amplitude of reflected ultrasound waves is decreased by 40 to 60 dB (100- to 1000-fold). Ultrasound waves that pass through to the adjacent tissue are subject to refraction. *Refraction* refers to a deflection of the ultrasound beam as it travels from one tissue type to another. An example of refraction is how an image of an object can be distorted when partially submerged in a fish tank or swimming pool. Refraction can bend ultrasound beams, making objects appear to be in locations where they do not exist. Scattering occurs when an ultrasound wave strikes a structure (e.g., red blood cell) that is less than

one wavelength in lateral dimension. The scattered ultrasound energy is radiated in all directions.

Acoustic impedance refers to the resistance an ultrasound wave meets when traveling through tissue. It is a function of tissue density and is defined by Equation 4:

$$Z = \rho \times c \quad (4)$$

Z, ϱ, and c indicate the acoustic impedance, tissue density, and propagation velocity, respectively. As tissue density increases, the faster the ultrasound beam moves through the tissue. For example, ultrasound waves are significantly slower in air (330 m/sec), faster in blood (1540 m/sec), and extremely fast in bone (4080 m/sec). The extent of ultrasound beam reflection is a function of the difference in acoustic impedances between two adjacent tissues. The larger the difference in acoustic impedance, the more ultrasound energy will be reflected. Bone-soft tissue and air-soft tissue interfaces reflect most of the ultrasound beam. Imaging structures deep to these interfaces are difficult.

Mismatches in acoustic impedance and attenuation are important to consider when imaging the heart with TEE. For example, sonographers find it difficult to visualize the aortic arch from the esophagus when scanning through air-filled trachea or carina. The ultrasound energy emitted from the TEE probe is significantly attenuated as it passes through the air in the trachea. Most of the ultrasound energy that does make it to the trachea-tissue interface is reflected as a result of the large difference between the acoustic impedances between air and tissue.

BASIC PRINCIPLES OF IMAGE OPTIMIZATION: GAIN, DEPTH, AND FOCUS

Gain is used to amplify low-amplitude ultrasound waves reflected back to the transducer. Gain represents how well the ultrasound system listens. It can be used to offset the large-amplitude signals returning from proximal structures from low-amplitude signals returning from distant structures. Many ultrasound machines have a series of sliding controls that allow the sonographer to adjust the gain at a given depth called the *time gain compensation* controls. One temptation when structures are not readily visualized in the brightly lit surgical unit is to turn up the gain. Although gain increases structure brightness, it comes at the cost of amplifying background noise. A better approach is to dim the surgical unit's lights and keep the gain at normal settings.

In echocardiography, the crystals emit very short pulses of ultrasound (approximately 1 microsecond [μsec]) and receive or "listen" for the reflected ultrasound for 250 to 500 μsec. The *pulse repetition frequency* (PRF) is the number of pulses that leave and return to the transducer in a single second. The PRF can be changed by changing the depth of an image. As image depth is increased, the time required to reach the target depth and return increases. Thus the number of cycles that can be completed within 1 second is reduced. The opposite also holds true; as imaging depth decreases, the PRF increases. The PRF is also described in hertz and is audible, ranging from 1 to 10 kHz.

Early echocardiographic displays used this principal to map out the depth of structures within the heart. The first

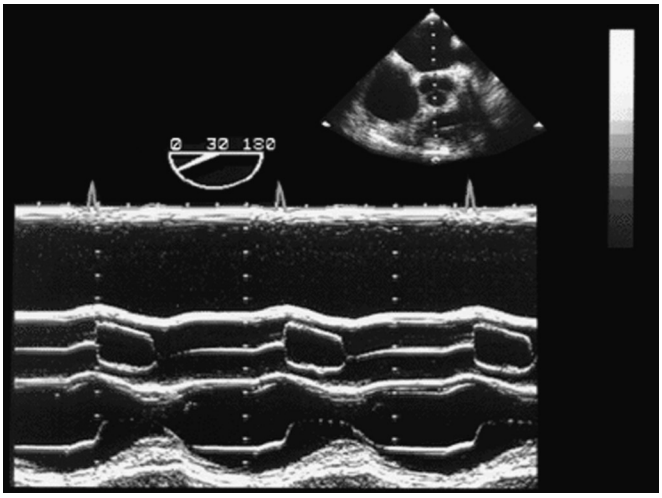

Figure 46-6. An M-mode transesophageal echocardiogram (TEE) of a normal aortic valve is shown. For reference, a single frame (stop action) of the two-dimensional cross section is shown *(top right).* The *dotted vertical line* through the 2-D TEE depicts the single line of sampling provided by the M-mode TEE over time (the horizontal axis for the lower two thirds of the figure). The TEE defines the systole and diastole. The three *tilted rectangles* are connected by the slightly *undulating line* and visualized in the middle of the M-mode image. These rectangles and lines are formed by the motion of the leaflets of the aortic valve as they open and close during the cardiac cycles shown. From top to bottom in this M-mode TEE, the structures indicated by the *white lines* are the posterior wall of the left atrium (just under the TEE), the posterior wall of the aortic annulus, the aortic valve (described above), the anterior wall of the aortic annulus, a pulmonary artery catheter, and the myocardium of the right ventricular outflow tract. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

echocardiograms, *motion* or *M-mode* studies, were one-dimensional views of cardiac structures produced by single crystal transducers with the results traced on moving photosensitive paper. Today, M-mode echocardiography is principally used to view rapidly moving structures, such as valve leaflets, because M-mode transducers can produce up to 1800 images per second (Figure 46-6). However, M-mode images reveal only a small portion of the heart at one time, making orientation and interpretation of spatial relationships difficult.

To generate 2-D images, ultrasound machines were configured to redirect the beam sequentially over an area or sector of interest. Transducers now contain a row of piezoelectric crystals (linear array). By introducing a small delay in the firing of adjacent crystals in the array (phased array), the ultrasound machine is now able to steer the resultant ultrasound beam. By varying the time delay between crystals, ultrasound machines are therefore able to steer the beam through a sector of interest (typically a 90-degree sector). Although 2-D techniques produce only approximately 30 images per second, the definition in 2-D images provides an enormous advantage in recognizing anatomic and pathologic landmarks (Figure 46-7). Images are displayed in *real time* on a monitor screen and digitally recorded for later review. In a similar fashion to steering the ultrasound beam, the *focal depth* of an ultrasound beam can be adjusted by triggering

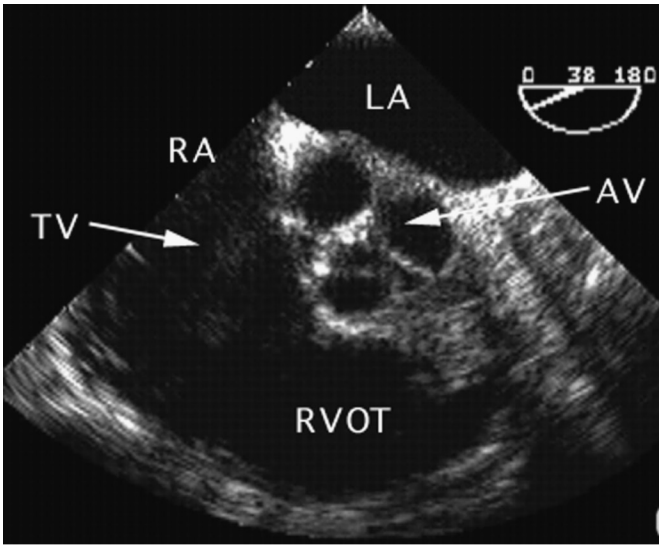

Figure 46-7. A stop-action, short-axis, two-dimensional cross section of a normal aortic valve (AV) is shown. This midesophageal short-axis view of the AV reveals the morphologic structure of the three cusps of this normal valve. *LA,* Left atrium; *RA,* right atrium; *RVOT,* right ventricular outflow tract; *TV,* tricuspid valve. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas, *New York, 1997, Churchill Livingstone.)*

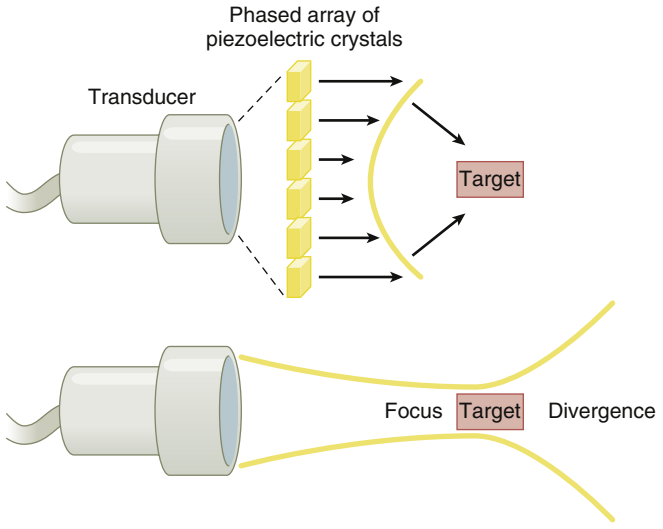

Figure 46-8. Schematic illustration depicts phasing the start of an array of piezoelectric crystals to focus an ultrasound beam. Crystals are sequentially fired from the outer edge to the middle of the array. The resultant concave wave converges at a point some distance from the transducer. The focal distance from the transducer is a function of the time delay between firing crystals from the edge to the middle of the array.

the piezoelectric crystals to concentrate the ultrasound beam at a desired depth (Figure 46-8). The focal depth is typically set at or just below the structure of interest in a 2-D image.

INTEGRATION OF FLOW AND STRUCTURE

By measuring the Doppler shift, modern ultrasonography quantifies blood-flow velocities. The Doppler shift is the shift in frequency of a wave when the source of the wave is moving (e.g., when moving red cells are reflecting the wave). When pulses of sound are used (pulsed-wave Doppler [PWD]), the operator defines a small area, termed *sample volume*, anywhere in the 2-D sector scan, and the ultrasonograph automatically converts the Doppler data in that sample volume to a display of the real-time blood-flow velocities. Thus PWD defines blood-flow velocities and their location within the heart and great vessels (Figure 46-9).

However, two important limitations apply. First, the Doppler shift is proportional to the cosine of the angle between the ultrasound beam and the direction of the blood cells. If the cells are moving directly parallel to the ultrasound beam, then the angle is zero and the cosine of zero is one. Thus at an angle of zero, Doppler echocardiography provides a true estimate of blood-flow velocity. At all other angles, the cosine is less than one, resulting in less Doppler shift and an underestimation of flow velocity. Clinically, angles of less than 15 degrees (the cosine is almost one) are insignificant to velocity estimation, whereas angles exceeding 20 degrees significantly attenuate the Doppler shift, necessitating caution in interpreting such data. This relationship is best stated in the Doppler equation:

$$V = (C \times F_d) \div (2F_0 \times \cos \theta)$$

where V is the velocity to be measured, C is the speed of sound in tissue (a constant), F_d is the Doppler shift in ultrasound frequency measured by the ultrasound machine, F_0 is the frequency of the transducer, and cos θ is the cosine of the angle between the direction of the blood flow and the ultrasound waves. Second, the maximum velocity of blood flow that can be unambiguously measured is defined by the Nyquist limit. The Nyquist limit is directly related to the ultrasound frequency and the PRF. The PRF is the number of pulses of ultrasound emitted per second. Because an emitted pulse must return before the next is emitted in PWD, an increase in the depth of the ultrasound scan decreases the PRF and the Nyquist limit. Thus the depth of the ultrasound scan is the principal determinant of the Nyquist limit under the control of the operator. If the velocity of blood flow exceeds the Nyquist limit, then sudden apparent flow reversal, or *aliasing*, will be depicted (Figure 46-10). Aliasing is analogous to the sudden apparent reversal of the direction in the stagecoach wheels visible in old Westerns when the velocity of the wheel spokes exceeded the frame rate of the movie camera. Typically, aliasing of PWD occurs at blood-flow velocities of 0.8 to1.0 m/sec. Normal flow within the heart may reach 1.4 m/sec and pathologic flows up to 6 m/sec. To measure these velocities, continuous-wave Doppler (CWD) is needed.

CONTINUOUS-WAVE DOPPLER

CWD uses two separate crystals: one to emit ultrasound continuously and one to receive ultrasound continuously. CWD is basically PWD with an infinite PRF that eliminates the problem of aliasing (Figure 46-11). However, this infinite pulse repetition rate allows insufficient time for the first pulse to return to the transducer before

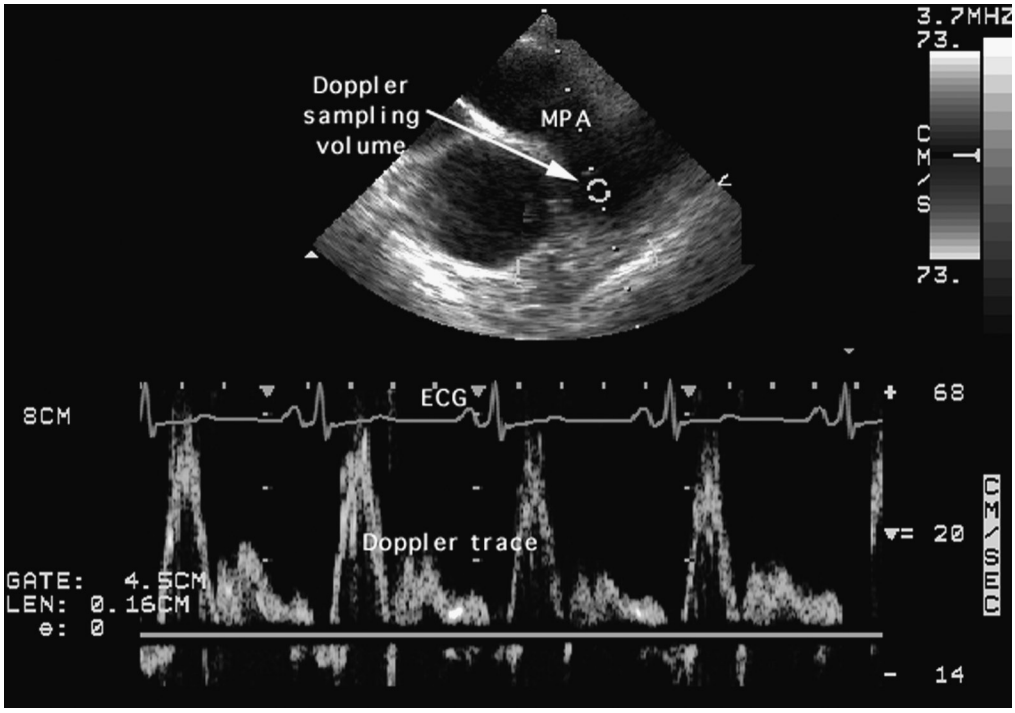

Figure 46-9. Pulsed-wave Doppler (PWD) echocardiogram of the main pulmonary artery (MPA). At the top of the echocardiogram is a still-frame image of the two-dimensional cross section used to position the Doppler sample volume *(broken white circle at the point of the arrow)*. The display *(in white)* of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume is visualized on the bottom third of the figure. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 68 cm/sec. Flow velocities below this line are negative (i.e., away from the transducer) to a maximum of –14 cm/sec. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

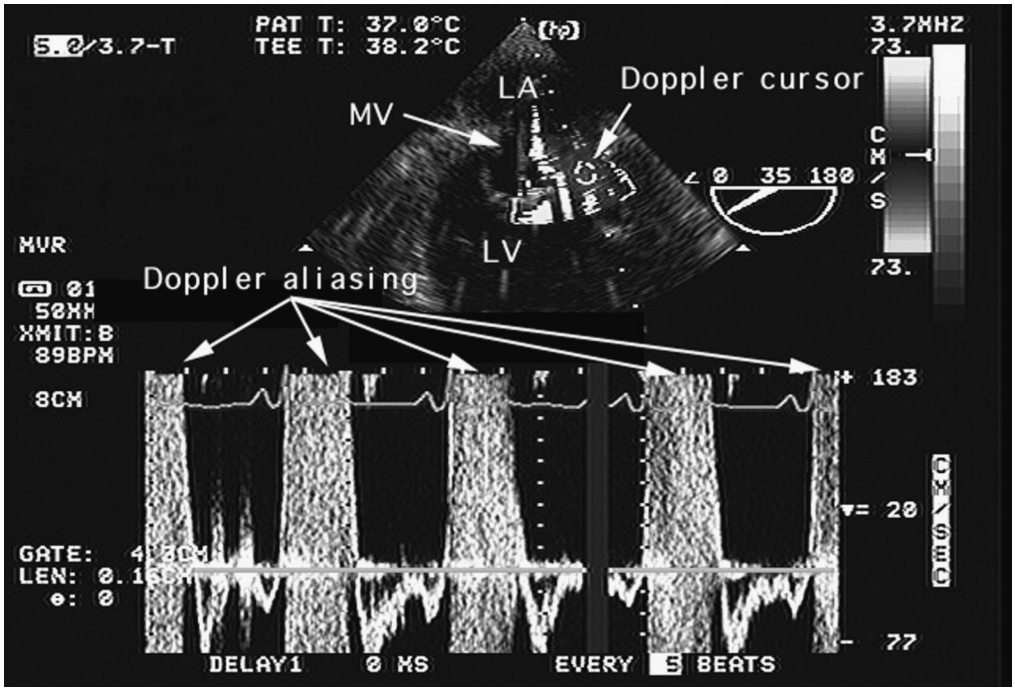

Figure 46-10. Pulsed-wave Doppler (PWD) echocardiogram with aliasing at high velocities. PWD measurement of blood-flow velocities in a mitral valve (MV) orifice during four cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sample volume *(broken white circle)*. The display *(in white)* of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume is visualized on the bottom third of the figure. The electrocardiogram provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 183 cm/sec. Flow velocities below this line are negative (i.e., away from the transducer) to a maximum of –77 cm/sec. This tracing documents significant mitral regurgitation (positive systolic velocities) but does not measure the peak velocity of regurgitated flow because it is beyond the Nyquist limit—the systolic velocities off the top of the scale are said to alias; that is, they go off scale and wrap around into the domain of negative velocities. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

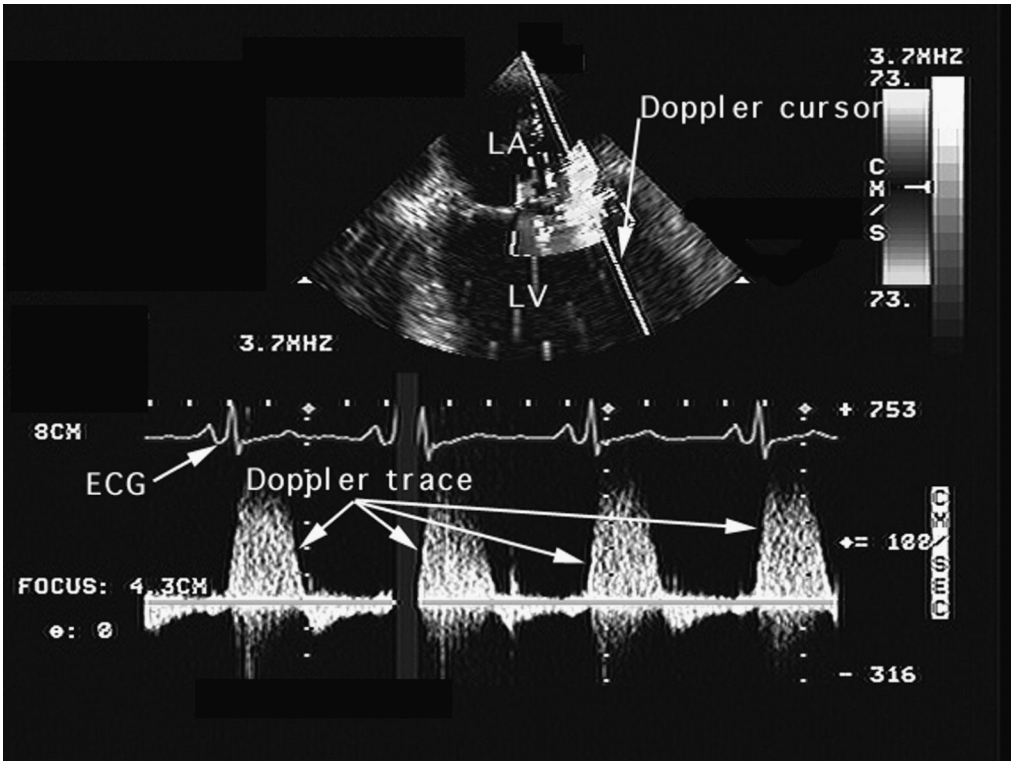

Figure 46-11. Continuous-wave Doppler (CWD) echocardiogram measures high-velocity flows without aliasing. CWD measurement of blood-flow velocities in a mitral valve orifice during four cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sample cursor *(diagonal white line)*. The display *(in white)* of all the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor is visualized on the bottom third of the figure. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 753 cm/sec. Flow velocities below this line are negative (i.e., away from the transducer) to a maximum of –316 cm/sec. This tracing documents significant mitral regurgitation (positive systolic velocities) with a peak blood-flow velocity of approximately 5 m/sec. Each white dot on the vertical axis equals 100 cm/sec or 1 m/sec). *LA,* Left atrium; *LV,* left ventricle; *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

the next is emitted. Consequently, the ultrasonograph cannot determine which pulse of sound was frequency shifted and therefore cannot precisely define the location of the moving target. Nonetheless, the maximum velocity can prove to be vital information; by simplification of the Bernoulli equation, Hatle and colleagues[19] and Holen and colleagues[20] have proven that:

$$\Delta P = 4V^2$$

where ΔP is the peak gradient across a stenosis and V is the maximum velocity determined by CWD in m/sec.[19,20] Thus CWD defines higher blood-flow velocities than PWD but, unlike the latter, CWD cannot precisely define the location of the velocities.

COLOR DOPPLER

Point-by-point determination of blood-flow velocities by PWD is too time consuming and does not reveal the instantaneous distribution of flow velocities within the cross-sectional image that is required for many diagnostic decisions. Color Doppler imaging was developed for this purpose. In color Doppler, a form of PWD, a color code is used to depict flow toward (red) and away (blue) from the transducer; lighter and darker shades of red and blue, respectively, denote relatively faster and slower velocities. Continuous color maps of flow are superimposed on gray-scale, cross-sectional images. However, color Doppler generally is a semiquantitative technique and, similar to PWD, will alias (color reversal) when the Nyquist limit is exceeded. Two aliasing patterns are easily recognized. The first pattern is *normal* aliasing in which the area of apparent flow reversal forms one or more broad, relatively homogenous color surfaces (Figure 46-12). Blood-flow velocities within a normal heart often produce this type of aliasing because they exceed the Nyquist limit for color Doppler (0.6 to 0.8 m/sec). The second type of aliasing results from disturbed or turbulent flow within the heart (e.g., mitral regurgitation) and is never normal (Figure 46-13). When the ultrasonograph detects two different velocities within the same small sample volume as a result of disturbed flow, it displays a mixture, or mosaic, of colors. These mosaics form jetlike configurations and are called *color jets*. Because color Doppler presents the spatial relationships between structure and blood flow, it enhances the recognition of valvular abnormalities and intracardiac shunts. The clinical features of PWD, CWD, and color Doppler are compared in Table 46-3.

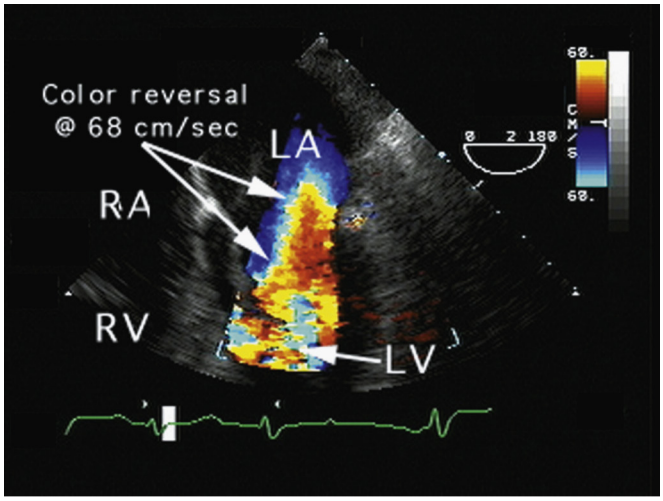

Figure 46-12. Normal color Doppler aliasing. In this echocardiogram, *normal* color Doppler aliasing is depicted because laminar flow of blood through the mitral valve and into the left ventricle (LV) exceeds the Nyquist limits (68 cm/sec, in this example; see color reference icon at the *upper right* of figure), resulting in a reversal of the color coding of flow direction. As noted in this figure, the color reversal occurs across fairly broad, regular areas but not in a random or point-by-point fashion as occurs with turbulent flows (always abnormal). In this example, the blue flow can be followed from high in the left atrium (LA) as it accelerates into the mitral orifice, and the color Doppler depicts the increasing flow velocities—the blue color becomes lighter and lighter until the Nyquist limit is reached. Then, color reversal occurs with light blue becoming yellow. At that reversal point, the velocity equals the Nyquist limit (68 cm/sec, in this example). Subsequent reversals may occur at that limit or multiples of that limit. *RA,* Right atrium; *RV,* right ventricle. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

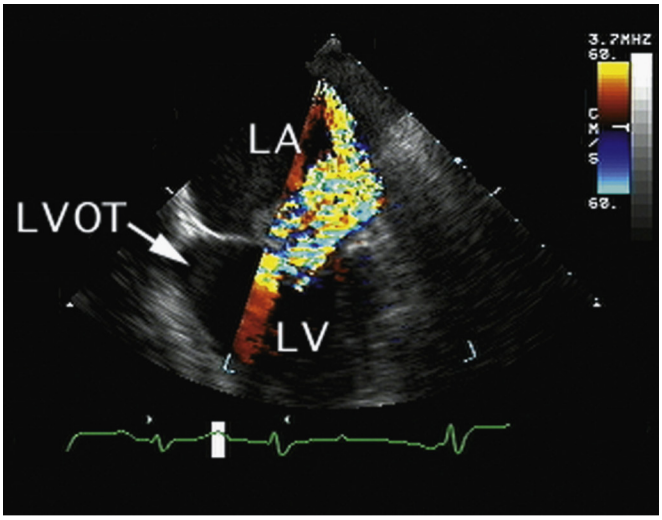

Figure 46-13. Color Doppler aliasing depicting turbulent flow. In this echocardiogram, color Doppler reveals aliasing attributable to severe mitral regurgitation. A broad-based systolic color jet emanates from the mitral valve and extends far into the left atrium (LA). This color jet is made up of a mosaic of colors mixed in a seemingly random, point-by-point fashion because the color jet results from the turbulent flow of mitral regurgitation. Turbulence is never normal in the heart, and thus mosaic color jets, such as the one shown in this figure, are highly valuable diagnostic signs of an underlying pathologic abnormality. *LV,* Left ventricle; *LVOT,* left ventricular outflow tract. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

TISSUE DOPPLER

Tissue Doppler imaging (TDI) is a relatively new use of PWD technology adapted to measure myocardial velocities instead of blood-flow velocities.[21] During normal LV contraction, the mitral annulus descends toward the apex of the heart. TDI measures the velocity of this descent (S_m), and S_m correlates with traditional measures of LV function including ejection fraction and the rate of increase of LV systolic pressure (dP/dt).[22,23] In addition, S_m decreases in the presence of myocardial ischemia and responds as expected with changes in inotropy.[24,25] The four-chamber cross section is best for measuring S_m; the sampling volume is placed at the lateral insertion point of the mitral valve into the left ventricle, and the cross section is aligned to ensure that the sampling cursor is directly parallel with the motion of the annulus. S_m is an easy and reproducible measurement. However, similar to measures of ejection fraction, it should be interpreted with caution when preload changes. Ama and associates tested its load dependence in 42 patients who were hemodynamically stable with normal segmental LV function after coronary surgery.[26] S_m did not significantly change in response to a 20% increase or decrease in mean arterial pressure induced by phenylephrine or nitroglycerine. However, S_m significantly increased when preload was augmented by rapid infusion of colloid. In summary, S_m is less dependent on afterload than estimates of ejection fraction but, similar to these other two measures, remains critically dependent on preload. The few measures of LV function that appear to be independent of both preload and afterload are not practical for clinical use.

TDI can also measure the diastolic function of the myocardium. An early diastolic tissue velocity (e′) and a late diastolic tissue velocity (a′) are usually present during each cardiac cycle and represent the intrinsic ability of the myocardium to relax actively during the early ventricular filling and the late atrial contraction filling. TDI use is suggested in combination with other modalities such as PWD mitral inflow velocities to assess the diastolic state and the estimation of LV filling pressure of patients.[27] (See the subsequent sections in this chapter on these topics.)

EQUIPMENT DESIGN AND OPERATION

TEE probes are a marvel of engineering. A miniaturized echocardiographic transducer (approximately 40 mm long, 13 mm wide, and 11 mm thick) is mounted on the tip of a gastroscope. Typically, the transducer is a phased-array configuration with 64 piezoelectric elements operating at 3.7 to 7.5 MHz. By sequential firing of the elements and an acoustic lens in the transducer housing, the ultrasound waves are formed into a 90-degree beam approximately 2 to 10 mm in thickness that emanates at right angles to the transducer. Similar to standard gastroscopes, two rotary knobs, or *wheel*s, control the movement of the tip

TABLE 46-3 **COMPARISON OF ADVANTAGES AND DISADVANTAGES OF DOPPLER MODALITIES**

Doppler Type	Advantages	Disadvantages	Clinical Uses
Pulse wave	Measures blood-flow velocities at selected areas of interest; 3-5 mm wide along the ultrasound scan line	Cannot measure fast blood-flow velocities (>1 m/sec) because of aliasing	Measures blood-flow velocities through pulmonary veins, mitral valve, and in low flow areas in the heart
Continuous wave	Detects blood-flow velocities up to 7 m/sec (not subject to the Nyquist limit)	Cannot identify the location of the peak velocity along the ultrasound scan line	Measures blood-flow velocities through the aorta, aortic valve, stenotic valve lesions, and regurgitant valvular jets
Color flow	Presents the spatial relationships between structure and blood flow	Similar to pulsed-wave Doppler, cannot measure fast blood-flow velocities because of aliasing	Enhances the recognition of valvular abnormalities, aortic dissections, and intracardiac shunts

of the scope. One wheel anteflexes and retroflexes the transducer (i.e., moves the transducer toward and away from the heart). The other wheel flexes the transducer rightward and leftward (Figure 46-14).

Currently, most multiplane transducers use the same transducer technology but mount the transducer on a rotating device that allows it to spin on its axis from 0 to 180 degrees within the tip of the gastroscope (transducer housing). Because cardiac structures and blood flow are not precisely aligned relative to the transducer, this design has significantly refined imaging capability. Matrix transducers accomplish the same rotation of the beam but do so electronically (i.e., without mechanically moving the transducer). The size of the probes have been decreased for pediatric applications by reducing the number of crystals and are now small enough for use in infants and neonates.

Ultrasonographs contain high-powered computers capable of initiating the ultrasound beam and processing the returning data. A series of electronic transforms (some guarded commercial secrets) produce the real-time images displayed on the video screen. All ultrasonographs share common technical aspects including gain, depth, and Doppler controls. However, the differences in technical aspects between manufacturers and even between models from the same manufacturer are sufficiently great as to prevent the formulation of any universal operating instructions. Fortunately, detailed instructions for each model are available in the operator's manual supplied with each ultrasonograph. Alternatively, cardiac sonographers are often excellent sources of instruction in the operation of these machines.

THREE-DIMENSIONAL IMAGING

Newer ultrasound machines offer the capability of producing 3-D images as recorded clips and as live 3-D images (also known as four-dimensional images with time being the fourth dimension). This technology represents a substantial jump in cardiac imaging, similar to the jump from M-mode to 2-D imaging in years past. Better visualization of heart valves, regurgitant valve lesions, cardiac chamber volumes (without geometric assumptions), regional wall motion, and 3-D stress imaging, among others, are some of the unique advantages of 3-D technology.[4]

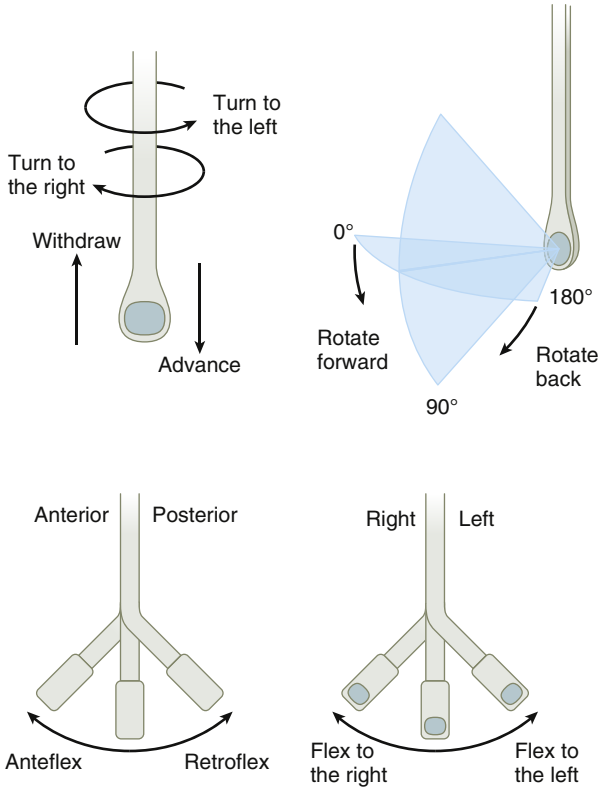

Figure 46-14. The terminology used to describe the movements of the transesophageal echocardiographic (TEE) probe is illustrated. *(Reproduced with permission from Shanewise JS, Cheung AT, Aronson S, et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography,* Anesth Analg *89:870-884, 1999.)*

THREE-DIMENSIONAL TRANSDUCERS

Beyond a linear array of transducers as with a 2-D probe, a 3-D probe has a matrix array of transducers. A matrix array can have 2500 to 3000 piezoelectric crystals within one probe.[28] Significant advances in computer-processing speed, the miniaturization of the necessary electronics, and the software were required

to make this technology available. Transthoracic and transesophageal 3-D probes operate in 2 to 4 MHz and 5 to 7 MHz ranges, respectively. Imaging modes available with matrix array probes include multiplane, 3-D, and 4-D (3-D live).

MULTIPLANE IMAGING

Multiplane imaging mode simultaneously presents a set of 2-D images, typically two images. One image is a reference, whereas the second can be rotated around the first in an axial rotation or in an elevational rotation (Figure 46-15, *A-B*). CFD can be superimposed to these images. Although not a true 3-D image, this simultaneous presentation offers sonographers a depiction of a structure from multiple angles and views with CFD in real time.

THREE-DIMENSIONAL LIVE IMAGING—NARROW VOLUME MODE

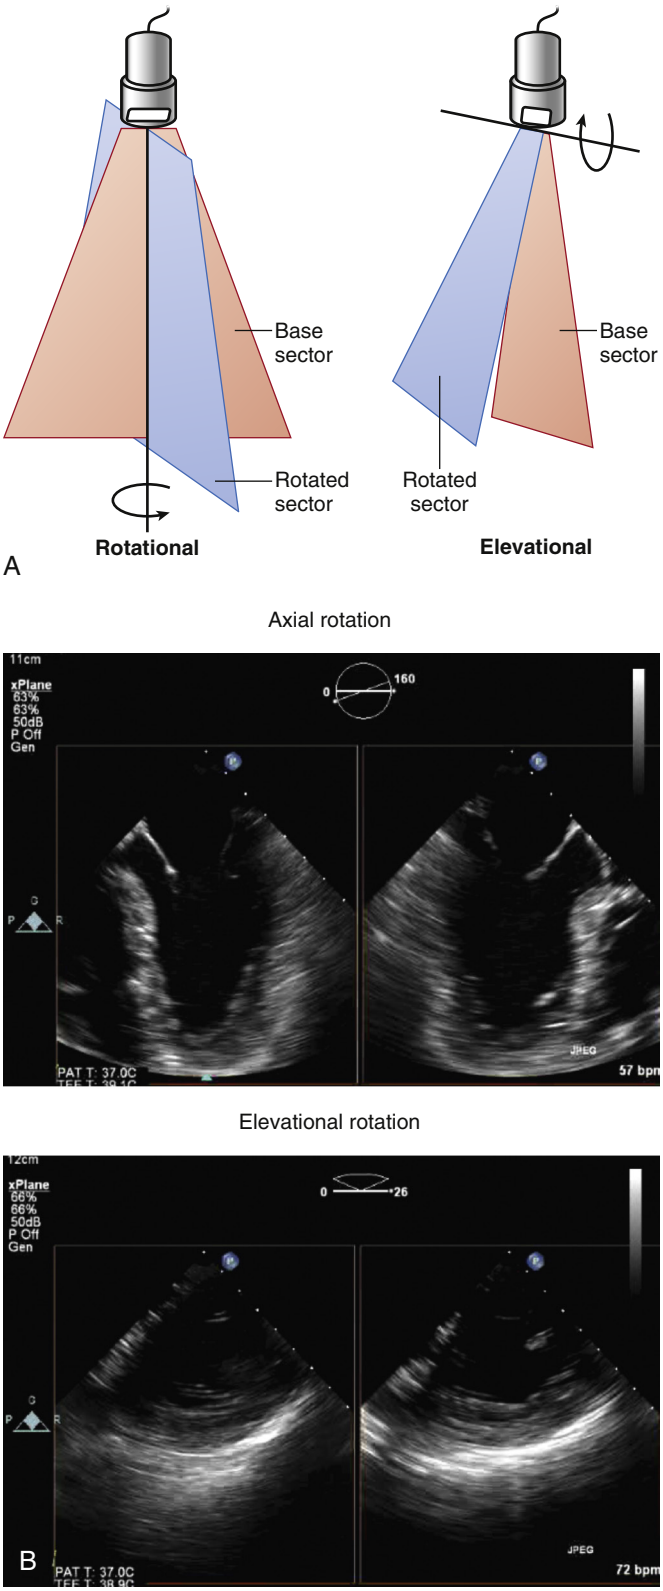
Three-dimensional live imaging offers a 3-D image presented in real time (Figure 46-16, *A-B*) and interrogates a *narrow* sector pyramidal volume and is useful in diagnosing complex problems (i.e., partial rupture of mitral chordae tendineae). It consists of two narrow sector widths (i.e., 30 by 60 degrees). A disadvantage is that it is limited in the volume it can interrogate, which may not include the entire area of interest. Although this mode provides good temporal and spatial resolution, the sector widths (i.e., sides of the pyramidal volume) must remain narrow to maintain this resolution.

THREE-DIMENSIONAL LIVE IMAGING—ZOOM VOLUME MODE

Similar to 3-D live—narrow, 3-D live—zoom offers real-time interrogation of a *wide* sector pyramidal volume truncated by the zoom window with good temporal and spatial resolution (see Figure 46-16, *A-B*). This feature allows sonographers an additional option to capture real-time 3-D volumes of the cardiac structures not well visualized with narrow 3-D imaging.

THREE-DIMENSIONAL IMAGING—FULL-VOLUME MODE

Three-dimensional images—full-volume mode —are obtained using *gated* acquisition. Gated acquisition divides the acquisition volume into a set of subvolumes. To ensure that each subvolume is measured at the same time in the cardiac cycle, the R wave in the electrocardiogram (ECG) is used as a trigger. The operator determines the number of subvolumes (e.g., 3 to 8), and that number determines the number of heartbeats required to cover the entire pyramid volume. The full-volume image is *stitched* together from the subvolume images (Figure 46-17, *A-B*). Stitching artifacts may occur in patients with arrhythmias in which the R wave is difficult to track or with substantial changes in chamber size with respiration (Figure 46-18). This technique does not present images in real time.



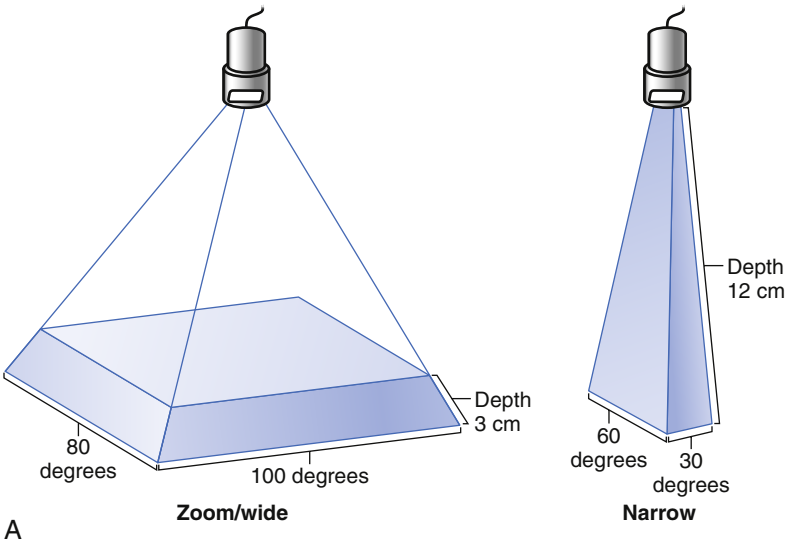


Figure 46-15. A, Rotational (*upper*) and elevational (*lower*) rotational biplane imaging are presented. *Red* and *blue* represent a schematic of the base and rotated sectors. **B,** Axial *(top)* and elevational (*bottom*) rotational biplane two-dimensional images. The base sectors *(left images)* and the rotated sectors *(right images)* are depicted. The *white dotted line* on each base sector image is the axis about which each secondary image is rotated.

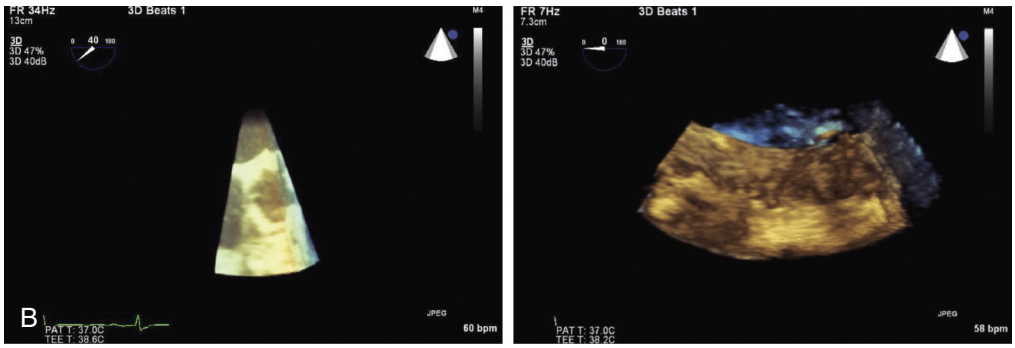

Figure 46-16. A, Three-dimensional (3-D) live images—zoom *(left)* and narrow *(right)* modes are demonstrated. A schematic of labeled sector widths and depth are each presented. **B,** 3-D live images of the mitral valve in the zoom mode and the aortic valve in the narrow mode are depicted.

COLOR-FLOW DOPPLER

As with 2-D imaging, CFD can be added to full-volume images but requires additional time to capture the Doppler information and superimpose it on the 3-D image. If using a real-time mode, then CFD may push the screen refresh frequency slower than 30 Hz, the frequency necessary for adequate temporal resolution in cardiac imaging. To minimize this limitation, pyramidal sector widths should be narrowed, depth reduced, or the zoom feature used to ensure an adequate screen refresh rate. Color Doppler can also be used in the 3-D full-volume mode. With the multiple subvolumes, the ultrasound machine will be able to display 3-D and color-flow data simultaneously. The same limitations of 3-D full-volume apply when color Doppler is added—imaging is not real time and images may suffer from the stitching artifact.

TEMPORAL VERSUS SPATIAL RESOLUTION

A major trade-off of the different 3-D imaging modes is between temporal and spatial resolution. Determinants of temporal resolution include pyramid width(s), image depth, and scan-line density. Spatial resolution is a function of the number of scan lines contained within a pyramid volume. High scan-line density, as observed with 2-D imaging, scans up to 128 lines in a 90-degree sector and provides good spatial resolution to visualize cardiac structures. When this scan-line density is implemented in three dimensions, however, large-volume imaging becomes impractical because the screen refresh rate drops well below 30 Hz, a necessary sampling rate to maintain adequate temporal resolution in cardiac imaging. Narrow and zoom (wide) modes are used in real-time 3-D imaging to maintain temporal resolution without decreasing the scan-line density and compromising spatial resolution.

Assuming the speed of ultrasound in tissue is 1540 m/sec, the influence of sector width(s) and pyramid volume, depth, and scan-line density on estimates of temporal resolution for various modes are presented in Table 46-4. Ultrasound machines use parallel processing to improve temporal resolution. This method acquires reflected ultrasound waves along multiple scan lines from a single transmission down one scan line. With this technique, ultrasound machines can achieve faster screen refresh rates. When used at extremes (i.e., the single transmission beam is far away from the receiving scan line), the signal-to-noise ratio decreases and the image quality deteriorates. Of note, the biplane mode offers the best spatial and temporal resolution yet does not offer true 3-D imaging. The trade-offs between spatial and temporal resolutions are evident between narrow and zoom versus full-volume imaging.

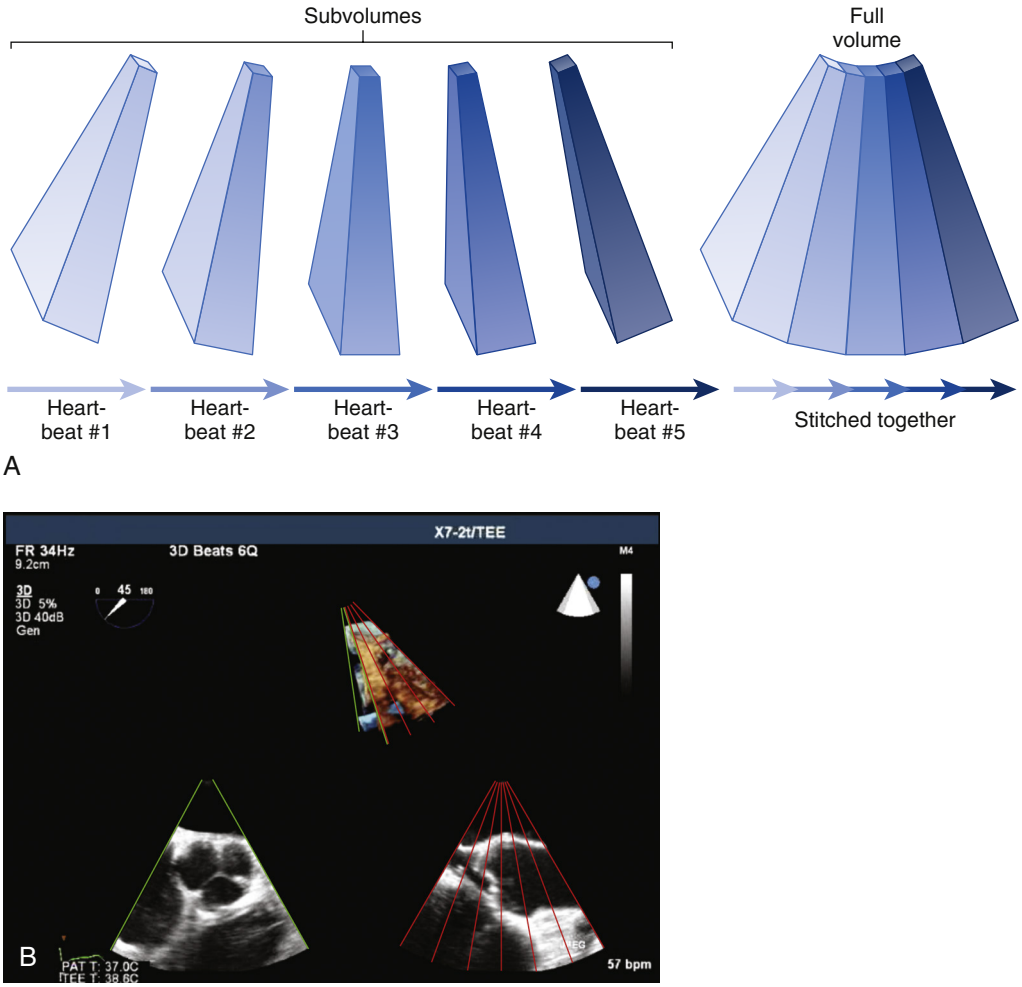

Figure 46-17. A, A schematic of a gated acquisition of a full-volume three-dimensional (3-D) image is depicted. Subvolumes are scanned in series using the R wave of the electrocardiogram as a trigger to scan each subvolume. The subvolumes are then stitched together to form the full-volume image. **B,** Subvolumes are created from a two-dimensional image by dividing up the image into seven subvolumes *(white lines)* to create a full-volume 3-D image.

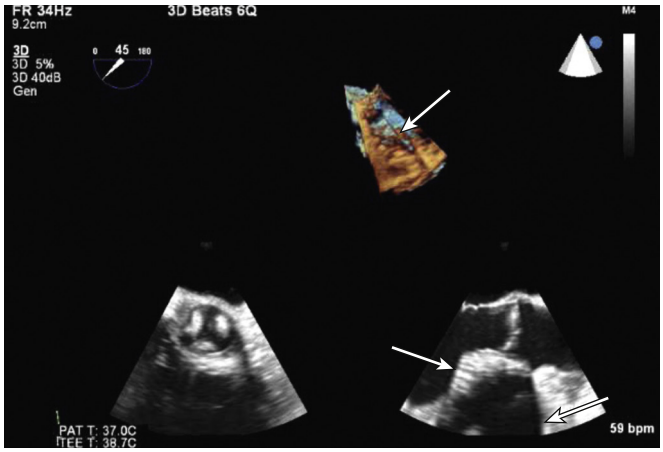

Figure 46-18. Full-volume image of the aortic valve with stitching artifact is demonstrated. Discontinuity is indicated along scan lines *(arrows)*.

THREE-DIMENSIONAL IMAGE MANIPULATION

One advantage of 3-D imaging (all modes) is that they can be rotated to visualize structures from various angles. Echocardiographers are not limited to 2-D images that may not capture an entire structure of interest at an angle best suited to interrogate it fully. A popular view is to rotate a 3-D image to visualize structures *en face*. This head-on view offers diagnostic advantages. For example, when exploring the function of a mitral valve or an aortic valve (AV) (Fig. 46-19), this feature provides visualization of spatial relationships that, in 2-D imaging, requires an often-complex spatial reconstruction in the mind of the echocardiographer. Three-dimensional images also provide a means to work through the image in a *sliced bread* fashion. Part or all of the heart can be explored in sagittal- and coronal-plane fashion.

When transitioning from 2-D to 3-D imaging, echocardiographers must conceptually move from considering the heart in various slices to a 3-D organ, much the way a surgeon does. To visualize structures deep within the

TABLE 46-4 **IMAGE REFRESH RATES FOR VARIOUS TWO-DIMENSIONAL AND THREE-DIMENSIONAL IMAGING MODES**

Mode	Depth (cm)	Scan-Line Density (Lines per Degree)	Sector Width(s) (in Degrees)	Image Refresh Rate (Hz)
Two dimension	12	High	90	50
Biplane	10	High	90 × 90	30
Three-dimension—narrow	10	Low	30 × 30	24
Three-dimension—zoom (wide)	3	Low	90 × 30	19
Full volume	12	High	90 × 90	<1
Full volume	12	Low	90 × 90	5

The values displayed are simulations and assume the speed of the ultrasound in tissue to be 1540 m/sec. Low and high scan-line densities were assumed to be 0.4 and 1.4 scan lines per degree of the scanned image.

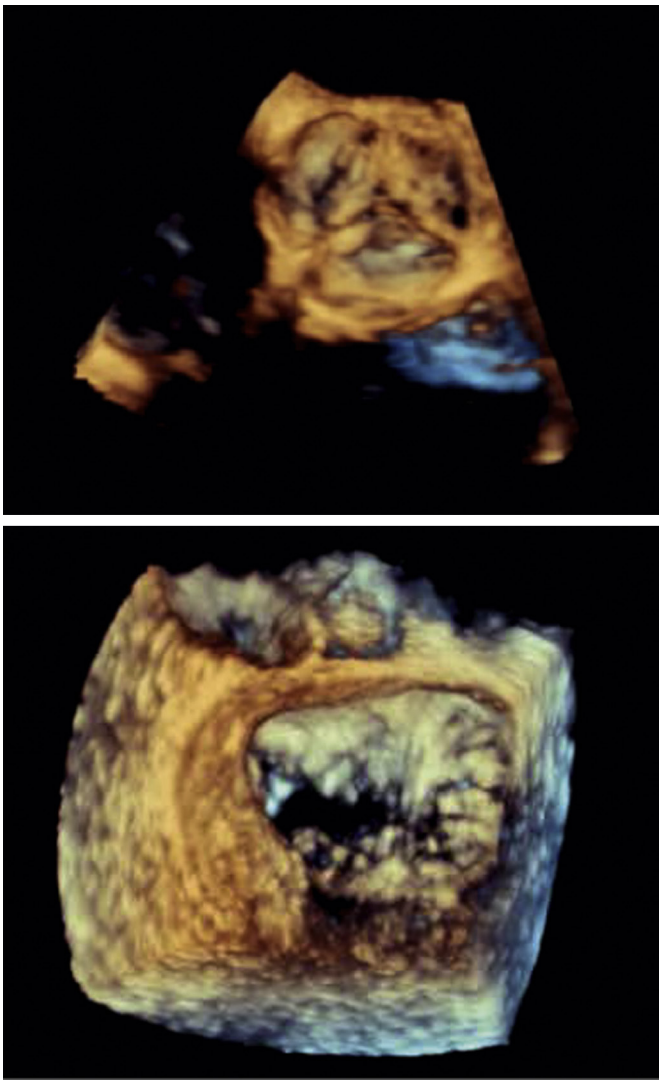

Figure 46-19. En face views of the aortic *(top)* and mitral *(bottom)* valves.

heart, more superficial structures are pealed back. Echocardiographers can cut out superficial structures to visualize internal ones by using a *cropping* tool. For example, to visualize the intraatrial septum in three dimensions, the lateral atrial walls are cropped out.

PIXEL AND VOXEL

From each scan line, reflected ultrasound is used to create an image. With 2-D, a grey scale is used to represent the amplitude of a reflected ultrasound wave from a portion of a scan line and assigned to a corresponding small space on a projected image called a *pixel*. A composite of pixels makes up the 2-D image. A similar process is used to assign small volumes according to a grey scale called a *voxel*.

BASIC TRANSESOPHAGEAL ECHOCARDIOGRAPHIC EXAMINATION

Before performing TEE, the operator must determine that the benefits of TEE outweigh the risks. Except in the presence of esophageal disease or injury, the risk is quite low. Absolute contraindications include prior esophagectomy, severe esophageal obstruction, esophageal perforation, and ongoing esophageal hemorrhage. Relative contraindications include esophageal diverticulum, varices, fistula, and prior esophageal surgery, as well as a history of a gastric surgery, mediastinal irradiation, unexplained swallowing difficulties, and other conditions that might worsen with the placement and manipulation of the TEE probe.

In some studies, TEE has been associated with an infrequent incidence of oral and pharyngeal injuries (0.1% to 0.3%), but in other studies, the incidence of postoperative gastrointestinal complaints did not significantly differ from that in comparable patients who had not undergone TEE.[29,30] The reported incidence of transient hoarseness after TEE is 0.1% to 12% in uncontrolled studies. Serious pharyngeal or esophageal injury after TEE has been reported but is rare.[31] Two case reports indicate the possibility of TEE-associated splenic injury.[32,33] Among 10,218 patients (in a multicenter European study) undergoing TEE (primarily outpatients), esophageal perforation occurred in one who subsequently died; the autopsy revealed a malignant tumor invading the esophagus.[34] Although bacteremia during TEE is uncommon, endocarditis has been reported in outpatients.[35,36] Endocarditis from intraoperative TEE has not been reported, and the risk is probably near zero because antibiotics are usually administered for the prevention of surgical wound infection. In infants, TEE has a low complication rate, but even an appropriate-sized TEE probe may obstruct the airway

distal to the endotracheal tube or compress the descending aorta[37] (also see Chapter 94).

Once the patient is anesthetized and the trachea securely intubated, the contents of the stomach should be removed by gentle suctioning. Gentle massage of the left upper quadrant of the abdomen during suctioning may help remove air that can otherwise degrade imaging. The patient's neck is extended, and the well-lubricated TEE probe is then introduced into the midline of the hypopharynx with the transducer side facing anteriorly. Usually, with minimal force, the probe will blindly pass into the esophagus, especially if the neck is extended. If the probe does not blindly pass, then a laryngoscope is used to lift the larynx anteriorly and the probe is placed into the esophagus under direct vision. During transducer insertion or withdrawal, the controls of the gastroscope must be in the neutral or relaxed position to allow the transducer to follow the natural course of the esophagus, thereby potentially minimizing the risk of injury.

Because of time constraints and relatively narrow diagnostic goals, anesthesiologists often perform a more limited intraoperative examination than described in the ASE/SCA's taskforce recommendation for a comprehensive TEE examination (see section, "Transesophageal Echocardiography Practice Guidelines" earlier in this chapter).[8,38] However, even when time is critical, the examination performed should allow at least the basic applications of TEE as outlined in the original guidelines for perioperative TEE, that is, to detect significant abnormal ventricular filling or function, extensive myocardial ischemia or infarction, large air embolism, severe valvular dysfunction, large cardiac masses or thrombi, large pericardial effusions, and major lesions of the great vessels.[6] A minimum of 8 different cross sections drawn from the 20 cross sections delineated in the comprehensive examination are required to meet these diagnostic goals. Four of the cross sections are imaged in both 2-D and color Doppler imaging to assess valvular function. The next paragraph describes the probe manipulations required to achieve these cross sections. (A review of Figure 46-14 is recommended to understand the terms used in the following description.)

After the TEE probe is safely introduced into the esophagus, it is advanced to the midesophageal (ME) level (28 to 32 cm measured at the upper incisors), and the AV is imaged in the short axis (SAX) by turning the probe, adjusting its depth in the esophagus, and rotating the multiplane transducer 25 to 45 degrees until the three cusps of the valve appear approximately equal in size and shape (Figure 46-20, *H*). Image depth is set at 10 to12 cm as required to position the AV in the center of the video screen. This cross section is ideal for the detection of aortic stenosis. This and all the subsequent cross sections are digitally recorded. Next, the probe is slightly turned to position the AV in the center of the video screen, and then the multiplane angle is rotated forward to 110 to 130 degrees to bring the long axis (LAX) of the AV in view (Figure 46-20, *I*). This cross section is best for the detection of ascending aortic abnormalities including type I aortic dissection. Color Doppler is used for the assessment of AV competence. For the detection of valvular stenosis and regurgitation, the Nyquist limit is set to 50 to 60 cm/sec.[39] Next, the Doppler is discontinued and the probe is turned rightward until the ME bicaval cross section comes into view (Figure 46-20, *L*). This cross section is usually best observed at a multiplane angle between 90 and 110 degrees and is ideal for assessing caval abnormalities, as well as compression of the right atrium from anteriorly located masses or effusions and the left atrium from posteriorly located masses or effusions. In addition, the bicaval cross section may reveal collections of air anteriorly located in the left or right atrium, as well as the structure of the interatrial septum including the foramen ovale. Next, the multiplane angle is rotated back to 60 to 80 degrees and the probe is turned leftward just past the AV to bring the ME right ventricular (RV) inflow and outflow cross section into view (Figure 46-20, *M*). Usually, an image depth of 12 to 14 cm is required to position the RV outflow track (RVOT) in the center of the video screen. This cross section reveals the contractile function of the RV, the RVOT, and the pulmonary valve function with the application of color Doppler. Next, the transducer is rotated back to 0 degrees, the probe is advanced 4 to 6 mm into the esophagus and gently retroflexed until all four cardiac chambers are visualized (ME four-chamber cross section) (Figure 46-20, *A*). Often, rotating the transducer 10 to 15 degrees enhances the view of the tricuspid annulus. Usually, an image depth of 14 to 16 cm is required to include the LV apex in the sector scan. In 2-D imaging, the free wall of the right ventricle and the lateral and septal LV wall segments are evaluated for contractile function. With color Doppler, both the mitral and tricuspid valves are assessed. Stenotic and regurgitant lesions can be accurately diagnosed. During this assessment, the image depth is decreased to 10 to 12 cm to afford a magnified view of the valves and color Doppler flow patterns. Next, color Doppler is discontinued, the left ventricle is positioned in the center of the screen, and the multiplane angle is rotated forward to 90 degrees to bring into view the ME two-chamber cross section (Figure 46-20, *B*). The image depth is returned to 14 to 16 cm. This cross section is best for revealing the function of the basal and apical segments of the anterior and inferior LV walls, as well as the anterior and inferior pericardial collections. When air emboli collect in the left ventricle, they can usually be best observed in this view as very echogenic areas located along the anterior apical endocardial surface. Then, the transducer is rotated forward to 135 degrees to reveal the ME LAX cross section, which is best for an assessment of the anteroseptal and posterior wall segments for contractile LV function (Figure 46-20, *C*). Together, the ME four-chamber, two-chamber, and LAX cross sections reveal all 17 segments of the left ventricle (Figure 46-21). However, the next and last of the basic cross sections provides a second look at the midventricular segments, as well as other benefits. To achieve this cross section, the transducer is rotated back to 0 degrees, the left ventricle is centered in the screen, and the probe is advanced 4 to 6 cm into the stomach. Then, it is gently flexed anteriorly to reveal the transgastric (TG) SAX cross section (Figure 46-20, *D*). This cross section is ideal for monitoring LV filling and contractile function. All major coronary arteries supplying the myocardium are viewed in this cross section. Moreover, changes in preload cause greater changes in the LV SAX cross section than in the LAX dimension, and

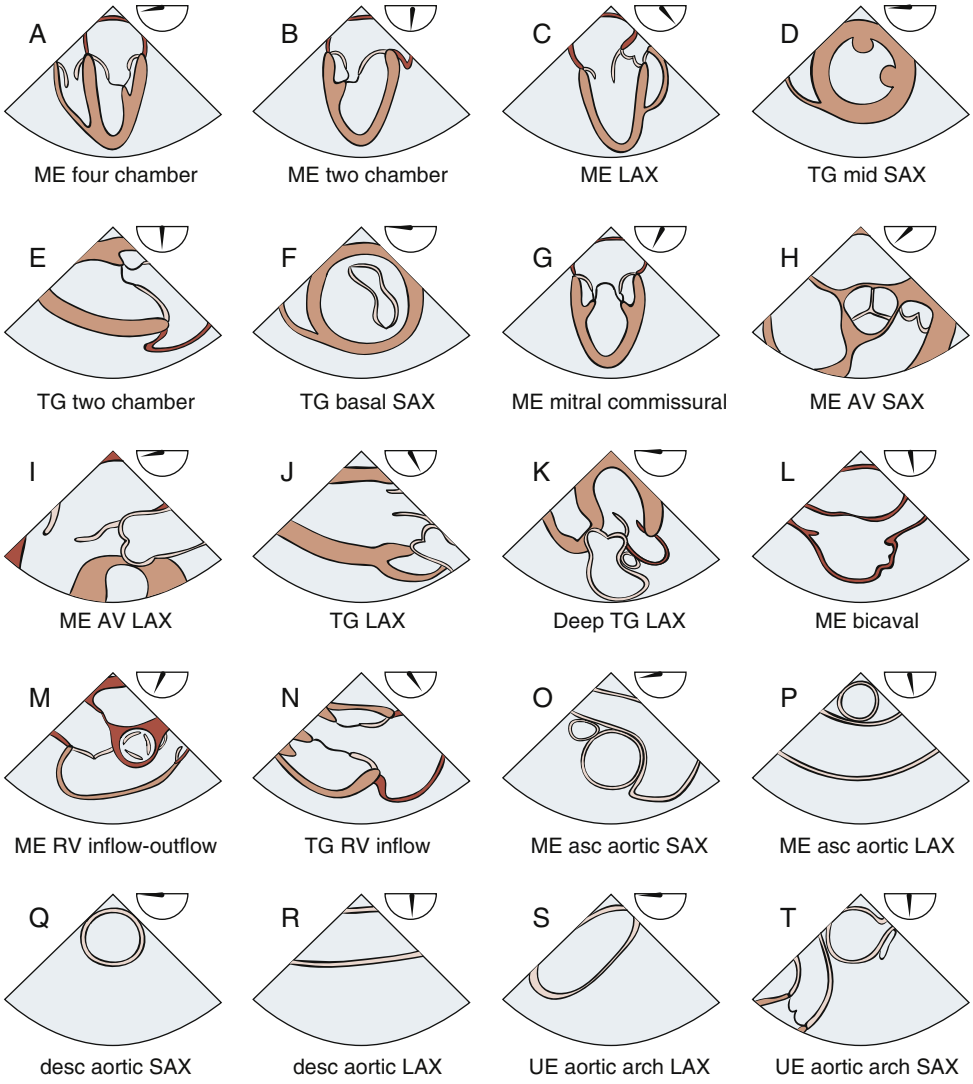

Figure 46-20. Transesophageal echocardiographic (TEE) cross sections in the comprehensive examination. Twenty standard cross sections and their abbreviated names are depicted by the line drawings. The text describes the probe manipulations required to produce each of the cross sections. *asc,* Ascending; *AV,* aortic valve; *desc,* descending; *LAX,* long axis; *ME,* midesophageal; *RV,* right ventricle; *SAX,* short axis; *TG,* transgastric; *UE,* upper esophageal. *(Reproduced with permission from Shanewise JS, Cheung AT, Aronson S. et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography,* Anesth Analg *89:870-884, 1999.)*

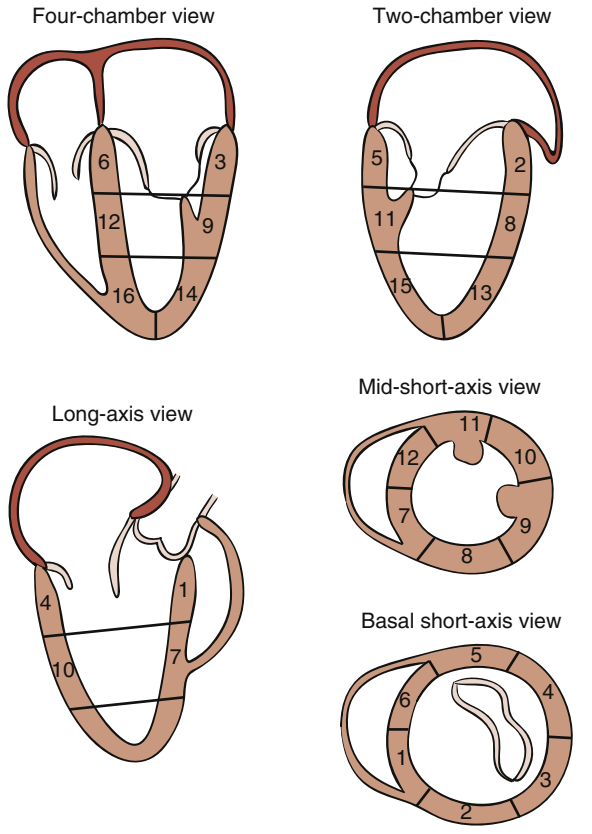

movement of the probe from this cross section is readily apparent because the papillary muscles provide prominent landmarks. Because this cross section is used to judge filling and ejection, the image depth is consistently set to 12 cm to enable the size and function of the heart to be easily judged relative to previously examined hearts.

In the authors' practice, one additional cross section is imaged in all patients as a part of the basic examination: the descending aorta in SAX (Figure 46-20, *Q*). The reason for this addition is the wealth of vital information this cross section can provide on the relative severity of atherosclerosis and the presence or absence of aortic dissection. (See the next section for a description of the technique required to image this cross section.)

COMPREHENSIVE TRANSESOPHAGEAL EXAMINATION

In addition to the 9 cross sections described in the preceding paragraph, 11 other cross sections are required to complete the comprehensive perioperative TEE examination delineated in the 1999 ASE/SCA taskforce recommendations.[8] When time permits or the diagnostic questions require, the comprehensive examination can be completed in any order deemed most appropriate by the operator. Shanewise and associates have described an examination sequence based on anatomic structures, and the reader is referred to this very detailed reference for an excellent approach.[8] However, when a single individual is responsible for anesthetic care and TEE, the comprehensive examination is completed as time permits after the basic examination has been recorded. When this is the case, the operator can use 3 of the 9 basic cross sections as take-off points for the other 11 cross sections, making the completion of the comprehensive examination a relatively easy sequence to remember and quick to perform.

With the probe positioned for the AV SAX cross section, the other six cross sections of the aorta are easily achieved. First, the probe is withdrawn slowly 1 to 3 cm, keeping the aorta in the center of the video screen to view the ascending aorta in SAX (Figure 46-20, *O*). As the probe is withdrawn, the operator views progressively more superior SAX cross sections of the aorta beginning with the sinotubular junction until the image is lost because of the interposition of the trachea between the esophagus and the aorta. Next, the multiplane angle is rotated

Basal Segments	Mid Segments	Apical Segments
1 = Basal anteroseptal	7 = Mid anteroseptal	13 = Apical anterior
2 = Basal anterior	8 = Mid anterior	14 = Apical lateral
3 = Basal lateral	9 = Mid lateral	15 = Apical inferior
4 = Basal posterior	10 = Mid posterior	16 = Apical septal
5 = Basal inferior	11 = Mid inferior	
6 = Basal septal	12 = Mid septal	

Figure 46-21. Five transesophageal echocardiographic (TEE) cross sections are presented with myocardial segments identified. A total of 16 myocardial segments are identified and named according to the standards adopted by the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists. *(Reproduced with permission from Shanewise JS, Cheung AT, Aronson S, et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography,* Anesth Analg *89:870-884, 1999. Since the time of this publication, a 17th segment has been added to the model, consisting of the apical tip of the left ventricle.)*

forward to 100 to 120 degrees and advanced slowly 1 to 3 cm, keeping the aorta in the center of the video screen to view the ascending aorta in LAX (Figure 46-20, *P*). These two cross sections are ideal for the pathologic assessment of the ascending aorta including type I aortic dissection and aortic atheromas. However, the most superior aspect of the aorta is rarely seen, including the take-off of the innominate artery because of the tracheal interposition previously noted. Next, the transducer is returned to 0 degrees, the image depth is decreased to 6 cm, and the probe is turned leftward past the cardiac structures to reveal the descending aorta in SAX (see Figure 46-20, *Q*). The probe is withdrawn and advanced with the aorta maintained in the center of the screen until the entire descending aorta has been examined in SAX. This maneuver is repeated with the transducer at 90 degrees to examine the descending aorta in LAX (Figure 46-20, *R*). Next, the transducer is returned to 0 degrees and the probe withdrawn until the distal (upper esophageal) aortic arch in LAX comes into view (Figure 46-20, *S*). Rotating the transducer to 90 degrees reveals the distal (upper esophageal) arch in SAX (Figure 46-20, *T*). The probe is turned leftward until the aorta just disappears from view and then is slowly turned rightward to identify the take-off of the left subclavian artery (well seen in most patients) and the left carotid artery (well seen in a minority of patients). These cross sections of the descending aorta and distal aortic arch reliably reveal dissections and atheromatous disease.

With the probe positioned for the ME four-chamber cross section, the ME mitral commissural cross section is easily achieved by positioning the coaptation point of the mitral valve in the center of the video screen and rotating the multiplane angle forward to approximately 60 degrees (Figure 46-20, *G*). This maneuver positions the ultrasound beam parallel to the closure line of the mitral leaflets and completes the LAX examination of the mitral valve. Although a detailed discussion of the mitral leaflet structure and function is beyond the scope of this chapter, Figure 46-22 summarizes an excellent approach to this challenging task.[40]

With the probe positioned for the TG mid-SAX cross section, the remaining five cross sections of the comprehensive examination are easily achieved in most patients. First, the left ventricle is centered in the video screen, and the multiplane angle is rotated forward to 90 degrees to reveal the TG two-chamber cross section (Figure 46-20, *E*). Although this cross section reveals the same structures as the ME two-chamber cross section, the viewing angle is orthogonal to the former viewing angle, and, as a result, subvalvular structures are better revealed. Next, the transducer is rotated to 100 to 120 degrees to reveal the TG LAX cross section (Figure 46-20, *J*). Again, this cross section reveals the same structures as the ME LAX dimension, but the TG LAX permits a more parallel alignment of the ultrasound beam with blood flow through the LV outflow track (LVOT) and AV. Next, the TG RV inflow cross section is achieved by returning the probe to the TG mid-SAX position, turning it rightward until the right ventricle is centered in the video screen, and then rotating the multiplane angle to 100 to 120 degrees to bring the RV apex into view (Figure 46-20, *N*). This cross section is ideal for viewing the RV inferior free wall. Next, the TG basal SAX is achieved by returning the probe to the TG mid-SAX dimension, releasing the flexion of the probe, withdrawing 1 to 2 cm, and then gently flexing the probe until the orifice of the mitral valve is seen in the SAX cross section (Figure 46-2, *F*). This cross section can prove vital in determining the precise location of mitral regurgitation.[40] Finally, the deep TG LAX cross section is achieved by returning the probe to the TG mid-SAX position, releasing the flexion of the probe, advancing it 6 to 8 cm into the stomach, fully flexing it once in the stomach, gently withdrawing it until minimal resistance is met at the gastroesophageal junction, and then slightly turning

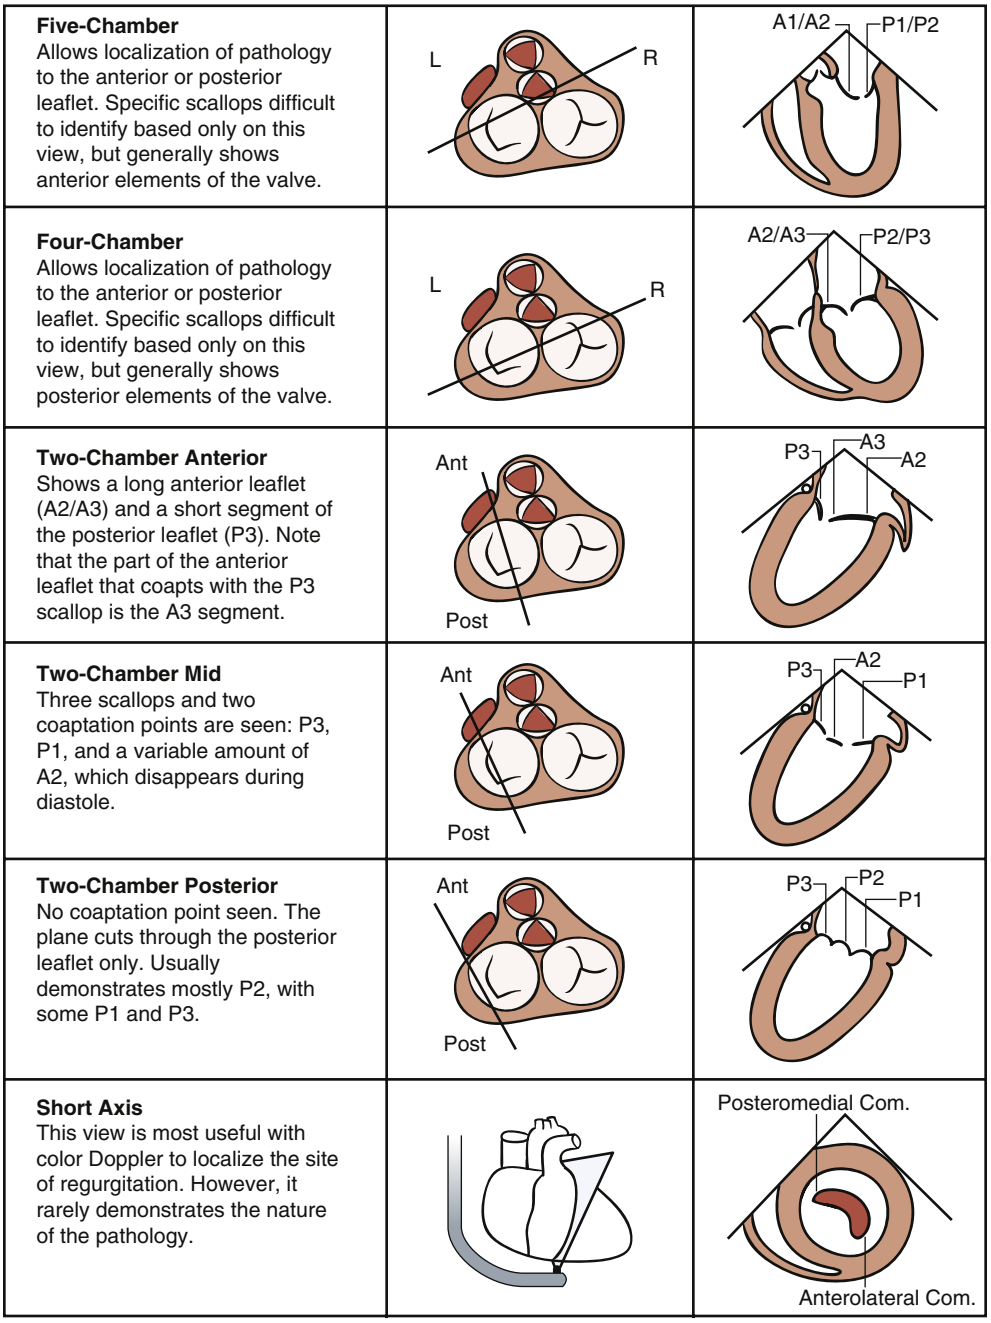

Figure 46-22. A systematic examination of the mitral valve is depicted. In this examination, the mitral valve is viewed in multiple cross sections to delineate the leaflet anatomy. The five-chamber cross section is accomplished by slightly withdrawing the probe from the standard four-chamber cross section until the left ventricular outflow track is in view. The *center column* shows the planes of the different cross sections as viewed from directly above the base of the heart. The two-chamber anterior, mid, and posterior cross sections are variations on the standard two-chamber cross section accomplished by turning the probe from the patient's right to left. P1, P2, and P3 refer to the three scallops of the posterior mitral leaflet, and A1, A2, and A3 refer to the juxtaposed segments of the anterior mitral leaflet. The *right column* shows the leaflet segments seen in the corresponding cross section. *(Reproduced with permission from Lambert AS, Miller JP, Foster E, et al: Improved evaluation of the location and mechanism of mitral valve regurgitation with a systematic transesophageal echocardiography examination,* Anesth Analg *88:1205-1212, 1999.)*

it leftward or rightward to reveal the LVOT and AV (Fig. 46-20, *K*). Usually this cross section does not resolve structures as well as the ME LAX cross section, but it does provide optimal beam alignment for Doppler interrogation of the LVOT outflow track and AV. Frequently, this cross section is the most difficult of the cross sections to achieve. If a few gentle attempts fail to accomplish it, it should be abandoned.

BASIC TRANSTHORACIC EXAMINATION

In patients with an unsecured airway, TTE is easier to perform than TEE because TTE is entirely noninvasive. TTE uses lower frequencies (1 to 3 MHz) than TEE to penetrate the greater distances inherent in the transthoracic technique, but all previously discussed modalities (M-mode, spectral Doppler, color Doppler, and TDI) can

be performed with TTE. Transthoracic cardiac probes are significantly different than the linear probes used to identify superficial vascular structures and nerve bundles. Thus, the probes used for ultrasound-guided nerve blocks and vascular access are not appropriate for TTE. TTE uses three standard *windows* (soft-tissue points that avoid boney interpositions between the transducer and heart): parasternal (PS), apical (AP), and subcostal (SC). The next paragraphs describe the probe manipulations required at these windows to achieve the TTE cross sections.

The examination begins with the patient turned halfway onto the left side with the left arm elevated alongside the head. Optimal imaging requires ultrasound gel between the probe and chest wall. Patients should be warned of the cold sensation of the gel on their skin. The PS long-axis (PS LAX) cross section is acquired first (Figure 46-23) by placing the probe on the left side of the sternum at the level of the fourth intercostal space and directing the ultrasound beam toward the patient's right shoulder. Appropriate adjustment of the image depth (15 to 18 cm), rotation, and angulation of the transducer reveals a small triangular segment of the right ventricle on the upper section of the display and the left ventricle chamber, left atrium, and aortic root in the middle section of the display. This cross section shows the same tomographic view as the ME LAX described in the TEE examination (see Figure 46-20, *C*). Similar to the ME LAX cross section, the PS LAX cross section permits an assessment of the structure and function of the AV, mitral valve, and the basal segments of the anteroseptum and posterior wall of the left ventricle. Sclerocalcific changes of the AV and reduction of the cusps excursion are demonstrated with aortic stenosis. Reduction of motion of the anterior leaflet of the mitral valve during diastole can be an indicator of mitral stenosis, LV dilation, LV dysfunction, elevated filling pressure, or any combination of these pathologic conditions. In this cross section, color Doppler allows the diagnosis of stenotic and regurgitant lesions of both atrioventricular valves. Next, the PS short-axis (PS SAX) cross section is obtained (Figure 46-24) by rotating the transducer 90 degrees clockwise and inferiorly angulating it toward the left hip until the right ventricle appears as a crescent-shaped structure at the top of the display and the left ventricle in the SAX is viewed at the bottom. This cross section shows the same tomographic view as the TG SAX described in the TEE examination (see Figure 46-20, *D*). In the absence of segmental dysfunction in the AP or basal segments of the heart, left and right ventricle sizes and contractile function can be accurately assessed from the PS SAX cross section.

The next cross sections are acquired from the AP window by placing the transducer in the fourth or fifth intercostal space lateral to the nipple line with the transducer marker (the notch or other landmark on the transducer indicating beam orientation) pointing toward the floor. Appropriate adjustment of the rotation and angulation of the transducer reveals the AP four-chamber (AP-4C) cross section (Figure 46-25) with the apex of the heart on the top of the display and the right and left atria on the bottom. This cross section shows the same tomographic view as the ME four-chamber described in the TEE examination (see Figure 46-20, *A*). The AP-4C cross section reveals the size

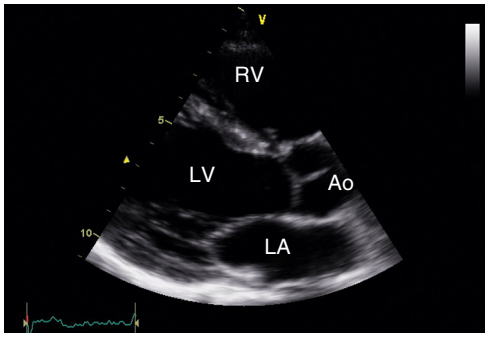

Figure 46-23. A transthoracic parasternal long-axis (PS-LAX), two-dimensional cross section of a normal heart is shown. This cross section reveals a small triangular segment of the right ventricle (RV) on the upper section of the display and the left ventricle (LV) chamber, the left atrium (LA), and the aortic (Ao) root in the middle section of the display. This cross section shows the same tomographic view as the midesophageal long-axis (ME LAX) cross section described in the transesophageal echocardiographic (TEE) examination (see Figure 46-20, *C*).

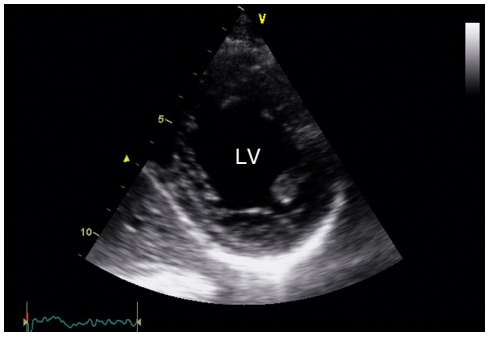

Figure 46-24. A transthoracic parasternal short-axis (PS-SAX), two-dimensional cross section of a normal heart is shown. This cross section reveals a small part of the crescent-shaped right ventricle at the top of the display and the left ventricle (LV) in the short-axis view in the rest of the image. This cross section shows the same tomographic view as the transgastric short-axis (TG SAX) view described in the transesophageal echocardiographic (TEE) examination (see Figure 46-20, *D*).

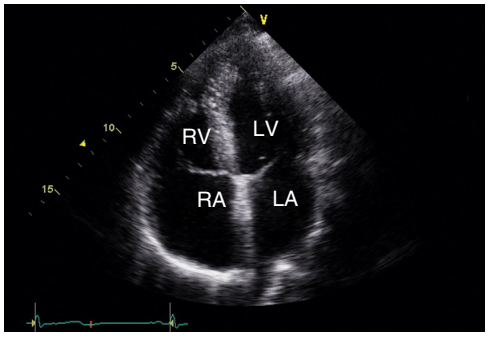

Figure 46-25. A transthoracic apical four-chamber (AP-4C), two-dimensional cross section of a normal heart is shown. This cross section reveals the apex of the heart on the top of the display and the right atrium (RA) and the left atrium (LA) on the bottom. This cross section shows the same tomographic view as the midesophageal four-chamber view described in the transesophageal echocardiographic (TEE) examination (see Figure 46-20, *A*). *LV,* Left ventricle; *RV,* right ventricle.

and global contraction of the ventricles, as well as the segmental function of their lateral walls and interventricular septum. Color Doppler of the tricuspid and mitral valves facilitates the diagnosis of valvular stenosis and regurgitation. In addition, the right upper pulmonary vein is visualized, and PWD estimates of the flow in this vein can help in fluid management (see subsequent sections on "Assessment of Ventricular Filling" and "Assessment of Ventricular Diastolic Function"). The next cross section is the AP two-chamber (AP-2C) view, which is acquired by rotating the transducer counterclockwise 60 degrees (Figure 46-26). This cross section shows the same tomographic view as the ME two-chamber described in the TEE examination and reveals segmental function of the anterior and inferior walls of the left ventricle (see Figure 46-20, *B*). The last AP cross section is the AP long-axis (AP LAX) view (Figure 46-27), which is obtained by rotating the transducer counterclockwise another 60 degrees until the LV outflow tract and AV are revealed in the bottom of the display. This cross section shows the same tomographic view as the ME LAX described in the TEE examination (see Figure 46-20, *C*). The AP-LAX provides an ideal vantage point for Doppler quantification of aortic stenosis and regurgitation because of the parallel direction of the ultrasound beam and blood flow.

The last two cross sections are acquired from the SC window with the patient in the supine position. The transducer is positioned flat under the right costal ridge next to the xiphoid appendix pointing toward the patient's left shoulder with the transducer marker pointing leftward. The SC four-chamber (SC-4C) view is seen (Figure 46-28) with the upper third of the display occupied by the liver and the heart below. RV free wall contractility and hemodynamically significant pericardial effusion are assessed best from this view. Finally, the SC inferior vena cava (SC IVC) cross section is obtained by rotating the transducer counterclockwise 90 degrees (Figure 46-29). The inferior vena cava (IVC) is demonstrated on the left side of the display as a rectangular echolucent structure inside the liver connecting to the right atrium. This view allows an assessment of the right-sided filling pressure by evaluating the size and collapsibility of the IVC in spontaneously breathing patients.[41]

When TEE is impracticable and cardiovascular status must be reliably evaluated, these basic TTE cross sections can provide most of the same information as TEE provides, thereby extending the benefits of echocardiography to many more surgical and critical care patients than when only TEE is available. The authors of this text predict that TTE will become the stethoscope of the future for anesthesiologists and other perioperative physicians who regularly care for patients who are critically ill. Already, residency programs in anesthesiology are incorporating TTE and TEE into their curriculum.[42,43] In addition, recent studies confirm the safety and value of noncardiologist physicians performing and interpreting TTE in the emergency department, during the perioperative period, and in the intensive care unit.[44-49]

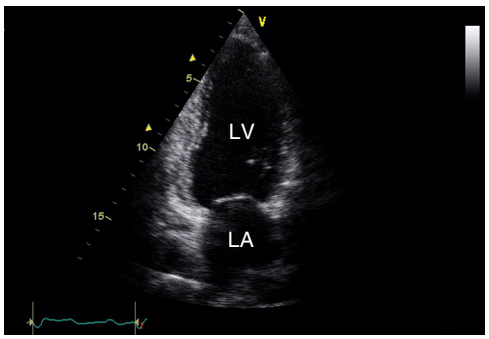

Figure 46-26. A transthoracic apical two-chamber (AP-2C), two-dimensional cross section of a normal heart is shown. This cross section reveals the left ventricle (LV) on the top (apex) and middle of the display and the left atrium (LA) on the bottom. This cross section shows the same tomographic view as the midesophageal two-chamber view described in the transesophageal echocardiographic (TEE) examination (see Figure 46-20, *B*).

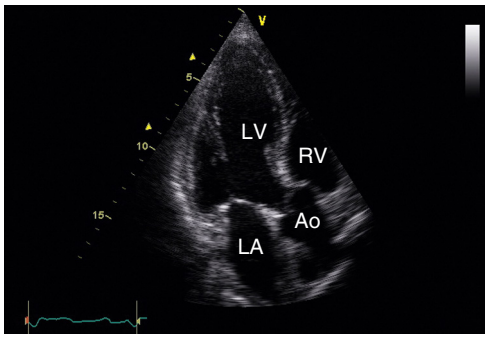

Figure 46-27. A transthoracic apical long-axis (AP-LAX), two-dimensional cross section of a normal heart is shown. This cross section reveals the left ventricle (LV) at the top (apex) and middle of the display and the left ventricular outflow tract and aortic valve (Ao) at the bottom of the display. This cross section shows the same tomographic view as the midesophageal long-axis (ME LAX) view described in the transesophageal echocardiographic (TEE) examination (see Figure 46-20, *C*). *LA,* Left atrium; *RV,* right ventricle.

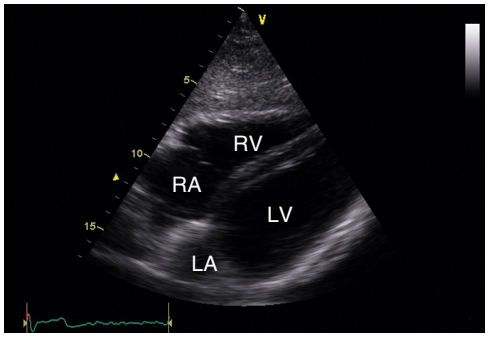

Figure 46-28. A transthoracic subcostal four-chamber (SC-4C), two-dimensional cross section of a normal heart is shown. The liver occupies the upper third of the display and the heart the lower two thirds. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

ASSESSMENT OF VENTRICULAR FILLING

TEE reveals changes in LV preload more reliably than filling pressures. In 30 patients scheduled for cardiac surgery, Cheung and associates removed 15% of each patient's blood volume in six equal aliquots before bypass surgery.[50] TEE demonstrated a significant decrease in cross-sectional area at end diastole after the removal of the first aliquot (approximately 200 mL) and a linear decrease with subsequent aliquots. The pulmonary artery occlusion

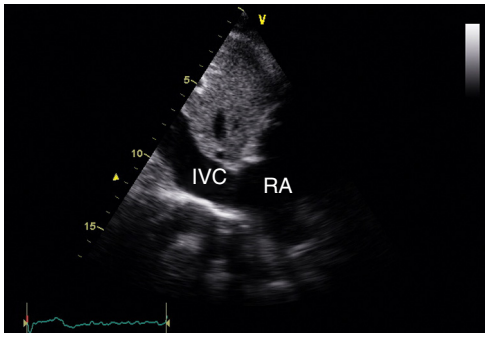

Figure 46-29. A transthoracic subcostal inferior vena cava (SC IVC), two-dimensional cross section of a normal heart is shown. The inferior vena cava (IVC) is seen on the left side of the display as a rectangular echolucent structure inside the liver connecting to the right atrium (RA).

and central venous pressures also declined but correlated poorly with the end of diastole. In most adults, an end of diastole of less than 12 cm^2 indicates hypovolemia, but values between 12 to 15 cm^2 may not because of variations in patient size and diastolic compliance. However, when a volume challenge increases the end of diastole, stroke volume also increases.[51] Although quantitative TEE measurements of ventricular preload are well validated as noted earlier, they are tedious and impractical to perform intraoperatively. Instead, clinicians assess LV filling and function subjectively with the "trained eye." This approach is a valid method to guide intravenous fluid administration. In patients with concentric hypertrophy, TEE may identify the need for higher-than-normal filling pressures to achieve optimal LV filling and function.[52]

In addition to estimating LV filling volume, TEE provides practical ways to estimate LV filling pressure. Placing the Doppler cursor at the junction of the left atrium and left superior pulmonary vein, Kuecherer and associates demonstrated that a systolic fraction of flow of less than 55% was a specific and sensitive sign of left atrial pressure greater than 15 mm Hg. This sign is easily detected as predominance of flow during diastole (Figures 46-30 and 46-31).[53] Significant mitral regurgitation, the presence of nonsinus rhythm, and extremes of cardiac output affect pulmonary venous flow and therefore limit this application of TEE. Alternative methods have been described that obviate some of these limitations.[54,55] However, the current use of TDI annular early diastolic velocity (e′) is recommended to assess the LV diastolic filling pressure.[27] As the LV diastolic relaxation and compliance deteriorate, the LV filling pressure and PW peak mitral inflow E velocity increase while the TDI e′ velocity decreases.[56] Thus the ratio of the E:e′ velocity correlates well with the LV filling pressure; a ratio under 8 is associated with normal LV filling pressures, whereas a ratio more than 15 is associated with increased filling pressures.[57] Although this method of estimating LV filling pressure is widely applicable, it is not valid in the presence of significant mitral annular calcification, mitral regurgitation or stenosis, or a prosthetic mitral valve.[27] Table 46-5 provides a summary of the echocardiographic parameters used for the estimation of LV filling pressures. Rudski and colleagues have published a summary of the echocardiographic techniques for assessment of RV filling and function.[58]

ESTIMATION OF CARDIAC OUTPUT

Real-time TEE images of LV filling and ejection permit qualitative, immediate detection of extreme changes in cardiac output. However, TEE can more precisely quantify cardiac output by measuring both the velocity and cross-sectional area of blood flow at appropriate locations in the heart or great vessels. The product of these measurements is stroke volume. Appropriately performed TEE estimates of cardiac output should fall within 0.3 to 0.8 L/min of thermodilution estimates, except in patients with severe tricuspid regurgitation when thermodilution may underestimate output.[59,60]

ASSESSMENT OF VENTRICULAR SYSTOLIC FUNCTION

Fractional shortening (FS) using M-mode measurements of the change in the midventricular SAX dimension during systole and fractional area change (FAC) using 2-D measurements of the change in the midventricular cross-sectional area during systole are commonly used measures of global LV function. They are calculated using two simple formulas:

$$FS = (EDD - ESD) \div EDD$$

and

$$FAC = (EDA - ESA) \div EDA$$

where EDD is the end-diastolic dimension, ESD the end-systolic dimension, EDA is the end-diastolic cross-sectional area, and ESA is the end-systolic cross-sectional area. Significant changes in FS and FAC are apparent by simply viewing the real-time images. Thus, severe LV depression is easy to detect with TEE. Although FS and FAC correlate reasonably well with other approximations of ventricular function, significant limitations apply. First, TEE often underestimates the LV long axis (it foreshortens the left ventricle). Second, the midventricular SAX view may be a poor guide to overall ventricular ejection, if other areas of the ventricle have significantly different function. Third, FS and FAC, similar to other traditional echocardiographic indices of systolic function, are load dependent; changes in preload and afterload significantly alter FAC without changing the intrinsic function of the ventricle.

Using echocardiographic estimates of LV end-diastolic and end-systolic volumes (EDV and ESV) to calculate the LV ejection fraction (LVEF) overcomes some of these limitations:

$$LVEF = (EDV - ESV) \div EDV$$

With 2-D images, a biplane method of disks (modified Simpson rule) is used. However, this technique is time consuming and will be effectively antiquated by modern 3-D machines that can measure LV EDV, ESV, and LVEF on a beat-by-beat basis without any assumptions about the shape of the ventricle.[4]

Measurement of RV function is more difficult than LV function because of the right ventricle's complex shape and response to changes in loading. However, severe RV dysfunction is not difficult to recognize. The hallmarks are severe hypokinesis or akinesis of the RV free wall,

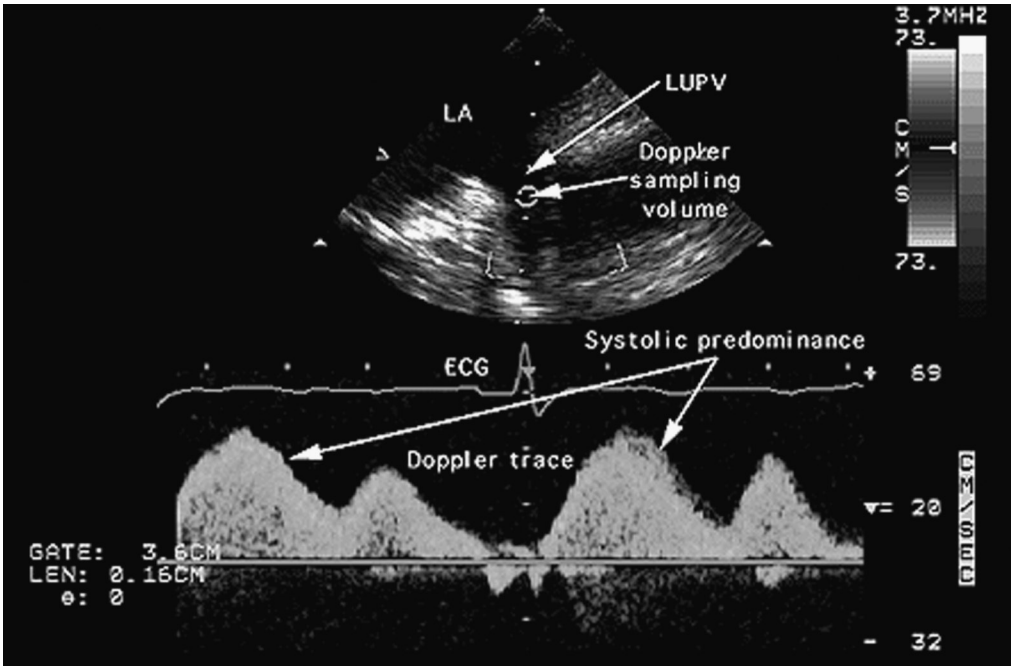

Figure 46-30. Pulsed-wave Doppler (PWD) measurement of normal blood-flow velocities in the left upper pulmonary vein (LUPV) is shown. At the top of the echocardiogram is a still-frame image of the two-dimensional cross section used to position the Doppler sample volume *(broken white circle)*. The display *(in white)* of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume is visualized on the bottom third of the figure. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above the line are positive (i.e., toward the transducer) to a maximum of 69 cm/sec. Flow below the line is negative (i.e., away from the transducer) to a maximum of –32 cm/sec. In this patient with normal left atrial pressure, systolic predominance of flow is evident; that is, more flow enters the left atrium (LA) during the period of ventricular systole than during ventricular diastole as evidenced by the greater peak and average flow velocities during systole than during diastole. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

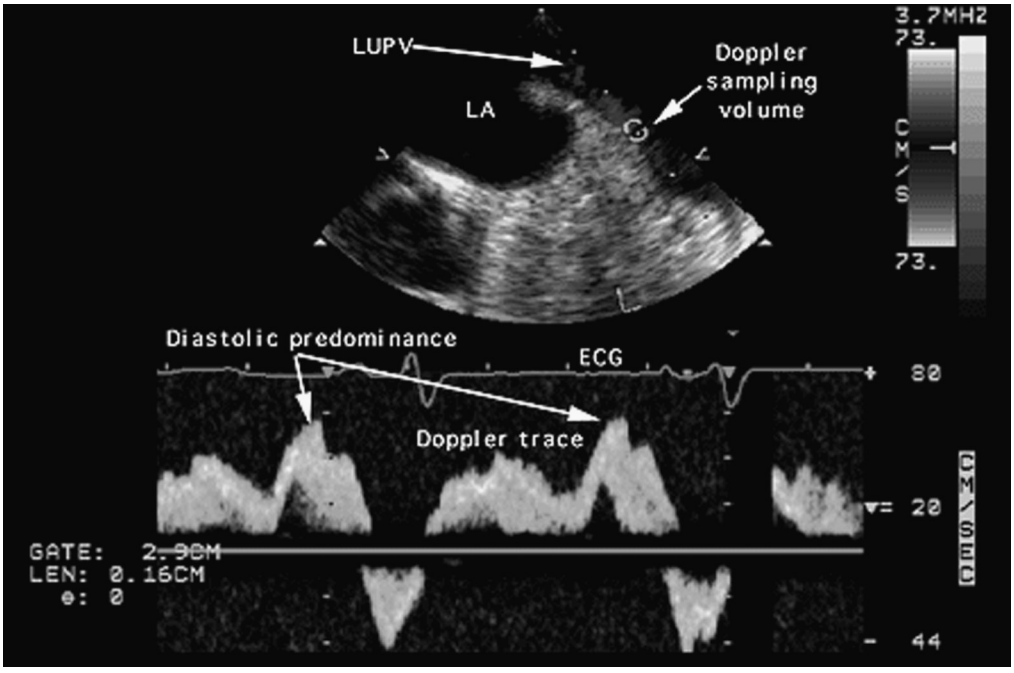

Figure 46-31. Pulsed-wave Doppler (PWD) measurement of blood-flow velocities in the left upper pulmonary vein (LUPV) is shown in a patient with abnormally high left atrial pressure. At the top of the echocardiogram is a still-frame image of the two-dimensional cross section used to position the Doppler sample volume *(broken white circle)*. The display *(in white)* of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume is visualized on the bottom third of the figure. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above the line are positive (i.e., toward the transducer) to a maximum of 80 cm/sec. Flow below the line is negative (i.e., away from the transducer) to a maximum of –44 cm/sec. In this patient with abnormally high left atrial pressure, diastolic predominance of flow is evident; that is, more flow enters the left atrium (LA) during the period of ventricular diastole than during ventricular systole as evidenced by the greater peak and average flow velocities during diastole than during systole. The negative flow velocities are due to atrial contraction pushing blood back into the pulmonary vein. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

TABLE 46-5 **PARAMETERS USED TO ESTIMATE LEFT VENTRICULAR FILLING PRESSURE**

Parameter	Values	Estimated Filling Pressure
Mitral inflow with Valsalva maneuver	>50% decrease in the E/A	Increased LAP
Pulmonary venous flow	Systolic fraction <40%	Decreased LA compliance and/or increased LAP
Pulmonary venous diastolic deceleration time	DT <175 ms	Increased LAP
Pulmonary venous A reversal	Ar >35 cm/sec	Increased LVEDP
	Ar – A duration >30 ms	Increased LVEDP
Color M-mode flow propagation velocity	Vp >50 cm/sec	Normal LAP
	E/Vp >2.5	Increased LAP
Tissue Doppler imaging	Septal E/e′ <8	Normal LAP
	E/e′ > 15	Increased LAP
Aortic regurgitation jet	End-diastolic peak velocity	LVEDP
	DBP – EDP gradient	
Mitral regurgitation jet	Peak MR jet velocity	LAP
	SBP – MR gradient	

A, Transmitral Doppler late-filling velocity; *Ar,* atrial systolic reversal wave; *E,* transmitral Doppler early-filling velocity; *DBP,* diastolic blood pressure; *DT,* deceleration time; *e′,* tissue Doppler early diastolic mitral annual velocity; *EDP,* end-diastolic pressure gradient measured across the aortic valve; *LA,* left atrium; *LAP,* left atrial pressure; *LVEDP,* left ventricular end-diastolic pressure; *MR,* mitral regurgitation; *SBP,* systolic blood pressure; *Vp,* velocity of left ventricular diastolic color M-mode propagation.

enlargement of the right ventricle so that it exceeds the size of the left ventricle, and a change in the shape of the right ventricle from crescent to round. When RV dysfunction is due to acute pulmonary hypertension, as occurs in pulmonary embolism, the intraventricular septum flattens or bulges leftward during systole.

However, several parameters can be used to assess the RV systolic function objectively, including myocardial performance index, tricuspid annular plane systolic excursion (TAPSE), RV FAC, 2-D RV ejection fraction (RVEF), 3-D RVEF, TDI-derived tricuspid lateral annular systolic velocity (S′), and RV longitudinal strain and strain rate.[58] TAPSE measures RV longitudinal function (decrease in the RV LAX during systole). TAPSE less than 16 mm indicates RV systolic dysfunction and has good correlation with techniques estimating RV global systolic function such as radionuclide-derived RVEF, RV FAC, and 2-D RVEF. S′ is easy to measure, reliable, and reproducible. S′ velocity less than 10 cm/sec indicates RV systolic dysfunction. The following formula defines RV FAC:

$$(\text{RV EDA} - \text{RV ESA}) = \text{RV EDA}$$

This method is good at quantitatively estimating RV systolic function with a lower reference value for normal RV systolic function of 0.35 (often expressed as 35%). RV FAC is obtained by tracing the RV endocardium both in systole and diastole from the annulus, along the free wall to the apex, and then back to the annulus, along the interventricular septum. The measurement of the RVEF is more difficult. The lower reference limit derived by pooled studies is 44%.

ASSESSMENT OF VENTRICULAR DIASTOLIC FUNCTION

Approximately one third of patients with symptomatic heart failure have normal LV systolic function. Their heart failure is due to diastolic dysfunction: abnormal diastolic relaxation and filling. TEE is an ideal tool for assessing diastolic function because of its unobstructed view of the mitral valve and pulmonary veins.[61] Normal flow across the mitral valve in diastole has an early higher velocity component generated by atrial pressure and ventricular relaxation (E wave on the Doppler echocardiogram) and a second lower velocity component generated by atrial contraction (A wave). At slower heart rates, these two waves are separated by a period of relatively little flow (diastasis). Three severities of diastolic dysfunction are diagnosed by the combination of flow patterns in the mitral valve and pulmonary veins (Fig. 46-32).[62] The least severe is *impaired relaxation,* which is characterized by a decrease in E-wave velocity, a decrease in the deceleration of early filling (demonstrated as decreased slope of the E wave and termed *deceleration time*), and an increase in the A-wave velocity to greater than the E-wave velocity, thereby reversing the E:A ratio. In impaired relaxation, left atrial pressure is normal, and therefore so is the pattern of pulmonary venous flow—the S wave is greater than the D wave. The second and more severe degree of diastolic dysfunction is termed *pseudonormal* and is characterized by the return of the normal E:A ratio because of a pathologic increase in left atrial pressure that results in abnormal pulmonary venous flow—the D wave is greater than the S wave. One simple way to confirm that the mitral flow pattern is pseudonormal and not normal is to reduce left atrial filling transiently with a Valsalva maneuver. If diastolic function is pseudonormal, then the E:A ratio will transiently reverse, with A being greater than E. If diastolic function is normal, then the normal ratio of E greater than A will persist and both waves will decrease in size. The third and most severe degree of diastolic dysfunction is termed *restrictive* and is characterized by an extremely high E-wave velocity, short deceleration time, and low A-wave velocity. In restrictive diastolic function, left atrial pressure is very high and results in an extremely small S wave and large D wave in the pulmonary veins. Patients with this pattern have a poor prognosis and suffer symptoms of congestive heart failure, regardless of their systolic function.[63]

For additional reading on this topic, the authors recommend two excellent reviews on perioperative assessment of diastolic function.[64,65]

TRANSESOPHAGEAL ECHOCARDIOGRAPHY DURING LIFE-THREATENING HYPOTENSION

Ultimately, hypotension has only two possible causes: inadequate cardiac output or inappropriately low systemic vascular resistance (Box 46-1). TEE is remarkably well suited for addressing this differential diagnosis. During severe hypotension, qualitative TEE estimates of ventricular filling and function serve as the practical guides for the

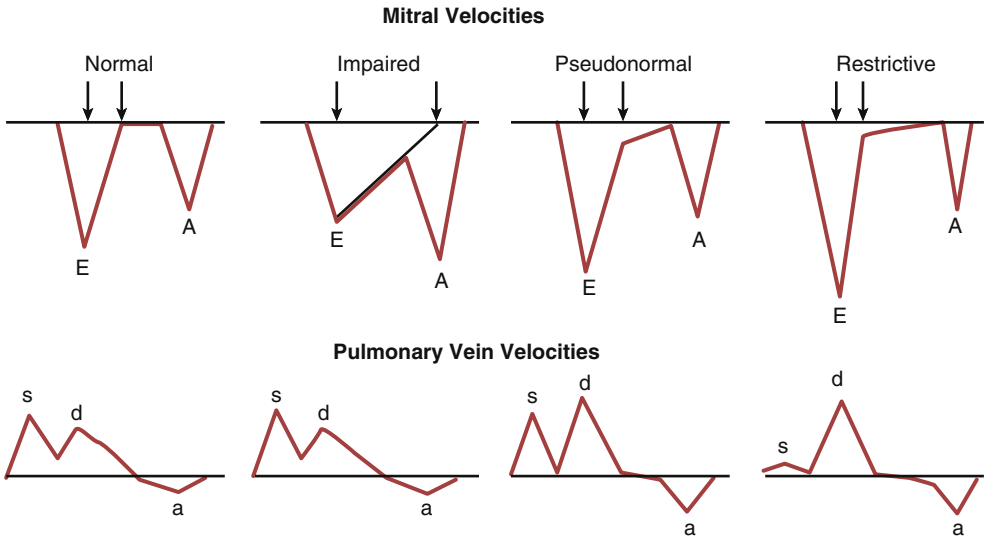

Figure 46-32. Line drawings representing simultaneous transesophageal pulsed-wave Doppler (PWD) recordings from the mitral annulus and right upper pulmonary vein are shown for normal, impaired, pseudonormal, and restrictive left ventricular diastolic function. The *solid red line* represents the slope of the E wave velocity. From the start of the line at the inflection point of the E wave until its intercept at the base line is the deceleration time. This time is depicted in each of the mitral velocity drawings by the *black arrows*. (Refer to the text for further details.)

BOX 46-1 ***Differential Diagnosis of Severe Hemodynamic Instability (Hypotension)***

Low cardiac index
- Hypovolemia
- Left ventricular systolic dysfunction
- Right ventricular systolic dysfunction
- Cardiac tamponade
- Severe valvular dysfunction
- Left ventricular outflow tract dynamic obstruction
- Pulmonary embolism

Low systemic vascular resistance

administration of fluids, inotropes, and vasopressors. An experienced observer can differentiate severe ventricular dysfunction from other life-threatening causes of hypotension. In severe LV failure, ventricular filling (as assessed by EDA) is increased and ejection is decreased, whereas in inappropriately low systemic vascular resistance, ventricular filling is usually normal or slightly decreased and ejection is significantly increased. Hypovolemia is easily recognized as a clear decrease in ventricular filling and a distinctive increase in ejection. Although inappropriately low systemic vascular resistance, severe aortic regurgitation, severe mitral regurgitation, and ventricular septal defect can demonstrate the same LV filling and ejection pattern on the TG SAX cross section, distinguishing these causes of hypotension is not difficult using other cross sections and color Doppler. LV dynamic obstruction and physiologic changes produced by tamponade are two other important possible diagnoses to consider when assessing patients with hemodynamic instability. Dynamic obstruction is observed in patients with concentric LV hypertrophy and relative hypovolemia. The hypertrophied LV muscle self-obstructs ejection of blood from the left ventricle, resulting in low cardiac output and significant eccentric mitral regurgitation. Physiologic changes produced by tamponade results when a pericardial effusion or other compression of the heart causes cardiac chamber pressures to be higher than filling pressures, resulting in the collapse of the chamber(s) and rapid deterioration of the cardiac output. Systolic atrial collapse usually precedes ventricular diastolic collapse. In general, a rapidly expanding small effusion is more detrimental to a patient's hemodynamic status than a larger and slowly accumulating effusion.

A dramatic example of the use of TEE in patients with hypotension is provided by a study of 60 consecutive patients with severe, persistent hypotension after cardiac surgery, despite intensive therapy guided by invasive monitors.[66] TEE confirmed the presumed cause of the hypotension in only 30 of these patients. In 2 patients, TEE revealed unsuspected cardiac tamponade and unsuspected hypovolemia in 6 others. In 5 patients, TEE prevented further unnecessary surgeries by proving that tamponade was not present, despite hemodynamic data suggesting the contrary. In another study, unstable patients in the cardiac operating room ($n = 57$) or the intensive care unit ($n = 83$) underwent emergent TEE.[67] Based on the TEE findings alone, 22 of these patients required urgent surgical interventions. The average time to diagnosis was 11 minutes. Still another study involving surgical patients who were critically ill proved TEE to be more cost-effective than TTE because the latter so often fails to reveal diagnostic images.[68] Moreover, TEE has prognostic value in patients who were critically ill with hypotension when it reveals nonventricular causes of hypotension (e.g., valvular or pericardial); patients are twice as likely to survive as those with other causes of hypotension.[69] Even in the setting of prolonged cardiopulmonary resuscitation, TEE may reveal crucial diagnostic information.[70]

DETECTION OF MYOCARDIAL ISCHEMIA

Within seconds after the onset of myocardial ischemia, affected segments of the heart cease to contract normally. In 50 patients undergoing cardiovascular surgery,

new intraoperative segmental wall motion abnormalities (SWMAs) diagnostic of myocardial ischemia (see next paragraph) occurred in 24 patients and ischemic ST-segment changes in only 6 patients.[71] In 3 patients who sustained intraoperative myocardial infarctions (MI), SWMAs developed in the corresponding area of the myocardium and persisted until the end of surgery, but only 1 of these 3 patients had intraoperative ischemic ST-segment changes. Subsequent studies in comparable patients confirmed these advantages of TEE over electrocardiographic monitoring.[72] In fact, new intraoperative SWMAs are more predictive of postoperative outcome than preoperative stress test–induced SWMAs.[73]

Limitations of TEE in the detection of ischemia should be recognized. When an area of the myocardium is clearly in view, segmental contraction can be difficult to evaluate if the heart significantly rotates or translates during systole or if discoordinated contraction occurs because of bundle branch block or ventricular pacing. Consequently, a valid system for assessment of SWMAs must evaluate both regional endocardial motion and myocardial thickening. A noticeable worsening of segmental wall motion and wall thickening (in the absence of similar global changes) is required to make the diagnosis of ischemia; even experts do not consistently interpret less pronounced changes. Not all SWMAs are indicative of myocardial ischemia. Myocarditis, MI, and myocardial stunning cause SWMAs. In coronary surgery, differentiating infarction, stunning, and ischemia is vitally important. When TEE reveals LV wall thickness of less than 0.6 cm, an old infarction in that thinned area is almost certain.[74] If inotropic stimulation improves the segmental motion of an SWMA, then stunning, not ischemia, is likely.[75] One other cause of SWMA is severe hypovolemia in patients with preexisting SWMAs.[76] However, with the exception of myocardial stunning and severe hypovolemia as noted earlier, a sudden, severe decrease of segmental contraction is almost certainly attributable to myocardial ischemia.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY IN CARDIAC SURGERY

NEW DIAGNOSES

TEE can reveal new diagnostic findings before cardiopulmonary bypass (CPB) that prompt changes in surgical management (also see Chapters 67 and 94). Skinner and associates reviewed 797 intraoperative TEEs to determine the cause of 46 unexpected new intraoperative findings; 20 were present in the preoperative echocardiographic studies but undiagnosed (reporting errors), 14 were attributable to limitations of TTE relative to TEE, 10 were due to a progression of disease, and 2 were due to interobserver variability.[77] Surgical management significantly changed in 18 out of 20 patients with reporting errors. However, the reported incidence of new intraoperative diagnoses with TEE varies widely (3.4% to 27% of cardiac cases) depending on the patient population, selected or consecutive use of TEE, and surgical practices, especially in the treatment of patent foramen ovale (PFO) and ischemic mitral regurgitation (IMR).[78-81] Recent studies help clarify the correct approach to these two variable surgical practices. First, Krasuski and associates reviewed the intraoperative TEE studies of 13,092 patients without a prior diagnosis of PFO who were undergoing cardiac surgery.[82] A new diagnosis of PFO was made intraoperatively in 2277 of these patients, and 639 of them underwent surgical closure. The patients who had PFO closure had 2.5 times greater odds of having a postoperative stroke, compared with a matched group of patients who did not have PFO closure. No long-term survival advantage resulted from PFO closure. Thus the new diagnosis of PFO during cardiac surgery should not prompt its closure without careful consideration of the additional risk of stroke. Second, Fattouch and associates randomly assigned patients with moderate IMR undergoing coronary artery bypass grafting (CABG) to receive CABG alone ($n = 54$) or CABG plus mitral valve repair (MVR) ($n = 48$).[83] Overall hospital mortality was 3% (one patient in the CABG group and two in the CABG/MVR group). Five-year survival rates were not statistically different between the groups (CABG at 88% versus CABG/MVR at 94%). However, patients in the CABG/MVR group had better postoperative exercise capacity and less cardiac distension than those in the CABG alone group. Only 40% of the patients in the CABG alone group had a decrease in their IMR, whereas 25% remained stable and 35% worsened. No patient in the CABG/MVR group had greater than mild IMR during the 5-year follow-up. A subsequent randomized multicenter trial has confirmed these findings[84]; however, neither trial is sufficiently powered (enough patients) to prove definitively the risks and benefits of adding MVR during CABG surgery in patients with mild-to-moderate mitral regurgitation.[85] Moreover, hemodynamic changes caused by general anesthesia alter the degree of mitral regurgitation (usually lessening it) thereby complicating surgical decision making. Restoring intraoperative blood pressure with phenylephrine to preoperative levels improves the concordance between preoperative and intraoperative assessment of mitral regurgitation, but discrepancies remain.[86] In patients undergoing coronary surgery, even mild mitral regurgitation identified by intraoperative TEE predicts a significantly greater likelihood of death or hospitalization for heart failure over the subsequent 3 years, compared with patients undergoing coronary surgery without mitral regurgitation.[87] Thus the decision to repair a regurgitant mitral valve during CABG surgery is complex and depends on many factors including the mechanism and degree of regurgitation, the ability of the patient to survive the additional surgery, and the skill of the surgeon.

AORTIC DISEASES

TEE may have a crucial role in surgical diseases of the aorta. The 2010 multidisciplinary guidelines on the management of thoracic aortic disease cite an 88% to 98% sensitivity and a 90% to 95% specificity for TEE in the detection of proximal aortic dissection.[88] In this true surgical emergency, speed is of the essence and TEE takes considerably less time than alternative diagnostic

techniques. To limit the time to surgery further, one center uses a regional strategy of direct admission to the operating room for patients with diagnosed or suspected acute aortic dissections.[89] TEE is performed in that facility under general anesthesia, and the decision to proceed with surgery is based on the results. In a different study, TEE reliably distinguished between subadventitial disruptions, which require emergent surgery and intimal tears, which do not.[90] Nevertheless, important TEE limitations should be noted including: TEE may miss dissections confined to the upper ascending aorta where TEE imaging is partially obstructed by the trachea, and TEE will not reveal coincident coronary lesions that should be bypassed during surgery. However, TEE can delineate the mechanisms and severity of any associated aortic regurgitation, thereby identifying patients in whom valve repair is likely to be successful.[91] Similarly, TEE-detected aortic atheromas have important implications. In 130 patients older than 65 years of age undergoing CABG, TEE detection of protruding atheroma of the ascending aorta proved to be the only independent predictor of stroke.[92] When these atheromas are detected by TEE, alteration of the aortic cannulation technique or raising the blood pressure during CPB may reduce the incidence or severity of stroke.[93,94] Although not as sensitive as epiaortic scanning for the detection of atheromas of the aortic arch, TEE is a good screening tool. If TEE reveals no significant atheromas in the ascending or descending aorta, then none are likely to be present in the arch.[95] When intraoperative TEE reveals severe atheromatous disease of the aorta, off-pump coronary surgery results in lower risk of death and stroke than on-pump surgery.[96]

In 2008, new guidelines were published on the intraoperative epiaortic ultrasonographic examination (scanning) of the aorta.[97] Epiaortic scanning avoids the limitation of TEE in assessing the ascending aorta and arch. These guidelines detail the clinical application of epiaortic scanning during heart surgery to evaluate the atherosclerotic disease burden in the ascending aorta and arch to guide proper cannulation strategies that may decrease the incidence of perioperative stroke.

VALVULAR DISEASES

TEE has profoundly affected valvular heart surgery. For example, in 205 consecutive patients undergoing posterior mitral leaflet quadrangular resection (the most common mitral repair technique) for treatment of mitral regurgitation, TEE revealed immediate failures in 24 patients (11%).[98] In 20 of these patients, TEE identified the mechanism of the failure and guided immediate further repair while 1 patient required valve replacement. In a different study, 437 patients underwent mitral valve repair by a variety of techniques.[99] During a mean follow-up period of 29 months, 41 patients (9%) required reoperation for repair failure. Successful initial repair as assessed by intraoperative TEE was the most important predictor of repair durability. Systolic anterior motion (SAM) of the mitral leaflet diagnosed with intraoperative TEE is a known complication of mitral repair surgery. In a study of 2076 patients undergoing mitral repair, TEE identified SAM in 174 patients (8.4%).[100] Four of these patients required immediate reoperation to relieve severe persistent SAM. In the others, SAM was medically managed. During a median follow-up period of 5.4 years, echocardiograms were available in 93 of these patients. SAM was present in 13 of them; in 4 patients, it was severe enough to cause partial LVOT obstruction. Thus, when TEE reveals SAM immediately after mitral repair, it can be medically managed in most patients with preload augmentation, arterial vasoconstriction, and/or beta blockade.[101] Landoni and colleagues have reported a stepwise approach to this strategy.[102] In patients with aortic regurgitation, TEE provides a highly reliable assessment of the underlying cause and is predictive of the reparability of the valve and of postoperative outcome.[103] During valve replacement surgery, TEE reliably detects periprosthetic leaks (surprisingly common). Although moderate or severe periprosthetic leaks should almost always undergo immediate repair, almost half of the small leaks resolve with the administration of protamine. However, surgically correctable prosthesis malfunction occurs in other patients and will be missed without the use of TEE. In a study of 417 patients undergoing valve replacement, immediate surgical correction was required in 15 patients (3.6%): periprosthetic leak (n = 8), immobilized leaflet (n = 4), coronary obstruction (n = 2), and xenograft incompetence (n = 1).[104] In a more recent study limited to patients undergoing elective AV replacement (n = 604), TEE revealed new information influencing surgery in 104 patients before CPB; changes regarding the mitral valve were the most frequent.[105] After CPB, TEE revealed unexpected findings requiring a second bypass in 20 patients. In the future, the incremental value of 3-D TEE in valvular heart surgery, especially mitral repair, may prove significant, but no doubt remains that properly performing and interpreting 3-D TEE requires substantial and additional operator expertise.[106]

Although a comprehensive review of valvular assessment is beyond the scope of this chapter, a brief overview of the most commonly used techniques should prepare the reader to fulfill at least the requirements for basic TEE practice, that is, to recognize gross valvular dysfunction. The degree of aortic stenosis is easily appreciated in the ME AV short-axis cross section in which the extent of leaflet opening can be visually estimated or directly measured with planimetry.[107] Severe stenosis is characterized by significant thickening of the leaflets and severely reduced leaflet motion (valve opening area of <1 cm^2). In the deep TG LAX cross section, CWD allows reliable estimation of the gradient across the AV (Figure 46-33).[108] In severe stenosis, the peak instantaneous gradient will exceed 64 mm Hg (CWD velocity exceeding 4 m/sec), provided cardiac output has not been significantly compromised. Noteworthy is the fact that the echocardiographic-derived AV gradient may be higher than the peak-to-peak gradient reported from a catheterization study because the latter does not measure the instantaneous gradient as does Doppler echocardiography. Additional information on the morphologic structure of the AV can be garnered from the ME AV LAX cross section including the dimensions of the annulus, sinotubular junction, and ascending aorta. The degree of aortic regurgitation is visualized best in this cross section. With color Doppler positioned over the leaflets and outflow track,

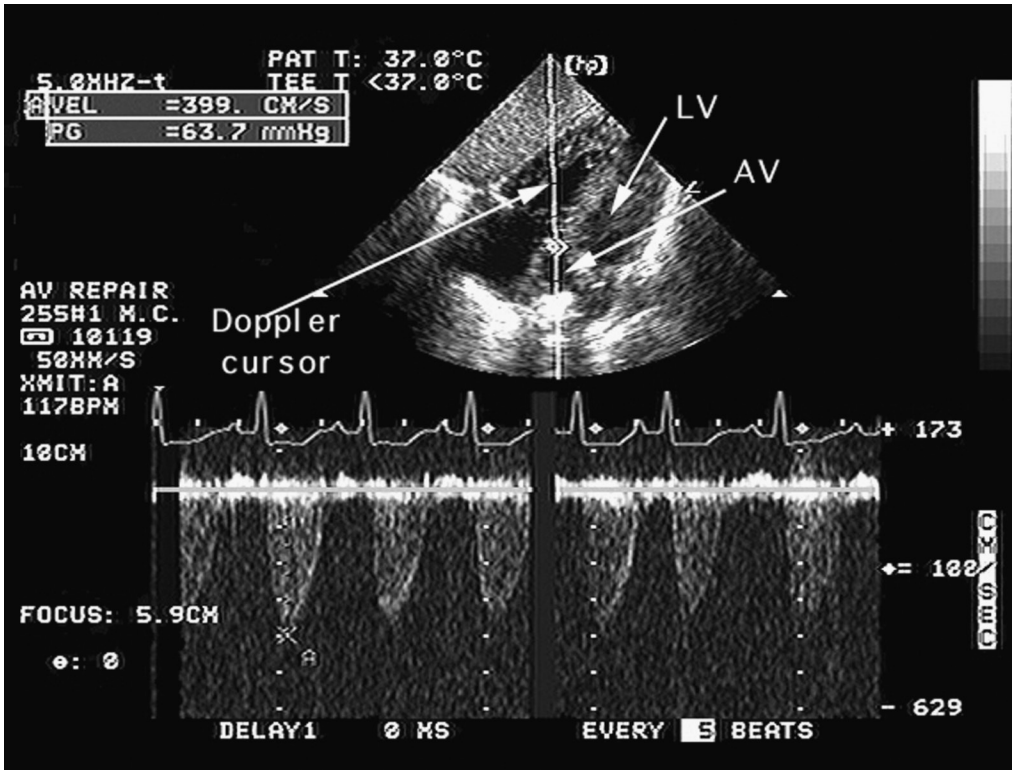

Figure 46-33. Continuous-wave Doppler (CWD) measurement of blood-flow velocities immediately above the aortic valve (AV) during seven cardiac cycles is shown. At the top of the echocardiogram is a still-frame image of the two-dimensional cross section used to position the Doppler sample cursor *(diagonal white line)*. The display *(in white)* of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor is visualized on the bottom third of the figure. The ECG provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. With this Doppler alignment, all flow velocities are negative (i.e., away from the transducer). The Doppler scale has been set to a maximum of –629 cm/sec, and this tracing documents significant aortic stenosis, a peak blood-flow velocity of approximately 4 m/sec (each *white dot* on the vertical axis equals 100 cm/sec or 1 m/sec) corresponding to a peak gradient across the AV of 64 mm Hg. *LV,* Left ventricle. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

aortic regurgitation is recognized as a color jet emanating from the valve during diastole. Even modest degrees of aortic regurgitation can be clinically significant during cardiac surgery, producing LV distention during CPB and diminishing the effectiveness of antegrade cardioplegia.[109] Mild regurgitation is characterized by a narrow-based, diastolic color jet (<2 mm at its origin in the valve) that occupies less than one third of the cross sectional area of the LVOT and extends minimally into the left ventricle (1 to 2 cm). Moderate regurgitation is a broad-based, diastolic color jet (3 to 5 mm) occupying less than two thirds of the cross-sectional area of the LVOT and extending moderately into the left ventricle (3 to 5 cm). Severe regurgitation is a broad-based, diastolic color jet (>5 mm) occupying the entire LVOT and extending well into the left ventricle (Table 46-6).

The presence and severity of mitral stenosis are easily determined with TEE using the ME four-chamber, two-chamber, commissural, and/or LAX cross sections, as well as the basal TG SAX cross section. Two-dimensional imaging reveals thickened leaflets that dome toward the left ventricle and open poorly. Color Doppler reveals laminar flow acceleration into the stenotic orifice and a turbulent jet emerging into the ventricle (Figure 46-34). PWD and CWD Doppler traces display a characteristic flow pattern with increased peak and mean velocities (Figure 46-35).

TABLE 46-6 **GRADING AORTIC INSUFFICIENCY**

Parameter	Mild	Moderate	Severe
Jet width or LVOT (%)	<25	25-60	>60
Vena contracta (mm)	<3	3-6	>6
Density of CWD jet	Faint	Moderately dense	Dense
P ½ time (msec)	>400	400-250	<250
Deceleration slope	<1.5	1.5-3	>3
Thoracic aortic flow reversal	Early diastole	Early-to-mid diastole	Holodiastolic
Regurgitant volume (mL)	<45	45-60	>60
Regurgitant fraction (%)	<30	30-55	>55
Regurgitant orifice area (cm^2)	<0.2	0.2-0.3	>0.3

CWD, Continuous-wave Doppler; *LVOT,* left ventricular outflow tract, P ½, pressure half time measured at the aortic valve; *vena contracta,* the base of the regurgitant jet at its origin.

Mathematical calculation from these traces, such as pressure half time, are the most precise methods to assess the severity of mitral stenosis; and formulas for these evaluations are built into the software of virtually every ultrasonograph.[110] In addition to the signs noted, severe mitral

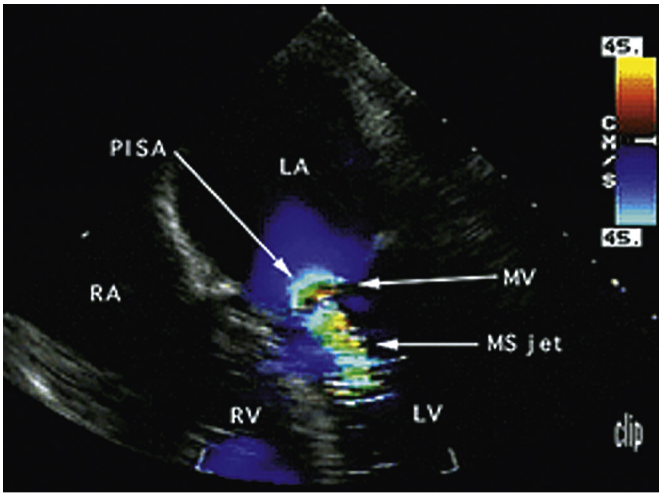

Figure 46-34. This four-chamber echocardiogram reveals a thickened and narrowed mitral valve (MV) indicating mitral stenosis (MS). Color Doppler demonstrates (1) the acceleration of blood flow into the stenotic valve (*light blue semicircular area immediately above the MV*, called the proximal isovelocity surface area [PISA]); (2) a narrow color jet across the valve itself; and (3) a 1- by 4-cm color jet extending from the under surface of the valve into the left ventricle (LV). *LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

stenosis always causes significant left atrial enlargement and left atrial spontaneous contrast. Spontaneous contrast is a swirling, smokelike appearance of 1-to 2-mm densities not attributable to exogenously administered contrast agents but to the aggregation of red cells in areas of low flow. Whenever left atrial enlargement and spontaneous contrast are noted, thrombus in the left atrium and, in particular, the left atrial appendage should be suspected and carefully examined.

The presence and severity of mitral regurgitation are evaluated from the same cross sections used for evaluation of mitral stenosis and with the same grading strategy used for aortic regurgitation (Table 46-7). Mild regurgitation is characterized by a narrow-based, systolic color jet (<2 mm at its origin in the valve) that occupies less than 25% of the left atrial cross-sectional area and extends less than one half of the distance to the posterior wall of the left atrium. Moderate regurgitation is a broad-based, systolic color jet (3 to 5 mm at its origin in the valve), occupying less than 50% of the left atrial cross-sectional area and extending 50% to 90% of the distance to the posterior wall of the left atrium. Severe regurgitation is a broad-based, systolic color jet (>5 mm), occupying most of the left atrium and extending into the pulmonary veins and left atrial appendage (Figure 46-36). Eccentrically-directed jets of mitral regurgitation that hug the wall of the atrium are generally associated with more severe valvular regurgitation than their cross-sectional area might suggest (see Figure 46-36). Moreover, eccentric-directed jets usually point away from the defective leaflet; that is, lateral-directed jets are usually associated with anterior leaflet defects and medial-directed jets are usually associated with posterior leaflet defects, provided the mechanism of regurgitation is leaflet prolapse or flail.[111] Severe mitral regurgitation is invariably associated with systolic reversal of pulmonary venous inflow (Figure 46-37).[112] The general guidelines previously listed are widely used, but many more criteria have been described for the assessment of mitral regurgitation.[39] Most importantly, the degree of regurgitation is exquisitely dependent on LV loading conditions. For practical purposes, quantitative measures of regurgitation, for example, the regurgitant orifice area based on the theory of proximal isovelocity surface area (PISA), are less often used in the operating rooms because of time restriction.

Pulmonary and tricuspid valve pathologic assessment are conducted in a fashion analogous to that described for the aortic and mitral valves (see Tables 46-6 and 46-7).

CORONARY DISEASE

In a study of 82 high-risk patients undergoing coronary artery surgery, the investigators used staged blindings of the cardiac surgeons and anesthesiologists at critical points during surgery to document the clinical impact of TEE. After these clinicians documented their planned management at each stage, the TEE results were revealed and led to at least one significant change in anesthetic management in 51% of patients and surgical management in 33% of patients including additional unplanned or revised grafts (15%) and unplanned valve procedures (20%).[113] These high-risk patients had postoperative infarction and mortality rates below predicted (1% versus 3% predicted, difference not statistically significant). In the study noted in the previous section involving 457 consecutive patients undergoing coronary artery surgery, TEE identified 71 new findings in 13% of patients. The new findings resulted in a change in surgical management in 6% of patients. After bypass, surgical management changed in 10 patients including graft evaluation or revision and mitral repair (also see Chapter 67).

CONGENITAL HEART SURGERY

Pediatric TEE probes are used in infants as small as 3 kg. Stevenson and co-workers reported that intraoperative TEE reliably detected residual cardiac defects in 17 (7%) of 230 consecutive patients undergoing congenital heart surgery.[114] These patients were immediately surgically treated for revision of the residual defects. However, a subsequent publication from the same center found that the number of residual defects missed by intraoperative TEE increased from 2% to 13% when the attending anesthesiologist, rather than a separate echocardiographer, performed TEE.[115] This study generated considerable controversy. Although this study does not resolve the issue of whether a separate echocardiographer is required to perform TEE adequately in patients undergoing congenital heart repairs, it does amply demonstrate that patients can suffer severe consequences when intraoperative TEE is not expertly performed, interpreted, and acted on. In this study, the deaths of seven patients may have been related to the delayed recognition of residual defects. With progress in pediatric congenital heart surgery, more children with palliated congenital heart disease will survive into

TABLE 46-7 **GRADING MITRAL INSUFFICIENCY**

	Trace	Mild	Moderate	Severe
Qualitative Parameters				
Angiographic grade	1+	2+	3+	4+
MV morphology	Normal	Normal or abnormal	Normal or abnormal	Abnormal (flail leaflet)
Color-flow MR jet	Small	Small and central	Intermediate	Very large central or eccentric jet to posterior LA wall
Flow-convergence zone	None	None or small	Intermediate	Large
CW signal of MR jet	Faint	Faint and parabolic	Dense and parabolic	Dense and triangular
LV and LA size and PA pressures	Normal	Normal		Usually dilated; elevated PAP
Semiquantitative Parameters				
Vena contracta width (mm)	<3	<3	3-6	≥7 (>8 for biplane)
Pulmonary vein flow	Systolic dominance	Systolic dominance	Systolic blunting	Systolic flow reversal
Mitral inflow	A wave dominance	A wave dominance	Variable	E wave dominant (>1.5 m/sec)
VTI mitral and VTI LVOT	<1	<1	Intermediate	>1.4
Quantitative Parameters				
Effective regurgitant orifice area (mm^2)	<20	<20	20-29; 30-39	≥40 ≥20
Regurgitant volume (mL)	<30	<30	30-44; 45-59	>60 >30

Modified from Lancellotti P, Moura L, Pierard LA, et al: European Association of Echocardiography recommendations for the assessment of valvular regurgitation. Part 2: mitral and tricuspid regurgitation (native valve disease), Eur J Echocardiogr *11:307-332, 2010.*

CW, Continuous-wave Doppler; *LA,* left atrium; *LV,* left ventricle; *LVOT,* left ventricular outflow tract; *MV,* mitral valve; *MR,* mitral regurgitation; *PA,* pulmonary artery; *PAP,* pulmonary artery pressure; *VTI,* velocity time integral.

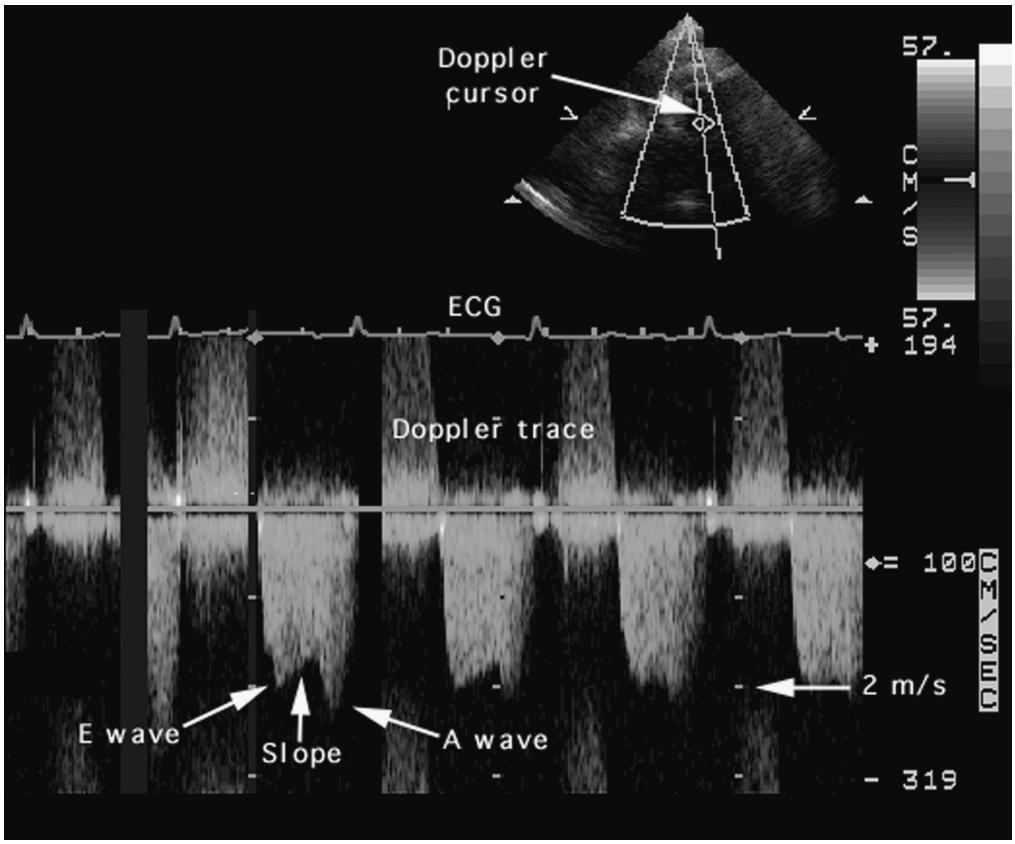

Figure 46-35. Continuous-wave Doppler (CWD) measurement of blood-flow velocities through a stenotic mitral valve is shown. At the top of the echocardiogram is a still-frame image of the four-chamber cross section used to position the Doppler cursor. The display *(in white)* of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor is visualized on the bottom third of the figure. The ECG is shown for timing purposes, and the *bold horizontal line* running through the Doppler tracing is the baseline (zero flow) for the flow velocities. Velocities displayed above the baseline are positive and represent flow toward the transducer. These velocities are attributable to mitral regurgitation and are so high that they exceed the scale used in this example. Velocities displayed below the baseline are negative and represent flow away from the transducer. These velocities are attributable to severe mitral stenosis and average approximately 2 m/sec, indicating a gradient across the mitral valve of 16 mm Hg. This echocardiogram also notes how slowly the flow velocity decreases after the peak of the E wave *(Slope).* The pressure half time can be calculated from this slope and is significantly increased in the presence of severe mitral stenosis. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas, *New York, 1997, Churchill Livingstone.)*

adulthood and will need cardiac and other kinds of surgery (also see Chapter 94). For excellent updates on TEE in adult and pediatric patients with congenital heart disease, the recent reviews by Russell and associates and Kamra and associates can be consulted.[116,117]

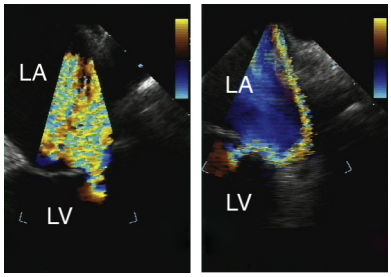

Figure 46-36. Two honed-down, stop-action, four-chamber transesophageal echocardiograms demonstrate severe mitral regurgitation. A large color jet *(left)* depicting turbulent flow emanating from the center of the mitral valve at its coaptation point is revealed. The mechanism of the regurgitation in this patient is annular dilatation. The broad base of the jet at the level of the valve leaflet and the extent of the jet's penetration into the left atrium are noted. The stop-action echocardiogram *(right)* reveals another broad-based jet with eccentric direction indicating prolapse of the anterior leaflet of the mitral valve. Wall-hugging jets such as this one have a small cross-sectional area because much of their energy is absorbed by the wall of the atrium.

OTHER DISEASES AND APPLICATIONS

TEE has a vital role in minimally invasive cardiac surgery and in the placement of cardiac support devices.[118,119] Thousands of other published reports document that TEE can reveal virtually any significant morphologic structure or pathologic function of the heart. TEE is particularly sensitive for abnormalities involving the left atrium and mitral valve including masses, thrombi, and emboli because of the proximity of left atrium and mitral to the TEE transducer. In contrast, pathologic abnormalities of the RV and LV apexes are less reliably detected. TEE is exquisitely sensitive to air embolism and, as a result, even insignificant amounts of air in the circulation can give rise to impressive densities on the video display. Currently, accurate estimation of the amount of air in the circulation is impossible using TEE. However, large amounts typically opacify the involved chambers until forming collections (i.e., very bright densities) in the most superiorly positioned parts of the chambers (i.e., anterior endocardial surface of the left ventricle in the supine patient). Pulmonary emboli may be observed with TEE if they lodge proximal to the bifurcation of the main pulmonary artery.

Anesthesiologists are asked to perform intraoperative TEE in an increasing number of procedures in the

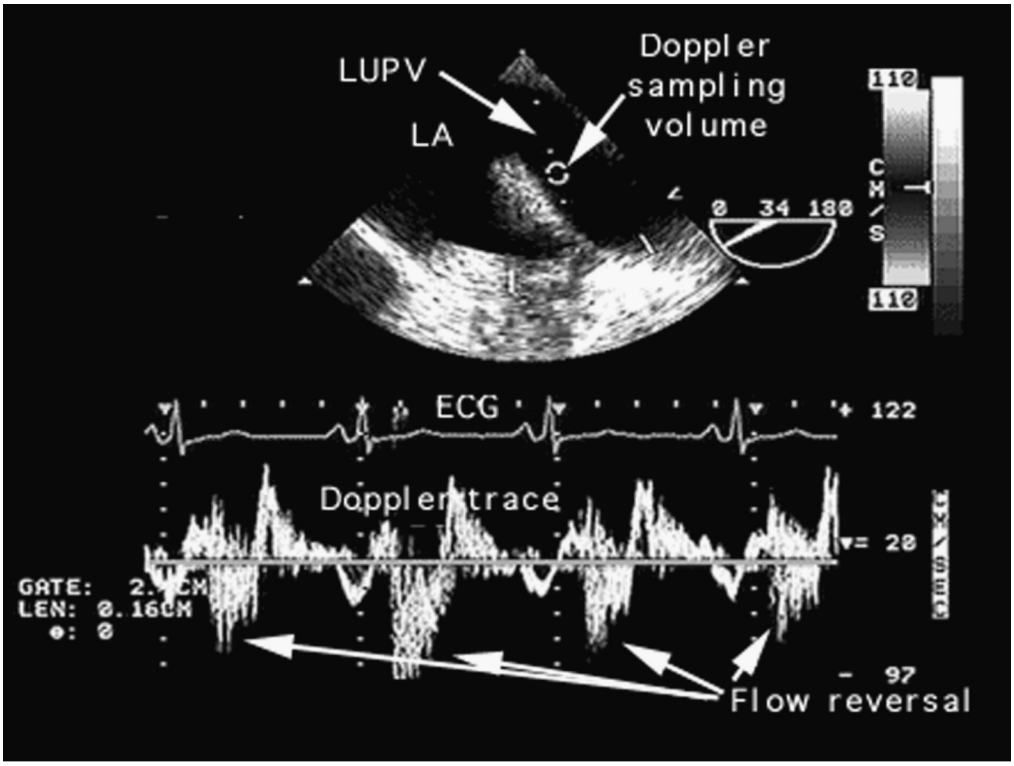

Figure 46-37. Pulsed-wave Doppler (PWD) measurement of blood-flow velocities in the left upper pulmonary vein is shown. At the top of the echocardiogram is a still-frame image of the two-dimensional cross section used to position the Doppler sampling volume *(broken white circle)*. The display of the instantaneous blood-flow velocities (vertical axis) versus time (horizontal axis) occurring in the left upper pulmonary vein is visualized on the bottom third of the figure. The ECG is shown for timing purposes and the *bold horizontal line* running through the Doppler tracing is the baseline (zero flow) for the flow velocities. Velocities displayed above the baseline are positive and represent flow toward the transducer (in this case, into the left atrium). Velocities displayed below the baseline are negative and represent flow away from the transducer (in this case, into the left upper pulmonary vein). This Doppler tracing documents systolic flow reversal (normally positive, that is, toward the left atrium in systole) and confirms the presence of severe mitral regurgitation. *(Reproduced with permission from Cahalan MK:* Intraoperative transesophageal echocardiography. An interactive text and atlas*, New York, 1997, Churchill Livingstone.)*

operating room, the catheterization laboratory, and in hybrid operating rooms. The role of imaging has evolved from complex cardiac evaluation to direct procedure guidance. TEE can be used to evaluate the correct position of central venous catheters, pulmonary artery catheters, and coronary sinus catheters. With the use of minimally invasive cardiac procedures, intraoperative TEE has become an essential tool for the safe application of these newer techniques. TEE is used to assess the correct position of venous CPB cannula in the right atrium, coronary sinus catheters, pulmonary vents, and endovascular aortic clamps. Box 46-2 lists procedures where TEE is routinely used for the direct guidance and evaluation of procedural results.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY IN NONCARDIAC SURGERY AND CRITICAL CARE

TEE has many of the same applications in noncardiac surgical patients and in patients who are critically ill as it does in cardiac surgical patients. Numerous case reports and case series document the effect TEE can have on patient management and outcomes. In the authors' practice, the leading indications are hemodynamic instability and massive blood loss, during which TEE has a vital role in determining the cause of the instability (see, "Transesophageal Echocardiography During Life-Threatening Hypotension") and in guiding volume resuscitation.[120,121] In the intensive care unit, TEE has similar applications, and these have been recently reviewed.[122,123]

BOX 46-2 ***Intraoperative Transesophageal Echocardiography for Guidance and Assessment of Cardiac Procedures***

- Femoral cannula placement during heart surgery (venoatrial placement)
- Coronary sinus catheter placement from the right internal jugular
- Left ventricular assist device inflow/outflow positioning
- Transmyocardial laser penetration positioning
- Left ventricular assist device positioning
- Right ventricular and pulmonary artery vent positioning
- Endovascular aortic clamp positioning
- Transcatheter aortic valve replacement assessment
- Percutaneous ventricular assist device positioning
- Intraaortic balloon pump positioning
- Atrial septal defect closure guidance and assessment
- Paravalvular leak site identification and closure guidance
- Transseptal puncture guidance
- Endovascular repair mitral regurgitation (mitral clip) assessment
- Transcatheter pulmonary valve replacement assessment
- Valvuloplasty assessments
- Pacemaker lead extraction evaluation and immediate follow-up
- Atrial fibrillation ablation guidance (three- and four-dimension applications)
- Left atrial appendage occluder positioning
- Pulmonary vein stent assessment
- Thoracic endovascular aortic repair guidance and assessment

DATA STORAGE, DOCUMENTATION, AND QUALITY ASSURANCE

Traditionally, echocardiograms were stored on videotape, and written reports of the results were placed in the patient's medical record. Currently, digital recording of individual cardiac cycles or multiple cycles is the standard. The resulting *loops* are transported via hospital networks or the Internet to secure servers where the studies can be rapidly retrieved. The SCA has published guidelines for a standardized reporting form for adult perioperative TEE (http://www.scahq.org/TEE/StandardizedReportforAdultPeriopEcho.aspx).

The ASE and SCA have published guidelines for continuous quality improvement (CQI) in perioperative echocardiography.[124] However, even relatively simple CQI interventions may produce dramatic results in the consistency of image acquisition and storage.[125] Periodic expert review of TEE interpretations is essential if practitioners are to reach and maintain their diagnostic potential. Collaboration between the departments of anesthesiology and cardiology is one approach to this review process that minimizes the duplication inherent in the formation of independent CQI programs.

CERTIFICATION

The National Board of Echocardiography (NBE) offers an examination and certification process for basic and advanced perioperative TEE (http://www.echoboards.org/content/verification-physicians-certification). At the basic level, the requirements are (1) passage of the NBE's basic perioperative echocardiography examination (basic PTeXAM), (2) current and unrestricted license to practice medicine, (3) board certification in anesthesiology, and (4) specific training in perioperative TEE. *Specific training* has two pathways, *supervised* and *practice experienced*. The practice experience pathway is the one most likely to apply to most anesthesiologists. It requires "at least 150 TEE examinations within the four (4) consecutive years immediately preceding the application with no less than 25 in any year." In addition, this pathway requires at least 40 hours of the American Medical Association (AMA) category 1 continuing medical education devoted to perioperative TEE. Of special note is the clear limitation the NBE has placed on basic TEE certification:

"The primary purpose of this certification is to provide anesthesiologists who use TEE as a monitor during general anesthesia an opportunity to demonstrate their competence with this technique. Certification in basic perioperative TEE is NOT intended to qualify an individual to use TEE as a diagnostic tool to direct or assess cardiac surgical interventions; the board certification in perioperative transesophageal echocardiography offered by the NBE since 2003 remains unchanged and still serves this purpose and from this point on will be referred to as Advanced PTE Certification.

In reality, most anesthesiologists practice somewhere between the basic and advanced levels. Regardless of the

level of practice, anesthesiologists must anticipate the need for consultation whenever the demands of anesthetic management, TEE interpretation, or both will be more than can be managed alone.

Chapter 47

Electrocardiography, Perioperative Ischemia, and Myocardial Infarction

GIORA LANDESBERG • ZAK HILLEL

Key Points

- The electrocardiogram (ECG) is an easy and important tool for diagnosing perioperative heart rate (HR) and rhythm abnormalities. Some of these abnormalities can be immediately dangerous, such as severe bradycardia, new atrioventricular (AV) blocks, and ventricular tachycardia (VT) or fibrillation, and require prompt diagnosis and treatment.
- Understanding the baseline ECG abnormalities of the patient undergoing high-risk cardiac surgery is an important part of the preoperative evaluation. Nevertheless, the ECG alone often does not provide sufficient information regarding the myocardial or valvular function and the risk of developing perioperative cardiac complications. For that purpose, some kind of stress test, either physiologic or pharmacologic, with or without cardiac imaging (nuclear or echocardiographic imaging) and/or coronary angiography is necessary.
- The ECG is an important tool for diagnosing acute myocardial ischemia, most often denoted by new or augmented ST-segment changes, such as significant ST-segment elevations or depressions.
- Myocardial ischemia is common in patients with a cardiac condition undergoing noncardiac surgery, predominantly during the early postoperative period (first 24 hours) and is almost exclusively ST-depression–type ischemia. Prolonged postoperative ST-depression–type ischemia strongly correlates with serum troponin increases, which in the first 3 postoperative days, will incrementally predict increased 30-day and long-term mortality.
- Postoperative myocardial infarction (MI) is most often a type 2 infarction; that is, it is due to prolonged myocardial oxygen supply-demand imbalance; although a type 1 infarction, which is a result of spontaneous plaque rupture and coronary thrombosis, may also occur. Therefore, therapeutic strategies to prevent and treat any potential cause of myocardial oxygen supply-demand imbalance, particularly an increase in the HR, should be applied whenever myocardial ischemia is detected or even considered. The prophylactic treatment by β-adrenergic blockers is controversial and can be hazardous in patients who are postoperatively hypotensive. Nevertheless, patients who are receiving chronic β-adrenergic blockade therapy must continue to take these drugs perioperatively unless contraindicated by their current or new hemodynamic status.

William Einthoven, who used a string galvanogram for his recordings, first invented the ECG in 1901. This time-honored and relatively simple tool remains, even today, a mainstay in clinical cardiac diagnosis and therapy. In the perioperative setting, the ECG serves two main functions: diagnosis and monitoring. In the preoperative period, standard 12-lead ECG is predominantly used for risk assessment. It provides information on the patient's baseline (chronic) cardiac status with regard to myocardial ischemia and conduction or rhythm abnormalities as part of the entire preoperative clinical assessment. Occasionally, the preoperative ECG may reveal acute or new abnormalities, especially with urgent or emergent operations, and in comparing current with previous ECGs. During and after surgery, the ECG can detect changes in rate and rhythm or myocardial ischemia. With many patients coming to surgery with pacemakers or implantable cardiac defibrillators in place, the ECG monitor enables the anesthesiologist to follow the proper function of these devices during the surgical procedure. (Perioperative management of these devices is described in Chapter 48.) During cardiac surgery, both myocardial

ischemia and arrhythmias are common, especially after separating from the cardiopulmonary bypass. The proper diagnosis and management of intraoperative ischemia and arrhythmias is especially part of the expertise of the cardiovascular anesthesiologist (see Chapters 67 and 68). A postoperative 12-lead ECG is often obtained in patients who are at high risk for developing new ischemic or rhythm changes. In all these scenarios, a good understanding of the principles of the ECG and its abnormalities is vital for the anesthesiologist. This chapter covers most aspects of ECG interpretation with a special emphasis on issues relevant to anesthesia and perioperative care.

ELECTROCARDIOGRAPHIC LEAD SYSTEMS

STANDARD RECORDING ELECTRODES AND LEADS

The small currents produced by the electrical activity of the cardiac muscle spread an electrical field throughout the body, which behaves as a volume conductor, allowing it to be recorded at various sites on the surface of the body as ECG signals. Electrodes (leads) placed at specific locations record the electrical potentials reaching the skin, and the output of these leads is amplified, filtered, and displayed. Two types of ECG leads are used: *bipolar* and *unipolar*. A bipolar lead consists of two electrodes placed at two different sites to measure the difference in potentials between these two electrodes. Unipolar leads measure the *absolute* electrical potential at one site in relation to a *reference,* or *remote* site, at which the potential is deemed to be zero. The standard clinical ECG includes recordings from 12 leads. These 12 leads include three *bipolar leads* (I, II, and III), six *unipolar precordial leads* (V_1 through V_6), and three *modified unipolar limb leads* (augmented limb leads aV_r, aV_l, and aV_f) (Table 47-1).

TABLE 47-1 LOCATION OF ELECTRODES AND LEAD CONNECTIONS FOR THE STANDARD 12-LEAD ELECTROCARDIOGRAM AND ADDITIONAL LEADS

Lead Type	Positive Input	Negative (Reference) Input
Bipolar Limb Leads		
Lead I	Left arm	Right arm
Lead II	Left leg	Right arm
Lead III	Left leg	Left arm
Augmented Unipolar Limb Leads		
aV_r	Right arm	Left arm plus left leg
aV_l	Left arm	Right arm plus left leg
aV_f	Left leg	Left arm plus left arm
Precordial Leads		
V_1	Right sternal margin, 4th intercostal space	Wilson central terminal
V_2	Left sternal margin, 4th intercostal space	Wilson central terminal
V_3	Midway between V_2 and V_4	Wilson central terminal
V_4	Left midclavicular line, 5th intercostal space	Wilson central terminal
V_5	Left anterior axillary line	Wilson central terminal
V_6	Left midaxillary line	Wilson central terminal

STANDARD ELECTROCARDIOGRAPHIC RECORDINGS

The ECG is normally recorded on special paper consisting of grids of horizontal and vertical lines. The distances between the vertical lines represent time intervals, whereas the distances between the horizontal lines represent voltages. The lines are 1 mm apart, with every fifth line intensified. The speed of the paper is standardized to 25 mm/sec. On the horizontal axis, 1 mm represents 0.04 second, and 0.5 cm represents 0.20 second. On the vertical axis, 10 mm represents 1 microvolt (mV). On every recording, a 1-cm (1-mV) calibration mark should indicate that the ECG is appropriately calibrated.

NORMAL ELECTRICAL ACTIVITY

P WAVE

Under normal circumstances, the sinoatrial (SA) node has the most rapid spontaneous depolarization rate and is therefore the dominant cardiac pacemaker. From the SA node, the impulse normally spreads to the atrioventricular (AV) node, through one left-sided and two right-sided pathways. The P wave is the result of normal depolarization of the atria, and its identification is important for the determination of normal sinus rhythm. The anatomically anterior right atrium is activated earlier, and only later does the signal shift posteriorly as activation proceeds over the left atrium. Therefore, the P wave in the right precordial leads (V_1 and, occasionally, V_2) is commonly biphasic, a positive deflection followed by a negative one, whereas in the lateral leads, the P wave is upright and reflects a right-to-left spread of the activation front.

PR INTERVAL

The PR interval is the temporal bridge between atrial and ventricular activation, during which the AV node, the bundle of His, the bundle branches, and the intraventricular conduction systems are activated (Fig. 47-1). Most of the conduction delay during this segment is due to slow conduction within the AV node. The normal PR interval measures 120 to 200 milliseconds (msec) in duration.

MYOCARDIAL ACTIVATION—THE QRS COMPLEX

The QRS complex is the manifestation of left and right ventricular muscle depolarization. Its pattern lead represents the sum of all electrical forces emanating from the wavefront propagation of ventricular electrical excitation aimed at the direction of that lead. Ventricular excitation spreads within several milliseconds from the bundle branches to the His-Purkinje fibers, which are broadly dispersed throughout the entire endocardial surfaces of both ventricles. Excitation of the Purkinje-ventricular

muscle junctions in the endocardium then proceeds by conduction from muscle cell to muscle cell to activate the entire ventricle thickness toward the epicardium. The normal pattern of activation of the ventricles starts in the interventricular septum with a vector oriented from left to right in the frontal plane and anteriorly in the horizontal plane (as determined by the anatomic position of the septum in the chest). This produces an initial small positive R wave in the right-sided leads (aV_R and V_1) and small negative waves (septal Q waves—less than 30 to 40 msec) in the left-sided leads (I, aV_L, V_5, and V_6). Subsequent QRS complex elements reflect the activation of the free walls of the left and right ventricles. However, because the right ventricular muscle mass is considerably smaller than the left ventricle, in reality, the QRS complex generally represents left ventricular (LV) activity with its main vector proceeding from right to left in the axial plane and anterior, followed by posterior vectors in the horizontal plane (R wave followed by a small S wave in the left-sided leads). The main vector of the QRS complex in the frontal plane serves to calculate the electrical axis of the heart, which is normally between –30 and +90 degrees. An axis more negative than –30 degrees is called *left axis deviation*, and an axis higher than +90 degrees is termed *right axis deviation*. The duration of the normal QRS complex is less than 120 msec (Fig. 47-2).

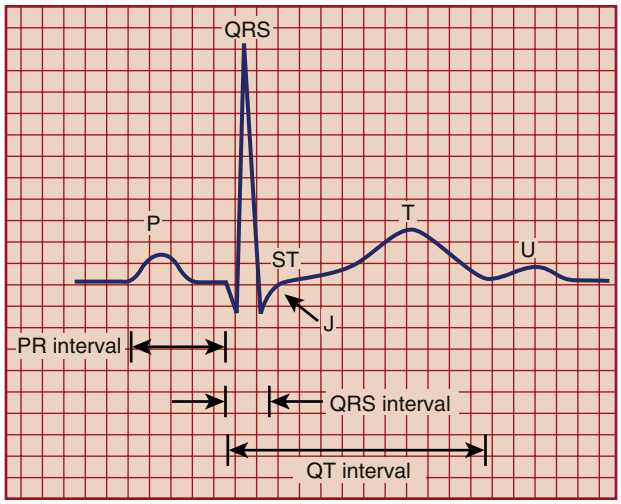

Figure 47-1. The waves and intervals of a normal electrocardiogram. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach*, ed 6. St. Louis, 1999, Mosby; and from Figure 9-11 in Zipes DP, Libby P, Bonow R, Braunwald E:* Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 7. Philadelphia, 2005, Saunders.)*

ST SEGMENT AND T WAVE

Repolarization of the ventricles generates the ST segment and T wave. Repolarization, similar to activation, occurs in a characteristic geometric pattern. Because the endocardial action potention lasts longer than that of its overlying epicardium, repolarization of the epicardium often starts earlier than in the endocardium. However, under normal conditions, regional differences in electrical recovery properties of the ventricles are present, and the transmural gradients predominantly determine ST-segment patterns.

Normally, concordance exists between the orientation of the QRS complex and the T wave, with both deflecting in the same direction. The junction of the QRS complex and the ST segment is called the *J junction*. The QT interval—the duration from the Q wave to the end of the T wave—is highly heart rate (HR)–dependent, and formulas have been developed to calculate the corrected QT interval (QTc), which, if prolonged, may be associated with serious ventricular arrhythmias. The T wave is sometimes followed by a small U wave, which may be associated with hypokalemia or hypomagnesemia electrolyte disturbances.

THE ABNORMAL ELECTROCARDIOGRAM

ATRIAL ABNORMALITY

The initiation of atrial electrical activation from a site other than the SA node occurs in one of two ways: (1) an escape rhythm if the normal SA nodal pacemaker slows or fails, or (2) an accelerated atrial ectopic rhythm if the automaticity of the ectopic site is associated with a rate higher than the SA. An abnormal morphologic appearance of the P wave (different from the native P) often expresses ectopic atrial activation. Most commonly, negative P waves are observed in the leads where the

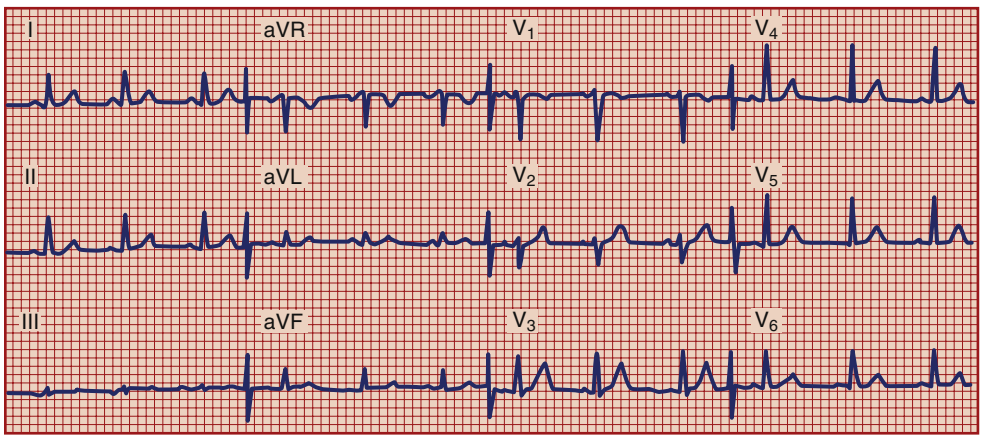

Figure 47-2. An example of a normal 12-lead electrocardiogram. *(From Figure 9-12 in Zipes DP, Libby P, Bonow R, Braunwald E:* Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 7. Philadelphia, 2005, Saunders.)*

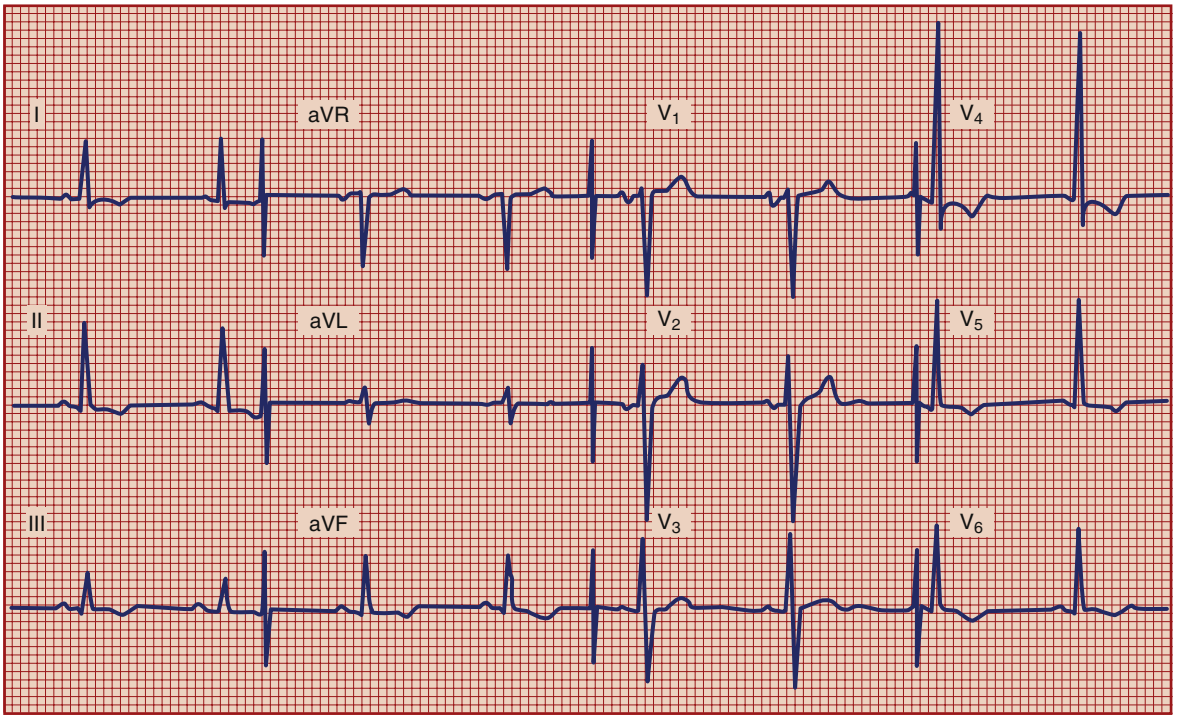

Figure 47-3. Left ventricular hypertrophy (LVH) on electrocardiography. Tall R waves on left-sided leads; and deep S waves on right-sided leads, down-sloping ST-segment depression and T-wave inversion opposite the main R-wave axis, and biphasic p wave signifying left atrial abnormality. *(From Zipes DP, Libby P, Bonow R, Braunwald E:* Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 7. Philadelphia, 2005, Saunders.)*

P wave is normally upright (leads I, II, aV_f, and V_4 through V_6), with or without a shortening of the PR interval. The exact site of an ectopic atrial pacemaker is usually of little clinical significance except that left-sided atrial ectopic rhythm is more often associated with LV or left heart valvular abnormalities, whereas right-sided ectopic rhythm is more common in patients with chronic obstructive lung disease or other causes of right heart dysfunction.

VENTRICULAR HYPERTROPHY AND ENLARGEMENT

Left ventricular hypertrophy (LVH) or enlargement produces changes throughout the QRST complex. The most characteristic is increased voltage of the QRS complex: tall R waves in left-sided leads (I, aV_l, V_5, and V_6) and deep S waves in right-sided leads (V_1 and V_2). ST-segment and T-wave amplitudes can be normal or increased. ST-segment depression with downsloping from a depressed J point and inverted asymmetric T waves are common in long-standing and severe LVH. Similarly, prolonged QRS duration beyond 110 msec reflects the longer duration of activation of the thickened ventricular wall (Fig. 47-3). Diagnostic ECG criteria for LVH have been developed, although their importance in the era of echocardiography has diminished. For example, Sokolow and Lyon found the following voltage criteria to correlate best with postmortem pathologic findings of LVH: S_{V1} + (R_{V5} or R_{V6}) >3.5 mV and/or R_{aVl} >1.1 mV.

Right ventricular hypertrophy (RVH) is signified on the ECG by abnormally tall R waves in the rightward-directed leads (aV_r, V_1, and V_2), reversal of normal R-wave progression in the precordial leads, deep S waves with abnormally small R waves in left-sided leads (I, aV_l, V_5, and V_6) and obvious right axis deviation (>110 degrees) (Fig. 47-4). Chronic obstructive pulmonary disease can lead to RVH, changes in the position of the heart in the chest, and hyperinflation of the lungs. Acute right ventricular pressure overload, such as that caused by pulmonary embolism, can produce a characteristic ECG pattern: a QR or qR pattern in the right-sided leads, an $S_1Q_3T_3$ pattern, and an acute incomplete or complete right bundle branch block (RBBB). However, even the classic $S_1Q_3T_3$ pattern occurs in only approximately 10% of patients with acute pulmonary embolism.

MYOCARDIAL ISCHEMIA

The ST-T segment, representing myocardial repolarization, is the ECG component most sensitive to acute myocardial ischemia. ST elevation, with or without tall positive (hyperacute) T waves, indicates transmural ischemia and is most often the result of acute coronary artery occlusion either by coronary thrombosis or vasospasm (Prinzmetal-variant angina). Reciprocal ST-segment depression may appear in the contralateral leads. Ischemia confined to the subendocardial area is usually denoted by ST-segment depression. Subendocardial, ST-depression–type ischemia typically occurs during episodes of symptomatic or asymptomatic (*silent*) stable angina pectoris, which is characteristic of ischemia occurring during exercise, tachycardia, or pharmacologic stress test in patients with significant but stable coronary artery disease (CAD) (Fig. 47-5).

MYOCARDIAL INFARCTION

With prolonged ischemia, the risk of developing myocardial necrosis or myocardial infarction (MI) is present. The MI signature on an ECG is decreased R-wave

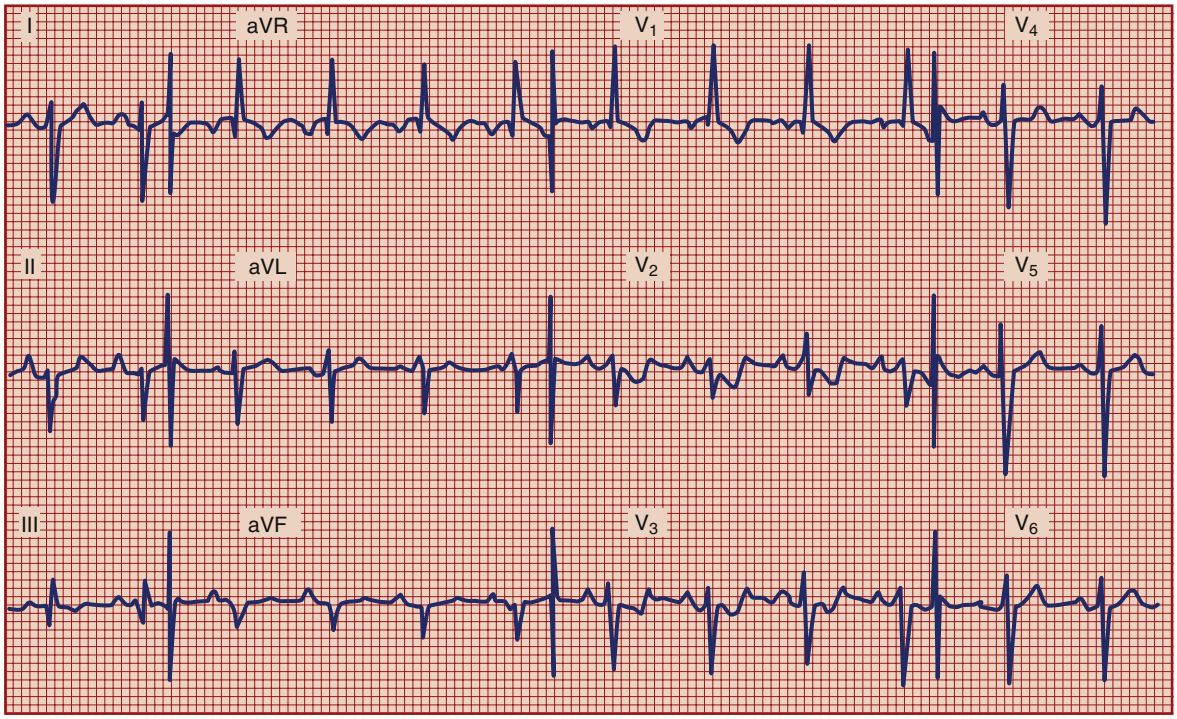

Figure 47-4. Severe right ventricular hypertrophy (RVH). Tall R waves on right-sided leads, deep S waves on left-sided leads, and T-wave inversions in right-sided leads ($S_1Q_3T_3$).

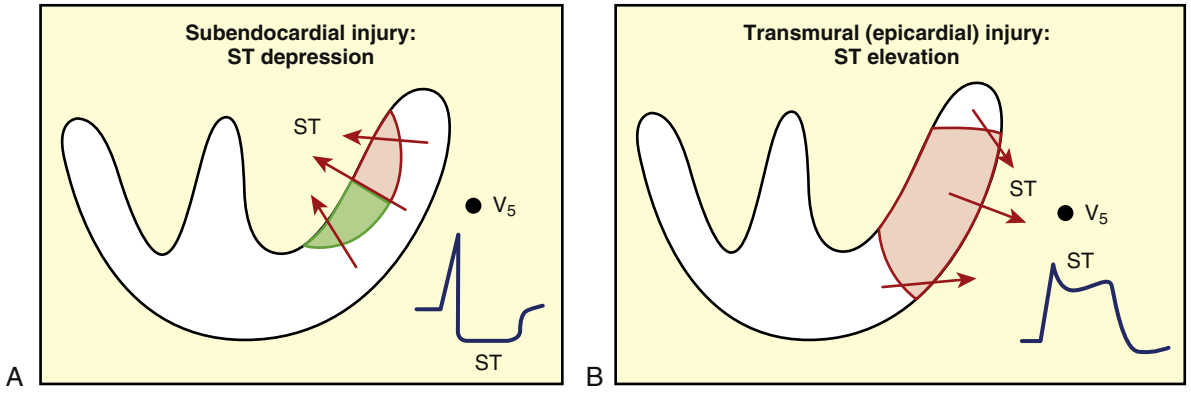

Figure 47-5. Patterns of injury currents. **A,** Acute subendocardial, ST-depression–type ischemia. **B,** Transmural, ST-elevation type ischemia. (From Zipes DP, Libby P, Bonow R, Braunwald E: *Braunwald's heart disease: a textbook of cardiovascular medicine,* ed 7, Philadelphia, 2005, Saunders.)

amplitude and pathologic Q waves, which may develop as a result of a loss of electromotive forces in the area of infarction. Transmural infarctions are more likely to culminate in abnormal Q waves, whereas subendocardial (nontransmural) infarctions are less likely to produce Q waves. However, pathologic studies have shown a wide overlap between the two entities and their ECG expression; therefore, *Q-wave* or *non–Q-wave* infarction is not synonymous with transmural or nontransmural infarction. Pathologic Q waves usually develop days after the onset of acute MI; once they develop, they seldom disappear and serve as an indicator for the location of the infarction. Persistent T-wave inversion may also be the only sign of chronic ischemia and a recent or an old MI. Pathologic Q waves, with ST-segment elevation that persists weeks or longer after an MI, strongly correlate with a severe myocardial mechanical dysfunction, akinesis, or ventricular aneurysm.

The ECG leads with ST-T changes or Q waves may help define the location and the coronary artery responsible for the ischemia or infarction. For example, precordial leads V_1 to V_3 correspond to the anteroseptal or apical walls of the left ventricle; leads V_4 to V_6 to the apical or lateral LV walls (Fig. 47-6); leads II, III, and aV_f to the inferior LV wall (Fig. 47-7); and the right-sided leads to the right ventricle. Posterior wall infarction induces ST-segment elevation or Q waves in leads placed over the left side and back (V_7 to $V_{9)}$ and reciprocal ST-segment depression or tall R waves in leads V_1 to V_3 may develop.

ELECTROLYTE ABNORMALITIES

The ECG is affected not only by structural or functional myocardial abnormalities but also by numerous metabolic and electrolyte aberrations.

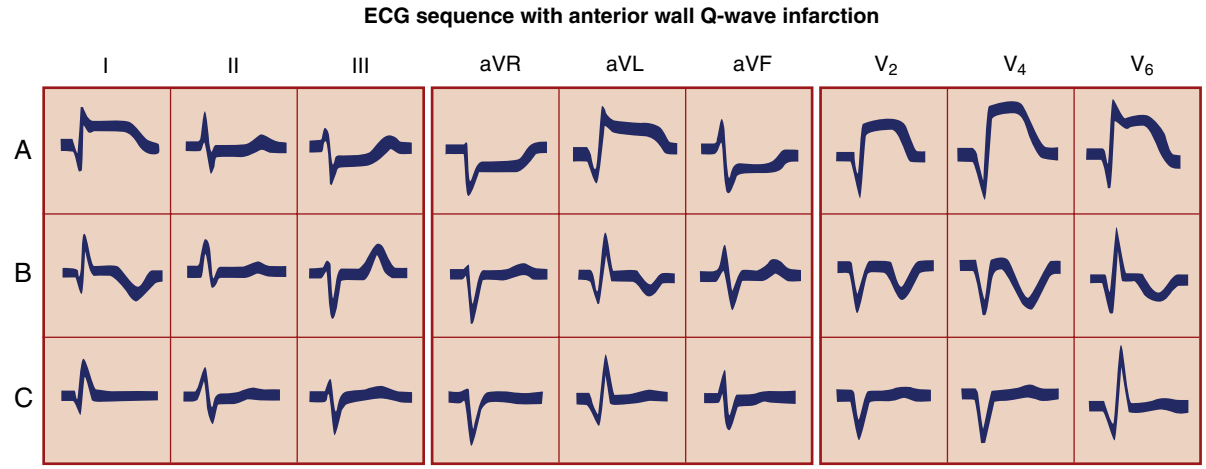

Figure 47-6. Acute ST-elevation–type anterior wall myocardial infarction. **A,** Acute phase: ST elevations and new Q waves. **B,** Evolving phase: deep T-wave inversions. **C,** Resolving phase: partial or complete regression of ST-T changes (and sometimes of Q waves). The reciprocal ST-T changes are noted in the inferior leads (II, III, and aV_F). *(From Figure 8-4 in Goldberg AL:* Clinical electrocardiography: a simplified approach*, ed 7. St. Louis, 2006, Mosby.)*

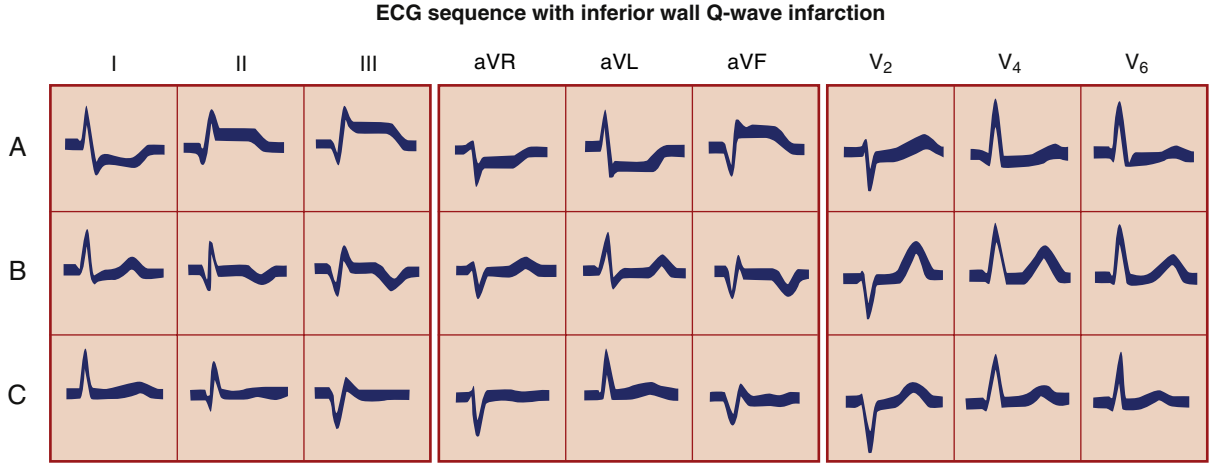

Figure 47-7. Inferior wall myocardial infarction. **A,** Acute phase: ST elevations and new Q waves. **B,** Evolving phase: deep T-wave inversions. **C,** Resolving phase: partial or complete regression of ST-T changes (and sometimes of Q waves). The reciprocal ST-T changes are noted in the anterior leads (I, aV_L, and V_2). *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

Calcium. Hypercalcemia shortens and hypocalcemia prolongs the phase 2 of the action potential duration, thus leading to an abbreviation or a prolongation of the QT interval, respectively. Severe hypercalcemia (e.g., total serum Ca^{2+} >15 mg/dL) causes a decrease in T-wave amplitude or T-wave inversion, and hypercalcemia may produce a high-takeoff ST segment in leads V_1 and V_2, simulating acute ischemia.

Potassium. Hyperkalemia leads to a distinctive sequence of ECG changes, starting with a narrowing and peaking of the T wave and a shortening of QT interval. Progressive hyperkalemia causes QRS widening, low P-wave amplitude, and PR interval prolongation with the possibility of second- to third-degree AV block (Fig. 47-8). Severe hyperkalemia leads to a sine-wave ventricular flutter and eventual asystole. Hypokalemia, in contrast, may cause ST-segment depression, flattened T waves, and prominent U waves, which may sometimes exceed the amplitude of T waves. Hypokalemia prolongs repolarization and leads to long QT(U) syndrome, predisposing to a torsades de pointes–type ventricular fibrillation.

Magnesium. Mild-to-moderate hypermagnesemia or hypomagnesemia is not associated with specific ECG changes. Yet, severe hypermagnesemia can cause AV and intraventricular conduction disturbances, including complete heart block and cardiac arrest (Mg^{2+} >15 mEq/L). Hypomagnesemia is often associated with hypocalcemia or hypokalemia and may predispose to long QT(U) syndrome and torsades de pointes.

ELECTROCARDIOGRAPHIC MONITORING SYSTEMS

NOISE FILTERING

Low-Frequency Filtering

All ECG monitors use filters to narrow the signal bandwidth in an attempt to reduce environmental artifacts and to improve signal quality. Low-frequency noise, such as that produced by respiration or any other patient motion, causes the tracing to wander above and below the

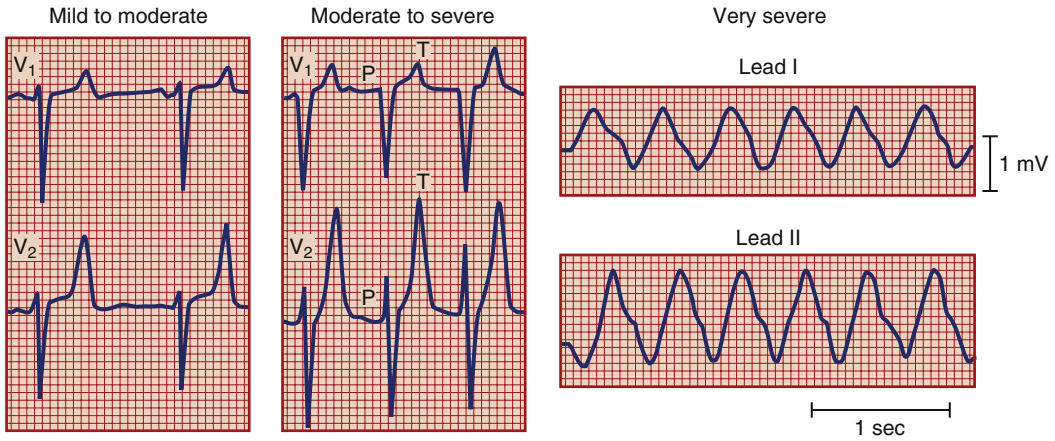

Figure 47-8. Electrocardiographic signs of hyperkalemia. The earliest change with hyperkalemia is peaking ("tenting") of the T waves. With progressive increases in the serum potassium concentration, the QRS complexes widen, the P waves decrease in amplitude and may disappear, and finally a sine-wave pattern leads to asystole unless emergency therapy is administered. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

baseline. Therefore, low-frequency filters are used in ECG monitoring. The HR in beats per minute (bpm) forms a rough lower bound for the frequency content in Hertz (Hz, cycles per second). Since HRs slower than 40 bpm (0.67 Hz) are uncommon, traditional low-frequency analog filters are used to cut off signals at frequencies below 0.5 Hz. However, such filters introduce considerable distortion into the ECG, particularly with respect to the level of the ST segment, resulting from phase nonlinearities that occur in areas of the ECG signal where frequency content and wave amplitude abruptly change, as occurs where the end of the QRS complex meets the ST segment. The 1975 American Heart Association (AHA) recommendations included a 0.05-Hz low-frequency cutoff for diagnostic ECGs. This recommendation preserves the fidelity of repolarization, but baseline drift can still be a problem. Current modern digital filtering provides more sophisticated methods for a higher cutoff for low-frequency filtration without those phase distortions observed with analog filtering. Thus, to reduce artifactual distortion of the ST segment, current AHA recommendations[1] suggest the low-frequency cutoff should be: (1) 0.05 Hz for monitors with analog filters and (2) 0.67 Hz or below for monitors and ECG recording devices with linear digital filters with zero phase distortion.

High-Frequency Filtering

High-frequency filters are needed to reduce distortions from muscle fasciculations, tremors, and electromagnetic interference from other electrical equipment. Older monitors used a 40-Hz filter to reduce electrical current interferences. However, the higher the frequencies contained in the filtered signal, the more accurate the measurement of rapid upstroke velocity, peak amplitude, and waves of short duration will be. A high-frequency cutoff of 100 Hz was considered adequate by the AHA in 1975 to maintain diagnostic accuracy during visual inspection of an ECG, although it has long been recognized that higher frequency components of the QRS complex may have clinical significance in patients with various forms of heart disease. According to current AHA recommendations, to measure routine duration and amplitudes accurately in adults, adolescents, and children, an upper frequency cutoff of at least 150 Hz is required, and an upper frequency cutoff of 250 Hz is more appropriate for infants.

Most modern ECG monitors allow the operator a choice among several bandwidths. The actual filter frequencies tend to vary among manufacturers. One manufacturer allows a choice of three different filtering modes: (1) a diagnostic mode with a bandwidth of 0.05 to 130 Hz for adults and 0.5 to 130 Hz for neonates, (2) a monitoring mode with a bandwidth of 0.5 to 40 Hz for adults and 0.5 to 60 Hz for neonates, and (3) a filter mode with a bandwidth of 0.5 to 20 Hz. Slogoff and associates evaluated the importance of bandwidth selection on the detection of perioperative myocardial ischemia and showed that the ST-segment positions with all systems using the lower filter limit (0.05 Hz) recommended by the AHA were similar.[2]

THREE-ELECTRODE ELECTROCARDIOGRAPHIC MONITORING

In contrast to the standard 12-lead ECG, in which the four limb electrodes are placed on the wrists and ankles, electrode placement for continuous cardiac monitoring is on the torso to reduce artifacts from limb movement, as well as to avoid tethering the patient. Therefore, the right arm (RA) and left arm (LA) electrodes are placed in the infraclavicular fossae close to the right and left shoulders, respectively, and the left leg (LL) electrode is placed below the rib cage on the left side of the abdomen. The ground or reference electrode (RL), if present, can be placed anywhere, but it is usually placed on the right side of the abdomen.

The three-electrode system is the simplest and most common mode of ECG monitoring in surgical units and intensive care units (ICUs). It allows monitoring three bipolar leads by recording the potential differences between each of three pairs of electrodes: lead I (positive electrode, LA; negative electrode, RA), lead II (positive electrode, LL; negative electrode, RA), lead III (positive electrode, LL; negative electrode, LA), or other

modified chest leads.[3] Three-electrode monitoring is usually adequate for tracking HR, detecting R waves for synchronized direct-current shock in cardioversion, and detecting ventricular fibrillation. However, it is inadequate for diagnosing more complex arrhythmias for which a *true* V_1 lead is necessary, such as to distinguish between right versus left bundle branch block (LBBB) or ventricular tachycardia (VT) and supraventricular tachycardia (SVT) with aberrant ventricular conduction. The three-electrode system is also inadequate for ST-segment monitoring because it does not provide multilead monitoring or precordial leads, which are often most sensitive for detecting ischemia. Modified chest leads such as CS_5 (the RA electrode is placed under the right clavicle, and the LA electrode is placed in the V_5 position) or CB_5 (the RA electrode is placed over the center of the right scapula, and the LA electrode is placed in the V_5 position) may be suitable for the detection of anterior wall myocardial ischemia; however, these modified leads are currently not recommended for monitoring myocardial ischemia.

FIVE-ELECTRODE ELECTROGRAPHIC MONITORING

In the five-electrode monitoring system, the four limb electrodes, LA, RA, LL, and RL placed at their corresponding monitoring locations allow any of the six limb leads (I, II, III, aVR, aVL, and aVF) to be obtained, and a fifth chest electrode can be placed in any of the standard V_1 through V_6 locations (Fig. 47-9). V_1 is the preferred lead for special arrhythmia monitoring, whereas the other precordial leads, especially V_3 to V_5, are the preferred leads for ischemia monitoring. The five-electrode monitoring system is currently the standard for monitoring patients with suspected perioperative myocardial ischemia. The differences in sensitivity and specificity among the different ECG leads in detecting myocardial ischemia are discussed later in this chapter.

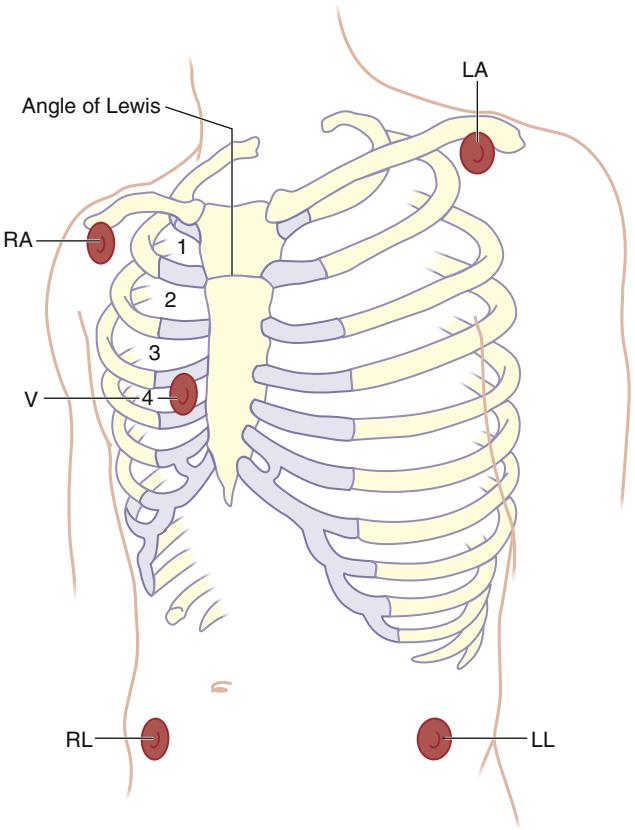

Figure 47-9. Commonly used five-electrode lead system allows the recording any of the six limb leads plus one precordial (V) lead. The lead placement for recording V_1 is shown. A limitation of this system is that only one precordial lead can be recorded. *(From Drew BJ, Califf RM, Funk M, et al: Practice standards for electrocardiographic monitoring in hospital settings: an American Heart Association Scientific Statement from the Councils on Cardiovascular Nursing, Clinical Cardiology, and Cardiovascular Disease in the Young,* Circulation *110:2721-2746, 2004.)*

TEN-ELECTRODE, TWELVE-LEAD ELECTROCARDIOGRAPHIC MONITORING

In 1966, Mason and Likar introduced a variation on positioning the standard limb electrodes of the 12-lead ECG during exercise stress testing to minimize artifacts in the limb leads caused by movement.[4] In this design, the RA and LA electrodes are attached to the right and left infraclavicular fossae and the LL electrode is attached to the left iliac fossa. The RL electrode can be positioned anywhere but is usually placed on the right iliac fossa for symmetry. Although the limb lead QRS complexes are slightly different in amplitude and axis and the precordial leads may also vary slightly from the standard 12-lead ECG recording, studies have shown that the ST-segment measurements during exercise stress testing are only incidentally affected when the Mason-Likar 12-lead ECG system is used, as compared with the standard 12-lead ECG.[5] A major advantage of cardiac monitors using the Mason-Likar 12-lead system is that ST-segment monitoring software has been developed to analyze all 12 leads and to sound an alarm for ST-segment changes, whether or not multiple leads are being displayed on the bedside or central monitor (Fig. 47-10). Therefore, if lead II is being displayed but the patient has a transient ischemic event involving lead V_5, then an ST-segment alarm is triggered. Not all manufacturers that offer the Mason-Likar lead system perform full 12-lead ST-segment analysis nor do they store all 12 leads for printing at a later time. Another advantage of the Mason-Likar lead system is that more than one precordial lead can be displayed at the same time. The disadvantage of the system for cardiac monitoring is that 10 electrodes are required and the 6 precordial electrodes often interfere with diagnostic (e.g., echocardiograms, chest x-ray images) and emergency (defibrillation sites) procedures. In addition, the precordial sites are difficult to maintain on patients with large breasts or hirsute chests.

HOLTER MONITORING

Holter monitoring, originally a cardiologist's tool, has been used by a number of anesthesiologists to document the perioperative incidence of arrhythmias or ischemia. In Holter monitoring, ECG information from two or three bipolar leads is recorded by a miniature recorder. Up to

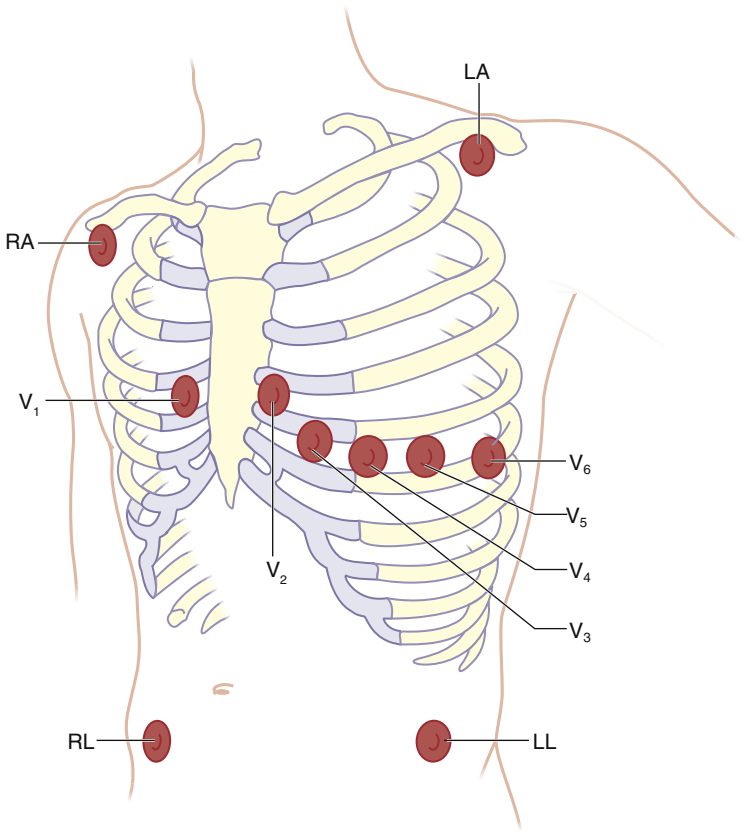

Figure 47-10. Mason-Likar 12-lead electrocardiographic (ECG) system. Anatomic locations for precordial leads are the same as for recording a standard 12-lead ECG, except that the limb leads are relocated from the standard 12-lead ECG positions on the wrists and ankles to the torso. *(From Drew BJ, Califf RM, Funk M, et al: Practice standards for electrocardiographic monitoring in hospital settings: an American Heart Association Scientific Statement from the Councils on Cardiovascular Nursing, Clinical Cardiology, and Cardiovascular Disease in the Young,* Circulation *110:2721-2746, 2004.)*

48 hours of ECG signals can be collected. Subsequently, the data are processed using a playback system, and the ECG signals are analyzed. On most modern systems, the playback unit includes a dedicated computer for rapid analysis and automatic recognition of arrhythmias and ischemia.

A significant early obstacle to the widespread use of conventional Holter monitoring in the perioperative period was its delayed, retrospective analysis and interpretation. This limitation was, to some extent, overcome by real-time Holter monitors, which record specific ECG segments for later playback and also analyze the rhythm and ST segment in real time to alert the user to an acute event.[6,7] However, despite significant technical progress, Holter monitoring devices continue to be limited primarily to clinical investigations.

ARRHYTHMIA INTERPRETATION AND MANAGEMENT

Little doubt remains that during prolonged visual ECG monitoring, certain arrhythmias may go undetected. It has been demonstrated that coronary care unit nurses failed to detect serious ventricular arrhythmias in 84% of their patients.[8] Subsequently, computerized monitors have been designed for the automatic detection of arrhythmias in an attempt to increase the detection rate of abnormal, potentially dangerous rhythms. These monitors use proprietary sophisticated algorithms such as pattern recognition, measurements of QRS width, onset, offset, amplitude, and area calculations to classify complexes into morphologic families.[9,10] Most monitors are capable of detecting potentially fatal arrhythmias such as severe bradycardia or asystole and dangerous tachycardia such as VT or fibrillation. Yet, no study to date has evaluated the accuracy, sensitivity, and specificity of these automated, real-time arrhythmia detection monitors. However, the detection of clinically important dysrhythmias in the cardiac ICU has been shown to improve significantly if a nurse watches the monitor and pays attention to the alarms.[11] Thus today's computerized monitoring systems still have not achieved the level of accuracy sufficient to eliminate the need for human surveillance; the alarms must be recognized and the ECG interpreted and acted upon by a knowledgeable person in a timely fashion (see also Chapters 67 and 68).

DIAGNOSIS OF ARRHYTHMIAS

Arrhythmias are common during and after surgery and have numerous causes. Postoperative dysrhythmias are most likely to occur in patients with structural heart disease. The initiating factor for an arrhythmia after surgery is usually a transient insult such as hypoxemia, cardiac ischemia, catecholamine excess, or electrolyte abnormality.[12] Using perioperative Holter recordings, Mahla and colleagues[13] evaluated how anesthesia and surgery affect the course of ventricular dysrhythmias (premature ventricular beats and repetitive forms of ventricular beats—couplets and nonsustained VT) preoperatively noted in patients with structural heart disease undergoing

noncardiac surgery. They concluded that the frequency of ventricular dysrhythmias was not associated with an adverse cardiac outcome. The incidence of perioperative dysrhythmia in patients with an adverse outcome (8%) did not differ from those with a good outcome. Patients undergoing cardiac surgery have a higher incidence of cardiac dysrhythmias. The incidence of new onset atrial fibrillation alone after cardiac surgery approaches 33% and is associated with a worse outcome.[14] Several major factors contribute to the development of perioperative arrhythmias:

1. **General anesthetics.** Volatile anesthetics, such as halothane or enflurane, produce arrhythmias, probably by a reentrant mechanism.[15] Halothane also sensitizes the myocardium to endogenous and exogenous catecholamines. Drugs that block the reuptake of norepinephrine, such as cocaine and ketamine, can facilitate the development of epinephrine-induced arrhythmias (see Chapter 28). In contrast, volatile anesthetics may have an antifibrillatory effect in response to acute coronary occlusion and reperfusion, at least in a canine model.[16] Sevoflurane may cause severe bradycardia and nodal rhythm when used in high concentrations during induction in infants,[17] and desflurane may prolong QTc within the first minute of anesthesia in patients with a normal heart.[18]
2. **Local anesthetics.** Regional anesthesia by central neuraxial blockade, the goal of spinal or epidural anesthesia, may be associated with a profound, albeit transient, pharmacologic sympathectomy (also see Chapters 36 and 56). This phenomenon may cause parasympathetic nervous system dominance, leading to mild to very severe bradyarrhythmias. This result is especially true when the blockade extends to very high thoracic levels. An inadvertent intravascular injection of a large dose of local anesthetic agent may lead to asystole and cardiac arrest that are difficult to treat.[19] One proposed treatment is the administration of 20% intralipid.[20,21]
3. **Abnormal arterial blood gases or electrolyte levels.** Excessive hyperventilation, especially in the presence of low serum potassium levels, may precipitate severe cardiac arrhythmias.[22] Alterations of blood gases or electrolytes may lead to arrhythmias by producing reentrant mechanisms or by altering phase 4 depolarization of conduction fibers. Electrolyte disturbances associated with cardiopulmonary bypass can also lead to intraoperative arrhythmias (see Chapters 59 and 67).
4. **Endotracheal intubation.** This maneuver may be the most common cause of arrhythmias during surgery and is often associated with hemodynamic disturbances by eliciting autonomic reflexes (see also Chapter 55).
5. **Autonomic reflexes.** Vagal stimulation may produce sinus bradycardia and may allow ventricular escape mechanisms to occur. Vagal stimulation may also produce AV block or even asystole. These reflexes may be related to traction on the peritoneum or to direct pressure on the vagus nerve during carotid surgery (see Chapter 69). During jugular vein cannulation, stimulation of the carotid sinus by palpation of the neck can lead to bradyarrhythmias. Specific reflexes, such as the oculocardiac reflex, can also produce severe bradycardia or asystole.
6. **Central nervous system stimulation and dysfunction of the autonomic nervous system.** Many ECG abnormalities can occur in patients with intracranial disease, especially subarachnoid hemorrhage. These abnormalities are most commonly ST-T wave changes and may easily mimic myocardial ischemia and MI[23] (see Chapter 70). The mechanism of these arrhythmias appears to be related to changes in autonomic nervous system tone.
7. **Preexisting cardiac disease.** Preexisting cardiac disease is probably the most common background for arrhythmias during anesthesia and surgery.[24] Patients with a preexisting tendency for atrial or ventricular arrhythmias are more likely to exhibit them during or after surgery in response to the perioperative stresses or secondary to acute withdrawal of oral antiarrhythmic medications, most commonly β-adrenergic blockers.
8. **Central venous cannulation.** The insertion of catheters or wires into the central circulation often leads to arrhythmias (see Chapter 45).
9. **Surgical manipulation of the cardiac structures.** Arrhythmias are often observed during the insertion of atrial sutures or the placement of venous cannulae for cardiopulmonary bypass during cardiac surgery (see Chapters 67, 68, and 94). These arrhythmias are usually self-limiting and cease at the end of manipulation.
10. **Location of surgery.** Dental surgery is often associated with arrhythmias because profound stimulation of sympathetic and parasympathetic nervous systems often occurs.[25] Junctional rhythms are often observed and may be caused by stimulation of the autonomic nervous system by the fifth cranial nerve. The oculocardiac reflex leads to severe bradycardia in response to traction of the rectus muscles of the orbit. This reflex, which is mediated by the trigeminal nerve as the afferent limb and the vagus nerve as the efferent limb, is especially sensitive in neonates and children and common during strabismus operations.

After an arrhythmia is recognized, determining whether it produces a hemodynamic disturbance, what type of treatment is required, and how urgently therapy should be instituted are important. Treatment should be promptly initiated if the arrhythmia results in significant hemodynamic impairment. Prompt treatment should also be instituted if the arrhythmia is a precursor for a more severe arrhythmia (e.g., frequent multifocal ventricular premature beats [VPBs] with R-on-T phenomenon can lead to ventricular fibrillation). In addition, arrhythmias that may be detrimental on the background of a patient's underlying cardiac disease (e.g., any tachycardia in a patient with mitral valve stenosis, aortic valve stenosis, or ischemic heart disease) need immediate attention. Arrhythmias can be classified by HR or by their anatomic origin in the heart. Using HR criteria, arrhythmias can be broken down into three categories: bradyarrhythmias (HR <60 bpm), tachyarrhythmias (HR >100 bpm), and conduction blocks (at any HR). The anatomic origin of an arrhythmia can be ventricular, supraventricular,

junctional, or elsewhere. Using the following checklist can simplify the diagnosis and treatment of arrhythmias when looking at an ECG display:

1. What is the HR?
2. Is the rhythm regular?
3. Is one P wave present for each QRS complex?
4. Is the QRS complex normal?
5. Is the rhythm dangerous?
6. Does the rhythm require treatment?

The following text analyzes some common intraoperative arrhythmias.

SINUS BRADYCARDIA

Sinus bradycardia is defined when the pacemaker site is in the sinus node, but the rate is slower than normal. Etiologic factors include drug effects, acute inferior MI, hypoxia, vagal stimulation, and high sympathetic blockade. Sinus bradycardia accounts for approximately 11% of intraoperative arrhythmias. The characteristics of sinus bradycardia are as follows:

1. HR: Is slower than 60 bpm. In patients on chronic β-adrenergic blocker therapy, sinus bradycardia is defined as a HR slower than 50 bpm.
2. Rhythm: Is regular, except for occasional escape beats from other pacemaker sites.
3. P/QRS: The ratio of the P waves to the QRS complexes is 1:1.
4. QRS complex: Has a normal morphologic appearance.
5. Significance: HRs slower than 40 bpm are poorly tolerated even in healthy patients and should be evaluated on the basis of their effect on cardiac output. Treatment is recommended if hypotension, ventricular arrhythmias, or signs of poor peripheral perfusion are observed. Sinus bradycardia may be part of the sick sinus syndrome, in which sinus node dysfunction can precipitate bradycardias, heart block, tachyarrhythmias, or alternating bradyarrhythmias and tachyarrhythmias.[26]
6. Treatment: Is not usually necessary. When treatment is deemed necessary, the following progression may be considered: (1) atropine, 0.5 to 1.0 mg by intravenous (IV) bolus, repeated every 3 to 5 minutes, up to 0.04 mg/kg or approximately a 3.0-mg total dose for the average 75-kg male patient); (2) ephedrine, 5 to 25 mg by IV bolus; (3) dopamine or dobutamine (if blood pressure is adequate), 5 to 20 μg/kg/min by IV infusion; (4) epinephrine, 2 to 10 μg/min IV infusion; and (5) isoproterenol, 2 to 10 μg/min by IV infusion. Temporary transcutaneous or transvenous pacing may be necessary for severe, drug-refractory sinus bradycardia. Immediate institution of transcutaneous pacing is especially important in symptomatic patients.

SINUS TACHYCARDIA

Sinus tachycardia is defined when the pacemaker site is in the sinus node, and the rate is faster than normal. Sinus tachycardia is the most common arrhythmia in the perioperative period. It occurs with such frequency that it is not included in most arrhythmia incidence studies. Common causes include pain, inadequate anesthesia, hypovolemia, fever, hypoxia, hypercarbia, heart failure, and drug effects. The characteristics of sinus tachycardia are as follows:

1. HR: Is faster than 100 bpm in the adult patient and may be as high as 170 bpm. Patients with significant CAD may not tolerate HRs as low as 70 to 80 bpm and may develop subendocardial ischemia. Similarly, patients with severe mitral or aortic stenosis may be sensitive to even moderate increases in the HR.
2. Rhythm: Is regular.
3. P/QRS: The ratio of the P waves to the QRS complexes is 1:1.
4. QRS complex: Is normal, but ST-segment depression with severe increases in HR and resulting myocardial ischemia may be associated.
5. Significance: Prolonged tachycardias in patients with underlying heart disease can precipitate MI and congestive heart failure because of the increased myocardial work required and the decreased supply of myocardial oxygen by means of decreased diastolic coronary perfusion time. A major diagnostic problem is encountered when the HR is 150 bpm, because this rate is common for sinus tachycardia, paroxysmal atrial tachycardia, or atrial flutter with a 2:1 block. These three arrhythmias can sometimes be separated by the use of carotid sinus massage, IV administration of edrophonium, or adenosine phosphate.
6. Treatment: The underlying disorder should be treated. Hypovolemia and light anesthesia are the most common causes. In patients with ischemic heart disease who develop tachycardia, β-adrenergic blockers should be judiciously used to prevent myocardial ischemia, regardless of whether ST-segment changes occur. Hypovolemia or other causes should also be addressed in these patients.

SINUS ARRHYTHMIA

In sinus arrhythmia, the impulses arise from the SA node and a variable HR characterizes the rhythm. The PR interval is normal, as is the QRS complex. Most commonly, but not invariably, the rate increases with inspiration and decreases with expiration. This arrhythmia occurs more often in children than in adults. The characteristics of sinus arrhythmia are as follows:

1. HR: Is 60 to 100 bpm.
2. Rhythm: Is irregular.
3. P/QRS: The ratio of the P waves to the QRS complexes is 1:1.
4. QRS complex: Has normal morphologic appearance.
5. Significance: Has little clinical significance.
6. Treatment: Is considered a normal finding and requires no treatment.

ATRIAL PREMATURE BEATS

An ectopic pacemaker site in the left or the right atrium initiates the atrial premature beat (APB). The shape of the P wave is different from the usual SA node P wave and may be inverted. The PR interval may be shorter or longer than normal, depending on the site of the ectopic

focus and on the refractoriness of the AV nodal pathway. The APB spreads through the AV node and ventricular conduction system and, in retrograde fashion, reaches the SA node, resetting the sinus pacemaker. The interval from the APB to the next sinus beat is therefore a normal sinus cycle (i.e., no compensatory pause). The absence of a compensatory pause is an important distinguishing feature between APBs and VPBs. Occasionally, APBs may find part of the ventricular conduction system refractory. In these instances, they travel down an aberrant pathway and create an abnormal QRS complex. They are then called *APBs with aberrant ventricular conduction* and can easily be confused with VPBs. Because the recovery period of the right ventricular conduction system outlasts that of the left, the most common form of aberration appears as an RBBB. Helpful points in separating APBs with aberrant ventricular conduction from VPBs include (1) the presence of a preceding P wave, usually abnormally shaped; (2) an RBBB configuration of the QRS complex; (3) the presence of an rsR′ ventricular complex in V_1; and (4) the finding that the initial vector forces are identical to the preceding beat but are usually the opposite with a VPB. The characteristics of APBs are as follows:

1. HR: Is variable, depending on the frequency of the APBs.
2. Rhythm: Is irregular.
3. P/QRS: The ratio of P waves to QRS complexes is usually 1:1. The P waves have various shapes and may even be lost in the QRS or T waves. Occasionally, the P wave is so early as to find the ventricle refractory, and a nonconducted beat occurs.
4. QRS complex: Is usually normal unless ventricular aberration occurs.
5. Significance: In one study, APBs represented 10% of all intraoperative arrhythmias. They have little clinical significance, but frequent APBs may lead to other, more serious supraventricular arrhythmias or may be a sign of digitalis intoxication.
6. Treatment: Is rarely necessary.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

A rapid regular rhythm, usually with a narrow QRS complex and lacking the normal SA node P wave, characterizes paroxysmal SVT (PSVT). The inclusion of tachycardias involving the AV node (Fig. 47-11) allows a useful classification of tachycardias as caused by reentry in the AV node, by apparent or concealed accessory AV pathways or, less often, by the SA node. Ectopic atrial or ectopic nodal tachycardias are also among the less frequent SVTs. Inappropriate or persistent sinus tachycardia is another variant. PSVT rhythms are usually abrupt in onset and termination. PSVT is easily distinguished from rapid atrial fibrillation, which is an irregular rhythm, or from rapid atrial flutter, which has flutter waves. The characteristics of PSVT are as follows:

1. HR: Is between 130 and 270 bpm.
2. Rhythm: Is usually regular unless the impulse originates from multiple atrial foci.
3. P/QRS: Has a 1:1 relationship, although the P wave may often be hidden in the QRS complex or T wave.
4. QRS complex: Is generally normal, but ST-T changes indicative of ischemia may be observed. Aberration of ventricular conduction may occur, complicating the differential diagnosis with VT. SVT may also be confused with sinus tachycardia, atrial flutter, and atrial fibrillation. In differentiating these rhythms, carotid sinus massage or edrophonium (5 to 10 mg IV) was traditionally used. More recently, adenosine (6 to 12 mg by IV bolus) has been used to slow the rate by transiently enhancing the normal degree of AV block or terminate the arrhythmia.[27] Esophageal electrocardiographic leads may also be helpful to better define atrial activity.[28]
5. Significance: PSVT can be observed in 5% of normal young adults and in patients with Wolff-Parkinson-White syndrome or other preexcitation syndromes. During anesthesia, PSVT accounts for up to 2.5% of all arrhythmias, and the arrhythmia has been associated with intrinsic heart disease, systemic illness, thyrotoxicosis, digitalis toxicity, pulmonary embolism, and pregnancy. When a patient is under anesthesia, PSVT can be precipitated by changes in the tone of the autonomic nervous system, by drug effects, or by intravascular volume shifts and can produce severe hemodynamic deterioration. Sometimes the PSVT may be associated with AV block because of the fast atrial rate and slow AV conduction. PSVT with 2:1 block represents digitalis intoxication in many patients.
6. Treatment: Often, this arrhythmia must be treated because of its rapid rate and associated poor hemodynamic function. One or several of the following treatments can be undertaken:
   a. Vagal maneuvers such as carotid sinus massage should only be applied to one side.[29]
   b. Adenosine, which is the drug of choice, is given by 6-mg rapid (2 seconds) IV bolus, preferably through an antecubital or central vein. If no response is elicited, the second and third doses of 12 to 18 mg of adenosine may be administered by rapid IV bolus.[30]
   c. Verapamil (2.5 to 10 mg given IV) successfully terminates AV nodal reentry in approximately 90% of patients. This was the first drug of choice but is now the second choice.[31]
   d. Amiodarone (150-mg infusion over 10 minutes for the loading dose) is a recent addition.[32]
   e. Esmolol (1 mg/kg by bolus and 50 to 200 mg/kg/min by infusion) has been shown to be effective.[33]
   f. Edrophonium or neostigmine by IV bolus can be administered.[34]
   g. Phenylephrine (100 μg by IV bolus) is administered if the patient is hypotensive.[35]
   h. IV digitalization is performed with one of the short-acting digitalis preparations: ouabain (0.25 to 0.5 mg administered IV) or digoxin (0.5 to 1.0 mg administered IV, slow loading).[36]
   i. Rapid overdrive pacing may be performed in an effort to capture the ectopic focus.[36]
   j. Synchronized cardioversion may be performed with incremental doses of energy of 100, 200, 300, and 360 J, preferably after light sedative premedication.[37] Electrode catheter ablation using radiofrequency energy has evolved as the definitive, long-term treatment for most persistent AV reentrant or focal atrial SVTs.[38]

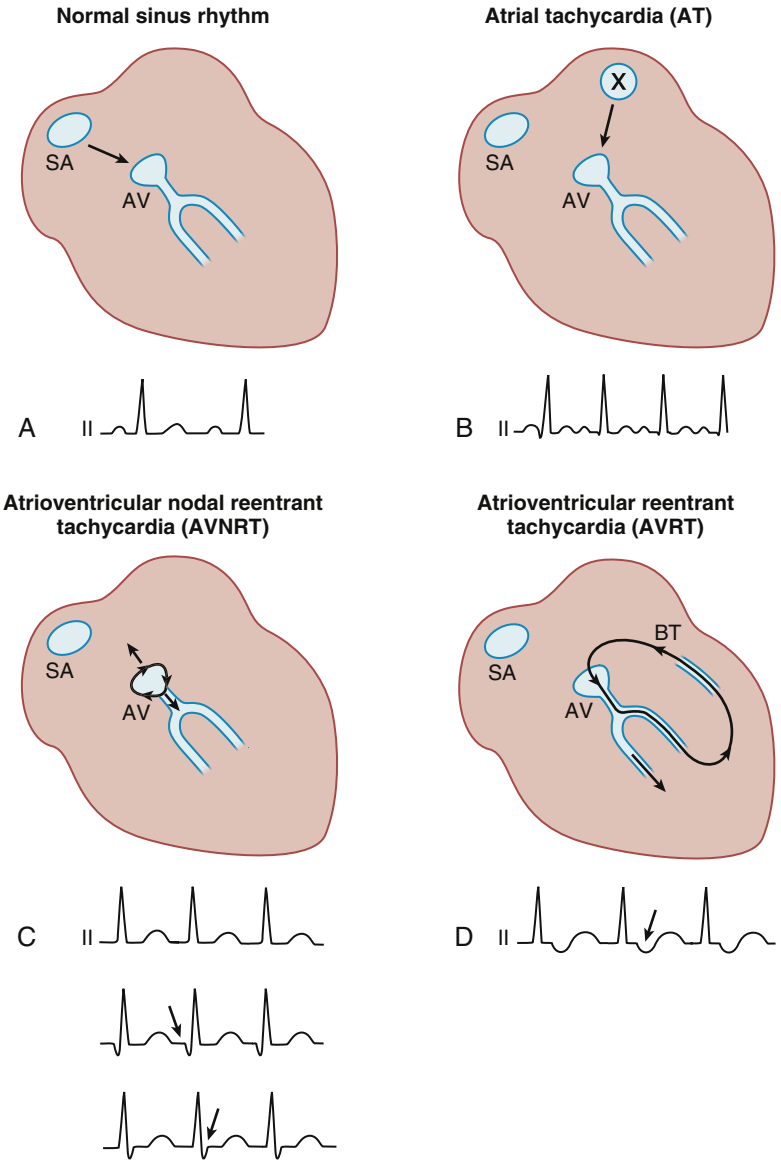

Figure 47-11. Major types of paroxysmal supraventricular tachycardia. **A,** Normal sinus rhythm. **B,** Atrial tachycardia (AT). A focus *(X)* outside the sinoatrial (SA) node automatically fires off at a rapid rate. **C,** Atrioventricular (AV) nodal reentrant tachycardia (AVNRT). The cardiac stimulus originates as a wave of excitation that spins around the AV nodal (junctional) area. As a result, retrograde P waves may be buried in the QRS complex or appear immediately before or just after the QRS complex *(arrows)* because of nearly simultaneous activation of the atria and ventricles. **D,** A similar type of reentrant (circus-movement) mechanism may occur with a bypass tract (BT) of the type found in Wolff-Parkinson-White syndrome. This mechanism is referred to as *atrioventricular reentrant tachycardia* (AVRT). The negative P wave is noted *(arrow)* in lead II, somewhat after the QRS complex. (With AVRT, the P wave in lead II may be negative or isoelectric.) *(From Goldberger AL: Clinical electrocardiography: a simplified approach, ed 7. St. Louis, 2006, Mosby.)*

ATRIAL FLUTTER

Atrial flutter most commonly represents a macro-reentrant arrhythmia that circulates in a specific manner in the right atrium (i.e., counterclockwise rotation as viewed in the angiographic left anterior oblique view). Because atrial flutter is associated with very fast HRs, it is usually accompanied by AV block. Classic sawtooth flutter waves (F waves) are usually present (Fig. 47-12). The characteristics of atrial flutter are as follows:

1. HR: The atrial HR is 250 to 350 bpm with a ventricular rate of approximately 150 bpm (2:1 or 3:1 AV conduction block).
2. Rhythm: The atrial rhythm is regular. The ventricular rhythm may be regular if a fixed AV block is present or irregular if a variable block exists.
3. P/QRS: Usually, a 2:1 block exists with an atrial rate of 300 bpm and a ventricular rate of 150 bpm, but the block may vary between 2:1 and 8:1. F waves are best observed in leads V_1 and II and in the esophageal lead.
4. QRS complex: Is normal. T waves are lost in the F waves.
5. Significance: Atrial flutter usually indicates the presence of severe heart disease. It is recognized with increased incidence in patients with CAD, mitral valve disease, pulmonary embolism, hyperthyroidism, cardiac trauma, cancers of the heart, and myocarditis.
6. Treatment: Pharmacologic or synchronized direct current (DC) cardioversion, when indicated, should be performed only after careful consideration or evaluation of a possible thromboembolic event.

   The initial treatment should be to gain control of the ventricular response rate with agents that slow AV node conduction:
   a. β-Adrenergic blockers such as IV esmolol (1 mg/kg by IV bolus) or propranolol
   b. Calcium channel blockers such as verapamil (5 to 10 mg given IV) or diltiazem[39]

      β-Adrenergic blockers and calcium channel blockers are also effective as pharmacoprophylaxis

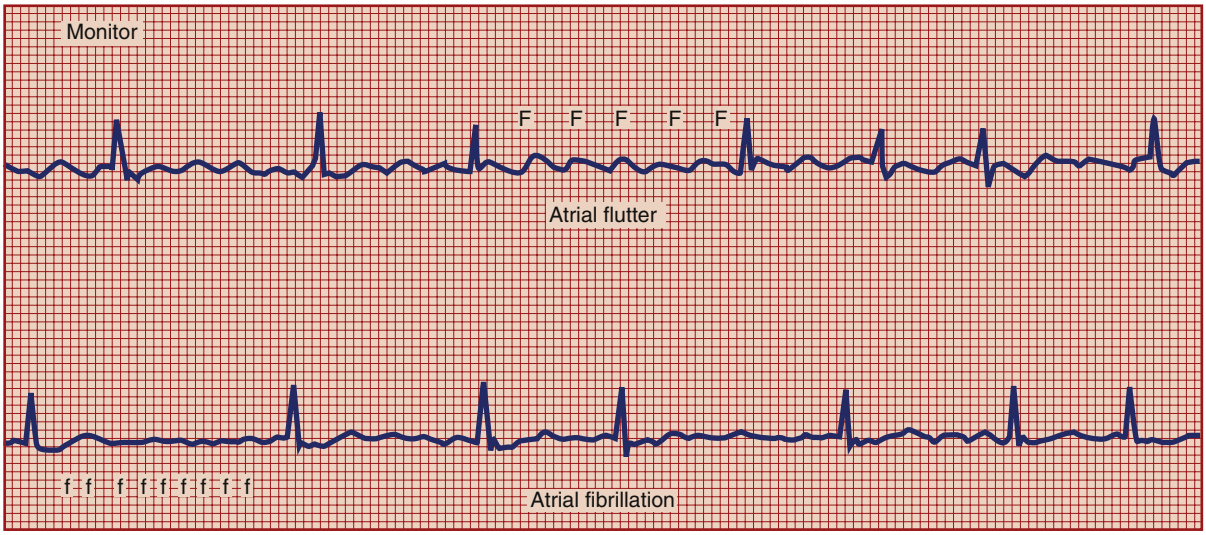

Figure 47-12. Atrial flutter and fibrillation. The "sawtooth" waves (F waves) are noted with atrial flutter and the irregular fibrillatory waves (f waves) with atrial fibrillation. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach*, ed 7. St. Louis, 2006, Mosby.)*

for the prevention of postoperative atrial tachyarrhythmias after thoracic and cardiac surgery.[40]

If the ventricular response is excessively rapid or secondary hemodynamic instability is present, or both, then the following guidelines are used:

a. Synchronized DC cardioversion is indicated, starting with a relatively high energy of 100 J and gradually increasing to 360 J.
b. The class III antiarrhythmic agent ibutilide (Corvert, 1 mg in 10 mL saline, or 5% dextrose in water (D_5W), infused IV slowly over 10 minutes) has been documented to convert atrial flutter to sinus rhythm in most patients with relatively new-onset atrial flutter[41] and may be repeated once. Although it is highly effective, life-threatening torsade de pointes (discussed later in this chapter) may occur hours after ibutilide administration, making 4- to 8-hour monitoring after treatment highly desirable.
c. Procainamide (5 to 10 mg/kg for the IV loading dose, infused no faster than 0.5 mg/kg/min) may rarely be used in an attempt to restore sinus rhythm after the ventricular response has been adequately controlled.[42]

ATRIAL FIBRILLATION

Atrial fibrillation is an excessively rapid and irregular atrial focus with no P waves appearing on the ECG; instead, a fine fibrillatory activity is seen (F waves, see Fig. 47-12) and is the most irregular rhythm; it is called *irregularly irregular* and may be associated with a pulse deficit. The characteristics are as follows:

1. HR: The atrial rate is 350 to 500 bpm, and the ventricular rate is 60 to 170 bpm.
2. Rhythm: Is irregularly irregular.
3. P/QRS: The P wave is absent and replaced by F waves or no obvious atrial activity.
4. QRS complex: Is normal.
5. Significance: The causes of atrial fibrillation are similar to those of atrial flutter. This rhythm is often associated with significant cardiac disease; however, idiopathic lone paroxysmal atrial fibrillation has become increasingly recognized. The clinical significance and treatment of atrial fibrillation are also similar to those of atrial flutter, except for two important considerations. The loss of an atrial *kick* from inefficient contraction of the atria may reduce ventricular filling and may significantly compromise cardiac output. After 24 hours, atrial fibrillation may be associated with the development of atrial thrombi, with resultant pulmonary and systemic embolization.

   Atrial fibrillation is the most common postoperative arrhythmia with significant consequences on patient health. Postoperative atrial fibrillation complicates up to 8% of all noncardiac surgeries, between 3% and 30% of noncardiac thoracic surgeries, and between 16% and 46% of cardiac surgeries. It has been associated with increased morbidity; mortality; and longer, more costly hospital stays. Several epidemiologic and intraoperative factors, as well as the presence of preexisting cardiovascular and pulmonary disorders, may affect the risk of atrial fibrillation after cardiac and noncardiac surgeries. It is typically a transient, reversible phenomenon that may develop in patients who possess an electrophysiologic substrate for the arrhythmia that is present before or as a result of surgery. The efficacy of β-adrenergic blockers in postoperative atrial fibrillation prevention is well documented. Perioperative amiodarone, sotalol, nondihydropyridine calcium channel blockers, and magnesium sulfate can reduce the occurrence of atrial fibrillation.[43]
6. Treatment:
   a. Acute atrial fibrillation: The treatment of acute atrial fibrillation is similar to that for atrial flutter. More attention should be focused on ventricular response, especially with the administration of IV diltiazem or esmolol. Ibutilide may restore sinus

rhythm, but it is less effective than in the treatment of flutter. Synchronized DC cardioversion should be used in patients with pronounced hemodynamic instability. However, if fibrillation is present for longer than 48 hours, then attempts to restore sinus rhythm may be associated with a heightened risk of thromboembolism. In this setting, for a patient with normal coagulation function, adequate anticoagulation for 3 to 4 weeks should be considered before attempting to restore sinus rhythm. New developments in electrophysiologic techniques for ventricular defibrillation with biphasic current shocks have shown superiority to the conventional monophasic current techniques (discussed later in this chapter). However, data regarding biphasic shocks for conversion of atrial fibrillation are still emerging. A randomized, double-blind, multicenter trial by the BiCard Investigators[44] demonstrated that for the cardioversion of atrial fibrillation, a biphasic shock waveform has greater efficacy, requires fewer shocks and lower delivered energy, and results in less dermal injury than a monophasic shock waveform. These results mirror those observed in the ventricular fibrillation trials.

b. Long-term therapy: Long-term therapy of atrial fibrillation varies and depends on factors such as whether the arrhythmia is constant or paroxysmal, the nature of the underlying heart disease, and the state of ventricular function or hemodynamic stability or reserve. In the older individual or in the setting of specific risk factors (e.g., hypertension, diabetes mellitus, severe LV systolic dysfunction), anticoagulation with warfarin should be strongly considered. When control of ventricular response is difficult with standard drugs (e.g., β-adrenergic blockers, calcium channel blockers, digitalis), electrode catheter ablation of the AV junction and permanent pacemaker insertion are sometimes used. Another treatment option for chronic or recurrent atrial fibrillation is the Maze procedure, often performed during cardiac surgery with cardiopulmonary bypass. During this procedure, a number of incisions or scars are made by means of radiofrequency, freezing, or microwaves on the left and right atrium, resulting in a disruption of the abnormal electrical pathways from the sinus node to the AV node. The scar tissue also prevents erratic electrical signals from recurring. In the absence of CAD or significant LV systolic dysfunction, class Ic antiarrhythmic agents (e.g., flecainide, propafenone) have become the agents of choice.[45] The use of class Ia drugs (e.g., quinidine, procainamide, disopyramide) has sharply diminished because of concerns about their significant proarrhythmic function and their systemic and organ side effects. The use of antiarrhythmic drugs that block repolarizing potassium currents (e.g., sotalol,[46] amiodarone[47]) has gained popularity for the suppression of atrial fibrillation in individuals with significant structural heart disease. Sotalol, however, has a much lower efficiency of converting atrial fibrillation than the class Ic agents. New class III agents show good efficacy in converting atrial fibrillation. Ibutilide converts rapidly, can be effective in up to 50% of patients,[48] and is more effective than sotalol or procainamide. Nevertheless, all these drugs also exhibit significant proarrhythmic properties.

JUNCTIONAL RHYTHMS

The AV node itself shows no intrinsic phase 4 depolarization. Cells in the node cannot act as pacemakers. Ectopic activity, however, may be initiated from sites just above and below the AV node. Considering these arrhythmias as AV junctional in nature makes sense. The resultant P wave is abnormal and, depending on the position of the ectopic pacemaker, may be close to, buried in, or after the QRS complex. Depending on the rate of fire of the ectopic pacemaker, the resultant rhythm is nodal premature, nodal quadrigeminy, trigeminy, or bigeminy, nodal rhythm, or nodal tachycardia. The characteristics of junctional rhythms are as follows:

1. HR: Is variable, between 40 and 180 bpm (i.e., nodal bradycardia to junctional tachycardia).
2. Rhythm: Is regular.
3. P/QRS: The ratio is 1:1 but, three varieties have been identified:
   a. High-nodal rhythm: The impulse reaches the atrium before the ventricle; the P wave therefore precedes the QRS but has a shortened PR interval (0.1 second).
   b. Mid-nodal rhythm: The impulse reaches the atrium and the ventricle at the same time. The P wave is lost in the QRS complex.
   c. Low-nodal rhythm: The impulse reaches the ventricle first and then the atrium; therefore, the P wave follows the QRS complex.
4. QRS complex: Is normal, unless altered by the P wave.
5. Significance: Junctional rhythms are common in patients under anesthesia (approximately 20%) especially with volatile anesthetic agents. The junctional rhythms frequently decrease blood pressure and cardiac output by approximately 15%, but they can decrease it up to 30% in patients with heart disease.[49]
6. Treatment: Usually, no treatment is required, and the rhythm spontaneously reverts. If hypotension and poor perfusion are associated with the rhythm, then treatment is indicated. Atropine, ephedrine, or isoproterenol can increase the activity of the SA node and take over as the pacemaker. Dual-chamber electrical pacing at a rate faster than a slow nodal rhythm is another option.

VENTRICULAR PREMATURE BEATS

VPBs result from ectopic pacemaker activity arising below the AV junction. The VPB originates in and spreads through the myocardium or ventricular conducting system, resulting in a wide (>0.12 second) and bizarre QRS complex. The ST segment usually slopes in the direction opposite to that of the main deflection of the QRS complex. No P wave is associated with a VPB, but retrograde depolarization of the atria or blocked sinus beats may obscure the diagnosis.

The most important entity in the differential diagnosis is APB with aberrant ventricular conduction. The distinction should be made whenever possible.

Although an APB normally reaches the SA node and resets the sinus rhythm, such an occurrence is rare when the ectopic pacemaker is in the ventricle. A VPB often blocks the next depolarization from the SA node, but the following sinus beat occurs on time. The result is a compensatory pause, consisting of the interval from the VPB to the expected normal QRS, which is blocked at the AV node, plus a normal sinus interval.

VPBs are common during anesthesia, accounting for 15% of observed arrhythmias. They are significantly more common in anesthetized patients with preexisting cardiac disease. Other than heart disease, known etiologic factors include electrolyte and blood gas abnormalities, drug interactions, brainstem stimulation, and trauma to the heart. The characteristics of VPBs are as follows:

1. HR: Depends on the underlying sinus rate and frequency of the VPBs.
2. Rhythm: Is irregular.
3. P/QRS: No P wave is associated with VPBs.
4. QRS complex: Is wide and bizarre, with a width of more than 0.12 second. If it is of an RBBB nature, then prominent R forces are present in V_1. If it is a LBBB in appearance, then notching of the S wave and less acute downslopes are common.
5. Significance: The new onset of VPBs must be considered a potentially serious event because, in certain clinical situations, the arrhythmia may progress to VT or ventricular fibrillation. These situations include coronary artery insufficiency, MI, digitalis toxicity with hypokalemia, and hypoxemia. VPBs are more likely to lead to fibrillation if they are multiple, multifocal, or bigeminal; occur near the vulnerable period of the preceding ventricular repolarization (i.e., R-on-T phenomenon)[50]; or appear in short-long-short coupling sequences.
6. Treatment: In most patients, VPBs (occurring as single, bigeminy, or trigeminy but excluding nonsustained VT) do not need to be treated, particularly if the patient does not have an acute coronary syndrome (ACS); but the presence of symptoms attributable to VPBs usually dictates the treatment. The first step in treatment is to correct any underlying abnormalities such as decreased serum potassium or low arterial oxygen tension. If the arrhythmia is of hemodynamic significance or if it is believed to be a harbinger of worse arrhythmias, then lidocaine is usually the treatment of choice, with an initial bolus dose of 1.5 mg/kg. Recurrent VPBs can be treated with a lidocaine infusion of 1 to 4 mg/min; additional therapy can be supplied with esmolol, propranolol, procainamide, quinidine, disopyramide, atropine, verapamil, or overdrive pacing.

VENTRICULAR TACHYCARDIA

The presence of three or more sequential VPBs defines VT (Fig. 47-13). Diagnostic criteria include the presence of fusion beats, capture beats, and AV dissociation. The specific morphologic appearance of the QRS complex may also be helpful in distinguishing VT from other arrhythmias. VT is classified by its duration and morphologic appearance. In duration, nonsustained VT lasts three beats and up to 30 seconds, and sustained VT lasts 30 seconds or longer. With monomorphic form, all complexes have the same pattern, and with polymorphic form, complexes constantly change patterns. Polymorphic VT with a long QTc is also called *torsade de pointes*. The characteristics of VT are as follows:

1. HR: Is 100 to 200 bpm.
2. Rhythm: Is usually regular but may be irregular if the VT is paroxysmal.
3. P/QRS: No fixed relationship exists because the VT is a form of AV dissociation in which the P waves can be observed marching through the QRS complex.
4. QRS complex: Is wide, more than 0.12 second in width, with similar morphologic criteria in lead V_1 as for VPB.
5. Significance: Acute onset is life threatening and requires immediate treatment.
6. Treatment: If the patient is hemodynamically stable, then amiodarone, administered in one or more doses of 150 mg given IV in 100 mL saline or D_5W over 10 minutes, followed by an IV infusion of 1 mg/min for 6 hours and 0.5 mg/min thereafter, is the recommended current treatment (maximum IV dose 2.2 g/24 hr). Although amiodarone produces less hypotension, compared with bretylium, hypotension and bradycardia are its main side effects. Amiodarone's pharmacologic effects persist for longer than 45 days. Lidocaine and procainamide have been used in the past with varying degrees of success to treat VT. Synchronized cardioversion is the indicated nonpharmacologic intervention in any wide complex tachycardia, whether monomorphic VT or a wide-complex SVT. Polymorphic VT with a normal QT interval is treated with amiodarone and cardioversion. Metabolic abnormalities and drug toxicity must be considered and treated. Polymorphic VT with prolonged QT interval is a more serious rhythm disturbance, and the recommended current treatment is IV infusion of 1 g of magnesium over 2 to 3 minutes. Precipitating metabolic or toxic causes should be treated. Overdrive pacing may also be helpful in this setting.

VENTRICULAR FIBRILLATION

Ventricular fibrillation is an irregular rhythm that results from a rapid discharge of impulses from one or more ventricular foci or from multiple wandering reentrant circuits in the ventricles (Fig. 47-14). The ventricular contractions are erratic and are represented on the ECG by bizarre patterns of various sizes and configurations. P waves are not seen. Important causes of the arrhythmia include myocardial ischemia, hypoxia, hypothermia, electric shock, electrolyte imbalance, and drug effects. The characteristics of ventricular fibrillation are as follows:

1. HR: Is rapid and grossly disorganized.
2. Rhythm: Is totally irregular.
3. P/QRS: No relationship is seen.
4. QRS complex: Is not present.

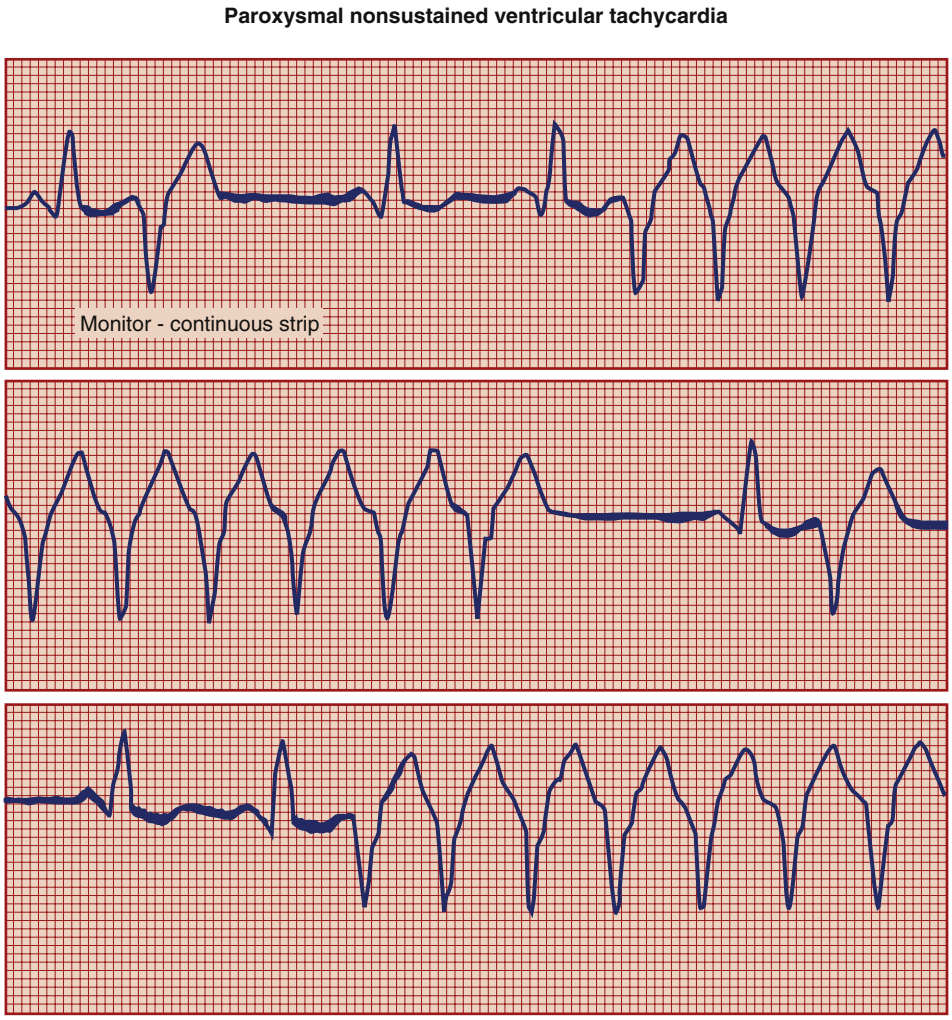

Figure 47-13. Short bursts of ventricular tachycardia. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

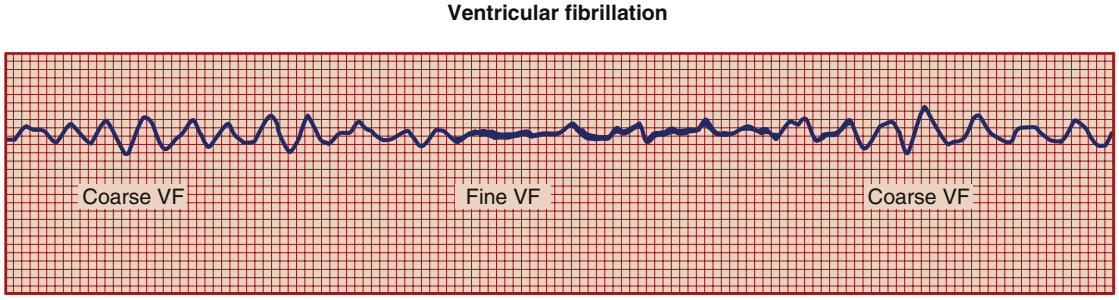

Figure 47-14. Ventricular fibrillation (VF) in the form of coarse and fine waves. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

5. Significance: No effective cardiac output exists, and artificial means, such as external cardiac massage, must be used to sustain life.
6. Treatment: Cardiopulmonary resuscitation must be immediately initiated, and then defibrillation must be performed as rapidly as possible. Asynchronous external defibrillation should be performed with a DC defibrillator, using incremental energies in the range of 200 to 360 J. The introduction of the biphasic (and rectilinear) transthoracic shocks has reduced the energy levels required and increased the efficacy of ventricular defibrillation. In a prospective, randomized, multicenter trial conducted by the ZOLL Investigators,[51,52] 120 J of biphasic current was superior to 200 J of monophasic current, especially in patients with increased chest wall impedance.

Early administration of 1 g of magnesium sulfate may facilitate defibrillation. In some instances, epinephrine has been used to coarsen the fibrillation just before and to facilitate defibrillation. Vasopressin has

been added as a drug for the treatment of ventricular fibrillation. The vasopressin dose is a single 40-unit IV bolus. If elected, subsequent administration of epinephrine should not be sooner than 5 minutes after vasopressin. Supportive pharmacologic therapy may include lidocaine, amiodarone, bretylium, procainamide, phenytoin, or esmolol.

Torsade de pointes, which may mimic ventricular fibrillation, is a life-threatening arrhythmia that occurs in the presence of disturbed repolarization; hence, its association with prolonged QT interval.[53] Discontinuation of drugs that predispose to QT-interval prolongation and correction of electrolyte abnormalities are essential in the treatment of torsades de pointes. Acute therapy may include defibrillation, 1 to 2 g of IV magnesium sulfate, IV amiodarone, IV isoproterenol, and overdrive pacing.[54]

CONDUCTION DEFECTS

Conduction defects are most often chronic, are present on the patient's preoperative ECG, and represent the patient's underlying disease state of the myocardium or conduction system. However, conduction defects may be observed for the first time during surgery and anesthesia. They can occur as a result of simple manipulation, such as the passage of a pulmonary artery catheter through the right ventricle, but they can also be a manifestation of myocardial ischemia. Because high-grade conduction defects (i.e., second- and third-degree AV blocks) often have deleterious effects on hemodynamic performance, their intraoperative recognition is important.

Three types of conduction system blocks are possible: SA block, AV heart block, and intraventricular conduction block. The bundle of His ECG used by cardiologists has greatly improved the understanding of conduction through the heart. In SA block, the block occurs at the sinus node. Because atrial excitation is not initiated, P waves are not found on the ECG. The next beat can be a normal sinus beat, a nodal escape beat, or a ventricular escape beat.

The second type of heart block is an AV heart block, or AV block, which may be incomplete or complete. First- and second-degree AV blocks are usually considered incomplete, whereas a third-degree AV block is considered to be complete heart block. First-degree AV block is often found in healthy hearts, in addition to CAD or the administration of digitalis. It is characterized by a PR interval longer than 0.21 second. All atrial impulses progress through the AV node to the Purkinje system. This form of heart block ordinarily requires no treatment. Second-degree AV block is associated with the conduction of some of the atrial impulses to the AV node and into the Purkinje system. It is further subdivided into two specific types. Mobitz type I block, or Wenckebach block, is characterized by progressive lengthening of the PR interval until an impulse is not conducted and the beat is dropped (Fig. 47-15). This form of block is relatively benign and often reversible, and it does not require a pacemaker. It may be caused by digitalis toxicity or MI and is usually transient. Mobitz type I block reflects disease of the AV node.

The other form of second-degree heart block is Mobitz type II block, which may reflect disease of the bundle of His and Purkinje tissues, especially when the QRS complex is broad. In this type, the less common and more serious form of second-degree heart block, dropped beats occur without any progressive lengthening of the PR interval (Fig. 47-16). This type of block has a serious prognosis because it frequently progresses to complete heart block and may require pacemaker insertion before major surgical procedures.

Third-degree AV block, also called *complete heart block*, occurs when all electrical activity from the atria fails to progress into the Purkinje system. The atrial and ventricular contractions have no relationship with each other,

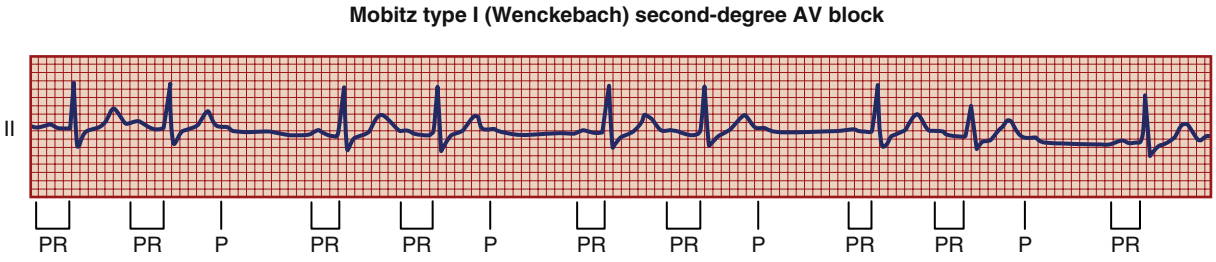

Figure 47-15. Mobitz type I (Wenckebach) block produces a characteristically syncopated rhythm with grouping of the QRS complexes (group beating). The progressive increase in PR intervals is noted with the third sinus P wave in each sequence not followed by a QRS complex. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

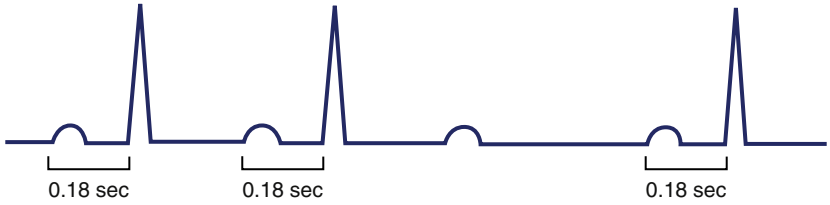

Figure 47-16. Mobitz type II atrioventricular block. The PR intervals remain constant as long as the QRS complex is not dropped, unlike in Mobitz type I. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

although each chamber regularly contracts. The ventricular rate is approximately 40 bpm. The QRS complex may be normal if the pacemaker site is in the AV node, but it is usually widened to longer than 0.12 second when the pacemaker site is located in the ventricle (Fig. 47-17). The HR is usually too slow to maintain adequate cardiac output, and syncope or Adams-Stokes syndrome may occur, as well as heart failure. These patients usually require insertion of a transvenous endocardial or epicardial pacemaker to increase their HR and cardiac output.

Intraventricular Blocks

Under normal conditions, activation of the left ventricle spreads simultaneously through both left anterior and left posterior fascicles. Blockage or even a modest delay in conduction in one of these fascicles results in a sequential rather than the simultaneous activation of the corresponding sites, producing characteristic abnormal ECG patterns (Fig. 47-18).

Left Anterior Fascicular Block. The left bundle branch of the bundle of His itself bifurcates distally into two fascicles, the anterior and the posterior. A left anterior fascicular block (LAFB) is relatively common as a result of the delicate structure of the left fascicle. It causes delayed activation of the anterosuperior LV wall and is characterized by pronounced (–45° to –90°) left axis deviation. LAFB may occur in persons without overt cardiac disease but is mainly found in patients with a wide range of myocardial and conduction system diseases, such as CAD or LVH. It has minimal and no independent prognostic significance.

Left Posterior Fascicular Block. A left posterior fascicular block (LPFB) is considerably less common than the

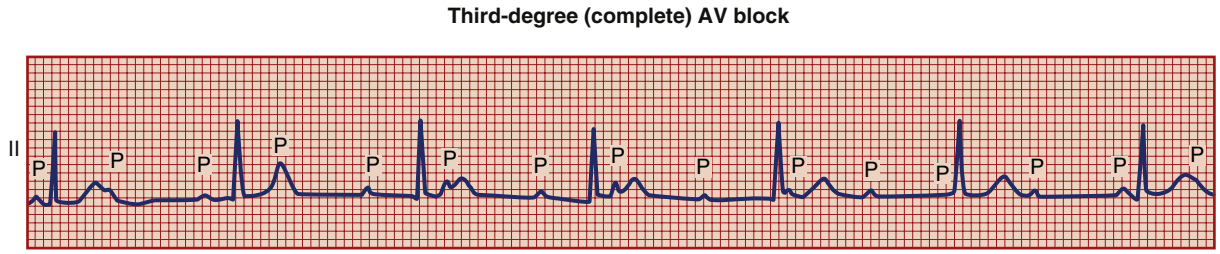

Figure 47-17. Complete heart block with underlying sinus rhythm is characterized by independent atrial (P) and ventricular (QRS complex) activity. The atrial rate is almost always faster than the ventricular rate. The PR intervals are completely variable. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

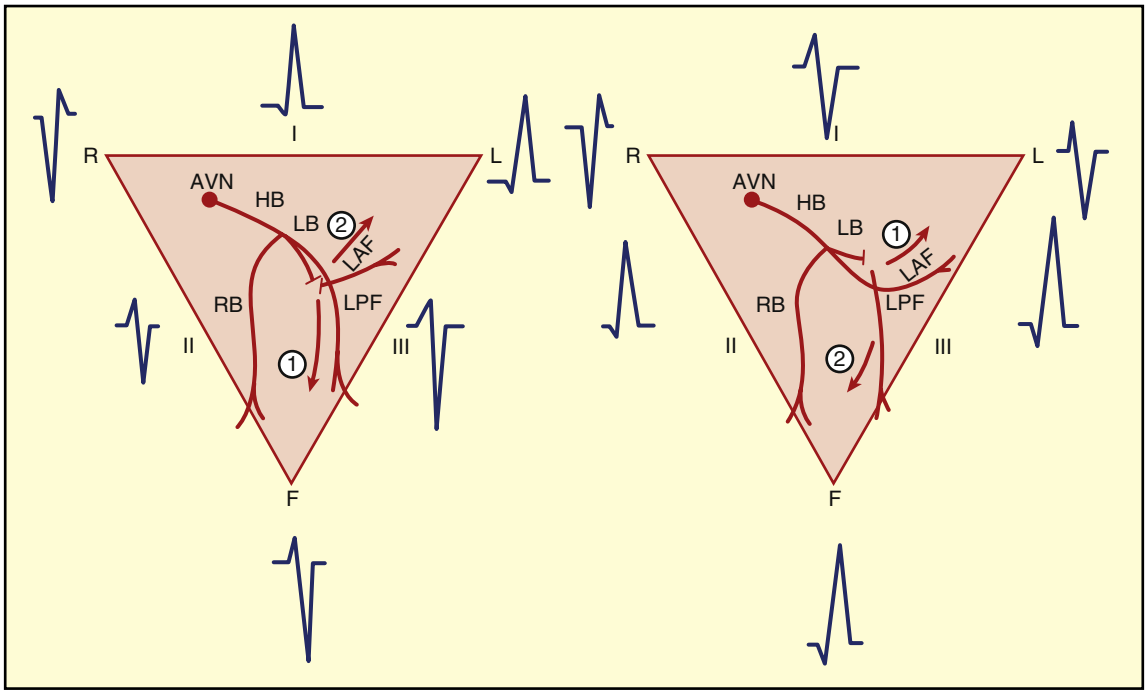

Figure 47-18. Diagrammatic representation of fascicular blocks in the left ventricle. Interruption of the left anterior fascicle (LAF) *(left)* results in an initial inferior *(1)* followed by a dominant superior *(2)* direction of activation (negative in II and positive in I and aV_L). Interruption of the left posterior fascicle (LPF) *(right)* results in an initial superior *(1)* followed by a dominant inferior *(2)* direction of activation (negative in I and positive in II and III). *AVN*, Atrioventricular node; *HB*, His bundle; *LB*, left bundle; *RB*, right bundle. *(Courtesy of Fisch C from Zipes DP, Libby P, Bonow R, Braunwald E:* Braunwald's heart disease: a textbook of cardiovascular medicine, *ed 7. Philadelphia, 2005, Saunders.)*

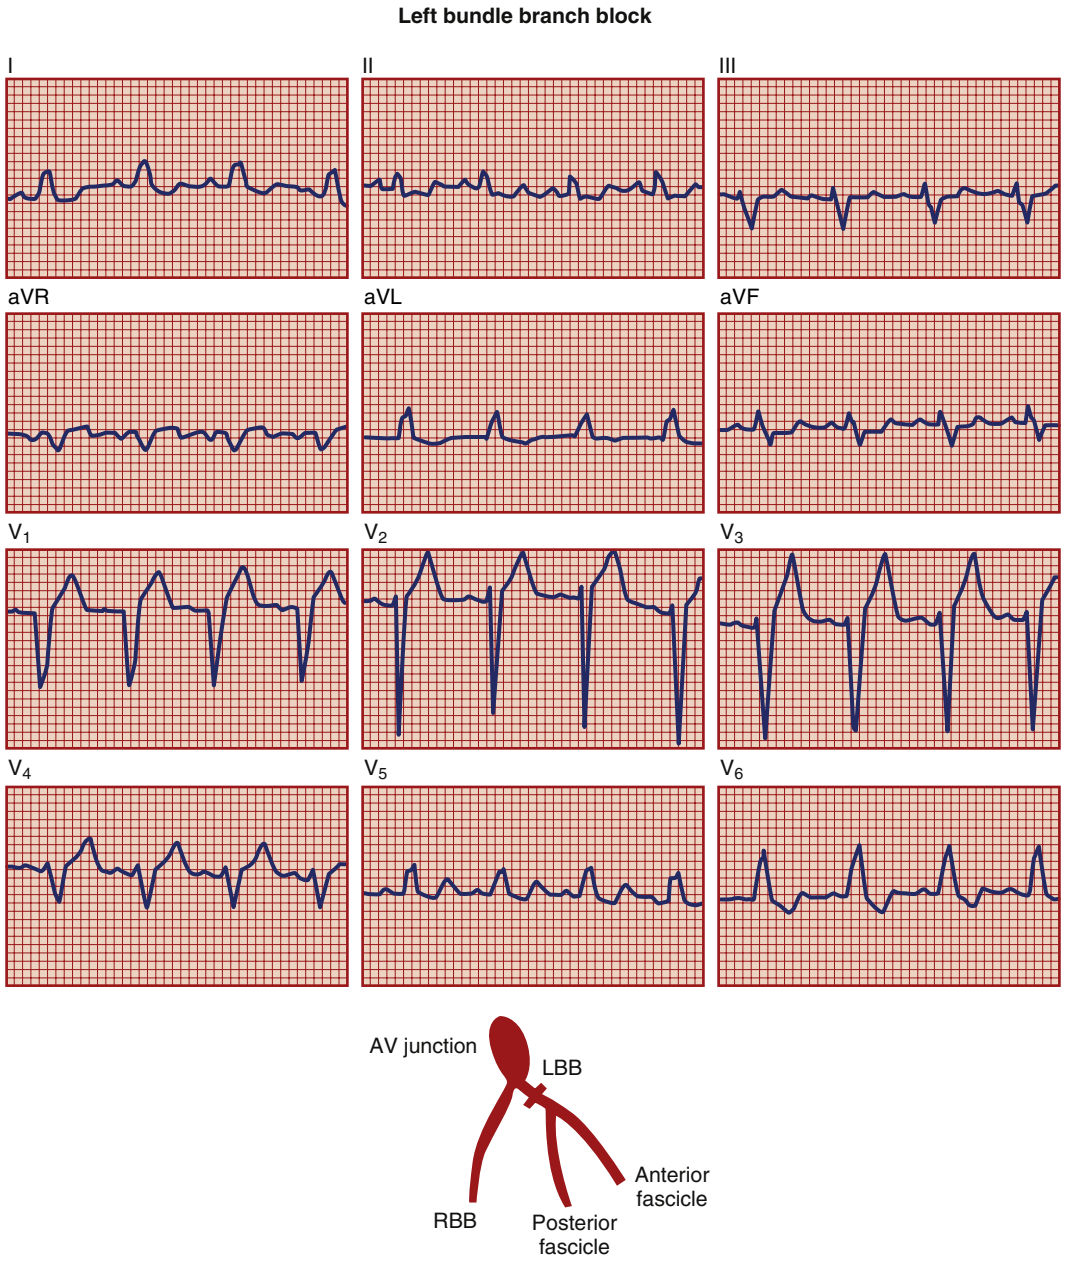

Figure 47-19. Left bundle branch block with its characteristic wide QS complex is noted in lead V_1 and the wide R wave in lead V_6 with slight notching at the peak. The inverted T waves in leads V_5 and V_6 (secondary T-wave inversions) are also characteristic of left bundle branch block. *AV*, Atrioventricular; *LBB*, left bundle branch; *RBB*, right bundle branch. *(From Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

anterior fascicular block because of the thicker structure of the right fascicle. It is also at a less vulnerable location near the LV inflow tract. LPFB results in delayed activation of the inferoposterior aspect of the left ventricle, and the ECG features of LPFB are pronounced right axis deviation (>120 degrees). LPFB can occur in patients with almost any cardiac disease but is unusual in otherwise healthy people. As in the case of LAFB, the overall QRS duration remains normal (<120 msec).

Left Bundle Branch Block. LBBB is caused by a serious delay or block of the main left bundle branch or in both of its two fascicles. This block results in a prolonged QRS duration, abnormal QRS complex, and ST-T wave abnormalities. A basic requirement is QRS duration ≥120 msec (Fig. 47-19). A broad, sometimes notched R wave is evident in the left-sided leads (I, aV_l V5, and V6) with deep S waves in the right precordial leads and absent septal Q waves. The QRS axis is highly variable. It can be normal or deviated to the left or even to the right. The ST-T waves are usually discordant with the direction of the QRS complex. LBBB is an ominous prognostic sign and has associated survival rates as low as 50%, probably reflecting the severity of the underlying cardiac disease. The QRS duration inversely correlates with LV ejection fraction and is one

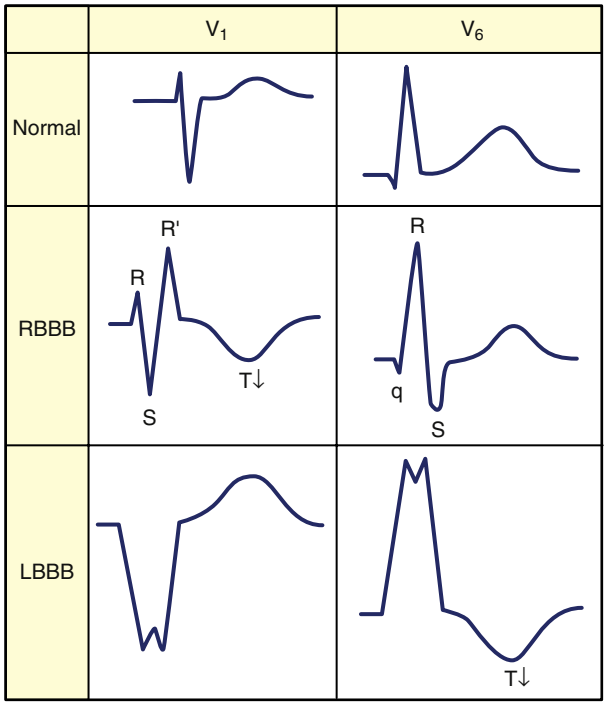

Figure 47-20. QRST changes in left bundle branch block (LBBB) are compared with the right bundle branch block (RBBB). *(From Zipes DP, Libby P, Bonow R, Braunwald E:* Braunwald's heart disease: a textbook of cardiovascular medicine, *ed 7. Philadelphia, 2005, Saunders; and from Goldberger AL:* Clinical electrocardiography: a simplified approach, *ed 7. St. Louis, 2006, Mosby.)*

of the criteria of current ventricular resynchronization therapy (biventricular pacing).

LBBB obscures or simulates other ECG patterns. In the presence of LBBB, the diagnosis of LVH, acute ischemia, or myocardial infarction may be difficult or impossible.

Right Bundle Branch Block. A conduction delay anywhere in the right-sided intraventricular conduction system causes an RBBB. The high prevalence of RBBB corresponds to the relative fragility of the right bundle branch, as suggested by the development of RBBB after minor trauma produced by right ventricular catheterization. The ECG manifestation of RBBB is prominent, and notched R waves with rsr', rsR', or rSR' on the right-sided leads and wide S waves on left-sided leads, along with QRS prolongation (≥120 msec), are evident. If the QRS duration is not prolonged, then this block is termed *incomplete RBBB*. As with LBBB, the ST-T waves are discordant with the QRS complex (Fig. 47-20).

RBBB is common in the general healthy population without clinical evidence of structural heart disease and has no prognostic significance in this group. However, in patients with organic heart disease, the new onset of RBBB predicts a higher rate of CAD, congestive heart failure, and mortality.

Trifascicular blocks usually consist of one of the foregoing bilateral bundle branch blocks (i.e., RBBB plus a LAFB or LPFB) in addition to a prolonged PR interval. Bundle of His ECGs are necessary to determine whether the AV conduction disturbance is localized in the AV node or whether it is distal, possibly representing an incomplete fascicular block in the last remaining fascicle.

REAL-TIME MYOCARDIAL ISCHEMIA MONITORING

Real-time ST-segment analysis first appeared in cardiac monitoring in the mid-1980s, and currently this feature is the standard in most ECG monitors. On some monitors, the ST-segment analysis is set up to turn on automatically when a five-electrode system is used. Unfortunately, however, anesthesiologists mainly use the five-electrode monitoring system with automatic ST-segment analysis in the surgical unit during surgery, but ST-segment monitoring is widely underused postoperatively in the postanesthesia care unit or ICU. A recent study has shown that even among coronary care units, less than 50% routinely use ST-segment monitoring for the detection of myocardial ischemia in patients admitted with ACSs.[55] Chief among the reasons for the underuse of ST-segment analysis are the frequent number of false alarms, the lack of education on how to use the technology, and the lack of knowledge of what to do in response to ST-segment alarms. In addition, no evidence exists as to whether the addition of computerized ST-segment ischemia monitoring improves patient outcomes in patients with ACSs or in patients after surgery.

Technically, the algorithm for ST-segment analysis is relatively simple. The computer determines in each ECG lead the voltage of the ST segment at 60 or 80 msec after the J point (termed as J+60 or J+80 msec) and compares it with the isoelectric point normally measured during the PR interval. One millimeter of ST-segment deviation is equivalent to a 100-mV difference. The changes in ST-segment level over time in each lead are displayed as ST-segment trends. Consequently, to overcome problems of noise and artifacts, most monitors use filters to exclude erroneous or abnormal ECG beats. Averaging processes are then used to calculate the mean ST-segment level over a period of 8 to 15 beats. Current monitors are trained to detect the J point automatically and calculate the J+60 msec ST-segment level. However, they also allow the operator to adjust manually the J-point and the ST-segment measurement point in patients with abnormal ECG patterns.

One major advantage of continuous ST-segment monitoring, compared with serial 12-lead ECGs, is that the electrodes stay in place and do not vary as standard 12-lead ECGs may do between different measuring sessions. However, for improved diagnostic accuracy of ST-segment monitoring, the following points should be recognized:

1. Changes in body position may cause ST-segment changes and lead to false ST-segment alarms. However, changes in QRS complex almost always accompany these positional ST-segment changes and therefore can be easily distinguished from true ST-segment deviations. In addition, returning the patient to the supine position may help distinguish true from positional ST-segment deviation. Changes in position of the heart in

the mediastinum have also shown to affect the ST segment. Mark and associates[56] observed that placement of a sternal retractor during cardiac surgery was associated with a reduction in V_5 R-wave amplitude. Simultaneously, V_5 S-wave amplitude and absolute ST-segment deviation were reduced. These investigators concluded that inclusion of an R-wave gain factor might improve perioperative ECG ischemia monitoring.

2. Many patients with CAD do not have perfectly isoelectric ST segments. Early repolarization (a normal variant), intraventricular conduction delays, ventricular hypertrophy, digitalis, and nonspecific ST-T wave abnormalities may cause baseline ST-segment abnormalities. Therefore, tailoring the ST-segment alarm parameters to the patient's baseline ST-segment level is important. Many current cardiac monitors with ST-segment monitoring software allow clinicians to set alarm parameters manually. If alarm parameters are set 1 to 2 mm around the isoelectric (0 mV) line rather than at the patient's baseline ST-segment level, then false alarms will frequently occur. Alarm parameters should be set 1 mm above and below the baseline ST-segment level in patients at high risk for ischemia. It should also be remembered that underlying ECG abnormalities might hinder ST-segment analysis in approximately 10% of the patients. These abnormalities include hypokalemia, digitalis, LBBB, Wolff-Parkinson-White syndrome, LVH with strain, and acute pericarditis. In these patients, other modalities for diagnosis of myocardial ischemia, such as transesophageal echocardiography, may be considered.
3. Most cardiac monitors with ST-segment monitoring software provide displays of ST-segment trends in a single lead or summated leads. Although such graphic trends are convenient for the quick identification of potential ischemic events, printing the ECG tracing in question to confirm that the ST-segment changes are the result of ischemia rather than of a transient arrhythmia (e.g., accelerated ventricular rhythm, new bundle branch block) is also of paramount importance.

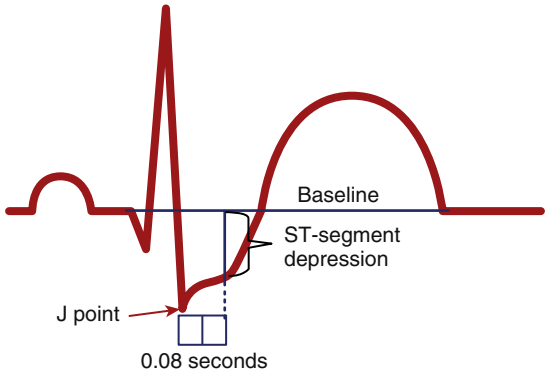

Figure 47-21. A demonstration of how the ST-segment deviation is measured at 80 msec after the J point (J+80 msec) is illustrated.

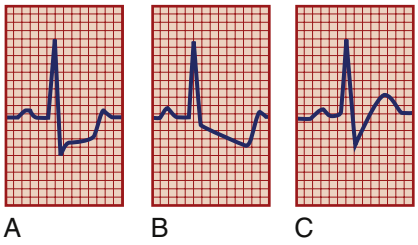

Figure 47-22. Horizontal ST depression (**A**) and down-sloping (**B**) ST depression are indicative of myocardial ischemia. Up-sloping ST depression (**C**) may be a normal finding.

ELECTROCARDIOGRAPHIC CRITERIA FOR ACUTE MYOCARDIAL ISCHEMIA

ST-DEPRESSION–TYPE ISCHEMIA

The ECG criteria most accepted for detecting myocardial ischemia on continuous ECG monitoring are those established and validated during exercise stress testing.[57] During stress testing and with acute subendocardial ischemia, the electrical forces responsible for the ST segment are deviated toward the inner layer of the heart, causing ST-segment depression (Fig. 47-21). With acute transmural (epicardial) ischemia, the electrical forces in the ischemic area are deviated toward the outer layer of the heart, causing ST-segment elevation in the overlying leads (see Fig. 47-5). As the HR increases, J-point or junctional up-sloping depression normally occurs. In patients with myocardial ischemia, however, the ST segment typically becomes horizontal (flattens) as the severity of ischemia increases. With progressive exercise or tachycardia during ischemia, the ST-segment depression may worsen; the ST segment may become down-sloping, even causing T-wave inversion in more than one ECG lead; and the patient may develop angina (Fig. 47-22). In approximately 10% of patients, especially those who are asymptomatic, ischemia may appear only in the recovery phase after exercise.

The criteria established for stress-induced ischemia are 1 mm (0.1 mV) or more of horizontal or down-sloping ST-segment depression measured 60 to 80 msec after the J point in at least three consecutive beats with a stable baseline. As previously mentioned, the ST-segment depression may be accompanied by T-wave flattening or inversion. Junctional or J-point depression is normal during exercise. In addition, a *rapidly up-sloping* ST segment (>1 mV/sec) that is also *depressed less than 0.15 mV* (1.5 mm) is considered normal. In patients with *slowly up-sloping* ST-segment depression in which the ST segment is *depressed 0.15 mV (1.5 mm) or more* at J+80 msec, the slowly up-sloping ST-segment depression may signify CAD.

Some patients have preexisting ST-segment abnormalities from a previous MI, bundle branch blocks, or LVH that make ST-segment interpretation more difficult. In these patients, additional horizontal or down-sloping ST-segment depression of 1 mm or greater from baseline is required to be considered as myocardial ischemia. Causes of ST-segment changes other than myocardial ischemia include drugs (most notably digitalis), temperature changes, hyperventilation, and position changes. The distribution of ST-depression–type ischemia correlates poorly with the specific location of CAD.

ST-SEGMENT ELEVATION–TYPE ISCHEMIA

ST-segment elevation in a non–Q-wave lead is extremely uncommon during stress testing, occurring in approximately 1% of patients with CAD, and suggests transmural myocardial ischemia caused by coronary vasospasm or a high-grade coronary narrowing. The ECG site of ST-segment elevation is relatively specific for the myocardial territory involved, in contrast to ST-depression–type ischemia. ST-segment elevation occurring during exercise testing in ECG leads with pathologic Q-waves does not indicate myocardial ischemia, but it does correlate with reduced LV function and a worse prognosis.

T-WAVE CHANGES

Body position, respiration, hyperventilation, and drug therapy, as well as myocardial ischemia or necrosis, largely influence T-wave morphologic appearance. Therefore, T-wave changes not accompanied by significant ST-segment displacement rarely signify myocardial ischemia. Pseudonormalization of T waves (i.e., inverted at rest, becoming upright during exercise) may, in rare instances, be a marker for myocardial ischemia.

In a meta-analysis that included 147 reports of patients who underwent both angiography and exercise testing, the sensitivity and specificity of the exercise ECG stress test for the detection of CAD were 68% and 77%, respectively.[58]

ELECTROCARDIOGRAPHIC LEAD SENSITIVITY FOR DETECTING PERIOPERATIVE MYOCARDIAL ISCHEMIA

During the perioperative period, ECG monitoring most commonly identifies stress-induced, ST-depression–type ischemia. Such ECG changes do not provide information about the location of the ischemic myocardial area. In contrast, ST-segment elevation indicating transmural ischemia, observed particularly during cardiac surgery, provides useful information about the myocardial segment and coronary perfusion territory responsible for the ischemic episode. Because the majority of modern patient-monitoring systems do not simultaneously monitor all 12 ECG leads, selecting which chest leads to monitor is of great importance, particularly in noncardiac surgery. During exercise stress testing, investigators have identified leads V_4 and V_5 as the most sensitive leads to detect exercise-induced ischemia (90% to 100% sensitivity).[59] London and colleagues[60] studied high-risk patients undergoing noncardiac surgery and showed that the greatest sensitivity for ischemia was obtained with lead V_5 (75%), followed by lead V_4 (61%). Combining leads V_4 and V_5 increased the sensitivity to 90%, whereas with the standard lead II and V_5 combination, the sensitivity was only 80%. They also suggested that if three leads (II, V_4, and V_5) could be simultaneously examined, the sensitivity would increase to 98%. More recently, Landesberg and associates[61] monitored continuous 12-lead ST-segment changes greater than 0.2 mV from baseline in a single lead or more than 0.1 mV in two contiguous leads at J+60 msec, lasting longer than 10 minutes in patients undergoing major vascular surgery. Troponins were used as markers for MI. They showed that, in fact, leads V_3 and V_4 were more sensitive than V_5 in detecting perioperative ischemia (87%, 79%, and 66%, respectively). Among patients who experienced an MI, V_4 was most sensitive for ischemia (83.3%), followed by V_3 and V_5 (75% each). Combined monitoring of two of these leads (V_3 and V_5) increased the sensitivity to approximately 97%.[64] The baseline, preanesthesia ST segment was above the isoelectric point in V_1 through V_3 and below the isoelectric point in V_5 through V_6. Lead V_4 was closest to the isoelectric level on the baseline ECG, rendering it most suitable for detecting ischemia. Lead V_4 also detected ischemia earlier and showed a greater ST-segment deviation. Martinez and colleagues,[62] who also used the same method to monitor postoperative ischemia in patients in the ICU after major vascular surgery, corroborated these main findings.

For patients with AVSs (i.e., those with atherosclerotic plaque disruption), monitoring limb lead III and leads V_3 and V_5 as the most sensitive combination for ischemia detection is recommended.[63] Monitoring a right-sided precordial lead (V_{4R}) may be of benefit in patients with occlusive disease of the right coronary artery,[64] as might inspection of posterior leads (V_7 to V_9) in suspected posterior ischemia.

Monitoring for intraoperative myocardial ischemia is commonly believed to be unnecessary in neonates. Whereas ECG lead systems for adults are concerned with the detection of ischemia and arrhythmias, neonatal ECG monitoring has focused on arrhythmia recognition alone. Results of some studies, however, suggest that the neonatal heart is more susceptible to ischemia than the adult heart.[65] These studies demonstrate the importance of calibrated ECG monitoring in neonates with congenital heart disease (see Chapter 94).

PERIOPERATIVE MYOCARDIAL ISCHEMIA AND INFARCTION

Perioperative myocardial ischemia monitoring in patients undergoing cardiac or noncardiac surgery started more than 20 years ago. Tinker[66] noted in 1980 the importance of intraoperative ST-segment monitoring via lead V_5 and determined that large fluctuations in systolic blood pressure, HR, or hypothermia with postoperative shivering are associated with ischemia. Coriat and colleagues[67] (1982) were pioneers in using Holter monitoring in patients undergoing major vascular surgery, showing that intraoperative ischemia on Holter monitoring was strongly associated with the severity of preoperative angina pectoris. In 1985, Slogoff and Keats[68] first demonstrated an association between intraoperative ischemia and postoperative MI. They showed that MI during coronary artery bypass graft (CABG) surgery is strongly associated with ischemia on Holter monitoring detected either before the induction of anesthesia or before the onset of cardiopulmonary bypass. During 1989, studies using perioperative Holter monitoring in patients undergoing major vascular surgery showed that early postoperative tachycardia-induced silent myocardial ischemia was frequent after surgery and associated

with postoperative clinical ischemic events.[69,70,71] In 1990, Mangano and associates[72] demonstrated that postoperative Holter-detected ischemia was most common (41%) and most predictive of adverse cardiac events, with a ninefold increase in the odds of postoperative cardiac morbidity and mortality, more than intraoperative or preoperative ischemia.

Between 1990 and 2003 a number of studies with perioperative ischemia monitoring were published.[73-87] Altogether, these studies included more than 2400 patients. Most studies included patients who underwent major vascular surgery, and most of the studies used Holter monitoring for perioperative ischemia detection (except the studies by Landesberg and colleagues who used continuous on-line 12-lead ECG monitoring). The data show that perioperative ischemia was common in these high-risk patients with an incidence between 24% and 63% and was almost exclusively ST-depression–type ischemia (97% to 100%). The average postoperative MI rate in these studies was 3.9% (range: 0.6% to 15%), the majority of which were non–Q-wave infarctions (66% to 100%). The incidence of all ischemic postoperative cardiac events was 7.3% (range: 3% to 37%), and the average mortality was 1.04% (range: 0% to 2.8%). An important observation was that postoperative ischemia duration was strongly associated with postoperative ischemic cardiac events. Patients with prolonged and often hours of postoperative ST-depression–type ischemia were likely to experience postoperative MI and serum biomarker elevation, whereas short episodes of ischemia (<30 minutes) were unlikely to culminate in MI. Perioperative ischemia was associated not only with early postoperative morbidity and mortality but also with long-term (5 years) morbidity and mortality.[90,88]

EXAMPLES OF PERIOPERATIVE ISCHEMIA AND INFARCTION

Example 1. Postoperative mortality related to HR-induced prolonged postoperative ST-depression–type ischemia. Frank and colleagues[73] published one of the first and most detailed cases of postoperative cardiac mortality related to HR-induced prolonged postoperative ST-depression–type ischemia detected on Holter monitoring. A patient who underwent lower-extremity arterial bypass surgery was observed with Holter monitoring, before, during, and after the procedure. His records showed that he had HR-related silent myocardial ischemia preoperatively that subsided intraoperatively, immediately after anesthesia was instituted, only to recur immediately as the patient woke up from the surgery. Figure 47-23 shows the ischemia progressively worsening after surgery until the patient suddenly died 10 hours after the surgery. Interestingly, the ST-depression–type ischemia of this patient occurred at a relatively low HR of 80 to 85 bpm and in the absence of significant blood pressure alterations. Two snapshots of ECG disclosure are presented at approximately 12 o'clock midnight: one at a HR of approximately 90 bpm, which showed deep ST-segment depressions and the other a short time later with a temporary slowing of the HR to approximately 60 bpm, which showed almost complete but transient resolution of the ST-segment depression. Although cardiac markers were not measured and no data were provided on myocardial function by ECG, it is suggested that the patient died as a result of prolonged, silent, HR-related, ST-depression–type ischemia, which was at least temporarily reversible by slowing his HR.

Example 2. Prolonged myocardial ischemia and infarction immediately after carotid endarterectomy surgery. A 70-year-old patient with a history of CAD and who was treated 7 years earlier with CABG now has reduced LV function, insulin-dependent diabetes mellitus, and peripheral vascular disease. On arrival to the surgical unit, the patient was connected to a continuous, 12-lead ECG monitor with on-line ST-segment analysis. During surgery, no ischemia was observed (Fig. 47-24). However, immediately after surgery and upon emergence from anesthesia, a significant ST-depression–type ischemia occurred in association with a moderate increase in HR to a maximum of 102 bpm, in accordance with vague pain in his jaw.

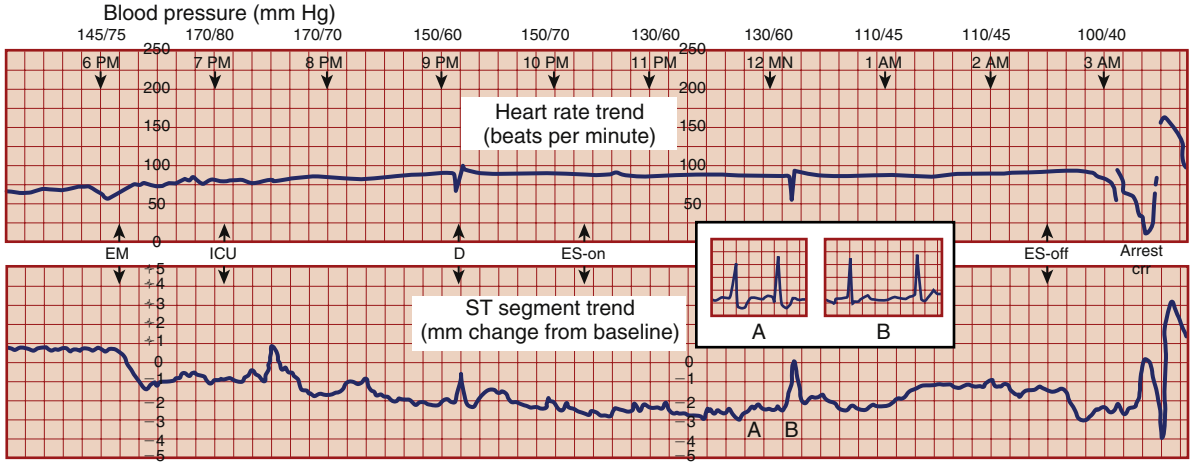

Figure 47-23. Heart rate and ST trends from emergence of anesthesia *(EM)* to cardiac arrest. *CPR*, Cardiopulmonary resuscitation; *D*, brief decrease in heart rate; *ES-off*, end of esmolol infusion; *ES-on*, start of esmolol infusion; *ICU*, intensive care unit admission. *(Modified from Frank SM, Beattie C, Christopherson R, et al: Perioperative rate-related silent myocardial ischemia and postoperative death,* J Clin Anesth *2:326-331, 1990.)*

Ischemic ST-segment changes lasted 193 minutes, after which the ECG completely reverted to its baseline. Nevertheless, an increase in troponin I to 10.2 ng/mL was measured 6 hours after surgery and up to 32.1 ng/mL on the morning after surgery (see Fig. 47-24; the figure insert depicts all 12-lead ECG complexes during peak ischemia superimposed on their baseline, preoperative pattern).[92] As demonstrated, significant ST-segment depression occurred in all the chest leads and was deepest in lead V_4 (–3.7 mm at peak ischemia). It is interesting to note the significant abnormalities—LVH, RBBB, left anterior hemiblock, and baseline ST-T changes—of this patient's baseline ECG. Despite these abnormalities, the continuous ST-trend monitoring in 12 leads combined with the significant troponin I elevation leave little doubt that the patient had prolonged (>3 hours) ischemia, which culminated in troponin elevation and, hence, MI.

Example 3. Prolonged postoperative ischemia and infarction in a patient with chronic total occlusion of one coronary artery. A 65-year-old patient was admitted for surgery because of an asymptomatic abdominal aortic aneurysm (7 cm). His medical history was only significant for hypertension, mild obesity (85 kg), and smoking until 12 years before admission. He had no clinical history of ischemic heart disease, but, because of a shortness of breath when climbing stairs, a preoperative thallium scan was performed (Fig. 47-25) that showed a moderate-to-severe, large reversible defect in the entire LV anterior wall.

On echocardiography, the size and function of both ventricles were normal with moderate mitral regurgitation. In light of the thallium scanning findings, the patient underwent preoperative coronary angiography (Fig. 47-26), which showed total ostial occlusion of the left anterior descending artery with retrograde filling through a large collateral from the right coronary artery.

Based on these findings, a decision was made not to perform preoperative coronary revascularization; instead, the patient was given bisoprolol (β_1-selective blocker) 50 mg daily for a month before he returned for surgery (aortobifemoral bypass).

As in the previous example, this patient was monitored during and after surgery by continuous 12-lead ECG with on-line ST-segment monitoring. Intraoperatively, the HR was 50 to 70 bpm, and no significant ST-segment changes were observed. However, immediately at the end of surgery and extubation, a significant ST-depression–type ischemia developed in association with an increase

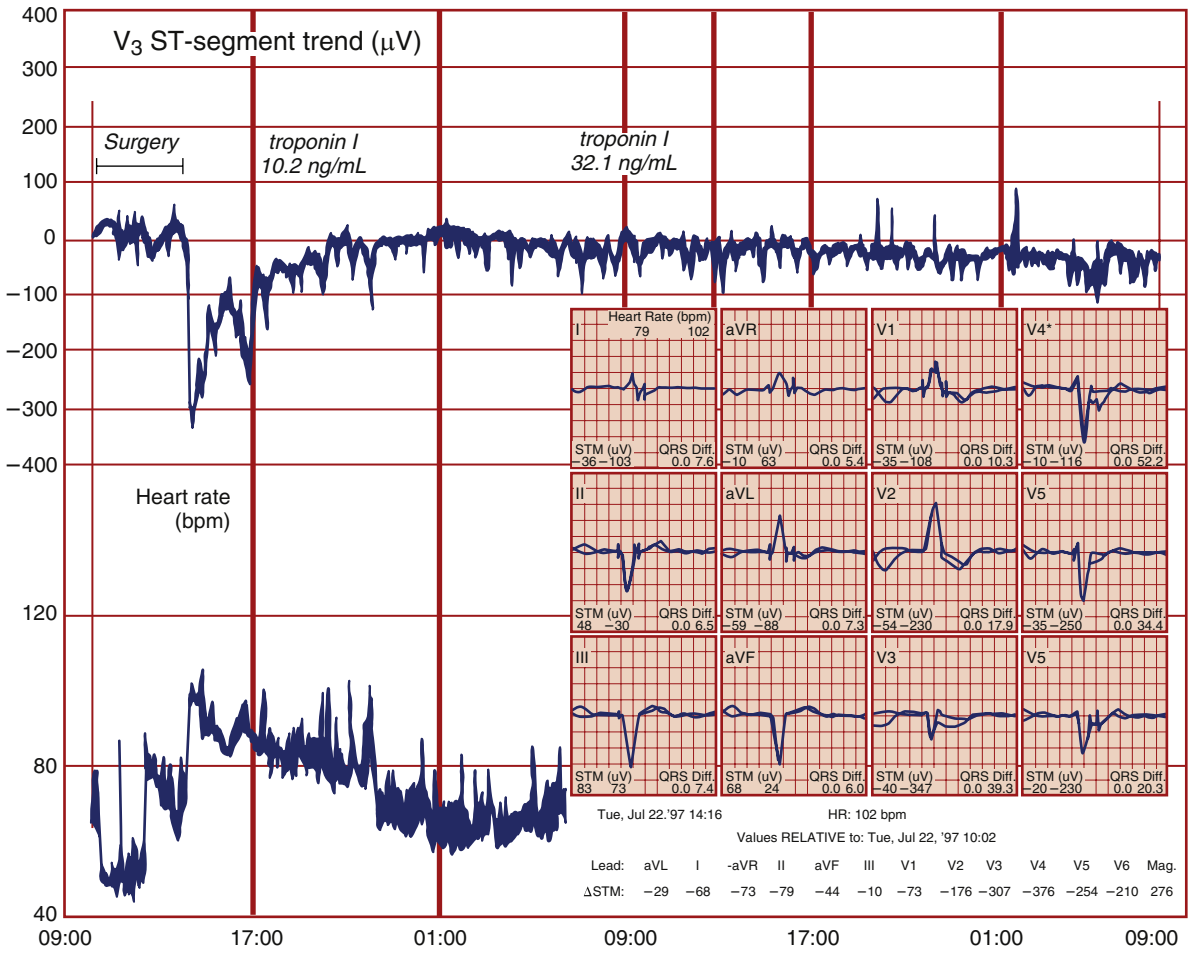

Figure 47-24. Lead V3 ST-segment and heart rate trends in a patient with prolonged (193 minutes) postoperative ST-segment depression and troponin elevation. The 12-lead ECG complexes at peak ischemia are superimposed on their baseline patterns *(insert)*.

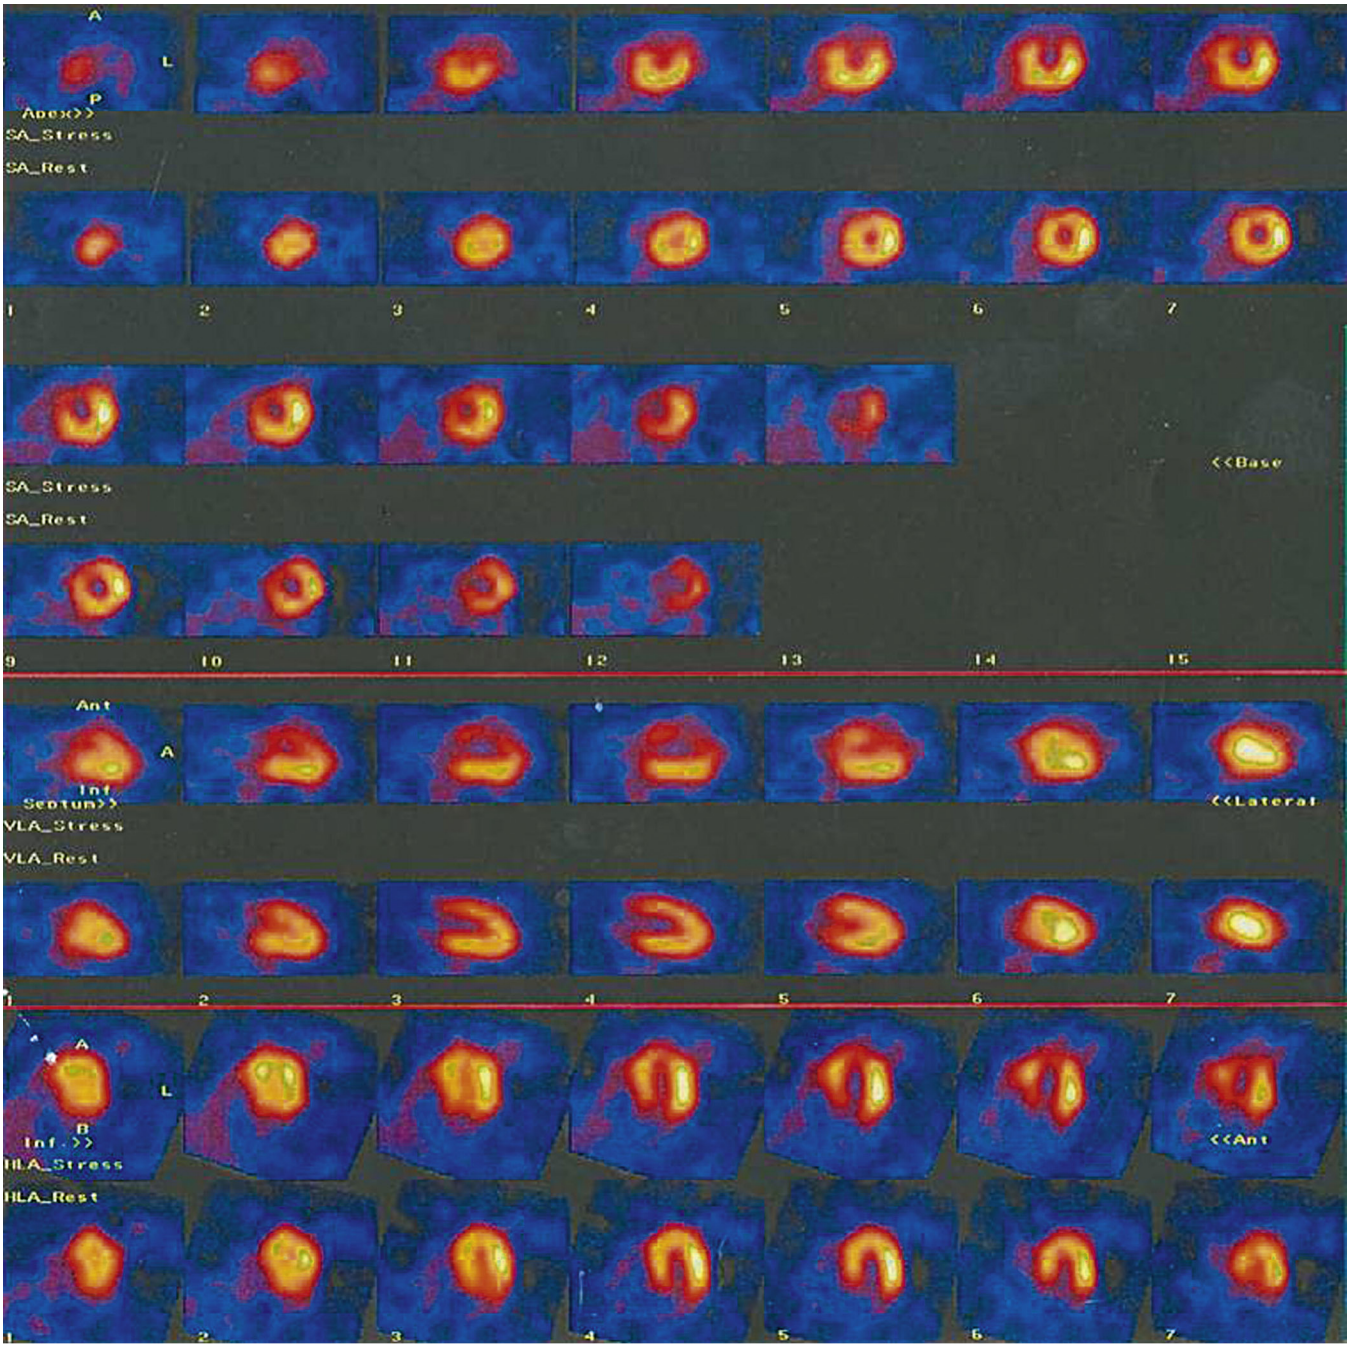

Figure 47-25. Preoperative dipyridamole-thellium single photon–emission computed tomographic scan of a patient scheduled for abdominal aortic surgery showing a moderate-to-severe reversible defect in the entire anterior wall.

in HR to a maximum of 98 bpm (Fig. 47-27) and a blood pressure of 155/86 mm Hg. IV esmolol and labetalol were immediately administered, and the ischemia subsided within 15 minutes. The patient was transferred extubated and comfortable to the ICU under continuous infusion of esmolol. In the ICU, the doses of esmolol had to be gradually escalated because of a persistent increase in HR. Postoperative pain was managed by the epidural catheter. Nevertheless, 5 hours aftter surgery, severe ST-depression–type ischemia recurred in the entire anterior wall. This time, the ischemia lasted more than 5 hours and responded poorly to β-adrenergic blocking drugs (see Fig. 47-27). The patient became delirious and developed shortness of breath. Treatment included IV diuretics and a slow infusion of packed red blood cells. Twenty-fours hours after surgery, the ischemic ECG changes regressed almost completely to normal, yet serum troponin T levels increased to 0.64 ng/mL and remained elevated for another 5 days.

This unique case demonstrates that postoperative MI may occur as a result of prolonged stress-induced ST-depression–type ischemia in the presence of stable CAD with chronic total coronary artery occlusion of even one coronary artery and without coronary plaque rupture.

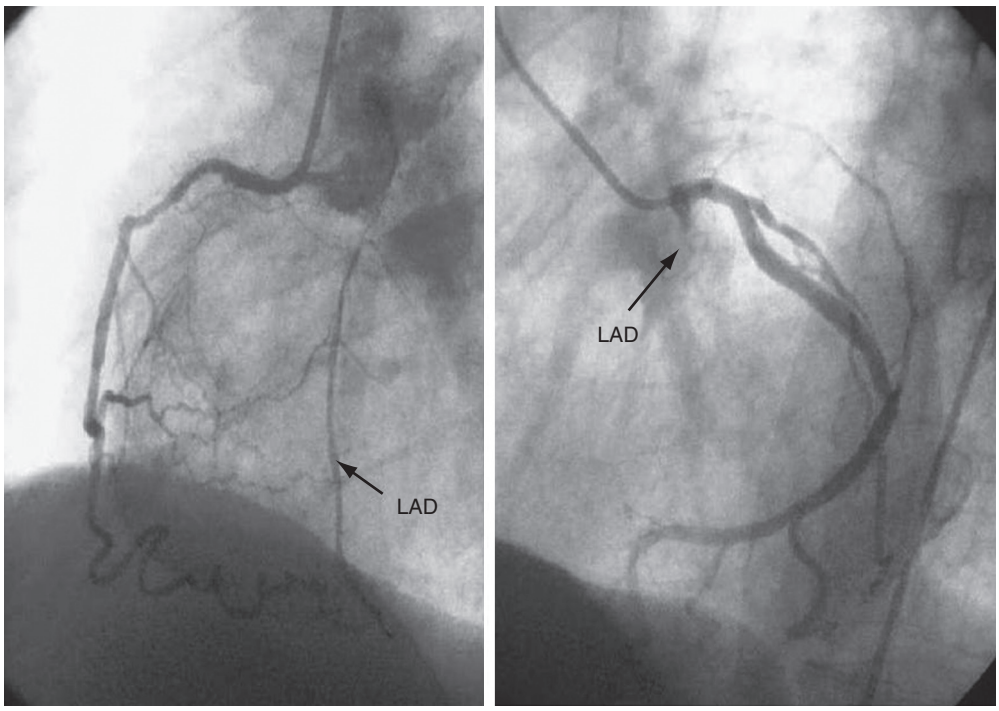

Figure 47-26. A coronary angiogram shows chronic total ostial occlusion of the left anterior descending (LAD) artery with excellent filling of the distal LAD by a collateral from the right coronary artery. A possible mild stenosis is also noted in the first marginal coronary artery.

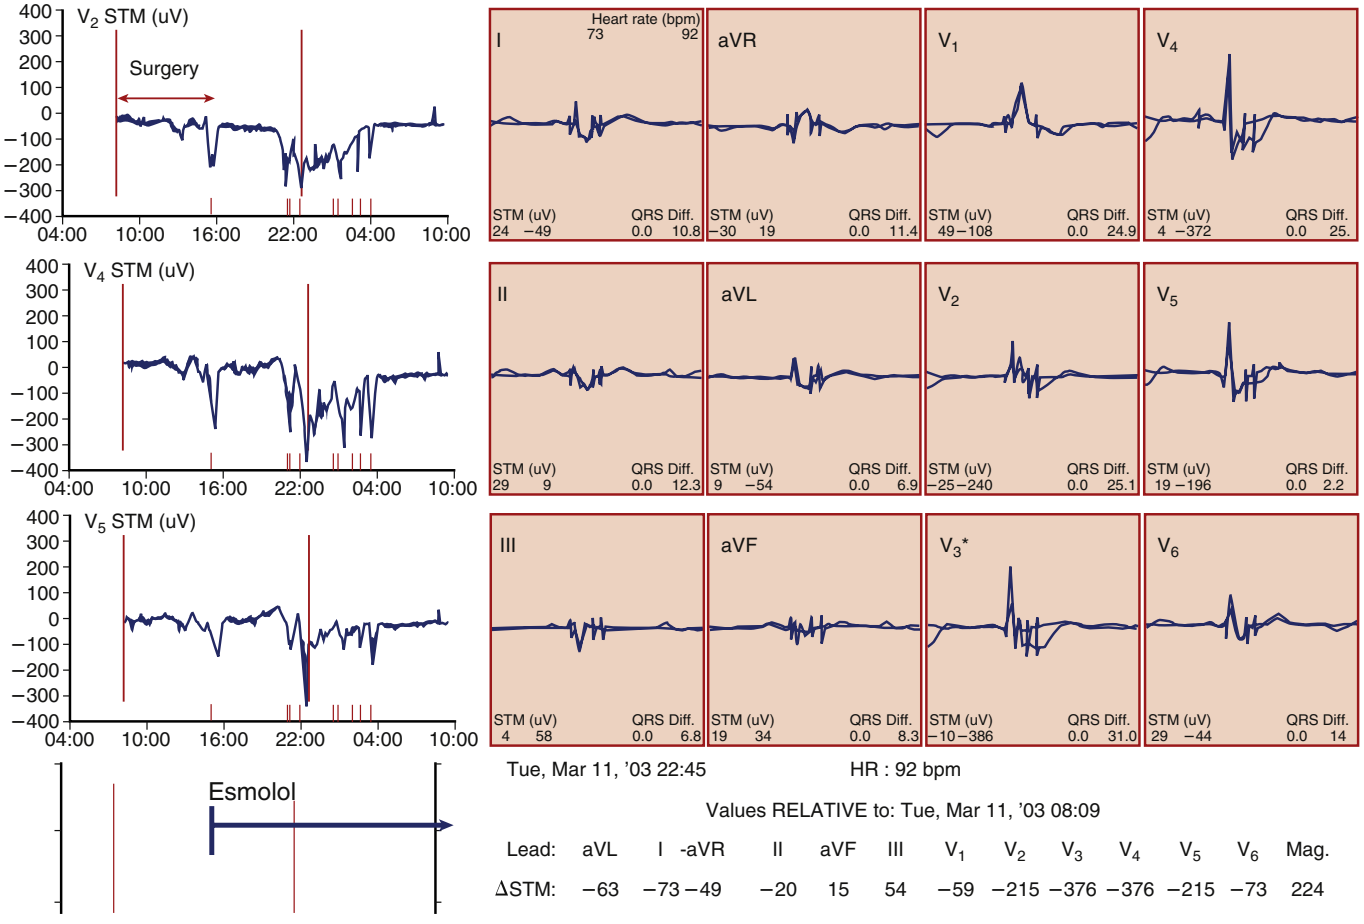

Figure 47-27. The perioperative ST-segment and heart rate trends of the patient are demonstrated on the left-sided panels. All 12-lead electrocardiographic complexes during peak ischemia, superimposed over the corresponding baseline (preoperative) complexes, are demonstrated on the right-sided panels. The ST-segment trends show two episodes of ST depression–type ischemia: a short episode of 15 minutes immediately at the end of surgery, followed by a 5-hour period of no ischemia and then another long episode of ST depression lasting longer than 5 hours. Ischemia is evident in all anterior leads but is maximal in V_3 and V_4 leads.

PATHOPHYSIOLOGIC MECHANISMS OF PERIOPERATIVE MYOCARDIAL INFARCTION

Two distinct mechanisms may lead to perioperative MI (PMI)[90]: (1) ACS and (2) prolonged, myocardial oxygen supply-demand imbalance in the presence of significant yet stable CAD. These mechanisms have been recently named type 1 and type 2 MIs by the collaborative Task Force for Universal Definition of MI.[91] A distinction between them is pivotal to therapeutic considerations (Fig. 47-28).

Acute Coronary Syndrome (Type 1 Myocardial Infarction)

The pathophysiologic processes of ACS have been extensively reviewed. Briefly, ACS occurs when an unstable or vulnerable plaque, typically one with a large lipid core, thin fibrous cap, and activated leukocytes,[92] undergoes spontaneous rupture or fissuring with subsequent exposure of thrombogenic material to the bloodstream, leading to acute coronary thrombosis, ischemia, and infarction. Clearly, plaque inflammation plays a pivotal role in spontaneous ACS.[93] In addition, however, external stimuli, such as those operating in the postsurgical setting, are believed to contribute to vulnerable plaque destabilization.

- Physiologic and emotional stresses are long known to be associated with acute MI, raising the hypothesis that sympathetic nervous system–induced hemodynamic, coronary vasoconstrictive, and prothrombotic forces promote plaque disruption and coronary thrombosis. Theoretically, the perioperative period is the perfect playground for such events. Plasma catecholamine and cortisol levels increase early after surgery[94] and may remain high for days.[95] Stress hormones increase with pain, greater surgical trauma, anemia, and hypothermia.[96,97] Plasma catecholamine levels have been shown to correlate with postoperative cardiac troponin elevations[16] and with thrombotic graft occlusion after vascular surgery.[98] However, an increased rate of plaque rupture and coronary thrombosis in the immediate postoperative period has not been confirmed when these postoperative stresses are at their peak.
- Tachycardia and hypertension, common in the perioperative period, may exert excess shear forces on

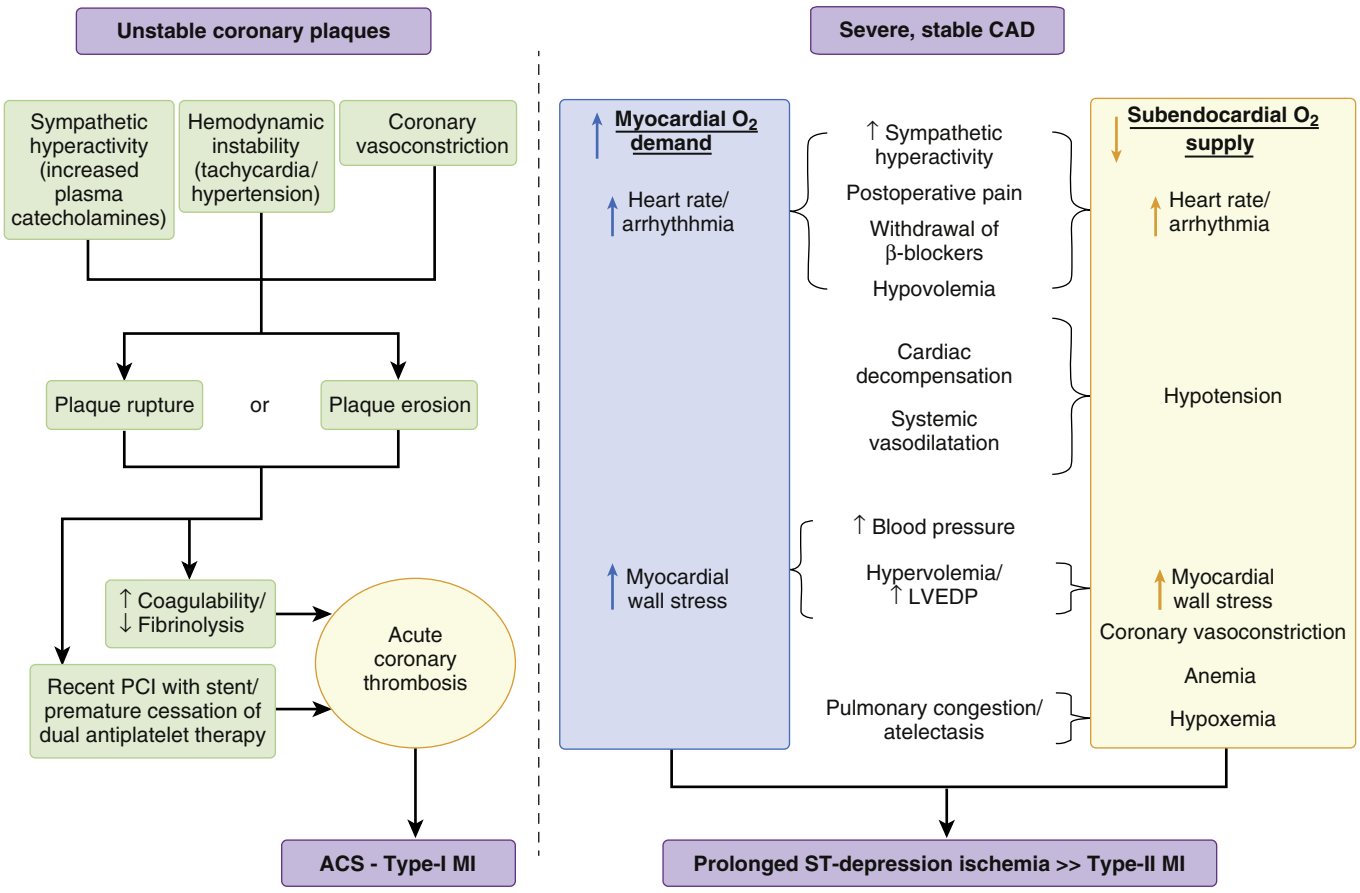

Figure 47-28. Two distinct mechanisms may lead to postoperative myocardial infarction: (1) type I—spontaneous plaque rupture or erosion and acute coronary thrombosis (acute coronary syndrome [ACS]); and type II—prolonged stress-induced myocardial oxygen supply-demand imbalance in the presence of severe yet stable coronary artery disease (CAD) (non-ACS). *LVEDP,* Left ventricular end-diastolic pressure; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention. *(Redrawn from Landesberg G, Beattie WS, Mosseri M, et al: Perioperative myocardial infarction,* Circulation *119:2936-2944, 2009.)*

vulnerable plaques with thin fibrous caps and high circumferential tensile stress or cause endothelial stripping or erosion of plaques with severe coronary stenosis, associated with high blood velocities.[99,100]

- Increased perioperative procoagulant agents (e.g., fibrinogen, factor-VIII coagulant, von Willebrand factor, α1-antitrypsin), platelet reactivity,[101] decreased endogenous anticoagulant medications (e.g., protein-C and antithrombin-III, α_2-macroglobulin),[102] and decreased fibrinolysis[103] have been reported. Postoperative hypercoagulability, however, is principally known for its venous thrombotic complications precipitated by stasis and immobilization. Reports on the association of hypercoagulability and/or decreased fibrinolysis with postoperative myocardial ischemia[104,105] or infarction[106] are rare. An association between impaired fibrinolysis and postoperative lower extremity arterial bypass thrombosis has been reported.[107] Attempts to mimic postoperative stress and hypercoagulability in healthy volunteers caused elevated tissue-plasminogen activator and protein-C activity, consistent with the inhibition of coagulation and augmented fibrinolysis and failed to cause an increase in coagulability.[108]

Myocardial Oxygen Supply-Demand Imbalance (Non–Acute Coronary Syndrome, Type 2 Myocardial Infarction)

Data obtained from studies using perioperative monitoring for myocardial ischemia in patients undergoing major, mostly vascular, surgery suggest an alternative, probably significantly more common pathophysiologic condition for PMI. Perioperative Holter monitoring for up to a week after surgery in patients at high risk for cardiac events consistently showed that silent, HR-related postoperative ischemia is common (up to 50%) postoperatively and associated with both in-hospital and long-term morbidity and mortality.[90,91] Postoperative cardiac complications, including sudden death, occur almost exclusively after prolonged (>30 minutes,[84,88] >2 hours,[81,82] or >5 hours[77,87]), silent ST-depression ischemia. These data have been corroborated by continuous perioperative 12-lead ECG monitoring with on-line ST-segment analysis after major vascular surgery and serial perioperative cardiac troponin measurements.[89,90] Troponin was elevated within hours after the onset of prolonged transient, ST-depression ischemia occurring early after the surgery, and the magnitude of troponin elevation correlated with the duration of ST-depression ischemia.[89] These findings led to the notion that prolonged, stress-induced ST-depression ischemia is a major cause of postoperative troponin elevation and myocardial infarction.

Importantly, however, sequential postoperative troponin measurements demonstrated that low-level, yet prognostically significant troponin elevations occur in patients at high risk who are undergoing major surgery with little or even no evidence of ischemia on ECGs.[90,109,110] Low-level troponin elevation (troponin T >0.03 ng/mL) occurred in as many as 24% of all patients early after major vascular surgery. Only 32% of patients had ECG evidence of ischemia. In contrast, among patients (8.7%) with conventional troponin elevations (>0.1 ng/mL), 88% had ischemia on continuous 12-lead ECG monitoring.[90] Higher troponin values were associated with longer ST-depression–type ischemia and with higher incidence of cardiac symptoms (e.g., pulmonary congestion, chest pain). Hence, prolonged postoperative ischemia, myocardial injury, and type 2 MI probably constitute a spectrum of clinical events ranging from silent, minor, myocardial injury with low-level troponin elevation and low frequency of ischemia on ECG to prolonged, overt ischemia in multiple ECG leads, associated with significant troponin elevation and PMI. Troponin elevation has an immense prognostic importance because troponin elevation measured in the first 3 postoperative days incrementally predicts both early (30 days)[111] and long-term (5 years)[90] postoperative mortality.

As opposed to coronary plaque rupture (type 1 MI) that typically occurs in relatively young and mildly occluding coronary plaques, prolonged stress-induced ST-depression–type ischemia and infarction (type 2 MI) occurs in patients with long-standing, high-grade, often multivessel yet stable CAD[93] (Fig. 47-29).

Multiple triggers may cause myocardial oxygen supply-demand imbalance in the postoperative period (see Fig. 47-28):

- Tachycardia is by far the main cause of postoperative ischemia and type 2 MI.[89,111] An increase in HR of 80 to 90 bpm in patients with significant CAD whose resting HR is 50 to 60 bpm may cause prolonged postoperative ischemia and PMI, demonstrating the low threshold for ischemia in patients after surgery.

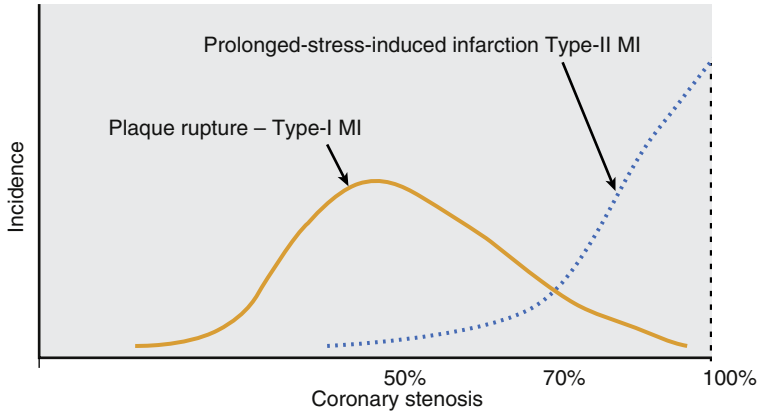

Figure 47-29. A schematic representation depicts the probability of type-I and type-II myocardial infarctions as a function of the severity of the coronary artery disease. Coronary plaque rupture mainly occurs in relatively nonoccluding coronary plaques, whereas prolonged myocardial oxygen supply-demand imbalance mainly occurs with severe, often multivessel coronary artery disease. *MI*, Myocardial infarction. *(Adapted from Landesberg G: The pathophysiology of perioperative myocardial infarction: facts and perspectives,* J Cardiothorac Vasc Anesth *17:90-100, 2003.)*

- Postoperative tachycardia is frequently associated with either hypotension, secondary to hypovolemia, bleeding, or systemic vasodilatation, or with hypertension induced by stress hormones and vasoconstriction, aggravating tachycardia-induced ischemia. The product of blood pressure and HR correlates with myocardial oxygen demand, whereas the quotient of arterial pressure divided by HR is critical for coronary perfusion, particularly in collateral-dependent myocardium.[112]
- Fluid overload in patients with reduced ventricular function may aggravate myocardial wall stress and subendocardial ischemia.
- Perioperative anemia,[113] hypoxemia, and hypercarbia are other common precipitants of myocardial ischemia in patients with significant CAD.
- Stress- and ischemia-induced coronary vasoconstriction[114,115] may further limit blood flow to areas with marginal coronary circulation.

TREATMENT AND PREVENTION OF PERIOPERATIVE ISCHEMIA AND INFARCTION

Because the majority of postoperative ischemic events and MIs are silent, the key to their prevention is a high index of suspicion and the early detection and treatment of any sign or symptom related to the heart such as chest pain, shortness of breath, hypoxemia, and ECG changes. Figure 47-30 proposes an algorithm for the prevention and treatment of perioperative ischemia and infarction. Unfortunately, however, no treatment strategy has thus far been tested by a large enough clinical trial.

The role of prophylactic perioperative β blockade remains highly controversial.[117,118] Nevertheless, the importance of preventing and treating even modest postoperative increases in the HR cannot be overemphasized. All causes of tachycardia, hypertension, hypotension, anemia, and pain should be aggressively treated. Treatment of tachycardia associated with hypotension is particularly challenging and requires an understanding of the patient's baseline and postoperative myocardial, valvular, and coronary physiologic condition. Frequently, vasopressors to maintain blood pressure and β-adrenergic blockers to slow HR while managing blood volume, postoperative pain, and respiratory function are necessary. Emergent coronary intervention, anticoagulant agents, or glycoprotein IIb/IIIa antagonists are rarely indicated in the immediate postoperative course and are hazardous because of the risk of bleeding, unless ST-segment elevation or intractable cardiogenic shock ensues.[119]

Anemia (hematocrit level <39%) independently predicts 30-day mortality, and its correction improved survival in one cohort study of patients who underwent noncardiac surgeries.[120] Blood transfusion improved survival in patients with CAD who were critically ill and hemoglobin less than 10% but not in patients without ischemia.[121] Other studies reported increased mortality and nosocomial infections with blood transfusion for hematocrit levels less

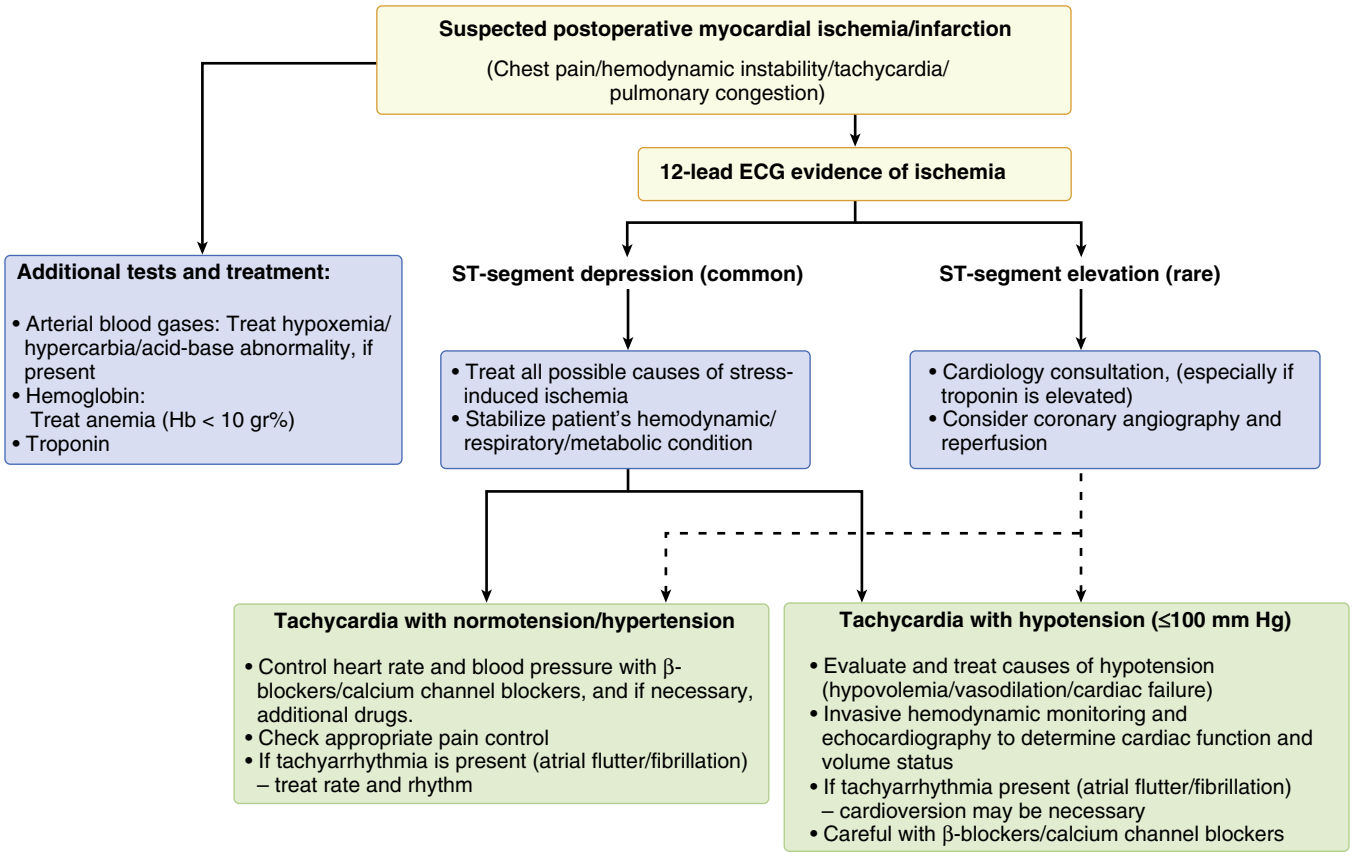

Figure 47-30. Algorithm for the prevention and treatment of perioperative ischemia and infarction. *(Redrawn from Landesberg G, Beattie WS, Mosseri M, et al: Perioperative myocardial infarction,* Circulation *119:2936-2944, 2009.)*

than 25% in stable patients with ACS,[122] in patients after cardiac surgery,[123] and in patients in the ICU.[124] Therefore, hematocrit levels between 25% and 33% is a gray zone in which transfusion must be individualized. Patients who are hemodynamically unstable postoperatively with ischemia may benefit from transfusion. Tight perioperative hemodynamic monitoring, including echocardiography, arterial line, central venous, or possibly pulmonary arterial pressure measurement, is often necessary to determine volume status and to avoid congestive failure.

Chapter 48

Implantable Cardiac Pulse Generators: Pacemakers and Cardioverter-Defibrillators

MARC A. ROZNER

KEY POINTS*

Preoperatively

- Identify the generator manufacturer and model (pacemaker, transvenous defibrillator, subcutaneous defibrillator) of the cardiovascular implantable electronic device (CIED).
- Establish preoperative contact with the patient's CIED physician or clinic to obtain appropriate records and a perioperative prescription (Heart Rhythm Society [HRS]). Have the CIED interrogated (American Society of Anesthesiologists [ASA]) by a competent authority shortly before the anesthetic regimen.
- Obtain a copy of this interrogation. Obtain a perioperative prescription from the CIED physician (HRS). Ensure that implantable cardioverter-defibrillator (ICD) treatment settings are appropriate and that the CIED will pace the heart.
- Consider replacing any CIED near its elective replacement period in a patient scheduled to undergo either a major surgical procedure or a surgical procedure where monopolar electrosurgery will be used within 25 cm of the generator.
- Determine the patient's underlying rate and rhythm to determine the need for backup (external) pacing support.
- Ensure that all magnet behavior (pacing, suspension of shock therapy) is appropriate if magnet use is planned.
- Program minute ventilation rate responsiveness "off," if present.
- Consider disabling all rate enhancements to prevent misinterpretation of cardiac rhythm.
- Consider increasing the lower rate limit to provide optimal oxygen delivery for major procedures.
- If electromagnetic interference is likely, (1) disable antitachycardia therapy if a defibrillator is present and (2) consider asynchronous pacing for some pacing-dependent patients. Magnet application may be acceptable for some ICDs (disable antitachycardia therapy) or pacemakers (provide asynchronous pacing). Asynchronous pacing from an ICD always requires reprogramming.

Intraoperatively

- Monitor cardiac rhythm with the pulse oximeter (plethysmography) or arterial waveform analysis.
- Consider disabling the "artifact filter" on the electrocardiogram monitor. If a minute ventilation sensor is present and active, ensure that respiratory rate monitoring is disabled.
- Ask the surgeon to operate without the monopolar electrosurgical unit (ESU).
- Use a bipolar ESU if possible; if not possible, then pure "cut" electrosurgery is better than "blend" or "coag," and ESU should be applied in short bursts (<4 seconds) separated by at least 2 seconds.

*Adapted from the American Society of Anesthesiologists (ASA) *Practice Advisory* (2005, revised 2011) and the Heart Rhythm Society (HRS), formerly the North American Society of Pacing and Electrophysiology (NASPE) and ASA *Consensus Statement* (2011) *for Perioperative Management of Patients With a Pacemaker or Defibrillator.*

KEY POINTS—cont'd

- Place the ESU dispersive electrode in such a way to prevent electricity from crossing the generator-heart circuit, even if the electrode must be placed on the distal forearm and the wire covered with sterile drape.
- If the ESU causes ventricular oversensing with pacing quiescence or atrial oversensing with inappropriate ventricular pacing, limit the effect by using short ESU bursts, relocating the dispersive electrode, or placing a magnet over the pacemaker (not indicated for ICDs)

Postoperatively

- Some patients require postoperative interrogation, especially if preoperative reprogramming took place. For "low-risk cases," HRS (but not ASA) states that this interrogation can take place in an ambulatory setting up to 1 month postoperatively. Some rate enhancements can be reinitiated, and a determination of optimum heart rate and pacing parameters should be made. Any patient with disabled antitachycardia therapy must be monitored until the antitachycardia therapy is restored.

The nature of anesthesiology practice requires a wide breadth of knowledge, often encompassing situations that occur rarely throughout a career. Nowhere in medicine does this task seem more difficult than the subject of the cardiac implanted electronic device (CIED). Many factors lead to confusion regarding the behavior of a CIED and the perioperative care of a patient with a CIED. Some patients have old, technologically outdated devices that still appear to function. New developments seem to take place rapidly, and case reports, textbooks, and literature reviews sometimes present incorrect material or do not keep pace with these new developments. Proprietary features, differing magnet behaviors (even among models from the same company), confusion regarding CIED type and available therapies, and the lack of standardization make synthesis of generalizations difficult, with the potential of putting the patient at risk. Finally, preventable adverse events that can cause injury or death in patients are thought to occur "by chance" (see the later section on temporary pacing).

Battery-operated pacing devices were introduced by C.W. Lillehei (a cardiothoracic surgeon) and Earl Bakken (an electrical technician) in 1958, just 4 years after the invention of the transistor. In 1960, Wilson Greatbatch, an engineer, created the first implantable battery-powered device in his barn in Buffalo, New York.[1] The natural progression of pacemaker (PM) developments led to the invention of the implanted cardioverter-defibrillator (ICD[†]) in approximately 1980 by Michael Morchower in Baltimore. First approved by the U.S. Food and Drug Administration (FDA) in 1985, implantation of ICDs required thoracotomy, a significant operation for the patient with poor heart function. Advances in electronic miniaturization, as well as improvements in battery technology, led to the development of very small (10-mL volume), but electronically complicated, programmable pacing devices.

Technologic advances (transvenous lead placement, antitachycardia[‡] pacing [ATP] capability, continued miniaturization, advanced pacing capability, and numerous survival benefits[2,3]) led to increases in ICD implantation. Since 1997, transvenous ICDs (T-ICDs) have been approved to provide permanent antibradycardia pacing.

Sophisticated three-chamber (atrium, right ventricle, and left ventricle) pacing to provide cardiac resynchronization therapy (CRT; also called biventricular [BiV] pacing) from both PMs (CRT-P) and ICDs (CRT-D) became available in the United States in 2001. In 2009, Cameron Health (San Clemente, Calif) received a CE mark (mandatory conformity marking for certain products sold within the European Economic Area since 1985) for their subcutaneous ICD (S-ICD). Boston Scientific/Guidant Medical/CPI (BOS; Natick, Mass) purchased this company in mid-2012 and received US FDA approval for the S-ICD in September 2012.

As noted, these advances and expanding indications for implantation can create confusion when caring for patients with CIEDs. A T-ICD in a pectoral position could be mistaken, by virtue of pacing "spikes" on the surface electrocardiogram (ECG), for a (non-ICD) PM. Additionally, T-ICDs have been inappropriately called "pacemaker/defibrillators" by medical personnel, the press, and patients. Given that pacing functions in T-ICDs respond to external stimuli (magnet placement, electromagnetic interference [EMI]) differently than do PMs, this confusion could harm the patient. For example, failure to disable shock therapy in the presence of EMI, thereby leading to inappropriate shock during a perioperative experience,[4] could actually shorten a patient's life.[5] Published data suggest that significant numbers of patients actually receive an inappropriate ICD shock during hospitalization.[6] Distinguishing a conventional PM from a T-ICD can be accomplished by examining the right ventricular (RV) lead system on a

[†] Although many authors and references identify this device as an "automatic implantable cardioverter-defibrillator or AICD," the term AICD is a brand name that was originally owned by CPI (Cardiac Pacemakers, Inc.), which was acquired by Guidant Medical Corporation and is now a part of Boston Scientific (Natick, Mass). The term PCD (Programmable Cardioverter-Defibrillator) belongs to the Medtronic Corporation (Minneapolis, Minn).

[‡] The terms antibradycardia and antitachycardia are used throughout this chapter. *Antibradycardia* refers to pacing to maintain a minimum rate. Thus, conventional pacemakers are antibradycardia devices. *Antitachycardia* refers to therapy delivered in the setting of tachycardia, and this therapy is designed to reduce the underlying heart rate.

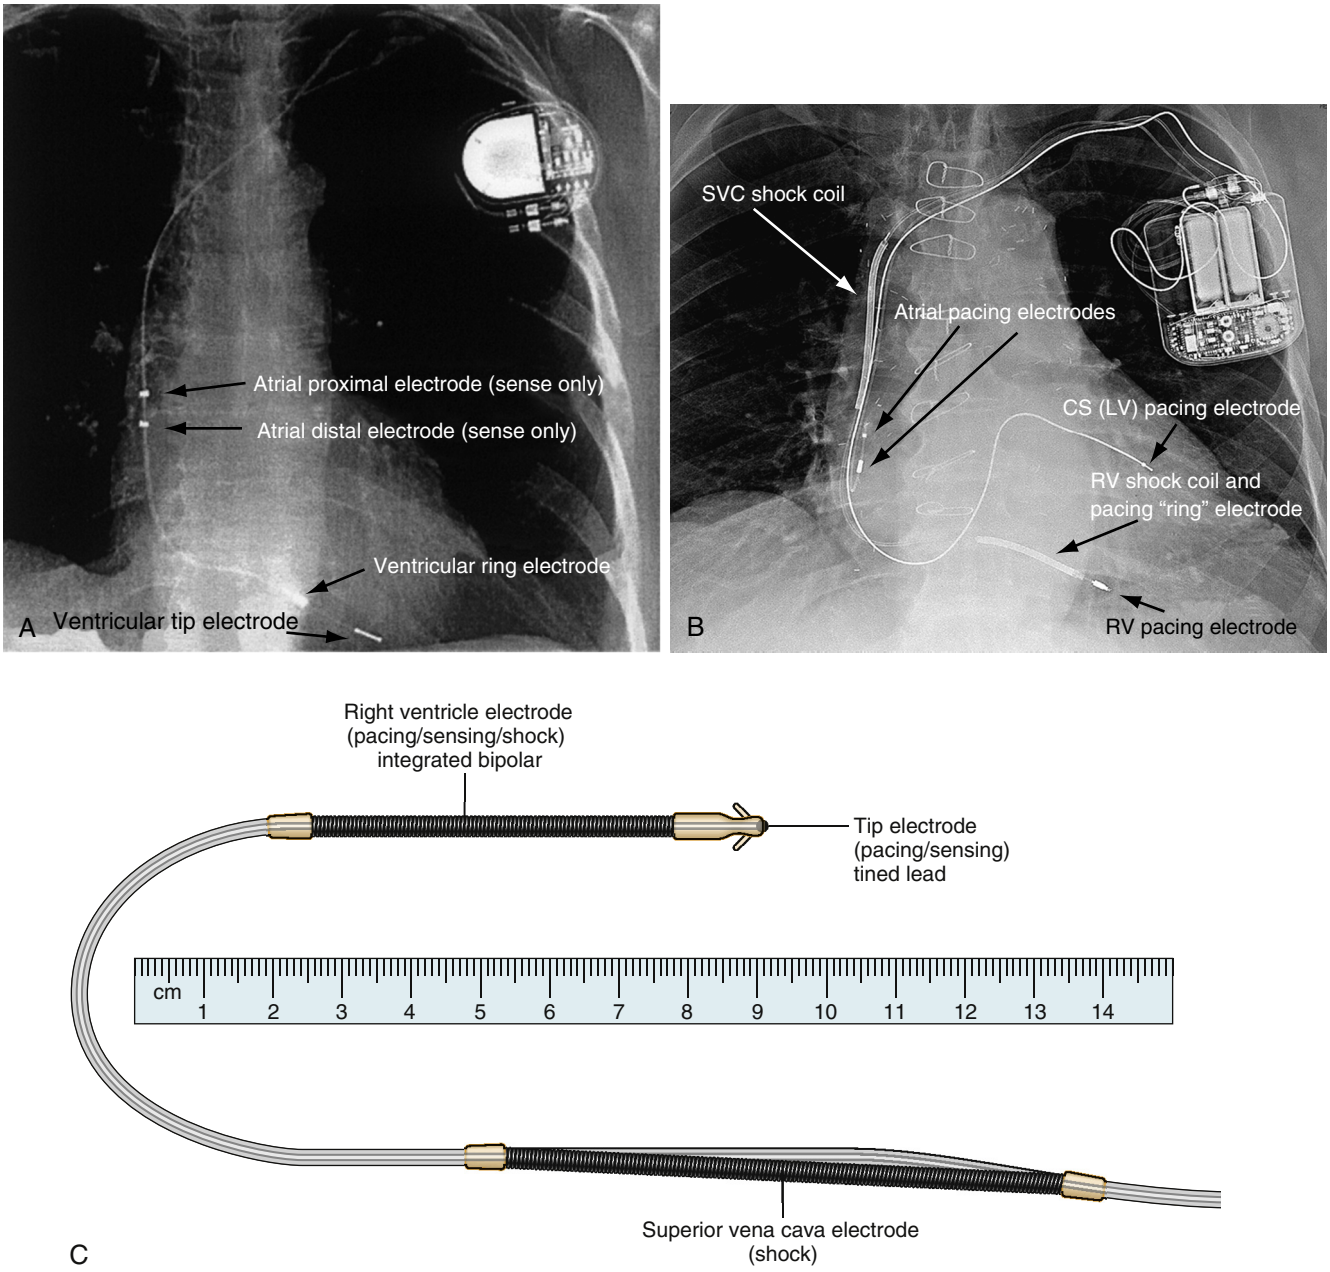

Figure 48-1. A pacemaker, an implantable cardioverter-defibrillator (ICD), and a right ventricular (RV) defibrillator lead are shown to assist in determination of the type of system using chest radiography. **A**, Conventional pacemaker with one quadripolar lead that provides atrial and ventricular sensing and ventricular pacing. This chest radiograph shows a number of features of a modern pacing system. The generator is located in the left pectoral region. The single lead enters the subclavian vein under the clavicle but superficial to the first rib (a common site for lead problems, although no problem is demonstrated here). This lead has two electrodes positioned within the right atrium to provide sensing to detect intrinsic atrial activity. The ventricular portion of the lead shows the classic bipolar pattern with a ring electrode just proximal to the tip electrode, and these electrodes can be used for sensing intrinsic ventricular activity as well as depolarizing the ventricle. This particular system is a VDD pacemaking system used to provide atrioventricular (AV) nodal activity in patients with a functioning sinoatrial node and atrium because this system cannot be used to depolarize the atrium. Because the surface electrocardiogram often demonstrates ventricular pacing that tracks the atrial activity, inspection of the surface electrocardiogram often produces an erroneous diagnosis of a dual-chamber (DDD) pacemaker. **B**, Defibrillator system with biventricular pacing capability. Note that three leads are placed: a conventional bipolar lead to the right atrium, a multipolar lead terminating in the right ventricle, and a unipolar lead to the coronary sinus (CS). The presence of a "shock" conductor in the right ventricle (called a "shock coil") distinguishes a defibrillation system from a conventional pacing system. Many ICDs have an additional shock coil in the superior vena cava (SVC). Typically, the SVC shock coil is electrically identical to the defibrillator case (called the "can"). When the defibrillation circuitry includes the ICD case, it is called "active can configuration." This particular system is designed to provide "resynchronization therapy" in the setting of dilated cardiomyopathy with a prolonged QRS complex (and frequently with a prolonged PR interval as well). The bipolar lead in the right atrium will perform both sensing and pacing function. Similarly, the tip electrode in the right ventricle along with the shock coil performs RV pacing and sensing functions. When the second RV pacing electrode is merged with the shock coil, the lead is called "integrated bipolar" because unipolar RV pacing is not permitted in an ICD system. The lead in the CS depolarizes the left ventricle (LV). Failure to depolarize one of the ventricles could result in ventricular oversensing (and inappropriate antitachycardia therapy) in an ICD. **C**, Integrated bipolar RV defibrillator lead. The tip of this lead becomes enmeshed in the RV trabeculae (called a "tined" lead), rather than engaging the myocardial wall with a screw ("active fixation"). This particular lead has an SVC shock coil as well.

chest radiograph (Fig. 48-1). A chest radiograph can also be used to identify the generator manufacturer (Fig. 48-2).

Pacemaking and defibrillation systems have a remarkable record for reliability, but they can, and do, fail. Laskey and associates analyzed FDA records for T-ICD report explantations for the period from 2003 to 2007 (459,000 T-ICDs and 256,000 CRT-Ds implanted) and found an annual explantation rate of 5.0% for T-ICD and 8.3% for CRT-D.[7] A similar study for PMs (1990 to 2002; 2.25 million implants) showed a 0.4% failure rate.[8] Thus, every patient with a cardiac generator should undergo regular in-office follow-up. For appropriately selected devices, remote (i.e., telephone) checks can be used to identify battery depletion, programming, sensing issues, arrhythmia detection (PM and ICD), and arrhythmia treatment (ICD). Some PMs and T-ICDs have automated sensing and capture testing that can report problems, but commanded iterative testing, such as pacing thresholds, cannot be performed. For "stable" PMs, Medicare coverage includes telephone evaluation every 4 to 12 weeks. The Heart Rhythm Society and European Heart Rhythm Association (HRS/EHRA) recommend evaluation (remote or in person) every 3 to 12

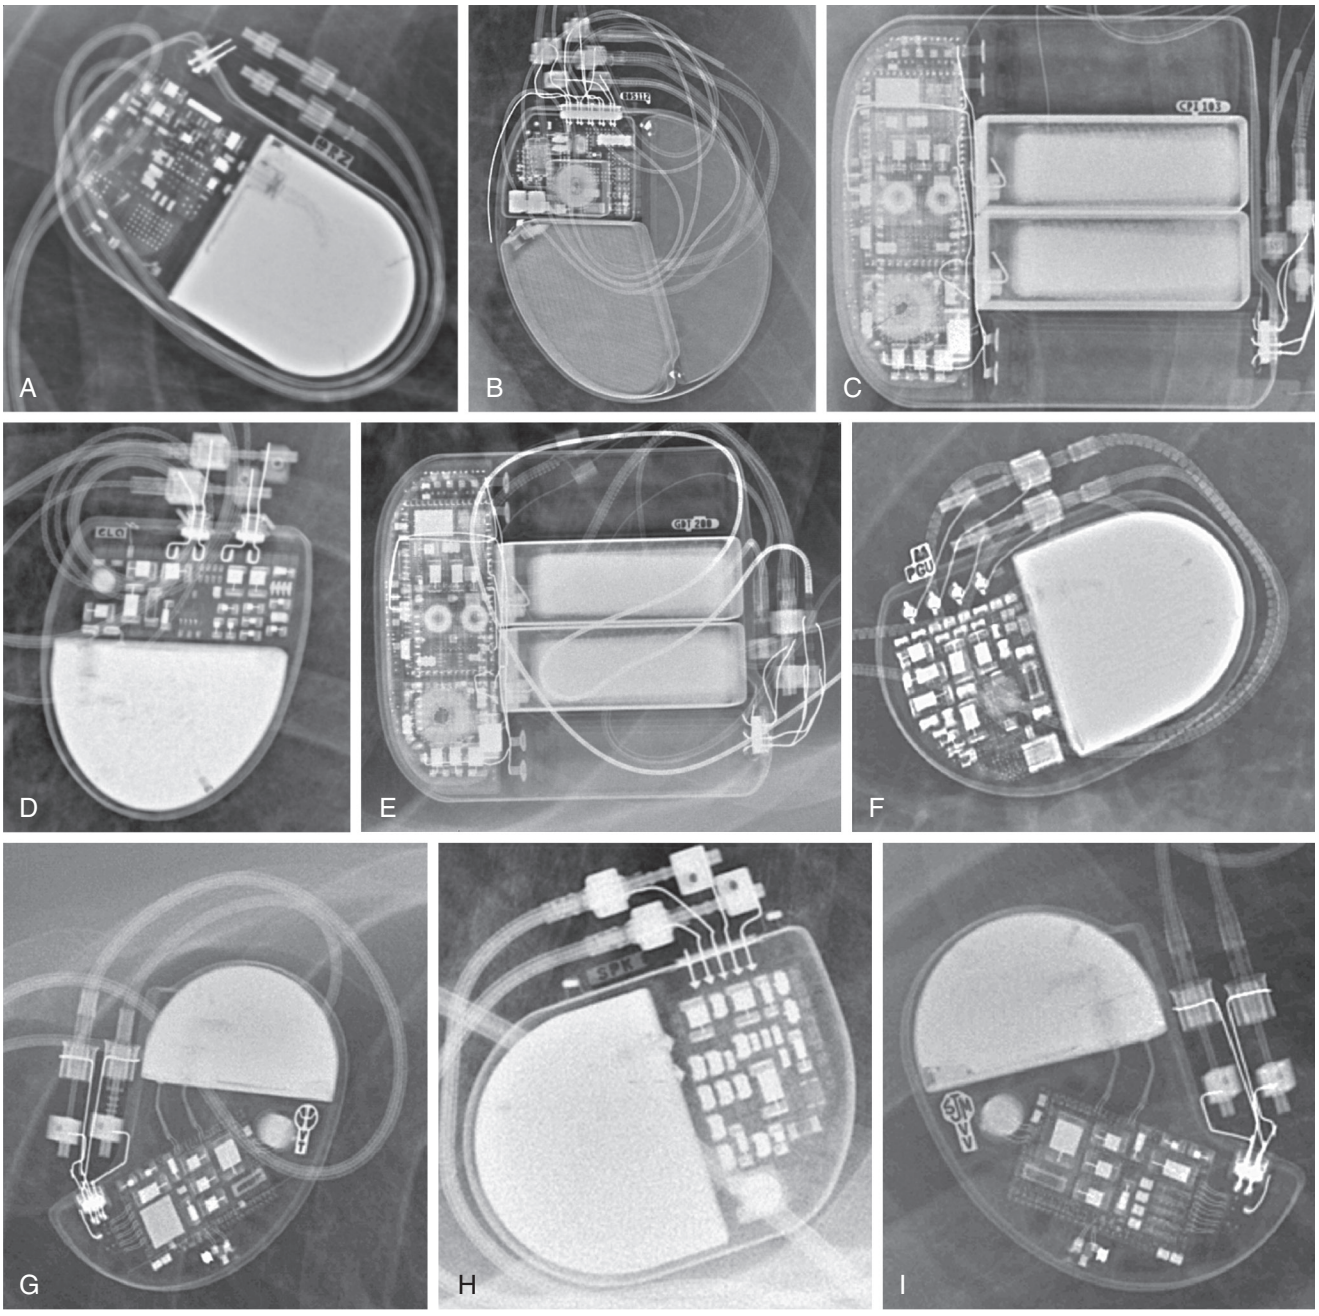

Figure 48-2. Radiographic identifiers for some generator manufacturers. Pacemaker and implantable cardioverter-defibrillator generators can be identified from operative dictations, patient cards, or some chest radiographs. Using digital x-ray equipment with postprocessing zoom capability, corporate x-ray logo identifiers from Biotronik (**A**), Boston Scientific (**B**),CPI (**C**), ELA (**D**), Guidant (**E**), Medtronic (**F**), Pacesetter (**G**), Sorin (**H**), and St. Jude Medical (**I**) are shown. For Sorin devices, all identifiers start with "SP," and the third character identifies the actual model. *Currently used logo.

months. Medicare coverage and recommendations (HRS/EHRA) include at least one in-person evaluation every year. Medicare has no coverage determination for ICD follow-up care; HRS/EHRA recommends evaluation (remote or in person) every 3 to 6 months with at least one in-person evaluation annually.[9,10]

Issues also develop leading to "notices," "product advisories," or "recalls" from the various manufacturers that may affect perioperative care. For example, BOS reported T-ICD magnet switch issues that could prevent delivery of shock. Two separate groups have been identified: (1) certain T-ICDs manufactured before 2005 (≈2000 remaining implants) whose magnet switches should be permanently disabled and (2) some T-ICDs manufactured between January 2006 and December 2007 (≈34,000 remaining implants) that must be checked for "tones/beeps" following any magnet removal. Any ICD with the magnet switch disabled will deliver a shock even with a magnet in place (Fig. 48-3).[4,11] The Medtronic (Minneapolis, Minn) Sprint Fidelis ICD lead series reports ventricular activity in the absence of true electrical systoles (oversensing), and this can result in failure to pace or the delivery of inappropriate shock (Fig. 48-4). Recommended actions included programming changes and use of telephone monitoring.[12] In December 2010, St. Jude Medical (Sylmar, Calif) reported that their Riata ICD leads (227,000 implanted) could develop insulation failures, resulting in inappropriate ICD discharge or pacing failures. They recommended in-office follow-up every 3 to 6 months.[13]

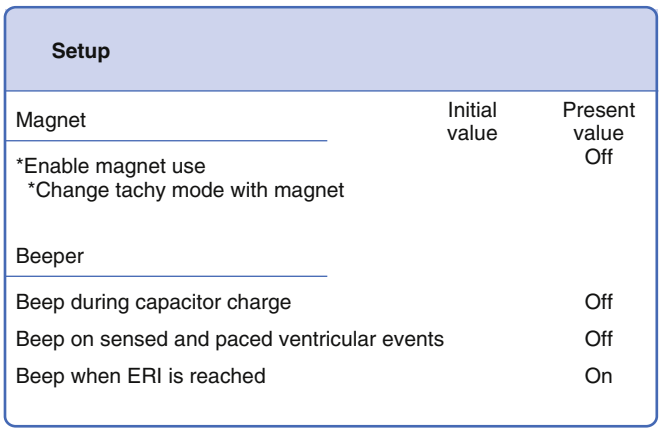

Figure 48-3. Magnet mode setup from a Guidant (now Boston Scientific) Contak Renewal 3 HE model H179. This implantable cardioverter-defibrillator (ICD) is part of an "Urgent Medical Device Safety Information and Corrective Action" letter to physicians from the Guidant Corporation on June 23, 2005, in which a magnet switch problem was announced. The corrective action was designed to disable the magnet switch permanently by programming. As a result, this ICD will not disable shock therapy in response to magnet placement. According to the notice, approximately 46,000 Guidant ICDs were affected and should have their magnet switch permanently disabled. Industry experts believe that fewer than 10,000 of these devices remained implanted and active after January 1, 2013. Note the line below the magnet switch report called "Change tachy mode with magnet." Effective with software released by Boston Scientific in October 2009, this setting was removed from all ICDs except the Contak Renewal Series. When present and enabled, this setting allows permanent deactivation of ICD function with the application of a magnet for more than 30 seconds. No Boston Scientific ICD with the "BOS" x-ray logo has this feature. *ERI,* Elective replacement indicator.

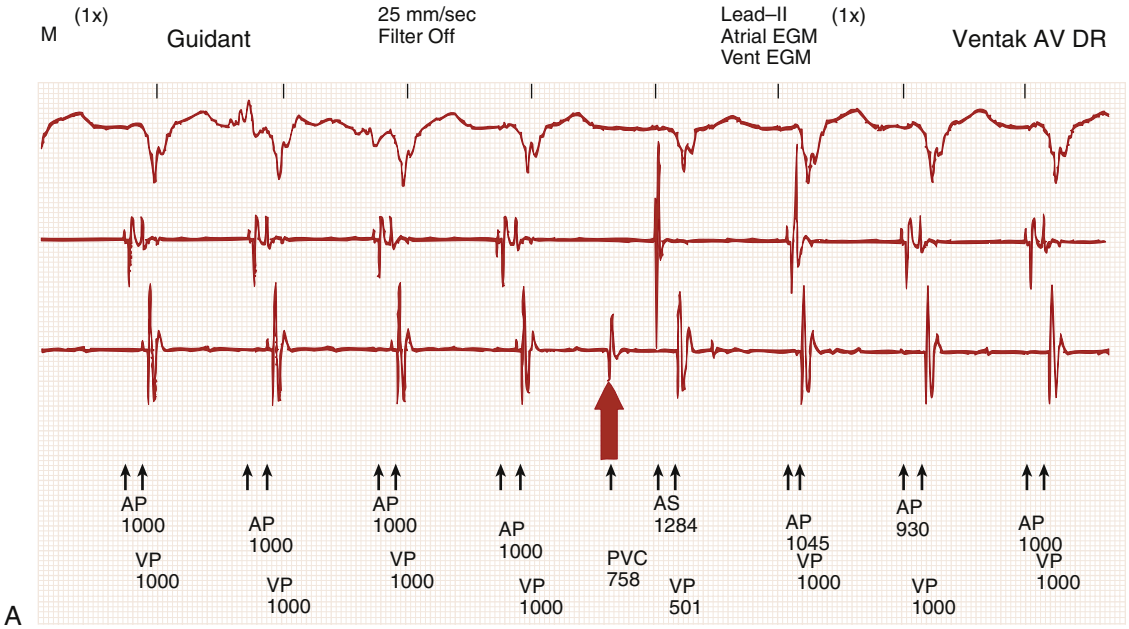

The complexity of PMs and ICDs, as well as the multitude of programmable parameters, limits the number of generalizations that can be made about the perioperative care of the patient with an implanted pulse generator (PG). Aging of the population, continued enhancements in implantable technology, new indications for implantation, and new devices continue to drive the growing numbers of implants. In 2005, the ASA published a *Perioperative Practice Advisory,* which was revised in 2011.[14] Also in 2011, the HRS and the ASA published an "Expert Consensus Statement,"[15] in which many experts from several societies tried to balance technical, economic, and safety issues in these patients. The Canadian Anesthesia Society and Canadian Cardiovascular Society (CAS/CCS) jointly published a statement in 2012,[16] and the United Kingdom's Medicines and Healthcare Products Regulatory Agency (MHRA) published guidelines in 2006 in which the use of "surgical diathermy/electrocautery" was anticipated.[17] The MHRA document is silent on the CIED patient who is undergoing a surgical procedure without the presence of EMI. All the documents report that care of the emergency patient is more complicated than is care of the elective surgical patient (Table 48-1).

Patients with an implanted cardiac PG often have significant comorbid disease in addition to their cardiac rhythm disturbance. The ability to care for these patients requires attention to both their medical and psychological problems. Anesthesiologists also need an understanding of the patient's PG, its functions, and likely idiosyncrasies in the operating or procedure room.

Finally, not all electronic generators implanted in the chest are cardiac devices, and devices resembling cardiac PGs have been implanted for indications unrelated to cardiac issues. When implanted in the pectoral position (the usual place for current cardiac PGs), these noncardiac devices can be mistakenly identified as cardiac PGs.[18] PG implantation has been approved by the FDA for pain control, thalamic stimulation to control Parkinson disease, phrenic nerve stimulation to stimulate the diaphragm in paralyzed patients, and vagus nerve stimulation to control epilepsy and depression.[19] Vagus nerve stimulation is also under consideration to treat heart failure,[20] as well as perhaps obesity.[21] Thus, when evaluating a patient with any PG, one must now determine whether the PG will be pacing the heart, stimulating the central nervous system, stimulating the spinal cord, or stimulating the vagus nerve.

PACEMAKERS

PM manufacturers report that more than 3000 generators have been manufactured by more than 26 named entities since the 1960s. Currently, industry experts report that more than 350,000 adults and children in the United States undergo new PM placement each year, and likely 3 million patients have PMs today. Worldwide, the prevalence probably approaches 5 million patients.

Figure 48-4. Ventricular oversensing from damaged leads. **A,** Real-time telemetry recording from a Guidant implantable cardioverter-defibrillator (ICD) with a Guidant 0154 right ventricular (RV) defibrillation lead reports a spontaneous ventricular (*red up arrow*) event that was not present on the surface electrocardiogram (ECG), termed ventricular oversensing. In this ICD, the pacing function was DDD (lower rate, 60 beats/minute; atrioventricular delay, 180 msec), and this patient depended on the ICD pacing function for his ventricular systoles. The *top tracing* is the surface ECG, the *second tracing* is the intracardiac atrial electrogram (EGM), and the *third tracing* is the intracardiac ventricular EGM. Along the *bottom* is the "marker channel," which shows the pacemaker's interpretation of events: AP is atrial pace, AS is atrial sense, VP is ventricular pace, and the inappropriate ventricular sensed event is labeled "PVC" because it occurs after a ventricular event without an intervening atrial event. This oversensing has prolonged the R-R interval between the fourth and fifth ventricular systoles because this patient depends on the pacing function for his ventricular systoles. In a pacing-dependent patient, this type of oversensing can lead to asystole. It can also provoke inappropriate antitachycardia therapy (i.e., shock) in a patient with native ventricular activity because these oversensed events can increase the apparent heart rate count to the ICD. **B,** A patient with a single-chamber Medtronic ICD and a Medtronic Sprint Fidelis RV defibrillation lead was found to have a significant ventricular oversensing issue at interrogation on April 26, 2005, before a head and neck surgical procedure. In this case the ICD is reporting 875 "short R-R intervals" (note the *arrow*) since the previous interrogation 15 days earlier (April 11, 2005). These data are consistent with a lead fracture causing intermittent "make-break" contacts. In this case, new counts began accumulating 12 minutes after the previous interrogation was complete. More than 100 counts/month is considered a problem; indications to replace the lead include ventricular oversensing in a pacing-dependent patient or a high rate of detection (frequently resulting in shock) triggered by this inappropriate oversensing. *EOL,* End of life; *ERI,* elective replacement indicator.

TABLE 48-1 BRIEF REVIEW AND COMPARISON OF PUBLISHED PERIOPERATIVE ADVISORIES FOR CARDIAC IMPLANTED ELECTRONIC DEVICES

	Preoperative Recommendation	Intraoperative Magnet Use	ESU Dispersive Electrode Placement	Postoperative Recommendation	Emergency Procedures	
					PM	ICD
ASA	"Timely interrogation" before elective surgery	Shuns magnet use in favor of reprogramming	Prevent presumed current path from crossing the chest or CIED system	Interrogation recommended; footnotes added to 2011 revision suggesting that CIED reinterrogation not needed if no monopolar ESU used	(silent)	
HRS/ASA	PM interrogation within 12 mo, ICD interrogation within 6 mo, and CRT interrogation within 3-6 mo; CIED physician must provide prescription for perioperative care	Magnet use suggested for asynchronous pacing (where needed in PM-treated patients) and disabling ICD high-energy therapy provided that patient position does not interfere with magnet access or observation	Prevent presumed current path from crossing the chest or CIED system	For most cases involving EMI (especially those inferior to umbilicus and where no preoperative reprogramming was performed), interrogation can take place within 1 mo as ambulatory procedure; for reprogrammed CIEDs, hemodynamically challenging cases, cardiothoracic surgery, RFA, and external cardioversion, interrogation before transfer from cardiac telemetry	Use 12-lead ECG to identify pacing need; presume dependence if 100% pacing Use magnet to mitigate pacing inhibition Cardiac monitoring until postoperative interrogation	Use magnet to suspend ICD tachyarrhythmia therapy
CAS/CCS	De novo interrogation likely not needed, but CIED physician must provide prescription for perioperative care	When reasonable, magnet use suggested for asynchronous pacing (as needed in PM-treated patients) and disabling ICD high-energy therapy	No mention	Clear plan for postoperative care established before elective case	Use 12-lead ECG to identify pacing need; presume dependence if 100% pacing; careful monitoring to determine magnet action; >5 second pauses if ESU interferes with CIED	
MHRA*	Preoperative contact with the PM or ICD follow-up clinic for evaluation and perioperative recommendations	Caution advised because magnet behavior can be affected by programming	"Ensure that the return electrode is anatomically positioned so that the current pathway between the diathermy electrode and return electrode is as far away from the pacemaker/defibrillator (and leads) as possible"	Follow-up clinic to prescribe postoperative follow-up	Attempt to follow routine steps; postoperative interrogation ASAP Magnet may create asynchronous pacing	Magnet may prevent inappropriate discharge

*The generic pacemaker code.[23] This code, initially published in 1983, was last revised in 2002 in an effort to keep current with technologic developments in the pacing field. The NBG code is a joint project from the North American Society of Pacing and Electrophysiology (NASPE: "N") and the British Pacing and Electrophysiology Group (BPEG: "B"). The "G" stands for generic.

A pacemaking system consists of an impulse generator and leads to carry the electrical impulse to the patient's heart. Leads are connected to the heart's chambers through the vena cava (transvenous leads), or they are directly sewn onto the surface of the heart (epicardial leads). Leads can be unipolar (one electrode per lead), bipolar (two electrodes per lead), or multipolar (multiple electrodes and wires contained within one lead with connections in multiple chambers) (see Fig. 48-1, *A*). Because two electrodes are required to complete a circuit, the second electrode in a unipolar configuration is the metal generator case. Use of the case as an electrode requires that the generator pocket be devoid of gas, and electrical continuity has reportedly been disrupted by the use of nitrous oxide.[22]

PMs with unipolar leads are more sensitive to the effects of EMI, and these systems produce larger "spikes" on an analog-recorded ECG. Most pacemaking systems (except older Autocapture devices from St. Jude Medical) pace in bipolar mode because bipolar pacing usually requires less energy. Bipolar sensing is more resistant to interference from muscle artifacts or stray electromagnetic fields. Often, bipolar electrodes can be identified on the chest film because they will have a ring electrode 1 to 3 cm proximal to the lead tip (see Fig. 48-1, *A*). However, generators with bipolar leads can be programmed to the unipolar mode for pacing, sensing, or both. Some PMs automatically switch to unipolar pacing or sensing on detection of a lead problem. Unipolar pacing is absolutely contraindicated in the presence of any ICD.

CODES

No discussion of PMs can take place without an understanding of the generic PM code, which was published by the HRS, formerly the North American Society of Pacing and Electrophysiology and Heart Rhythm UK, formerly the British Pacing and Electrophysiology Group. This code (NBG§) was initially published in 1983 and was last revised in February 2002.[23] It describes the basic behavior of the pacing device (Table 48-2). PMs also come with a variety of terms generally unfamiliar to the anesthesiologist, many of which are shown in the glossary at the end of this chapter.

The first two positions of this code (chamber[s] paced and chamber[s] sensed) seem relatively straightforward. Although early PMs provided only ventricular support, current models can provide pacing in the atria and ventricles, and these devices can also be programmed to determine intrinsic activity in these chambers. The code does not describe the array of diagnostic data that can be accumulated by these devices.

Probably the most confusing aspect of the NBG code is the third position (response to sensed event). Most PMs are programmed either to the DDD mode (atrial and ventricular ["dual-chamber"] pacing and sensing, both triggered and inhibited mode) or to the VVI mode (ventricular pacing in the inhibited mode). Two other modes frequently found are VDD (ventricular pacing with atrial tracking) and DDI (dual-chamber pacing and sensing, but inhibited mode only). In the United States, atrial-only PM placement (AAI mode) is unusual; however, these devices are implanted in patients with sinus node disease, but intact atrioventricular (AV) conduction, in other countries. The NBG third position describes the following behavior:

D (Dual): DDD and VDD pacing provide AV synchrony. In the DDD setting, atrial pacing takes place in the "inhibited" mode (i.e., the pacing device will emit an atrial pulse if no sensed atrial event [or intervening ventricular event, because any ventricular event will reset atrial timing] takes place within the appropriate timeframe). In DDD or VDD devices, once an atrial event has occurred (whether native or paced), the pacing device ensures that a ventricular event follows (up to the upper tracking rate [UTR; see the glossary at the end of the chapter]).

I (Inhibited): The appropriate chamber is paced unless intrinsic electrical activity is detected during the pacing interval. For the DDI mode, AV synchrony is provided only when the atrium is paced. If intrinsic atrial activity is present, then no AV synchrony is provided by the pacing function.

T (Triggered): The pacing device emits a pulse only in response to a sensed event. The triggered mode is used when the device is being tested.

The VDD and DDI modes deserve further comment. VDD pacing is used for the patient with AV nodal dysfunction but intact and appropriate sinus node behavior.

§The NBG code is a joint project of the North American Society of Pacing and Electrophysiology (NASPE) and the British Pacing and Electrophysiology Group (BPEG), now known as the Hearth Rhythm Society and Heart Rhythm Society UK, respectively. The "N" is NASPE, the "B" is BPEG, and the "G" stands for generic.

VDD pacing is accomplished with a single lead that incorporates atrial sensing electrodes, as well as ventricular conductors that can both pace and sense (see Fig. 48-1, *A*). A VDD device has no atrial pacing capability. As a result, in a patient who depends on atrial contraction to augment cardiac output, events that result in VVI pacing (e.g., sinus rate lower than programmed rate, battery depletion) or asynchronous ventricular pacing (e.g., magnet placement in many devices, EMI) can lead to deteriorating hemodynamics.[24,25]

DDI pacing is indicated for the patient who has a dual-chamber pacing device and also has episodes of paroxysmal atrial dysrhythmia (e.g., paroxysmal atrial fibrillation). DDI pacing prevents high ventricular rates (i.e., pacing at the UTR) that could result from attempted tracking of the atrial arrhythmia, and it provides AV synchrony only when the atrium is paced. Many DDD programs enter the DDI mode on detection of high (programmable) atrial rates (called Mode Switch, Automatic Mode Switch, or Atrial Tachy Response, depending on the manufacturer). When the mode is switched to DDI, perturbations (e.g., very high [>400/minute] atrial rates, EMI from the electrosurgical unit [ESU], or magnet placement and removal) may revert back to DDD pacing, with the resultant appearance of AV pacing or ventricular pacing at the UTR (see the section on magnets later in this discussion of pacemakers).

Rate modulation (the fourth position) also remains a poorly understood concept. Because some patients cannot increase their heart rate in response to increased oxygen demand (chronotropic incompetence), PM manufacturers have devised certain mechanisms to detect "patient exercise," such as sensors that detect vibration, respiration, and pressure (Box 48-1). As the sensor detects "exercise," it increases the pacing rate (termed-sensor indicated rate). As the exercise tapers, this sensor-indicated rate returns to the programmed lower rate. The sensitivity of these sensors to their exercise signals and the rates of change in pacing are programmable features in current generators. Activation of rate-response algorithms, resulting in an increased paced rate in the operating room, whether from vigorous chest wall skin preparation, pressure on the generator, or EMI in a minute ventilation device, has led to inappropriate treatment and harm to the patient.[26,27]

With the 2002 revision of the NBG, the fifth column describes multisite pacing functionality (it had been used to describe antitachycardia function, but this scheme has been abandoned, and a generic defibrillator code has been established). Atrial multisite pacing may prevent atrial fibrillation,[28] and ventricular multisite pacing is an acceptable treatment for pacing the patient with dilated cardiomyopathy (DCM).[29-31]

BOX 48-1 ***Rate Modulation (Activity) Sensors Available or Under Investigation****

Currently Approved in the United States

Vibration sensor
Motion sensor
Minute ventilation (bioimpedance sensor)
QT interval (Vitatron only)
Right ventricular pressure (Biotronik only)

Under Investigation

Right ventricular stroke volume
Blood pH
Blood temperature
Mixed venous oxygen sensor
Systolic time intervals
Evoked response
Intracardiac impedance

*Of the types of sensors used to detect exercise in a patient with a cardiac pacemaker, five are currently approved in the United States, although many others remain under investigation. Some devices have two sensors and can be programmed for cross-checking to prevent increases in heart rate from spurious causes. Minute ventilation sensors are very sensitive to stray electromagnetic interference, and patients have been inappropriately treated for pacemaker-driven tachycardias as a result. Perioperative experience with right ventricular pressure sensors is minimal at this time. Most pacemaker experts recommend that rate modulation be programmed to "off" in the perioperative period to prevent confusion between intrinsic tachycardia and pacemaker-induced tachycardia (e.g., see Schwartzenburg and associates[121]).

BOX 48-2 ***Pacemaker Indications****

Symptomatic diseases of impulse formation (sinus node disease)
Symptomatic diseases of impulse conduction (atrioventricular nodal disease)
Long QT syndrome
Hypertrophic obstructive cardiomyopathy†*
Dilated cardiomyopathy †*

*Indications for permanent pacing are shown. Most patients with pacemakers currently fall into the first two categories (sinus node or atrioventricular nodal disease).
†Requires 100% ventricular pacing to be effective. Thus, short atrioventricular delays (≈120-150 msec) are programmed.

INDICATIONS

Indications for permanent pacing are shown in Box 48-2 and are reviewed in detail elsewhere.[32] Classically, antibradycardia pacing treats patients with sinus node disease (improper impulse formation) and AV nodal disease (improper impulse conduction). CRT pacing for the patient with DCM requires left ventricular (LV) pacing, usually through a lead placed into the coronary sinus (CS) (see Fig. 48-1, *B*) or sewn onto the LV free wall. In patients with significant RV-to-LV activation time, loss of capture in a ventricle can lead to ventricular overcounting with resultant inappropriate antitachycardia therapy for the patient with a DCM pacing defibrillator.[33,34] Pacing continues to be explored to reduce the outflow tract obstruction in hypertrophic obstructive cardiomyopathy (HOCM) in both adults and children because paced ventricular conduction takes place in a left bundle branch pattern (the LV septum depolarizes after the other segments, rather than as the early systolic event).[35]

Pacing for HOCM and DCM requires careful attention to pacer programming. To be effective in these patients, the PM must provide the stimulus for ventricular depolarization, and AV synchrony must be preserved.[36] PM inhibition or loss of pacing (i.e., from native conduction, atrial irregularity, ventricular irregularity, development of junctional rhythm, or EMI) can lead to deteriorating hemodynamics in these patients.

CRT pacing may cause inappropriate lengthening of the QT interval in susceptible patients, and this lengthening has been reported to be associated with torsades de pointes.[37] As a result of this report, the prudent anesthesiologist should ensure adequate access to rapid defibrillation for patients with BiV pacing accomplished with a conventional PM.

MAGNETS

Despite often repeated folklore, most PM manufacturers warn that magnets were never intended to treat PM emergencies or prevent the effects of EMI. Rather, magnet-activated switches were incorporated to produce pacing behavior that demonstrates remaining battery life and, sometimes, pacing threshold safety factors.

Placement of a magnet over a generator may produce no change in pacing because *not all PMs switch to a continuous asynchronous pacing mode when a magnet is placed*. Moreover, not all models from a given company behave the same way. Possible effects of magnet placement are shown in Table 48-3.[38-40] In some devices (Biotronik [Berlin, world headquarters; Lake Oswego, Ore, U.S. headquarters], BOS, Pacesetter, St. Jude Medical, Telectronics), magnet behavior can be altered or completely eliminated by programming. For generators with programmable magnet behavior, only an interrogation with a programmer can reveal current settings.

For all generators, calling the manufacturer remains the most reliable method for determining magnet response and for using this response to predict remaining battery life (telephone numbers for the device manufacturers are shown in Appendix 48-1). As battery voltage falls, the magnet response can be used to detect the following:

Intensified follow-up interval (IFI) or elective replacement near (ERN): The device must be checked frequently (approximately every 4 weeks for most models).
Elective replacement indicator (ERI) or elective replacement time (ERT): The device is nearing the end of its useful life and should be electively replaced.
End of life (EOL): The device has insufficient battery power remaining and should be replaced immediately.

On application of a magnet, some devices perform a threshold margin test (TMT). In this test, one of more of the PM pulses is reduced in amplitude, pulse width, or both, in an attempt to gauge the safety margin for pacing voltage. Loss of capture on these TMT pulses indicates an inadequate safety margin for pacing (Fig. 48-5). Some devices from St. Jude Medical (formerly Pacesetter) with the Siemens "Vario" feature reduce the ventricular pacing energy over 16 cycles to demonstrate the pacing threshold. As a result, many pacing cycles can take place at insufficient energy for ventricular capture, and this can produce periods of asystole while the magnet is applied.[41]

Occasionally, PM-mediated tachycardia (PMT) can ensue on removal of the magnet from a dual-chamber PM (Fig. 48-6). These cases of PMT result from P waves conducted in retrograde fashion during asynchronous ventricular pacing, most commonly when the magnet rate is lower than the patient's intrinsic rate. PMT from retrograde AV nodal conduction also can occur in any DDD or VDD pacing device following EMI, premature ventricular contraction, or a noncaptured atrial pace. When present, retrograde P waves can be "tracked," typically resulting in ventricular pacing at the UTR. Each paced ventricular cycle results in another retrograde P wave, thereby producing tachycardia. Should this behavior be observed in a conventional PM, it can be treated by application, then removal, of the magnet provided the PM has asynchronous pacing with magnet application. Magnet application does not terminate PMT in an ICD.[42] Most CIED devices can be programmed to recognize these cases of PMT and periodically omit one ventricular pacing pulse, or lengthen one AV delay cycle, during UTR pacing.

In addition, as noted previously, the patient with a dual-chamber device that has detected a high atrial rate and "mode-switched" to prevent UTR pacing could have the mode switch reset on application and removal of the magnet. These patients then undergo UTR pacing until criteria are met to return to the mode-switch mode. Distinguishing PMT caused by retrograde P waves from UTR pacing resulting from high atrial rates (before mode-switch entry) can be very difficult. In general, however, mode-switch secondary to rapid atrial rates takes place within 10 to 15 seconds, and PMT from retrograde P waves is quite persistent.

PREANESTHETIC EVALUATION AND PACEMAKER REPROGRAMMING

Preanesthetic management of the patient with a PM includes evaluation and optimization of coexisting disease (see also Chapter 39). American College of Cardiology (ACC) guidelines suggest that cardiac testing (stress tests, echocardiograms) should be dictated by the patient's underlying diseases, medications, symptoms, interval from the last testing, and planned intervention.[43]

No special laboratory tests or radiographs are needed for the patient with a conventional PM. Chest radiographs rarely depict lead problems, and a standard chest radiograph may exclude the generator or its markings. Furthermore, most radiologists are unfamiliar with pacing issues.[44] However, a patient with a CRT device may need a chest radiograph to document the position of the CS lead, especially if central line placement is planned. CS leads have no fixation and may be more easily dislodged than a standard PM or ICD lead. Spontaneous LV dislodgment likely occurs in at least 4.7% of patients,[45] at a rate of 2.3% annually.[46]

Important features of the preanesthetic device evaluation are shown in Appendix 48-2. The ASA advisory recommends a recent PM interrogation; the other 3 advisories recommend contact with the patient's CIED physician and clinic. However, in abstract form, Rozner and associates reported more than 30% noncompliance with in-person follow-up guidelines in 161 consecutive preoperative patients, as well as the need to replace 5% of PMs preoperatively for battery depletion.[47] Remote evaluation provides some assurance of battery longevity, but it does not provide rigorous evaluation of the pacemaking system.

TABLE 48-3 **PACEMAKER MAGNET BEHAVIOR***

Pacemaker Company		Magnet Mode Designation	Explanation
Biotronik (except INOS and DROMOS)		AUTO	In normal operation, 10 asynchronous events at 90 beats/min, then returns to original programmed mode, without rate responsiveness. Pacing is at lowest available rate (LRL, sleep rate, or hysteresis rate). If battery at ERI, 10 asynchronous events at 80 beats/min in VOO mode, then either VDD (dual-chamber) or VVI (single-chamber) pacing at 11% lower than lowest available rate. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place.
		ASYNCH	Asynchronous pacing at 90 beats/min in normal operation. At ERI, 80 beats/min (single-step change) in VOO mode regardless of original programming. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place.
		SYNCH	In normal operation, pacing in original programmed mode, without rate responsiveness. Pacing is at lowest available rate (LRL, sleep rate, or hysteresis rate). If battery at ERI, then either VDD (dual-chamber) or VVI (single-chamber) pacing at 11% lower than lowest available rate. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place.
Boston Scientific/Guidant Medical/CPI (Cardiac Pacemakers, Inc.)		ASYNCH	Asynchronous pacing at 100 beats/min in normal operation, 85 beats/min at ERT (single-step change). Insignia and all "BOS" label devices have an intermediate step (90 beats/min) at ERN. For Triumph and Prelude models, see Medtronic pacemakers, below. Insignia and all "BOS" label devices emit a reduced 3rd pacing pulse (on ventricular lead for dual chamber devices) to demonstrate adequacy of pacing output.
		OFF	No change, magnet is ignored. OFF is the magnet mode after a "power on reset," which can occur secondary to EMI.
		EGM mode	No change in pacing. Magnet application initiates data collection.
Sorin (formerly ELA Medical)			Asynchronous pacing at 96 beats/min gradually declining to 80 beats/min at ERI. Sorin pacemakers take 8 additional asynchronous pacing cycles (the final 2 cycles are at LRL with long atrioventricular delay) on magnet removal.
Medtronic			Asynchronous pacing at 85 beats/min in normal operation, 65 SSI regardless of original programming if ERI (single-step change). Most Medtronic pacemakers emit one or more ventricular pulses during the first 3-7 asynchronous events (which may be at a rate of 100 beats/min) at a reduced pulse width or voltage to demonstrate adequacy of ventricular pacing output. A Medtronic dual-chamber pacemaker will revert to single-chamber, ventricular-only behavior on detection of ERI regardless of prior programming. Such behavior could result in hemodynamic embarrassment in a patient with sinus node disease and a bad ventricular lead.
St. Jude Medical (not including Telectronics)	"SJM" x-ray logo	Battery Test	Asynchronous pacing at 98.6 (100 for Accent/Anthem series) beats/min gradually decreasing to 86.3 or less beats/min at ERI.
		OFF	No magnet response.
		Event snapshots	No change in pacing. Magnet application causes pacemaker to collect data. Identity and Entity models lack this feature.
		Event snapshots + Battery Test	For a magnet placed 2 seconds, pacing mode and rate are unchanged, and the device stores an electrogram. If the magnet is placed ≥5 seconds, the Battery Test mode (see earlier) is activated. Identity and Entity models lack this feature.
	Pacesetter x-ray logo (ψ)	Battery Test	Asynchronous pacing and the rate depends on specific model. In general, a pacing rate of less than 90 beats/min should prompt further evaluation.
		OFF	No magnet response.
		VARIO mode (present in some models)	VARIO results in a series of 32 asynchronous pacing events. The rate of the first 16 paces reflects battery voltage, gradually declining from 100 to 85 beats/min at ERI. The next 15 paces are used to document ventricular pacing capture safety margin. The rate will be 119 beats/min with gradually declining pacing voltage. The sixteenth pace of this group is at no output. The next pace restarts the 32-event sequence. The 32-event sequence repeats as long as the magnet remains in place.

AV, Atrioventricular; *EGM,* electrogram; *EMI,* electromagnetic interference; the device should be replaced immediately; *ERI,* elective replacement indicator; the device should be replaced promptly; the FDA requires pacemakers to perform safely for at least 3 months from onset of ERI; *ERN,* elective replacement near; the device should be undergoing monthly checks (same as IFI); *ERT,* elective replacement time (same as ERI); for Boston Scientific/Guidant/CPI, at ERT rate-responsive programming is cancelled; at 3 months after ERT, only single-chamber operation continues; the device needs monthly battery checks; *LRL,* lower rate limit; the programmed lower rate, or set point, of the pacemaker; *SSI,* single-chamber, inhibited mode; if implanted for ventricular pacing, SSI = VVI; if implanted for atrial pacing, SSI = AAI.

*The effects of appropriately placing a magnet over a pacemaker are shown. Column 1 shows the pacemaker manufacturer. If the magnet response is programmable, then column 2 shows the various programmable modes available. The first mode shown for a company is the default mode. Column 3 shows the effect on pacing therapy for the magnet mode shown in column 2. Unless otherwise specified, asynchronous pacing takes place, without rate responsiveness, in the chambers originally programmed. Thus, a dual-chamber program would result in DOO pacing, and a single-chamber program would result in VOO (ventricular) or AOO (atrial) pacing, and a biventricular, dual-chamber device would be DOOOV.

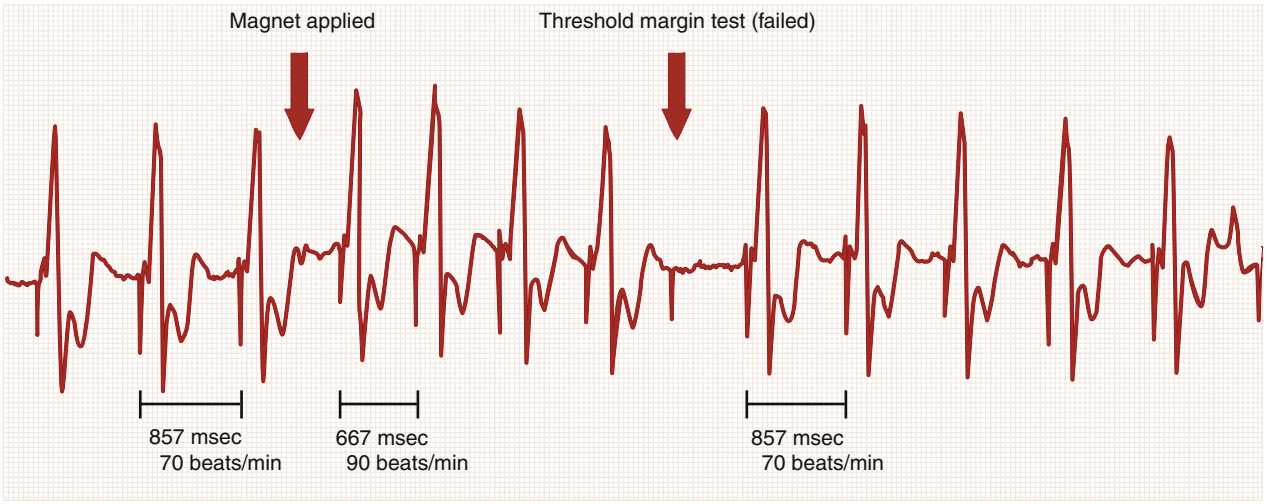

Figure 48-5. Threshold margin test (TMT) demonstrating an inadequate safety margin for pacing. Application of a magnet to some pacemakers produces asynchronous pacing in which one or more pacing stimuli are emitted with reduced ventricular pacing voltage, pulse width, or both. This sequence is used to determine, without formal pacemaker interrogation, the adequacy of pacing energy settings. In this electrocardiographic strip from an Intermedics device, the patient was being paced in the VVI mode at a rate of 70 beats/minute (equal to 857-msec intervals). On application of the magnet, this pacemaker produced four intervals (five pacing stimuli) of asynchronous pacing at a rate of 90 beats/minute (667-msec intervals), thus demonstrating adequate battery voltage for this device (pacemaker response to magnet placement depends on the manufacturer and sometimes the programming). At the fifth pacing stimulus after magnet application, the pacemaker performed a TMT by reducing the stimulus pulse width to 50% of the programmed value (equal to 50% of programmed energy). Failure of this stimulus to produce ventricular systole (i.e., failure to capture) demonstrates a dangerously low safety margin for ventricular pacing because pacing pulse width should be at least three and generally four times the threshold for capture. After these five initial stimuli, Intermedics pacemakers then pace asynchronously at the programmed lower rate (70 in this case) for 60 additional cycles. On completion of these 64 cycles (65 stimuli), Intermedics pacemakers return to programmed values and ignore the magnet.

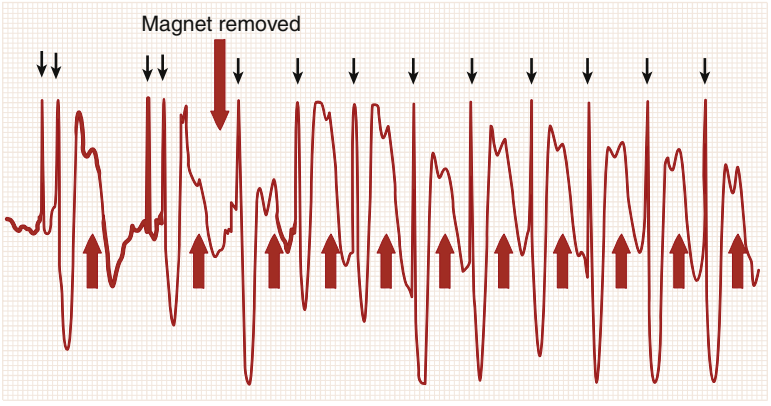

Figure 48-6. Pacemaker-mediated tachycardia (PMT) after removal of the magnet from a pacemaker. This patient had a dual-chamber pacemaker implanted for atrioventricular (AV) nodal disease, and she was pacemaker dependent for ventricular activity. She had a sinus rate of 75 beats/minute before application of the magnet with appropriate ventricular pacing (strip not shown). Her programmed AV delay was 200 msec. With magnet application, her pacemaker produced asynchronous AV sequential pacing (DOO mode) at a rate of 60 beats/minute. This strip is from an electrocardiographic recorder that enhances the pacemaker artifact indicated by *black, downward arrows*. Because the asynchronous "magnet" rate of this device was lower than her intrinsic atrial rate, many of the atrial pacing stimuli were applied during an atrial refractory period (called functional noncapture). A consequence of atrial noncapture can be retrograde AV nodal conduction with depolarization of the atria after depolarization of the ventricle or ventricles. The retrograde P waves are shown with the *red upward arrows*. While the magnet is applied, this retrograde depolarization of the atria is ignored. Shortly after the magnet was removed (shown), a paced ventricular event occurred, followed by retrograde AV nodal conduction. With the ensuing depolarization of the atria from this retrograde conduction, the pacemaker sensed an atrial event and responded by pacing the ventricle 200 msec later. Yet another retrograde P wave appears, and each ventricular pace in response to a retrograde P wave created yet another ventricular pace. The result is PMT at the upper tracking rate (programmed here to 130 beats/minute) of the pacemaker. PMT from retrograde AV nodal conduction can occur in any DDD or VDD device with magnet removal, a premature ventricular contraction, or a noncaptured atrial pace. Treatment of this PMT should be reapplication of the magnet. Some pacemakers can be programmed to eventually delay one AV cycle when pacing at the upper tracking limit to "break" PMT. Magnet application is ineffective in PMT in a patient with an ICD.

BOX 48-3 *Situations Probably Requiring Pacemaker Reprogramming**

Any rate-responsive device (see text; problems are well known,[121,122] and they have been misinterpreted, with the potential for injury to the patient[55,59,63,67]; the Food and Drug Administration has issued an alert regarding devices with minute ventilation sensors[65] [see Box 48-4])
Special pacing indication (hypertrophic obstructive cardiomyopathy, dilated cardiomyopathy, pediatric patients)
Pacing-dependent patient
Major procedure in the chest or abdomen
Rate enhancements present that should be disabled
Special procedures (see text)
- Lithotripsy
- Transurethral resection
- Hysteroscopy
- Electroconvulsive therapy
- Succinylcholine use
- Magnetic resonance imaging (generally contraindicated by device manufacturers)[123]

*In some situations and for certain patients, a cardiac implanted electronic device should be reprogrammed either to avoid potential injury to the patient or to prevent a pacemaker rhythm that could be confused with pacing system malfunction.

BOX 48-4 *Pacemakers With Minute Ventilation (Bioimpedance) Sensors**

Tempo (1102, 1902, 2102, 2902)

*Pacemakers with minute ventilation (bioimpedance) sensors frequently respond to electromagnetic interference (EMI) with pacing at the upper sensor rate.[63,67] These tachycardias also can be produced by connection to an operating room electrocardiographic monitor because many of these devices inject electrical signals through the electrocardiographic leads to determine respiratory rate or lead disconnection.[62,64] In 1998, the U.S. Center for Devices and Radiologic Health issued a safety alert calling for the deactivation of any minute ventilation (bioimpedance) sensor before exposing a patient to a potential source of EMI or connection to medical devices.[65]

For PMs, interrogation with a programmer remains the most reliable method for evaluating battery voltage, battery impedance, lead performance, and adequacy of current settings. Special attention should be paid to patients from countries where CIEDs may be reused, because of possibly increased malfunction rates.[48] For any PM with a battery voltage less than 2.6 volts or battery impedance (where available) greater than 3000 ohms, the company should be consulted about the possible need for elective replacement of the device preoperatively.

Appropriate reprogramming is the safest way to avoid intraoperative problems, especially for pacing-dependent patients in whom EMI (most commonly monopolar "Bovie" electrosurgery) will be present (Box 48-3). Assistance may be available from the PM manufacturers (see Appendix 48-1 for company telephone numbers). However, interrogation of any generator with or without reprogramming requires a medical prescription and supervision by an appropriately trained physician.[9,49] Hospital guidelines and policy should reflect the need for a competent physician to review and validate any care delivered by a company representative.

Reprogramming a PM to asynchronous pacing at a rate greater than the patient's underlying rate usually ensures that no oversensing during EMI will take place, thus protecting the patient. However, in one case report, a Telectronics device opened its output circuitry (i.e., no pacing stimuli were delivered) in the presence of high-voltage EMI.[50] Furthermore, at our institution, two PMs in the DOO mode dropped their rate during use of monopolar coagulation ESU, presumably because of high battery current drain.

Reprogramming a device *will not* protect the device from internal damage or reset caused by EMI. Additionally, setting a device to asynchronous mode causes the PM to ignore premature atrial or ventricular systoles, which could lead to R-on-T pacing and malignant rhythm, especially in the patient with significant structural compromise of the myocardium.[51,52]

In general, rate responsiveness and other "enhancements" (e.g., atrial fibrillation suppression, hysteresis, managed ventricular pacing, sleep rate, AV search) should be disabled by programming to prevent misinterpretation of the cardiac rhythm.[53-55] Older reports of pacing threshold changes during both intrathoracic[56] and nonchest surgical procedures,[57] as well as significant noncardiac acute disease,[58] drive the issue of postoperative pacing threshold testing in nonautomated devices.

Special attention must be given to any device with a minute ventilation (bioimpedance) sensor because inappropriate tachycardia has been observed secondary to mechanical ventilation,[27,59] monopolar "Bovie" electrosurgery,[59-61] and connection to an ECG monitor with respiratory rate monitoring[62-67] (Box 48-4). Sometimes, this PMT has led to inappropriate, unsuccessful pharmacologic treatment of the tachycardia,[27] with injury to the patient.[26]

INTRAOPERATIVE (OR PROCEDURE) MANAGEMENT OF PACEMAKERS

Although no special monitoring or anesthetic technique is required for the patient with a cardiac generator, attention must be given to several concerns (see also Chapters 45 and 67).

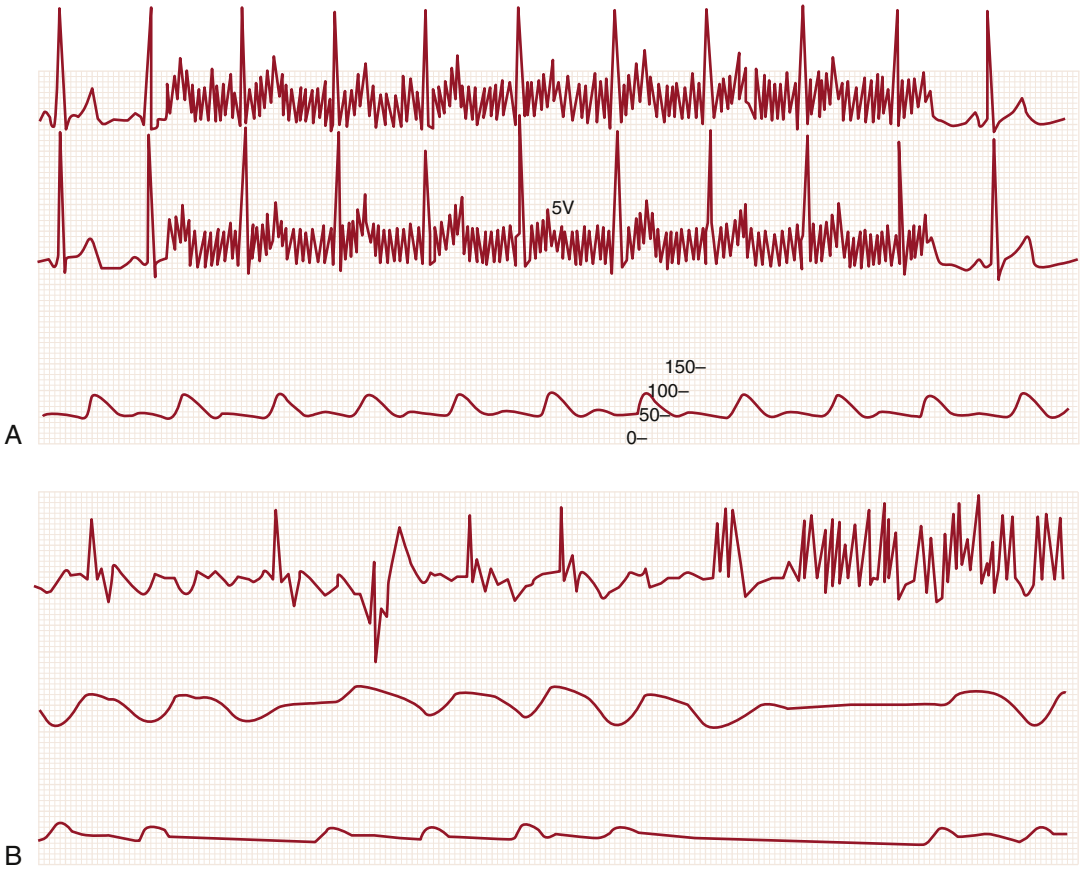

Figure 48-7. Disabling the pacemaker artifact filter on a digitally processed electrocardiographic (ECG) monitor results in the "painting" of environmental noise (electromagnetic interference [EMI]) as pacemaker artifacts. **A,** Effects of "cut" monopolar electrosurgical unit (ESU) application. Because the patient's underlying rate exceeded the pacemaker's programmed lower rate limit, no pacing took place. However, activation of the ESU in the "cut" mode produced sufficient electromagnetic noise that the monitor began "painting" pacemaker artifacts at a rate of approximately 20 Hz. The *top tracing* is the ECG lead II, the *middle tracing* is ECG lead V_5, and the *bottom tracing* is the invasive arterial pressure waveform. **B,** The effects of "Coagulation" ESU application produced ventricular oversensing with pacemaker inhibition and left this patient with compromised cardiac output. Evidence also shows inappropriate monitor "painting" of pacemaker artifacts from the EMI. The *top tracing* is ECG lead II, the *middle tracing* is the pulse oximeter plethysmogram, and the *bottom tracing* is the invasive arterial pressure waveform. *(From Rozner MA: Review of electrical interference in implanted cardiac devices,* Pacing Clin Electrophysiol *26:923-925, 2003.)*

First, ECG monitoring of the patient should include the ability to detect pacing discharges. Currently, most ECG monitors in both the operating room and the intensive care unit perform digital acquisition and analysis of ECG signals, and they are subject to considerable interference from a variety of sources.[68] In their default settings, these monitors often filter high-frequency signals, thus resulting in the exclusion of pacing artifacts. Disabling this filtering causes the monitor to "paint" pacing spikes onto the display. Even with the filtering disabled, however, pacing artifacts do not always appear because modern leads may accomplish pacing with very low-amplitude pulses. Moreover, given that many digital monitors analyze only one lead for these signals (and then "paint" on artifacts on every lead), placement of the ECG leads can markedly affect the detection axis.[¶] In practice, when a patient with known pacing is monitored, sometimes changing the "analysis" lead on the monitor results in the appearance of pacing signals. Unfortunately, when the high-frequency filter is disabled, EMI, especially from the use of the monopolar ESU, can lead to inappropriate "painting" of pacing artifacts on the monitor (Fig. 48-7).[17,69]

Second, monitoring of the patient must include the ability to ensure that paced electrical activity is converted to mechanical systoles. Mechanical systoles are best evaluated by pulse oximetry plethysmography or arterial pressure waveform display.[14,49]

Third, published perioperative experience with CRT pacing remains limited. These patients often have ejection fractions less than 30%, and they depend on pacing in both ventricles to improve their cardiac output. Loss of ventricular pacing from any cause (e.g., AV dyssynchrony [atrial fibrillation, atrial flutter, appearance of junctional rhythm], myocardial ischemia, acid-base disturbance, change in pacing threshold, ESU interference) can cause an immediate decrease in cardiac output. With the exception of transesophageal echocardiography, no beat-to-beat monitoring of cardiac output has demonstrated any utility in detecting loss of LV capture. Patients with HOCM pacing can depend on ventricular pacing to limit LV outflow tract obstruction.

¶Most monitors manufactured since 2005 have much improved capability to detect and display pacing artifacts, although they still filter these high-frequency signals in their default setup mode.

Fourth, some patients may need an increased pacing rate during the perioperative period to meet an increased oxygen demand. This subject is often not addressed. PM-treated patients reportedly have high postoperative morbidity and mortality,[70] and failure to address tissue oxygen demands and cardiac output needs could contribute to this problem.

Fifth, appropriate equipment must be on hand to provide backup pacing and defibrillation if needed. Cardiac generators, although hardy, occasionally perform some untoward maneuver or fail, even in the absence of EMI.[71] Acceptable but inappropriate behavior of a PM or ICD can create an inhospitable situation. Even a properly working, dual-chamber PM can produce R-on-T pacing and ventricular tachycardia (VT), especially in the setting of a junctional rhythm or PVCs (Fig. 48-8).

The medical team caring for the patient with an implanted cardiac PG must understand that the patient has been deemed needy of this device by a physician who is an expert in the diagnosis and management of cardiac rhythm issues. Few anesthesiologists are qualified to contradict this diagnosis, yet some persist in providing anesthesia without appropriate backup pacing and defibrillation equipment on hand.

Monopolar "Bovie" ESU use remains the principal intraoperative issue for the patient with a PM. Between 1984 and 1997, the FDA was notified of 456 adverse events with PGs, 255 from electrosurgery or external defibrillator, and a "significant number" of device failures.[72] Monopolar ESU is more likely to cause problems than bipolar ESU, and PMs with unipolar electrode configurations are more sensitive to EMI than are PMs with bipolar configurations.[73] The most common effect of ESU on pacing function is ventricular oversensing, which causes pacing inhibition (see Fig. 48-7, *B*). Sometimes, the generator detects significant EMI and begins pacing asynchronously at the programmed lower rate. This behavior is called noise or reversion mode pacing, even though the PM does not actually change modes. Noise reversion is not present in some ICDs and is programmable in others.

Magnet placement during electrosurgery may prevent aberrant PM behavior. Newer generators are believed to be relatively immune to spurious reprogramming from EMI, although they can undergo a reset condition that will likely alter the programmed settings.[49,74,75]

If monopolar ESU is to be used, then the electrosurgical dispersive electrode (often misidentified as the "grounding pad") must be placed to ensure that the ESU current path does not cross the pacemaking system. Some authors recommend placement of this electrode on the shoulder for head and neck procedures or the distal arm (with sterile draping of the wire) for breast and axillary procedures.[73,76] Procedures using only monopolar ESU or with special EMI pacing ramifications include the following:

Electroconvulsive Therapy: This treatment may require nonsensing (asynchronous) mode to prevent myopotential-induced oversensing with resultant PM inhibition.[77]

Lithotripsy: The cardiac generator must be excluded from the lithotripter field. If the lithotripter triggers its output on the sensed ECG "R" wave, atrial pacing should be disabled to prevent the lithotripter from inappropriately firing on the atrial pacing artifact (see Chapter 72).

Magnetic resonance imaging (MRI): MRI requires special expertise, including the ability to immediately reprogram a CIED. The literature reports that MRI exposure can lead to magnet switch closure (magnet mode activation), CIED reprogramming, inappropriate high-rate pacing, generator damage, myocardial injury, lead failure, or arrhythmia. Except for CIED resets to safety parameters,[75] no significant complications have been reported, even in large series.[78] On February 8, 2011, the FDA approved a Medtronic PM with MRI-conditional labeling; conditions include MRI energy limitations, a requirement for ECG and pulse oximeter plethysmography monitoring, completion of cardiac monitoring and radiology training, and peri-MRI scan reprogramming.[79] Medtronic has introduced a "second-generation" MRI-conditional PM into the U.S. market with similar conditions but with automated testing and reporting features Only PMs from Medtronic have MRI labeling in the United States at this time, but Biotronik (ICD and PM), BOS (PM), and St. Jude Medical (PM) have received MRI labeling in other countries.

Nerve stimulator testing or therapy: Nerve stimulators can cause PM oversensing, with resultant PM inhibition[80] and cardiac arrest.[81] Nerve stimulators have been used intraoperatively to inhibit undesired cardiac pacing[25] or arrest the cardiac rhythm for endovascular stent placement.[82] In patients with an ICD, inappropriate detection of neuromuscular stimulators, transcutaneous electrical nerve stimulation, and chiropractic electrical muscle stimulation as VT or VF has been reported.[83,84] Nerve stimulators can also interfere with ECG monitoring of PM artifacts.[69] As with ESU current, the electrical path for nerve stimulator current should not cross the generator system or the chest (see also Chapter 53).[85]

Radiofrequency ablation: Noncardiac radiofrequency ablation, especially when kept inferior to the umbilicus, behaves primarily like unblended "cut" monopolar ESU. Although problems seem to be rare, the HRS recommends postoperative interrogation before discharge from cardiac monitoring.[49]

Succinylcholine or etomidate use: Reports of myopotential problems on administration of succinylcholine[86] or etomidate[87] have been described (see also Chapters 30 and 34). In the succinylcholine case, muscle fasciculations may have caused ventricular oversensing with resultant PM inhibition, but the case is difficult to interpret. No ECG tracings were published, and the PM was damaged during subsequent defibrillation. Using programmers, I have witnessed succinylcholine administration to more than 50 patients with PMs or defibrillators without finding any myopotential oversensing. The etomidate issue is also questionable because the particular PM had other issues.[88] However, myopotential oversensing (in the absence of succinylcholine) has been observed to interfere with PM function[89] or cause inappropriate ICD therapy (see also Chapter 34).[90]

Transurethral resection and uterine hysteroscopy: Transurethral resection of the bladder or prostate and hysteroscopic procedures generally use monopolar ESU, and device reprogramming may be needed to

Figure 48-8. Normal dual-chamber pacemaker timing can produce R-on-T pacing. **A,** This strip demonstrates functional ventricular undersensing of a premature ventricular contraction (PVC) with resultant R-on-T pace leading to torsades de pointes in a normally functioning, appropriately programmed pacemaker (PM). This patient had a dual-chamber PM in the DDD mode with a programmed lower rate of 70 beats/minute (R-R interval of 857 msec) and atrioventricular (AV) delay of 200 msec. With these parameters, the pacemaker will pace the atrium 657 msec after any previous ventricular event. Atrial pacing is labeled A, and ventricular pacing is labeled V. The *top tracing* is electrocardiographic (ECG) lead II, the *middle tracing* is ECG lead V_5, and the *bottom tracing* is the invasive arterial blood pressure waveform. Approximately 660 msec after the first QRS complex (*1*) on the strip (which was adequately sensed by the pacemaker), an atrial stimulus was emitted. At 200 msec after this atrial pace, a ventricular stimulus was emitted and appeared to depolarize the ventricle (*2*). Approximately 660 msec later (3), the patient experienced a PVC. Because the pacemaker was preparing to emit the atrial stimulus, it had disabled its ventricular sensing element (called post atrial ventricular blanking, see also Figure 48-13) and failed to sense this PVC (termed functional undersensing). At 200 msec after the atrial stimulus, no ventricular event had been sensed, so the pacemaker emitted a ventricular stimulus on the T wave. Because the ventricle was in a refractory period from the PVC, no depolarization of the ventricle occurred (called functional noncapture). At 660 msec from this attempted V-pace, the pacemaker again paces the atrium (*4*), and it appears that the next V-pace captures the ventricle. At point *5,* a repeat of the events at point *3* occurs (i.e., the pacemaker disabled its sensing elements in preparation to pace the atrium and again failed to detect the PVC). This time, however, the V-pace on the T wave produced torsades de pointes. **B,** This strip was obtained from a Medtronic programmer during interrogation of a Kappa 700 dual-chamber pacemaker. The *top tracing* is ECG lead II, and the *bottom tracing* is the "marker channel," which shows the pacemaker's interpretation of events. This pacemaker was programmed to the DDD mode with a lower rate of 60 beats/minute. The AV delay was 200 msec. As a result, after any ventricular event, the pacemaker will emit an atrial pulse at 800 msec if no intervening atrial or ventricular event takes place. This patient had junctional rhythm at 75 beats/minute (corresponding to an R-R interval of 800 msec), so the pacemaker emitted an atrial pulse just as the junctional event occurred. Because the pacemaker disables its ventricular sensing element when emitting the atrial pulse, it failed to detect the ventricular event and emitted the ventricular pulse 200 msec later, on the T wave. This inappropriate pacing takes place every other cycle because every other junctional event is sensed approximately 600 msec after the previous ventricular pace. Decreasing the AV delay diminishes the likelihood of pacing during the vulnerable period of the ventricle. AP is an atrial pace, VP is a ventricular pace, and VS is a ventricular sensed event. The third complex deserves comment. The pacemaker sensed this ventricular event as it re-enabled its sensing element, and the pacemaker cannot tell whether the sensed event is a true ventricular depolarization or an "echo" of the atrial pace. When a signal from the ventricle is sensed within 30 to 90 msec after an atrial pace, many CIEDs immediately emit a ventricular pacing stimulus. Called a ventricular safety pace, this pacing stimulus is designed to protect the patient from inappropriate sensing of the atrial signal by the ventricular channel, which would then inhibit the ventricular output. The safety pace is emitted at 110 msec to prevent R-on-T pacing. This feature is also called nonphysiologic AV delay by some manufacturers. R-on-T pacing can be appropriate (but not ideal) behavior of a DDD or DDI pacemaker in the setting of PVCs, as well as a junctional rhythm. It can also be seen with atrial or ventricular undersensing.

prevent PM oversensing with resultant PM inhibition. A resectoscope that includes the current-return electrode on the shaft (the irrigation medium is normal saline) could limit EMI to the generator but has not been carefully tested in this environment.

PACEMAKER FAILURE

PM failure has three causes: (1) generator failure, (2) lead failure, or (3) failure of capture. Generator failure is rare in a device that has been previously evaluated and not near the end of its useful battery life, unless the generator (or leads) is struck directly by the ESU. Lead failure, also unusual but reported during patient repositioning,[91] can result in undersensing (intrinsic activity is not detected), oversensing ("detection" of events unrelated to intrinsic activity), or failure to deliver sufficient energy to the myocardium to produce a depolarization (loss of capture). Myocardial changes that lengthen the refractory period or increase the energy requirement for depolarization (failure to capture) can result from myocardial ischemia or infarction, acid-base disturbance, electrolyte abnormalities, or abnormal antiarrhythmic drug levels.

The response to PM failure depends on the clinical situation. A patient with a perfusing rhythm and stable vital signs can be observed while a plan is made to correct the problem. For a patient with inadequate perfusion, the following steps can be tried (while cardiopulmonary resuscitation is in progress when appropriate):

1. A magnet can be applied if the PM is known to revert to an asynchronous mode, which will also eliminate sensing behavior in these devices. Magnet application may add to the hemodynamic embarrassment in the setting of inadequate pacing safety margins[52] or the onset of automated TMT.[39]
2. Temporary pacing can be initiated, and it can be transthoracic (transcutaneous), transvenous, or transesophageal. Transesophageal (atrial) pacing requires a functional atrium and AV node for ventricular activation, so it is contraindicated in patients with atrial fibrillation or flutter. It is also generally contraindicated in the presence of a permanent PM (or ICD). In the setting of external pacing, the ECG can be misinterpreted because the PM artifacts are large compared with the QRS complexes (Fig. 48-9, *A*). Successful ventricular pacing has been reported with transesophageal PMs, but it remains unreliable,[92] and it produces inferior hemodynamics compared with atrial pacing (Fig. 48-9, *B*). Any external pacing may further inhibit PM output at energies that do not produce myocardial capture.[93]
3. Sympathomimetic drugs can be administered to decrease depolarization threshold or increase heart rate, or both. Epinephrine (0.5 to 1 μg/minute) or dopamine (5 to 20 μg/kg/minute) should be considered. Isoproterenol (0.5 to 10 μg/minute) is often recommended, but this drug is not widely available, and its use may produce hypotension. Atropine may be helpful.
4. Causes of myocardial ischemia should be sought and corrected. Myocardial ischemia can substantially increase the energy required for ventricular capture.[94]
5. Disturbances of electrolyte balance, antiarrhythmic drug levels, and acid-base equilibrium should be investigated and corrected. Potassium, calcium, and magnesium abnormalities, as well as amiodarone, can raise depolarization thresholds. Moreover, potassium flux, ionized calcium level, and acid-base equilibrium can be affected by hyperventilation and hypoventilation.
6. If none of the foregoing measures succeed, consideration should be given to placement of epicardial leads by the surgical staff.

POSTANESTHESIA PACEMAKER EVALUATION

A PM that was reprogrammed for the perioperative period should be reset appropriately. For nonreprogrammed devices, the performance and timing of a postoperative interrogation will depend on the nature of the case and the CIED team caring for the patient. Certainly, interrogation is warranted if any issues appear. Consideration should be given to increasing the lower paced rate in a chronotropically incompetent patient if increased cardiac output will benefit the patient during convalescence.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

The development of an implantable, battery-powered device able to deliver sufficient energy to terminate VT or ventricular fibrillation (VF) represents a major medical breakthrough for patients with a history of ventricular tachydysrhythmias. These devices reduce deaths in the setting of malignant ventricular tachydysrhythmias,[95,96] and they have been long considered superior to antiarrhythmic drug therapy.[97] Initially approved by the FDA in 1985, more than 120,000 devices will be implanted in the United States this year, and industry sources report that more than 300,000 patients have these devices today. Furthermore, results from the Sudden Cardiac Death–Heart Failure Trial (SCD-HeFT, which showed that prophylactic placement of an ICD is superior to drug therapy in any patient with an ejection fraction <0.35 and *without* evidence of arrhythmic inducibility) led to a significant increase in the number of patients for whom ICD therapy is indicated.[98]

Numerous technologic advances have been applied since the first ICD was placed, including substantial miniaturization (pectoral pocket placement with transvenous leads is the norm), as well as battery improvements that now permit permanent pacing with these devices. Thus, one could easily confuse a pectoral T-ICD with a PM.

Like PMs, ICDs have a four-place generic code (NBD[¶]) to indicate lead placement and function, as shown in Table 48-4.[99] The most robust form of identification, the label form, expands the fourth character into its component generic PM code (NBG).

[¶]The NBD code is a joint project from NASPE (the "N") and BPEG (the "B"). The "D" stands for defibrillator.

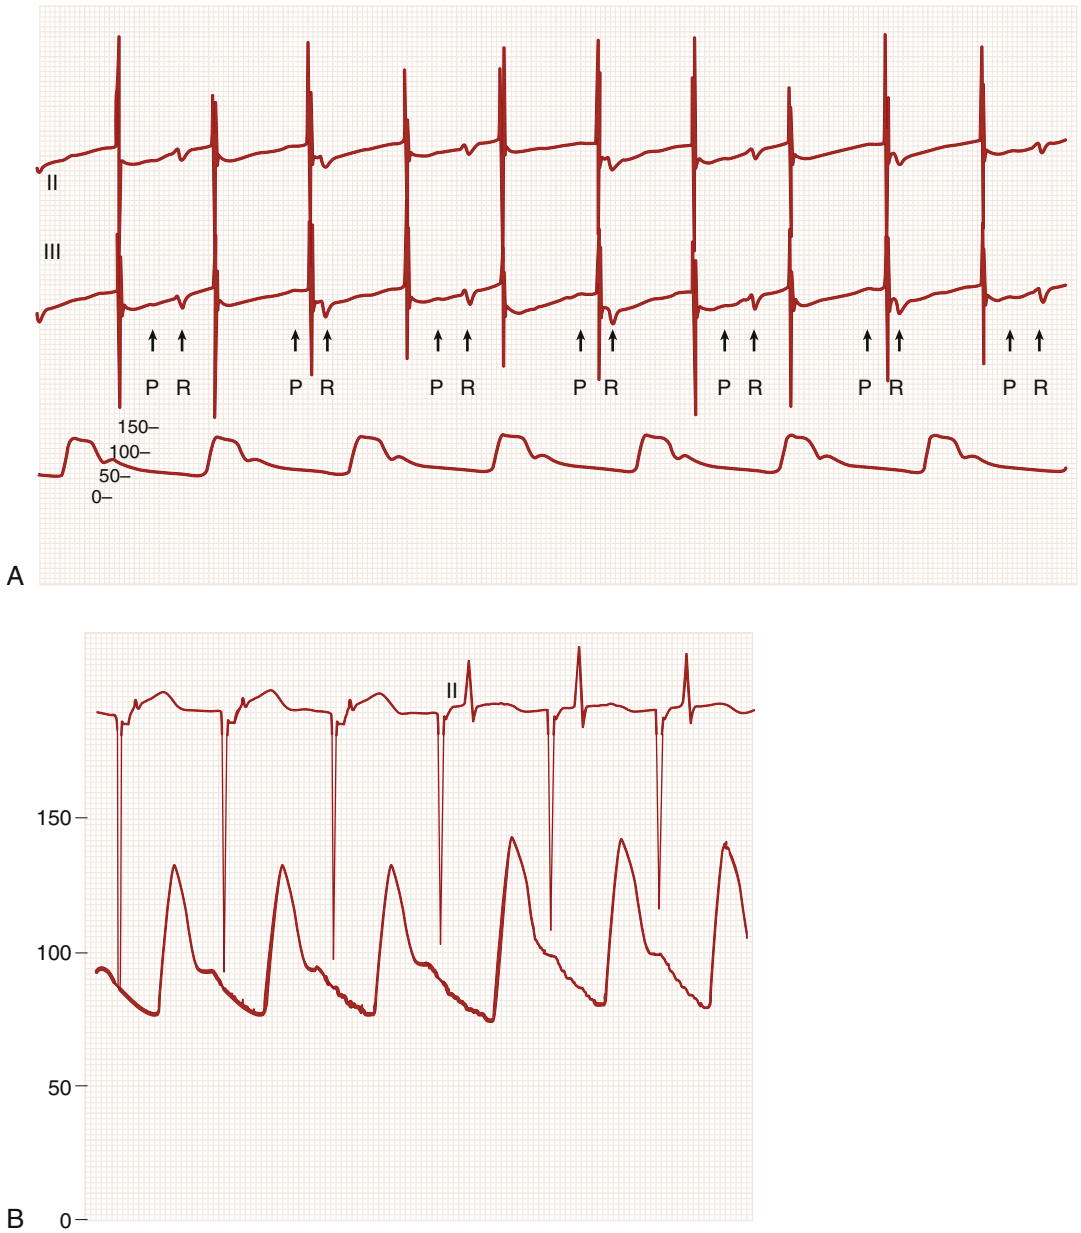

Figure 48-9. Issues with a transesophageal atrial pacemaker (TAP). **A,** Improper placement of a TAP demonstrating atrial noncapture. The *top recording* is electrocardiographic (ECG) lead II, the *middle recording* is ECG lead III, and the *bottom recording* is the invasive arterial pressure waveform. Sinus bradycardia with evidence of tissue underperfusion developed in this 72-year-old man. A TAP (CardioCommand, Tampa, Fla.) was placed, and the large ECG artifacts at 75 beats/minute were misinterpreted by personnel and by the ECG monitor as ventricular systoles (capture). This strip shows an underlying sinus rate of 50 beats/minute with a first-degree atrioventricular block (PR interval of 280 msec). The patient's native atrial (P) and ventricular (R) depolarizations are noted. The arterial pressure waveform confirms pacing noncapture. **B,** Direct ventricular activation with a transesophageal pacemaker. The *top recording* is ECG lead II, and the *bottom recording* (enhanced vertical scale) is the invasive arterial pressure waveform. This strip is from an obese 61-year-old woman with diabetes and hypertension who was undergoing transsphenoidal hypophysectomy. Shortly after induction of anesthesia, sinus bradycardia at 37 beats/minute and mild hypotension developed. A transesophageal pacemaker was placed but was advanced too far into the esophagus. This strip was recorded during "pullback." The ventricle was directly activated in the first four events, with a resultant wide-complex QRS and average blood pressure of 135/75 mm Hg. On pullback, the atrium was activated, the QRS returned to a narrow complex, and blood pressure increased to 143/80 mm Hg. Except for the bradycardia, this patient had a normal heart and did not have a permanently placed generator.

The Cameron Health–BOS S-ICD system consists of a PG implanted along the lateral chest wall with a single lead tunneled subcutaneously to the area superficial to the heart (Fig. 48-10). The principal advantage of the S-ICD implant is the ability to implant the device without gaining central venous access. The principal disadvantages include the inability to use the S-ICD to provide bradycardia support, the lack of ATP features, higher energy defibrillation thresholds (DFTs), larger size, and shorter battery life than a single-chamber T-ICD. Approximately 11.8% of all ICD patients have experienced an inappropriate shock.[100]

TABLE 48-4 NORTH AMERICAN SOCIETY OF PACING AND ELECTROPHYSIOLOGY/BRITISH PACING AND ELECTROPHYSIOLOGY GROUP GENERIC DEFIBRILLATOR CODE (NBD)*

Position I	Position II	Position III	Position IV†
Shock Chambers(s)	Antitachycardia Pacing Chamber(s)	Tachycardia Detection	Antibradycardia Pacing Chamber(s)
O = None **A** = Atrium **V** = Ventricle **D** = Dual (**A**+**V**)	**O** = None **A** = Atrium **V** = Ventricle **D** = Dual (**A**+**V**)	**E** = Electrogram **H** = Hemodynamic	**O** = None **A** = Atrium **V** = Ventricle **D** = Dual (**A**+**V**)

*The NBD code is a joint project from the North American Society of Pacing and Electrophysiology (NASPE) (the "N") and the British Pacing and Electrophysiology Group (BPEG) (the "B").[99] The "D" stands for defibrillator.
†For robust identification, position IV is expanded into its complete NBG code. For example, a defibrillator programmed to ventricular shock and antitachycardia pacing along with biventricular pacing functionality would be identified as VVE-DDDRV, assuming that the pacing section was programmed DDDRV. Currently, no hemodynamic sensors have been approved for tachycardia detection (position III).

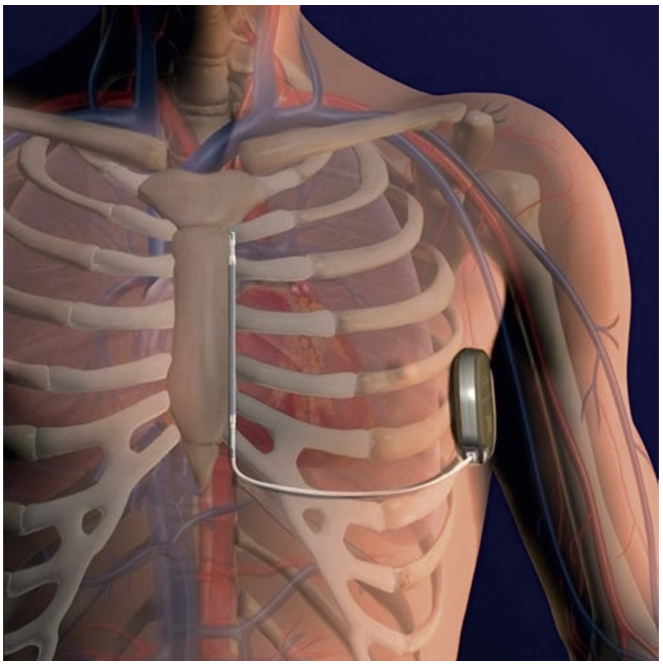

Figure 48-10. The Cameron Health–Boston Scientific subcutaneous implantable cardioverter-defibrillator. A schematic drawing of this system (CE mark 2009; U.S. Food and Drug Administration approval in 2012) is shown. This system consists of a generator implanted along the lateral chest wall with a lead tunneled into position over the heart. *(From Hauser RG: The subcutaneous implantable cardioverter-defibrillator: should patients want one?* J Am Coll Cardiol *61:20-22, 2013.)*

All T-ICDs have many programmable features to detect and treat both tachyarrhythmias and bradyarrhythmias. Essentially, these devices measure each cardiac R-R interval and categorize the rate as normal, too fast (short R-R interval), or too slow (long R-R interval). When the device detects a sufficient number of short R-R intervals within a period of time (all programmable), it begins an antitachycardia event. Depending on arrhythmia characteristics (primarily rate) and device programming, the internal computer chooses ATP (less energy use, better tolerated by patient) or shock. If the ICD chooses ATP, shock may be delayed; each cycle of ATP can delay shock 6 to 15 seconds. If shock is chosen, an internal capacitor is charged. Charging time depends on the desired output, and an additional 6 to 15 seconds may pass during a maximum shock. Charging time is lengthened by lower battery voltage, time from last charge,[#] and lower temperature.

Most ICDs are programmed to "reconfirm" VT or VF after charging to prevent inappropriate shock therapy. All T-ICDs can be programmed to begin ATP immediately on initiating a charge cycle (ATP while charging, which does not delay shock). Typically, T-ICDs deliver 6 to 18 shocks per event. Once a shock is delivered, no further ATP takes place. Despite considerable improvement in detection of ventricular dysrhythmias, more than 10% of T-ICD shocks are for rhythm other than VT or VF, and supraventricular tachycardia (SVT) remains the most common cause of inappropriate shock therapy.[6] Inappropriate ICD therapy, whether shock or ATP, has been shown to injure myocardium,[101] and it appears that any therapy, whether appropriate or inappropriate, shortens a patient's life expectancy when compared with patients not receiving therapy.[5,102] The likely results of these reports will be to delay initiation of T-ICD therapy for at least 30 to 60 seconds following onset of arrhythmia.

Programmable features in current ICDs to differentiate VT from SVT include the following[103]:

1. Onset criteria: In general, onset of VT is abrupt, whereas onset of SVT has sequentially shortening R-R intervals.
2. Stability criteria: In general, the R-R interval of VT is relatively constant, whereas the R-R interval of atrial fibrillation with rapid ventricular response is quite variable.
3. QRS width criteria: In general, the QRS complex width in SVT is narrow (<110 msec), whereas the QRS width in VT is wide (>120 msec).
4. "Intelligence" in dual-chamber devices attempts to associate atrial activity with ventricular activity.
5. Morphology waveform analysis includes comparison with stored historical templates.

When the R-R interval becomes sufficiently short for VF detection, most ICDs begin a shock sequence. As noted earlier, once the device delivers shock therapy, no further antitachycardia pacing takes place.

[#]The capacitor in an ICD "deforms" during inactivity, thus leading to increased time needed to charge the capacitor. To mitigate the effects of deformation, all ICDs perform nontherapeutic charging of their capacitor ("reforming") at a programmable periodic interval (usually 1 to 6 months).

BOX 48-5 ***Indications for Implantable Cardioverter-Defibrillators***

Ventricular tachycardia
Ventricular fibrillation
Brugada syndrome (right bundle branch block, ST-segment elevation in electrocardiographic leads V_1 to V_3)
Arrhythmogenic right ventricular dysplasia
Long QT syndrome
Hypertrophic cardiomyopathy
Prophylactic use in the patient who has CM without electrophysiologic testing to justify placement: MADIT II (EF <30%, ischemic CM)[98]; MUSTT (EF <40%, ischemic CM with nonsustained ventricular tachycardia)[97]; SCD-HeFT (EF <35%, and CM of any cause)[3]

CM, Cardiomyopathy; EF, ejection fraction, MADIT II, Multicenter Automatic Defibrillator Implantation Trial II; MUSTT, Multicenter Unsustained Tachycardia Trial; SCD-HeFT, Sudden Cardiac Death in Heart Failure Trial.

A T-ICD will begin pacing when the R-R interval is too long. Single-chamber T-ICDs implanted into patients with sinus rhythm typically are programmed to VVI pacing mode with a backup rate of 40 to 50 beats/minute. In July 1997, the FDA approved devices with sophisticated dual-chamber pacing modes and rate-responsive behavior for patients with T-ICD who need permanent pacing (≈20% of patients with ICDs). Because of the Dual Chamber and VVI Implantable Defibrillator (DAVID) study, which suggested that DDD pacing in a patient without a clear need for dual-chamber pacing decreased survival when compared with single-chamber device placement,[104] many electrophysiologists program long (>250 msec) AV delays in these patients to limit ventricular pacing. As noted earlier, however, long AV delays can lead to R-on-T pacing (see Fig. 48-8, *A*). In addition, many manufacturers of T-ICDs have designed algorithms to limit RV pacing. Some of these algorithms allow dropped QRS events, which can resemble second-degree Mobitz II block or pacing system malfunction.

INDICATIONS

Initially, ICDs were placed for hemodynamically significant VT or VF (Box 48-5). Additional indications associated with sudden cardiac arrest include patients awaiting heart transplantation[105] and patients with long QT syndrome,[106] Brugada syndrome (right bundle branch block, ST-segment elevation in leads V_1 to V_3), and arrhythmogenic RV dysplasia.[107,108] Studies suggest that ICDs can be placed prophylactically (i.e., used for primary prevention) to prevent sudden cardiac arrest in patients with hypertrophic cardiomyopathy,[109] as well as in patients after myocardial infarction with an ejection fraction lower than 30%,[98] but these devices are of no benefit after coronary artery bypass grafting. Three-chamber T-ICDs have been FDA approved for patients with DCM.

MAGNETS

As in PMs, magnet behavior in some ICDs can be altered by programming. Most devices suspend tachydysrhythmia detection (and therefore therapy) when a magnet is appropriately placed to activate the magnet switch (Table 48-5). Some devices from BOS, Pacesetter, and St. Jude Medical can be programmed to ignore magnet placement, and some BOS ("GDT" label) ICDs have had their magnet function permanently disabled because of a magnet switch issue (e.g., see Fig. 48-3).[11] For BOS devices, if the magnet mode is enabled and the T-ICD is enabled for antitachycardia therapy, the T-ICD will emit beeps synchronized to R waves (older BOS T-ICDs with a CPI or GDT label) or at 1 Hz (most BOS or BSC label T-ICDs) to signify adequate placement of magnet and suspension of tachyarrhythmia detection (thus disabling therapy). If any BOS T-ICD emits a constant tone when a magnet is applied, then antitachycardia therapy will remain disabled, even when the magnet is removed. Many BOS T-ICDs with the GDT label must be auscultated following magnet removal to ensure that tone emission has ceased, thus indicating that the magnet switch has returned to the open position.[11]

To ensure correct magnet placement on their devices, Medtronic marketed a device called the Smart Magnet. Manufacturing ceased in approximately 2005 because not many of these devices sold. This battery-powered instrument contains a magnet and a radiofrequency (RF) receiver. All Medtronic generators broadcast RF destined for the programmer on magnet placement, and the Smart Magnet detects this RF transmission and illuminates the "found" light when an ICD is under the magnet. Medtronic recommends that the Smart Magnet be taped onto the patient. During EMI (e.g., monopolar ESU), signal transmission from the T-ICD to the Smart Magnet can be interrupted, and the ICD "found" light often turns off. In this setting, however, the T-ICD remains disabled because the physical presence of the magnet, rather than the RF communication, disables the antitachycardia therapy.

No ICD provides asynchronous pacing with magnet placement. T-ICDs from Sorin (Milano, Italy, world headquarters; Arvada, Colo, U.S. headquarters) change their pacing rate (but not mode) to indicate battery status. Interrogating the device represents the most reliable method for determining magnet response. Contact with the CIED clinic or the manufacturer may provide additional information.

PREANESTHETIC EVALUATION AND REPROGRAMMING

In addition to evaluating and optimizing any comorbid diseases in the patient with an ICD, the ASA advisory recommends preoperative T-ICD interrogation. The other three statements recommend contact with the CIED clinic and physician. T-ICDs store considerable data on the occurrence of dysrhythmias. Because ATP is well tolerated, most patients remain unaware of this intervention. For any patient scheduled to undergo an elective procedure, the onset of new dysrhythmias likely warrants investigation of the problem before the procedure (Fig. 48-11). HRS/EHRA recommends 3- to 6-month follow-up with either in-office or remote (telephonic at this time) evaluation.[9] As with PMs, remote follow-up does not allow iterative testing of sensing or pacing thresholds. Medicare has no coverage determination for ICD follow-up.

TABLE 48-5 MAGNET BEHAVIOR OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS*

ICD Manufacturer		Magnet Mode Designation	Effect on Tachycardia Therapy	Effect on Bradycardia Therapy (regular pacing)	Magnet Mode Confirmation
Biotronik			Disabled	None	None
Boston Scientific (Guidant Medical, CPI)	"GDT," "CPI," "BOS 119," "BOS 203" x-ray label	ON	Disabled	None	Short beep with each detected heartbeat or constant tone†
		OFF	None	None	None
	All other "BOS" x-ray label	ON	Disabled	None	Short beep every second or constant tone†
		OFF	None	None	None
	Subcutaneous ICD		Disabled but tone for only 60 seconds	None	Short beep every second for 60 seconds, then no additional sounds (but tachyarrhythmia therapy disabled)
Medtronic	AT-500‡		Disabled	None	None§
	All others		Disabled	None	
Pacesetter and St. Jude Medical		NORMAL	Disabled	None	None
		IGNORE	None	None	
Sorin (was ELA Medical)			Disabled	Pacing rate, but not mode, changes to 96 (new device), declining to 80 beats/min, indicating elective replacement time	Pacing rate change as noted

ICD, Implantable cardioverter-defibrillator.

*The effects of appropriate magnet placement on an implantable cardioverter-defibrillator (ICD) are shown. Column 1 shows the manufacturer. Some manufacturers have multiple responses that can be determined by the x-ray identifier. If the magnet response is programmable, then column 2 shows the various magnet modes available. The first mode shown is the usual mode. A device reset from electromagnetic interference could produce some other mode (i.e., magnet mode disabled). Column 3 shows the effect on antitachycardia therapy (defibrillation and antitachycardia pacing) for the magnet mode shown in column 2. Only ICDs from Sorin Medical alter their antibradycardia pacing rate on magnet placement (column 4), and this pacing rate can be used to predict remaining battery life, provided the patient's native heart rate is less than the magnet rate. Only ICDs from Boston Scientific/Guidant/CPI produce reliable audio feedback for confirmation of magnet placement (column 5). For devices from Pacesetter and St. Jude Medical, device interrogation is required to determine the magnet mode.

†For Boston Scientific/Guidant/CPI T-ICDs, if the magnet mode is programmed to "on," appropriate magnet placement immediately disables tachycardia detection and therapy, and tachycardia therapies remain disabled for as long as the magnet remains appropriately applied. When magnet mode is enabled in these devices, the ICD will emit either a constant tone or beep to identify appropriate magnet placement. If the device emits a constant tone, then tachycardia therapy is disabled whether or not a magnet is present, and tachycardia therapy will not be present even after the magnet is removed. If any of these ICDs emit a beep (ICDs with GDT or CPI x-ray codes emit each beep with either paced or sensed R waves; most ICDs with BOS x-ray code emits a beep every second), then a properly working ICD will be enabled for tachycardia therapy on magnet removal. Any Boston Scientific/Guidant/CPI ICD that does not emit a sound when a magnet is applied should undergo immediate device interrogation.

‡The Medtronic AT-500 series defibrillators provide antitachycardia pacing in the atrium only, and usually after a delay often exceeding 1 minute from the onset of atrial tachyarrhythmia. They do not have any shock coils on any lead and are very difficult to distinguish from a conventional two-chamber pacemaker. They have no apparent magnet response. The x-ray identifier on these devices includes the Medtronic M, but the first character is I. All other Medtronic cardiac generators have the Medtronic M, with the first letter identifier P.

§Some Medtronic ICDs emit a tone for 15 to 30 seconds when a magnet is placed on the device. However, this tone is not continuous with magnet placement, and it is not interrupted with immediate magnet removal. As a result, the tone cannot be used for confirmation of appropriate magnet placement.

Determination of the need for elective replacement of an ICD resulting from battery depletion is more complicated than with PMs. Prediction of remaining ICD battery longevity obtained at interrogation is a feature available only in the newest of ICDs. For devices without battery longevity estimates, the capacitor charge time reflects battery status, and the manufacturer should be consulted when charge time exceeds 12 seconds. General statements about battery voltage in ICDs cannot be made because ICDs have different numbers of battery cells.

Most ICDs should have their antitachycardia therapy disabled before the use of any device causing EMI. The use of monopolar ESU can cause inappropriate shocks. Casavant and associates found a stored electrogram sequence in an ICD, a finding suggesting that the device had misinterpreted monopolar ESU during dermatologic facial surgery as VF.[111] Figure 48-12 shows inappropriate VT detection that occurred intraoperatively. Additionally, one report exists of a central line guidewire interacting with the RV lead, thus leading to a short-circuit shock and subsequent failure of the T-ICD.[112]

The comments in the pacing section (including Appendix 48-2 and Box 48-3) apply here for any ICD with antibradycardia pacing. Many ICDs have no noise reversion behavior, so ESU-induced ventricular oversensing may lead to nonpacing in the patient who depends on the ICD for pacing.

INTRAOPERATIVE (OR PROCEDURE) MANAGEMENT OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

At this time, no special monitoring (resulting from the ICD) is required for the patient with an ICD. ECG

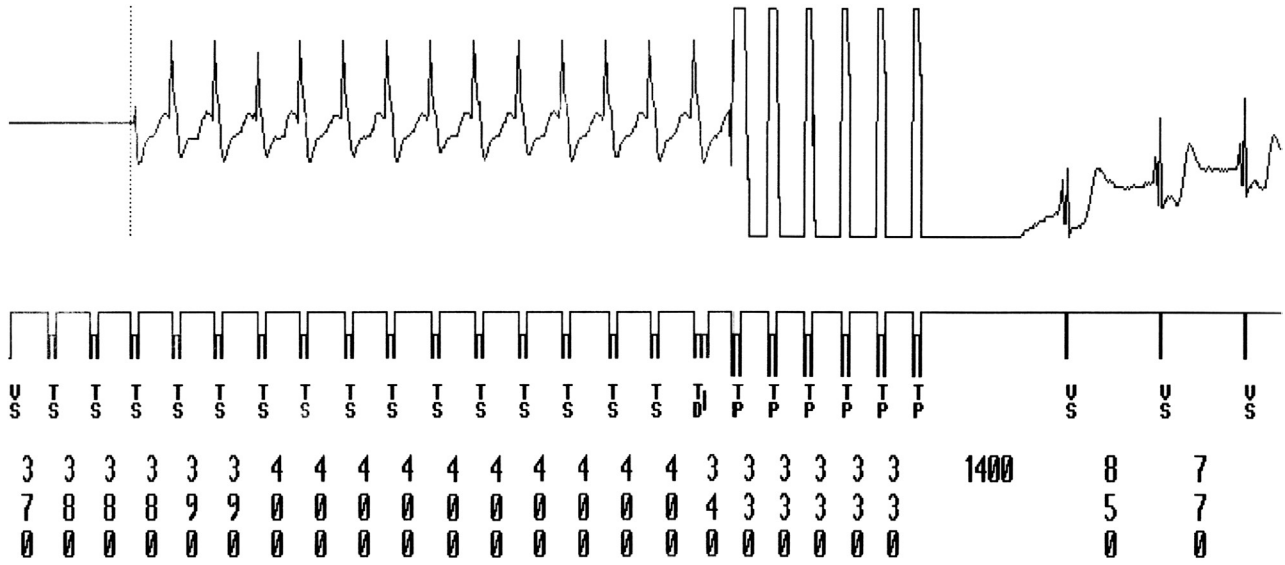

Figure 48-11. Unexpected ventricular tachycardia (VT) with antitachycardia pacing was found in this patient during her preoperative visit. A 65-year-old woman with a history of VT had undergone implantation of a Medtronic single-chamber defibrillator approximately 8 months previously. She had not had any dizziness or syncopal episodes since placement of an implantable cardioverter-defibrillator (ICD). Preoperative interrogation of her device revealed VVE-VVI programming, along with an episode of tachycardia at 150 to 162 beats/minute that was detected by the ICD as VT. The ICD delivered a six-beat burst of antitachycardia pacing at 182 beats/minute, which converted the tachycardia back to sinus rhythm. No backup pacing was needed after the VT was terminated. The *upper tracing* is a digitized ventricular electrogram that was stored in the ICD during the tachycardic event. The *lower tracing* is the "marker channel," which reports the interpretation of each event by the ICD. The numbers below the marker channel represent the interval (in milliseconds). The rate is calculated by dividing the interval into 60,000 msec/minute. TD marks the final event that starts therapy. TS represents an interval in the VT zone, TP is an antitachycardia pace event, and VS is an intrinsic ventricular depolarization with a rate that is neither too fast (short interval) nor too slow (long interval). This device was set to detect VT as 16 consecutive ventricular events with a rate between 146 and 200 beats/minute and to deliver antitachycardia pacing at 84% of the last R-R interval (the last interval was 400 msec, so antitachycardia pacing was delivered at a rate of 182 beats/minute (330 msec).

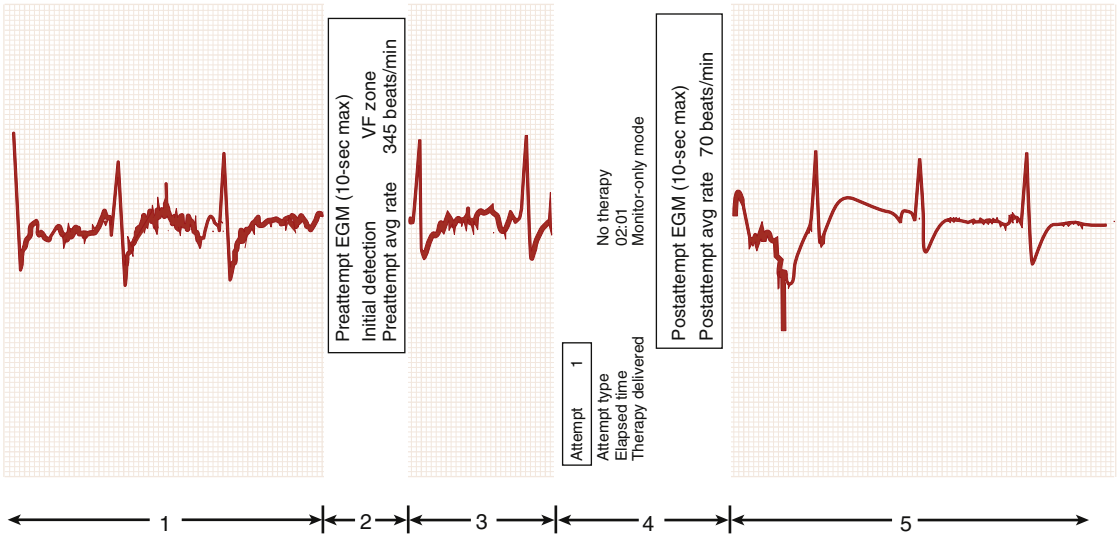

Figure 48-12. Electromagnetic interference (EMI) from the monopolar electrosurgery unit (ESU; "Bovie") caused an implantable cardioverter-defibrillator (ICD) to detect ventricular fibrillation (VF). This stored electrogram (EGM) was one of 73 found at the end of a 4-hour surgical procedure in which considerable monopolar electrosurgery was used. This patient had a Guidant Medical ICD in the VOE-VVI mode. The patient's ICD had been placed in a "monitor only" mode before surgery. As a result, the ICD recorded any instance of ventricular dysrhythmia that would have triggered therapy, but it could not actually deliver therapy. From *left to right: 1,* the EGM demonstrates a ventricular rate of 70 beats/minute, but with considerable noise on the baseline; *2,* a VF event was declared for the detected heart rate of 345 beats/minute, and the ICD charged its capacitor; *3,* the ICD was programmed to "reconfirm before shock," and the ventricular rate remained 70 beats/minute with noise on the baseline; *4,* again, the noise caused the ICD to believe that the patient remained in VF, and the ICD would have delivered a shock, except that it was programmed to "monitor only"; and *5,* because the noise is gone (the ESU had stopped), the ICD declares the event over after "successful" defibrillation.

monitoring and the ability to deliver external cardioversion or defibrillation must be present during the time of ICD disablement. Should cardioversion or defibrillation be needed, the defibrillator pads should be placed to avoid the PG to the extent possible. Nevertheless, the patient, not the ICD, is being treated. When a magnet is used to prevent ICD discharge, simple removal of a magnet may not produce immediate antiarrhythmic therapy. The actual rate of the tachycardia versus the lowest treatment zone rate, as well programmed therapy delays, could lead to lengthy treatment postponements. The recommendations in the section on intraoperative (or procedure) management of pacemakers apply here, as well, to T-ICDs (S-ICDs have no permanent pacing at this time).

No special anesthetic techniques have been championed for the patient with an ICD. Most of these patients have severely depressed systolic function, dilated ventricular cavities, and significant valvular regurgitation. Thus, the choice of anesthetic technique should be dictated by the underlying physiologic derangements that are present. Conflicting data have been published regarding the choice of anesthetic drugs and changes to DFT. In 1992, Gill and associates examined DFTs in dogs and concluded that neither halothane nor isoflurane changed DFTs in open chest defibrillation compared with a pentobarbital infusion.[113] However, Weinbroum and colleagues evaluated DFTs in humans during ICD implant and found that halothane, isoflurane, and fentanyl increased DFTs.[114] Even with these increases, however, these increased DFTs were still substantially lower than the maximum energy generally available in ICDs, and these increases would not have been noted under usual testing conditions.

POSTANESTHESIA EVALUATION

Any ICD that was reprogrammed for an intervention must be reinterrogated and re-enabled, and deaths from failure to re-enable an ICD have been reported.[115] All recorded events should be reviewed, and counters should be cleared. The pacing parameters (T-ICD only) must be checked and reprogrammed as necessary.

SPECIAL SITUATIONS: VENTRICULAR ASSIST DEVICES AND TEMPORARY PACING

Most patients with a ventricular assist device (VAD) also have a T-ICD. Although this subject exceeds the scope of this chapter, several important issues should be highlighted. First, the VAD can interfere with telemetry between the ICD and the programmer, thus resulting in the inability to modify parameters quickly[116] and possibly necessitating T-ICD replacement.[117] Several "workarounds" have been proposed, including changing the LVAD speed, covering the telemetry wand with an iron skillet, or encasing the wand and cord with metallic shielding material.[116,118] Before placement of a T-ICD in a patient with a VAD, or placement of a VAD in a patient with a preexisting CIED, compatibility issues should be investigated. Second, in many of these patients who then undergo orthotopic heart transplantation, the T-ICD is disabled by programming, and the transvenous leads are cut at the level of the superior vena cava. Unfortunately, any subsequent device reset from cosmic radiation or EMI will restore single-zone shock behavior in all T-ICDs,[49] so a patient may actually receive high-energy therapy to their superior vena cava, with likely disastrous result.

The second special situation is temporary pacing. Temporary pacing devices can be used for bradycardia unresponsive to pharmacologic therapy, bradyarrhythmias complicating myocardial infarction, heart rate support following cardiothoracic surgery, delivery of ATP to the atrium or ventricle in an attempt to treat a tachydysrhythmia, bridge to permanent PM placement, and protection for potential catastrophic failure of a CIED expected to be exposed to strong EMI in a pacing-dependent patient. Pacing can be esophageal, transcutaneous, transvenous, or epicardial. In a patient with a CIED, placement of a temporary pacing device requires CIED reprogramming for temporary pacing testing (e.g., threshold evaluation) because the energy of temporary pacing that fails to depolarize the myocardium could inhibit permanent pacing. A T-ICD must be disabled to prevent inappropriate shock during temporary pacing testing and also if central venous access is planned.[112]

Esophageal pacing requires an intact atrium and AV node. Thus, esophageal pacing remains absolutely contraindicated when a history of atrial dysrhythmia (e.g., atrial fibrillation) or significant AV block exists. This technique requires a specially adapted esophageal probe and a unique generator. Pacing is AOO only, which usually causes no problems, even when the native heart rate exceeds the programmed heart rate. The pacing artifacts typically appear as large, negative "spikes" that can produce overcounting by the ECG monitor and can be confused as QRS events (see Fig. 48-9).

Transcutaneous pacing is accomplished by placing conducting electrodes on the skin, preferably in an anteroposterior position. Device instructions should be followed. Pacing is ventricular only, and this may not produce appropriate hemodynamic support without atrial transport.

Transvenous and epicardial pacing can be atrial, ventricular, AV, or BiV, depending on the catheter or wires and the pacing generator used. Transvenous pacing requires central venous access, and complete sterile barrier technique seems indicated in any patient, especially when a preexisting CIED is present. Three different types of transvenous catheters are available at this time: a simple balloon-tipped bipolar catheter without a hemodynamic channel; a pulmonary artery catheter with one or two extra lumina for placement of bipolar wires into the atrium, right ventricle, or both; and a multielectrode pulmonary artery catheter intended for atrial-RV pacing. Both transvenous pacing and epicardial pacing require a battery-powered external generator. In any patient with only a ventricular lead (whether transvenous or epicardial), the temporary pacing generator should be programmed only to VVI pacing because the use of DDD pacing (in the absence of a functioning atrial lead) can instigate VT secondary to R-on-T pacing (Fig. 48-13).[51] The use of the DDD pacing mode

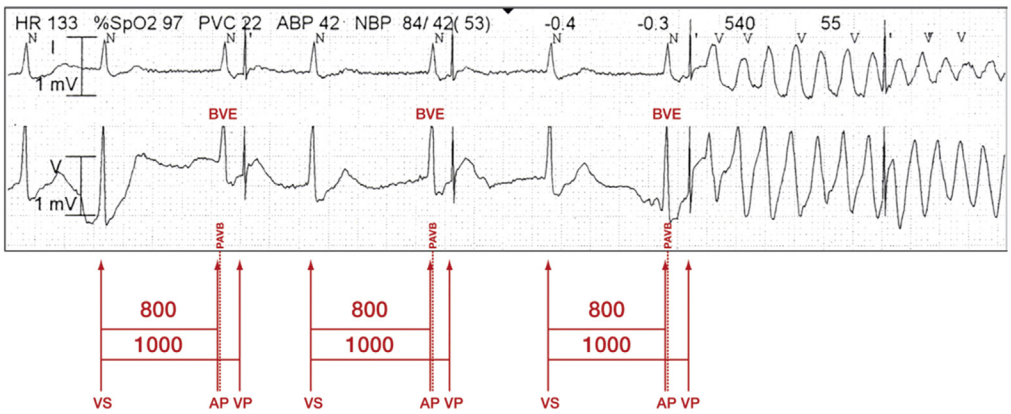

Figure 48-13. DDD pacing without atrial lead initiates ventricular tachycardia (VT) by R-on-T pacing. Temporary external dual-chamber pacing without an atrial lead produced several R-on-T paces, one of which initiated polymorphic VT. This patient had undergone elective aortic valve replacement with root repair, three-vessel coronary artery bypass grafting, and a partial Maze procedure 8 hours earlier. His underlying rhythm was atrial fibrillation. Tracings are electrocardiogram lead I (*upper*) and lead V_5 (*lower*). Pacemaker (PM) settings were DDD mode; pacing rate was 60 beats/minute; and AV delay was 200 msec, resulting in a VV cycle length of 1000 msec and a ventriculoatrial time (VA) of 800 msec. AP is presumed atrial pace, BVE is a blanked ventricular event secondary to postatrial ventricular blanking, VP is ventricular pace, and VS is presumed ventricular sense. At the expiration of the VA timer, the PM presumably emitted an AP because no atrial signal had been sensed. The PM then invoked a 20- to 36-msec postatrial ventricular blanking period to prevent any ventricular oversensing resulting from the AP. As a result, the native ventricular event was not sensed (BVE), resulting in a VP 200 msec after the AP. The VP fell on the vulnerable period of repolarization, thus initiating VT. *ABP,* Arterial blood pressure; *HR,* heart rate; *NBP,* noninvasive blood pressure; *PVC,* premature ventricular contraction; *Spo_2,* peripheral oxygen saturation. *(From Schulman PM, Stecker EC, Rozner M: R-on-T and cardiac arrest from dual-chamber pacing without an atrial lead,* Heart Rhythm *9:970-973, 2012.)*

(default mode of many temporary PMs) with only an RV lead appears to be a common practice, and this R-on-T phenomenon appears poorly understood, given that the occurrence of R-on-T–induced VT in this situation has been ascribed to "chance."[119] Some dual-chamber external pacing generators switch from VVI to DDD pacing without warning or confirmation when changing parameters other than pacing mode.[52] Temporary pacing should be discontinued as soon as possible.

SUMMARY

Electronic miniaturization has permitted the design and use of sophisticated electronics in patients who need artificial pacing and/or automated cardioversion or defibrillation of the heart. These devices are no longer confined to merely keeping the heart beating between a minimum rate (pacing function) and a maximum rate (ICD functions) because they are now used as therapy to improve the failing heart. Furthermore, the advent of sophisticated pacing algorithms that change heart rate or AV intervals, as well as permit occasional dropped QRS events, can mimic behavior that may be interpreted as "light anesthesia" (increased pacing rates) or pacing system malfunction. Inappropriate treatment of these events can lead, and has led, to injury and death in these patients.

Both the aging of the population and the ability to care for a patient with increasingly complex disease suggest that anesthesiologists will be caring for many more patients with these devices, and we must be prepared for this situation. Safe and efficient clinical management of these patients depends on an understanding of implantable systems, indications for their use, and the perioperative needs they create.

GLOSSARY

Atrial Fibrillation (AF) Suppression (formerly Dynamic Atrial Overdrive): A programmable rate enhancement for CIEDs that increases the pacing rate in response to the presence of intrinsic atrial activity. AF suppression is designed to pace the atrium at a rate just above the intrinsic rate to prevent atrial fibrillation.[120] Its presence and maximal pacing rate should be identified before an anesthetic regimen because elevated pacing rates may prompt treatment, which will not affect the heart rate but may harm the patient. Consideration should be given to disabling this feature intraoperatively, especially if monopolar ESU will be used superior to the umbilicus, where EMI would be expected.

Atrioventricular Delay: The time that a dual-chamber system waits after detecting (or initiating) an atrial event before pacing the ventricle. Some generators shorten this time as heart rate increases (termed rate-adaptive AV delay or dynamic AV delay). Some generators can be programmed to extend the AV delay to search for intrinsic conduction (search AV delay). Some generators prolong an AV delay after any atrial event in which the last ventricular event was intrinsic (AV delay hysteresis). In a patient with a conducting AV node, the sensed AV delay is slightly longer than the PR interval on the surface ECG (see Fusion Beat and Pseudofusion Beat) because the ventricular sensing element is attached to the apex of the right ventricle and detects the depolarization only after RV activation (typically >60 msec after activation of the AV node).

Automatic Rate. See Lower Rate Limit

Bipolar Lead: An electrode with two conductors. Bipolar pacing typically uses less energy than unipolar pacing, and it produces smaller artifacts on analog monitors.

Bipolar sensing is more resistant to oversensing from muscle artifact or stray electromagnetic fields. Most pacing generators (but not ICDs) can be programmed to unipolar mode (separate settings for pacing and sensing), even in the presence of bipolar electrodes.

EGM Mode (Electrogram Storage Mode): Passive acquisition and internal storage of ECG data for diagnostic purposes while pacing (or monitoring) with programmed parameters. A PM programmed to enter the EGM mode on application of a magnet will not demonstrate asynchronous pacing behavior.

Fusion Beat (FB): A PM spike delivered shortly before a native depolarization of the ventricle that alters the morphology of the QRS, often misdiagnosed as undersensing. With an FB, the pacing stimulus is delivered after the activation of the AV node but before the sensing element detects the PM-induced depolarization. It is similar to preexcitation of the ventricle seen in Lown-Ganong-Levine syndrome or Wolff-Parkinson-White syndrome. Confirmation of appropriate sensing behavior can be made by lengthening the sensing interval (i.e., lengthening the AV delay). Fusion beats suggest, but should not be used to confirm, ventricular capture. See also Pseudofusion Beat.

Generator: The device with a power source and circuitry to produce an electrical impulse designed to be conducted to the heart. Typically, cardiac generators are placed in a pectoral pocket, and leads are inserted into the right atrium, right ventricle, or both. Since 1995, ICDs have also been approved for pectoral pocket placement.

Hysteresis: If present, the amount by which the patient's intrinsic rate must fall below the programmed rate before the generator begins pacing. Some pacers periodically decrease the pacing rate to search for resumption of intrinsic activity (called search hysteresis). These functions, when present, can mimic PM malfunction.

ICD (Implantable Cardioverter-Defibrillator) Mode: The designation of chambers shocked, chambers paced for antitachycardia pacing, method of tachycardia detection, and chambers paced for antitachycardia therapy. Table 48-4 shows the NASPE/BPEG generic ICD code.

Lower Rate Limit (LRL, also Automatic Rate or Programmed Rate): The lowest sustained regular rate at which the generator will pace. Generators convert this value into the maximum allowable R-R interval and emit a pacing pulse at the expiration of this time. Dual-chamber pacing devices subtract the AV delay to determine the maximum allowable interval from a ventricular event to the expected atrial event.

Mode Switch: In dual chamber (AV) systems, a feature designed to limit ventricular pacing during high atrial rates (whether atrial fibrillation, flutter, or tachycardia) by temporarily switching to DDI(R) / VVI(R) depending upon the manufacturer. The mode switch detect rate, duration of high rate tracking (pre-mode switch) and return to dual chamber tracking mode upon termination of the atrial high rate can be manufacturer and programming dependent. Often, removal of a magnet in the setting of a high atrial rate will lead to transient ventricular pacing at the upper tracking rate until mode switch occurs. EMI can also cause inappropriate mode switch with resultant loss of atrial transport producing hemodynamic embarrassment.

Oversensing: Detection of undesired signals that are interpreted as cardiac activity. Ventricular oversensing can lead to ventricular pause (PM or ICD) or inappropriate antitachycardia therapy (ICD). Atrial oversensing can lead to inappropriately high paced ventricular rates in DDD or VDD devices; these ventricular systoles occur in the absence of true atrial systoles, and hemodynamic compromise can result.

Pacing Mode: The designation of chambers paced, chambers sensed, sensing response, rate responsiveness, and antitachyarrhythmia function for a PM system. Table 48-2 shows the NASPE/BPEG generic PM code.

Programmed Rate. See Lower Rate Limit

Pseudofusion Beat (PFB): A PM spike delivered shortly after a native depolarization without alteration of the QRS morphology. PFBs are often misdiagnosed as undersensing, and they result from the position of the sensing electrode relative to the depolarizing wavefront (see Fusion Beat). Confirmation of appropriate sensing behavior can be made by lengthening the sensing interval (i.e., decreasing the program rate [atrial FB] or lengthening the AV delay [ventricular PFB]). PFB cannot be used to confirm electronic capture.

Rate Enhancements: Features such as rate-adaptive AV delay (shortens the AV delay with increasing heart rate), AV search hysteresis (lengthens or shortens the AV delay to produce intrinsic AV conduction), AF suppression (also called dynamic atrial overdrive; increases the lower rate on appearance of native atrial depolarization, thus creating nearly constant atrial pacing but at a rate only slightly higher than the patient's intrinsic rate), rate smoothing (limits changes in ventricular paced rates resulting from changes in atrial rates; rising and falling rate limits can be programmed separately), sleep rate (see Sleep Rate), ventricular rate regulation (similar to rate smoothing but used only during atrial fibrillation), and hysteresis (see Hysteresis). Each of these enhancements can produce pacing or nonpacing that can mimic PM dysfunction, and consideration should be given to disabling these enhancements before any anesthetic regimen.

Rate Modulation: The ability of the generator to sense the need to increase heart rate in response to the patient's activity. Mechanisms include (1) a mechanical sensor in the generator to detect motion or vibration, (2) electronic detection of the QT interval (shortens during exercise), (3) transthoracic impedance to measure changes in respiration, and (4) sensors for central venous blood temperature or oxygen saturation (see Table 48-3). Some generators now incorporate multiple sensors. The pacing rate determined by the rate modulation algorithm is called sensor indicated rate.

Rest Rate: A rate lower than the programmed rate, invoked by the pacing device after some period (manufacturer specific) of patient inactivity, which is determined by the exercise sensor.

Sensor Indicated Rate: The pacing rate determined by the sensor in a PM programmed to a rate-responsive mode (fourth character of NBG = R).

Sleep Rate (also Circadian Rate): The rate (lower than the programmed rate) at which the pacing generator will pace during programmed "nighttime" hours. Travel across time zones can lead to maladaptive behavior when using this feature.

Undersensing: Failure to detect a desired event.

Unipolar Lead: An electrode with only one conductor. Some devices with bipolar leads are programmed to the unipolar lead mode. Systems with unipolar leads produce larger spikes on the ECG than bipolar leads. Systems with unipolar leads use the generator case as the second conductor. Unipolar pacing or sensing modes cannot be programmed in an ICD.

Upper Sensor Rate (USR, also Upper Activity Rate or UAR): The maximum rate to which a rate modulated CIED can drive the heart. The USR is not affected by UTR because when USR becomes active, the CIED is pacing the atrium.

Upper Tracking Rate (UTR, also called Upper Rate Limit or URL): In dual chamber (AV) systems, the maximum rate at which the ventricle can be paced regardless of the atrial rate. When the atrial rate exceeds this rate, the observed AV delay will lengthen and some QRS events can be dropped, a behavior that appears similar to Wenckebach rhythms.

APPENDIX 48-2 *Preanesthetic Cardiovascular Implantable Electronic Device (Pacemaker, Implantable Cardioverter-Defibrillator) Evaluation*[*]

Determining the indication for and date of initial device placement
Identifying the type of device (pacemaker, implantable cardioverter-defibrillator) and manufacturer
Determining the patient's underlying rhythm and rate (if any)
Identifying the number and types of leads
Determining the last generator test date and battery status
Obtaining a history of generator events (if any)
Obtaining the current program information (device interrogation), including mode, rate, and rate enhancements
Ensuring that generator discharges become mechanical systoles with adequate pacing safety margins
Ensuring adequate safety margin for sensing events (if intrinsic events are present)
Ensuring that magnet detection is enabled (magnet behavior and rate should be recorded)
Determining whether the pacing parameter should be reprogrammed, which will depend on, for example, pacing dependency, surgery type and location, and need for increased heart rate

*The preanesthetic cardiovascular implantable electronic device evaluation should consist of a device interrogation. The foregoing statements can be fashioned into a request to the cardiologist or pacemaker service. For implantable cardioverter-defibrillators, the term *generator events* includes a history of antitachycardia therapy.

Chapter 49

Neurologic Monitoring

CHRISTOPH N. SEUBERT • MICHAEL E. MAHLA

Key Points

- Intraoperative neurologic monitoring has four key principles:
  - The pathway at risk during the surgical procedure must be amenable to monitoring.
  - The monitor must provide reliable and reproducible data.
  - If evidence of injury to the pathway is detected, some intervention should be possible.
  - If changes in the neurologic monitor are detected, they may have prognostic value even if no intervention is possible. In this situation, the direct benefit to the patient from early detection of impending neurologic injury is minimal.
- Few randomized prospective studies have evaluated the efficacy of neurologic monitoring modalities.
- Anesthesiologists can improve the efficacy of monitoring by maintaining good physiologic homeostasis and stable levels of anesthesia during parts of the surgical procedure that place the nervous system at greatest risk.
- Based on clinical experience and nonrandomized studies, four practice patterns for use of neurologic monitoring have emerged:
  - In some procedures, monitoring is recommended and is used by most centers.
  - In certain procedures, monitoring is used frequently in some centers but not in others.
  - Some procedures have no clear clinical experience or evidence indicating that monitoring is useful at all (experimental use).
  - In certain procedures, monitoring is used selectively for patients believed to be at higher than usual risk for intraoperative neurologic injury.
- Good communication among surgeons, anesthesiologists, and neurophysiologists is essential to optimizing the utility of monitoring.

Neurologic monitoring in the context of anesthesia care for a patient spans a wide spectrum of techniques, diverse procedures, and various intraoperative or even postoperative settings. Techniques for monitoring fall into two broad categories: (1) techniques to assess metabolic integrity of the nervous system, which include either global or regional determinations of blood flow or oxygenation; or (2) techniques to assess functional integrity, which similarly may be global or focused on specific anatomic components of the nervous system.

The procedures and settings in which neurologic monitoring is typically applied all share the characteristic that changes in the monitored parameters can be corrected or minimized by either modifying the surgical approach or manipulating variables under the control of the anesthesiologist. Monitored procedures range from procedures in which monitoring dictates the surgical approach, such as localization of the motor strip during tumor operations or neurologic examination during "awake" craniotomy, to procedures that by their nature put parts of the nervous system at increased risk.

In many procedures that require neurologic monitoring, the anatomic target is also susceptible to drugs administered in the course of an anesthetic regimen. The anesthesiologist and the surgeon must be aware not only of limitations inherent in individual monitoring techniques but also of nonsurgical factors that influence the monitoring results. The monitoring approach ideally should anticipate nonsurgical factors by providing a degree of redundancy that helps distinguish localized surgical trespass from a systemic event.

For some procedures, neurologic monitoring is a marker of the quality of care and is routinely employed because outcome data support its use. Examples include correction of scoliosis and resection of vestibular schwannomas. More frequently, the approach to monitoring is

based on local conventions and surgical expectations. In this latter case, monitoring utility depends on the following: (1) a good understanding of the technique's capabilities and limitations by anesthesiologists, surgeons, and the intraoperative monitoring team; (2) good communication; and (3) mutual collaboration to allow corrective action in the presence of changing signals or to prevent false alarms that disrupt surgical procedures.

Individual monitoring modalities are initially described in isolation so that the clinician can appreciate the inherent strengths and weaknesses of each. Then this information is used to develop suitable approaches to various clinical settings that combine and integrate individual techniques to optimize neurologic outcome for patients. Finally, this chapter reviews the manner in which neurologic monitoring is currently useful and the areas where more work is needed to determine the more specific indications for monitoring in surgical patients in the future.

MONITORING MODALITIES

MONITORS OF ADEQUACY OF NERVOUS SYSTEM BLOOD FLOW

Adequacy of cerebral blood flow (CBF) can be monitored by two principal methods. The first method assesses blood flow itself, with the implicit assumption that "normal" flow provides adequately for the metabolic needs of the brain. The second approach assesses oxygen delivery either locally or globally, with the implicit assumption that "normal" values at the site of measurement reflect adequate blood supply throughout the central nervous system (CNS). However, these assumptions have limitations, as exemplified by global or hemispheric CBF in the context of a patient's disease process.

In the normal brain, values of hemispheric CBF of approximately 50 mL/100 g/minute reflect adequate oxygen delivery for maintaining structural integrity and function. Values of less than 20 to 25 mL/100 g/minute are associated first with failure of function and, on further decrease, with structural damage.[1] In neurosurgical patients, structural integrity and function may be altered by both disease processes and anesthetic drugs, which influence interpretation of measured CBF. A CBF of 40 mL/100 g/minute in a patient in barbiturate coma after resection of an arteriovenous malformation may represent hyperemia (because metabolic demand is very small), whereas the same CBF in a patient with a mass lesion may reflect a modest decrease in cerebral perfusion pressure secondary to increasing intracranial pressure. Thus, the clinical response to an abnormal value requires context and clinical judgment.

Global Blood Flow Monitoring Techniques (Noninvasive)

Intravascular Tracer Compounds. Direct measurement of CBF is possible by determining kinetics of wash-in or washout, or both, of an inert tracer compound, a method originally described by Kety and Schmidt.[2] The most widely used measurement technique involves administration of a radioactive isotope of xenon-133 (^{133}Xe), followed by measurement of the radioactivity washout with gamma detectors placed over specific areas of the brain. Depending on the number of detectors, this method can provide a spatial resolution of 4 cm. In normal brain, flow at different depths may be inferred from the early washout, which should reflect high-perfusion cortical gray matter, and late washout, from low-perfusion deeper white matter.

Drawbacks of the method are the patient's exposure to radioactive compounds and the need for externally placed and potentially cumbersome detector equipment, which may interfere with the operation itself in the case of intracranial surgical procedures. Focal areas of hypoperfusion may be missed because of underlying or overlying adequate flow, a phenomenon described as look-through.[3] Despite these shortcomings, ^{133}Xe washout has been used at a few major centers for intraoperative monitoring during operations such as carotid endarterectomy.[4-8] Modern variations of the same concept are mean transit time determinations of intravascular contrast agents during neuroimaging for determining locoregional blood flow[7,8] or a double-indicator technique for determining global CBF.[9] All these techniques share the limitation of providing a snapshot of CBF in time instead of continuous monitoring.

Transcranial Doppler Ultrasound. Transcranial Doppler (TCD) ultrasound is a technique that infers CBF from measurements of the blood flow velocity in the large conducting arteries of the brain. The TCD probe transmits pulses of sound waves through the thin temporal bone in a variation of the pulsed wave Doppler technique with which anesthesiologists may be familiar from echocardiography. When these sound waves are reflected off the red blood cells back toward the TCD probe, the velocity of the reflected sound waves is changed because the blood cells themselves are in motion toward or away from the probe. This phenomenon is known as the Doppler shift and is directly related to flow velocity and flow direction of the blood cells. Blood flow is more rapid during systole and in the center of a vessel and slower in diastole and near the vessel wall. TCD imaging records a spectrum of flow velocities whose outline resembles an arterial waveform tracing. These concepts are illustrated in Figure 49-1.

Intraoperatively, TCD measurements are usually made by continuous monitoring of the middle cerebral artery for the purpose of detecting either significant changes in flow velocity or the presence of particulate emboli. As a diagnostic study, in addition to the middle cerebral artery, the anterior cerebral, anterior communicating, posterior cerebral, and posterior communicating arteries can be examined through the temporal bone window. The basilar, ophthalmic, and internal carotid arteries also can be insonated through the foramen magnum (TCD probe at the back of the flexed neck) (basilar artery), the closed eyelid (with reduced sound energy) (ophthalmic artery and carotid syphon), and near the angle of the jaw (internal carotid artery). An important limitation of TCD ultrasound is that most of the examination is performed through the temporal bone, which may be thick enough to preclude an adequate examination in 10% to 20% of patients.[10,11]

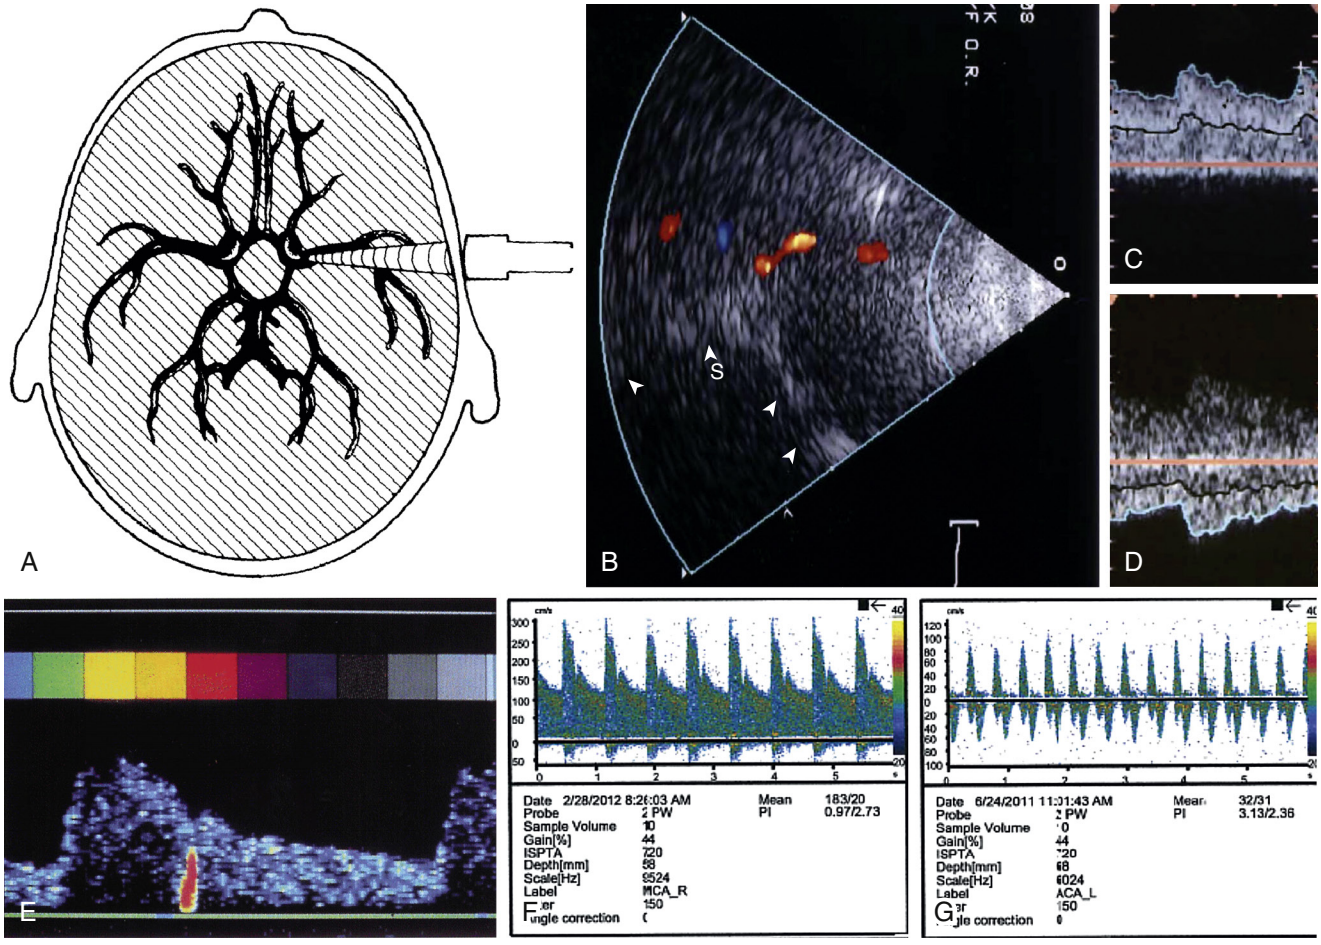

Figure 49-1. A, Transcranial Doppler monitoring is done by insonating the arteries at the base of the brain through a thin part of the temporal bone. **B,** If this procedure is performed with an imaging probe, some intracranial structures, such as the cerebral peduncles (*white triangles*) or the sella complex (*white triangle labeled "S"*), can be visualized. The captured Doppler signals originate from the right middle, right anterior, and left anterior cerebral arteries. **C,** Normal Doppler spectrum obtained from the middle cerebral artery. By convention, flow toward the probe is displayed as a waveform above the baseline. **D,** Doppler profile of the bifurcation of the terminal internal carotid artery as it branches into the middle cerebral artery (flowing toward the transducer) and the anterior cerebral artery (flowing away). This flow signal can be obtained if the transducer is focused as shown in **A. E** to **G,**Examples of three clinical applications of transcranial Doppler. **E,** Emboli are highly echogenic and appear as high-energy transient signals. On the audible output, these emboli are easily noticed as brief beeps or chirps. **F,** Doppler profile of a middle cerebral artery in a patient with severe vasospasm after an aneurysmal subarachnoid hemorrhage (compare with **C**). **G,** Transcranial Doppler examination consistent with intracranial circulatory arrest. A brief systolic inflow is followed by retrograde flow during diastole.

Two assumptions that are intuitive and plausible, but ultimately unproven, must be made for TCD-measured blood flow velocity to have a direct relationship with CBF. First, blood flow velocity is directly related to blood flow only if the diameter of the artery where the flow velocity is measured and the measurement angle of the Doppler probe remain constant. In practical terms, finding a means to affix the TCD probe in a way that prevents dislodgment or movement during monitoring is challenging. The second assumption requires that CBF in the basal arteries of the brain is directly related to cortical CBF. Because TCD monitoring is typically performed mainly using the middle cerebral artery, this assumption may be invalid if collateral blood flow by leptomeningeal collateral vessels from anterior and posterior cerebral artery territories is adequate. Although these two assumptions constrain the utility of TCD imaging as a standalone monitor of CBF, the changes in flow velocity seen in typical applications (discussed subsequently) are large enough to provide useful clinical information.

More important, TCD ultrasound is the only continuous neurologic monitoring technique that provides early warning for hyperperfusion and for the number of emboli delivered to the brain during various phases of an operation. Because of their high echogenicity, emboli show up in the TCD spectrum as high-intensity transient signals (HITSs) (see Fig. 49-1), easily identified as brief beeps or chirps within the background of the Doppler sounds.

Jugular Bulb Venous Oxygen Saturation. The degree of oxygen extraction by an organ can be monitored by measuring the oxygen saturation of the mixed venous blood that drains that organ. In the case of the brain, jugular bulb venous oxygen saturation ($Sjvo_2$) measures the degree of oxygen extraction by the brain and represents

the balance between cerebral oxygen supply and demand. To monitor $Sjvo_2$, a fiberoptic catheter is inserted in retrograde fashion into the jugular bulb through the internal jugular vein under fluoroscopic guidance. The fiberoptic bundle emits near-infrared light and records light reflected back to the catheter, a technique known as reflectance oximetry. Because near-infrared light can travel several centimeters in tissue and is mostly absorbed by hemoglobin, oxygen saturation of the surrounding tissue can be monitored (i.e., the jugular venous blood). Correct tip placement is crucial to minimize admixture of extracranial venous blood. To decrease the risk of complications, usually only one side is monitored.

Several theoretical limitations of the technique may interfere with proper interpretation of $Sjvo_2$ values and trends. Although nearly all blood from the brain drains through the jugular veins, intracranial mixing of venous blood is incomplete and may result in differences between right-sided and left-sided measurements. The dominant jugular vein (i.e., the right for most patients) drains predominantly cortical venous blood, whereas the contralateral jugular vein drains more of the subcortical regions.[12] Despite such regional differences, $Sjvo_2$ must be considered a monitor of global cerebral oxygenation because inadequate perfusion to a focal brain region may not decrease $Sjvo_2$ values less than the normal range of 55% to 75%. Because $Sjvo_2$ represents the balance between supply and demand, interpretation of the absolute value of $Sjvo_2$ must take the clinical circumstances into account.

Cerebral Oximetry. Cerebral oximetry is a noninvasive technique that, similar to $Sjvo_2$ monitoring, uses reflectance oximetry to measure the oxygen saturation of the tissues underneath the sensor. Typically, two sensors are applied to both sides of the forehead. The light passes not only through parts of the frontal brain but also through the overlying skull and scalp. Contamination of the oximetry signal by extracranial blood sources is a serious concern, although the use of two sensing diodes with different distances from the light source within one sensor patch and adjustments of the algorithm of the oximeter may minimize this problem.[13,14]

Because two thirds to four fifths of the cerebral blood volume is venous blood, cerebral oximetry determines predominantly local venous oxygen saturation.[15] It can be expected that, in the presence of cerebral ischemia, oximetry values decrease as a result of increased oxygen extraction, well before function fails or permanent neuronal damage ensues. The simplicity of its use and the familiarity with the principles of treating decreases in systemic mixed venous oxygen saturation have made cerebral oximetry a popular trend monitor in operations that potentially cause decreases in blood flow to the vessels of the head. The use of cerebral oximetry during such procedures has some significant limitations, however. First, adequacy of global cerebral perfusion is inferred from measurements over the frontopolar brain. Second, normative data on normal values or expected changes for cerebral oximetry are largely absent, but preoperative application of the sensors allows the start of a trend in conjunction with a neurologic baseline examination.

An example of how these limitations play out is provided by a study of the use of cerebral oximetry during 100 carotid endarterectomies in awake patients.[16] Cerebral oximetry was able to identify 97.4% of patients with adequate CBF as indicated by the absence of clinical symptoms. The monitor frequently indicated inadequate CBF, defined as a 20% decrease in cerebral oxygen saturation from the preclamp baseline, although the patient had no clinical symptoms of inadequate CBF. The false-positive rate of 66.7% may simply illustrate that oxygen extraction increases before function fails. The real problem is that the lower limit of acceptable regional oxygen saturation is unknown in a large population of patients.[17] The value may be different from patient to patient, and the addition of anesthetic drugs that influence cerebral metabolism may confuse the picture further.

Tissue-Level Blood Flow Monitoring Techniques (Invasive)

Tissue-level monitoring for the brain is by definition invasive. All monitors in current clinical or research use are implanted through a burr hole, extend either into the white matter or ventricular system, and typically use a bolt for stabilization. They all share a 1% to 2% risk of bleeding, infection, or ischemia related to the implantation procedure.[18] A second shared feature is their limited spatial resolution (i.e., each monitoring probe monitors only a limited area of brain surrounding the probe). When these monitors were first developed, optimal placement of the device was not clear, given such limited spatial resolution. Based on today's appreciation of the impact of secondary neurologic insults on the ultimate outcome, tissue-level monitoring is best performed in morphologically and functionally normal tissue that is part of the penumbra or vulnerable zone of interest.[19-21] Placing a blood flow monitor into the brain tissue supplied by an aneurysm-carrying artery in the setting of a subarachnoid hemorrhage maximizes, but does not ensure, the chances of early detection of vasospasm.

Of the tissue-level monitors, two have undergone sufficient refinement to be in wider clinical use. They represent the two principal modes of assessing adequate blood flow: assessing CBF through thermal diffusion monitoring and assessing oxygen delivery through tissue partial pressure of oxygen (Po_2) monitoring.

Thermal Diffusion Cerebral Blood Flow Monitoring. Thermal diffusion CBF monitoring is based on the idea that the rate at which heat dissipates in a tissue depends on the tissue's thermal conductive properties and the blood flow in that area. Because thermal conduction properties remain constant, changes in heat dissipation reflect changes in blood flow and can be expressed quantitatively in the conventional units of CBF as mL/100 g/minute. In practice, the probe consists of a thin catheter with two thermistors placed 5 mm apart (Fig. 49-2). When inserted, both thermistors are located in subcortical white matter. The proximal or passive thermistor measures brain temperature, whereas the distal or active thermistor is heated to 2° C higher than the temperature measured by the passive thermistor. The power required to sustain the

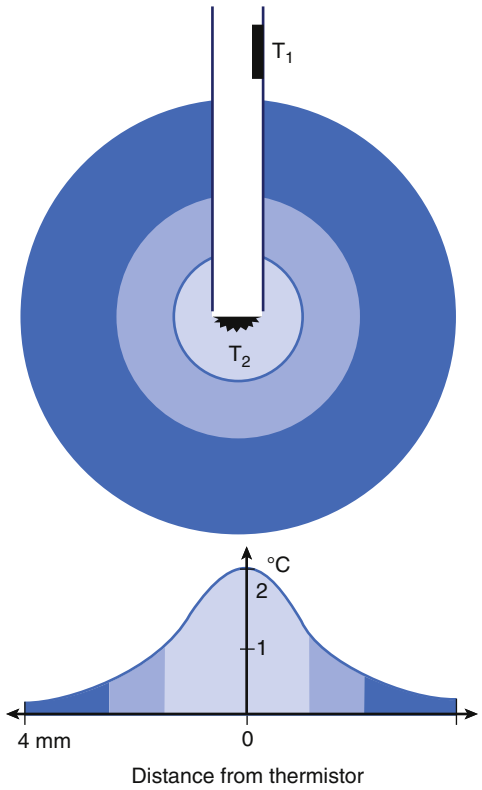

Figure 49-2. Thermal diffusion measurement of cerebral blood flow. The probe is placed in the subcortical white matter. It contains a passive thermistor (T_1) that measures brain temperature and is located outside of the area influenced by the active thermistor. The active thermistor (T_2) is heated to 2° C higher than brain temperature. The energy required to maintain that increase in temperature is proportional to cerebral blood flow.

2° C temperature difference is directly proportional to CBF. The initial rate of propagation of the thermal field is used to establish the fixed conductive component of heat transfer.

The short-term performance of this technology was validated against stable xenon computed tomography (CT) in patients with head injury, and the technology performed well across a wide range of CBF values in a sheep model of hypercarbia, hyperventilation, and cardiac arrest.[22] In continuous clinical use, the probe shows some drift and recalibrates at regular intervals.[23] To avoid thermal tissue injury, measurement is automatically suspended if the passive thermistor measures a brain temperature of 39.1° C. Because fever is a frequent complication, particularly in patients with severe brain disease, the inability to monitor during a febrile episode may constitute a true limitation of the technique.

Tissue Partial Pressure of Oxygen Monitoring. Localized monitoring of tissue Po_2 is based on an oxygen-sensitive electrode originally described by Clark.[24] The diffusion of oxygen molecules through an oxygen-permeable membrane into an electrolyte solution causes an electric current that is proportional to Po_2. Currently available catheter-based electrodes provide stable recording conditions over long periods. Similar to regional CBF probes, they are placed into the subcortical white matter.

Most of the data on brain tissue oxygen levels ($P_{Br}O_2$) come from studies in patients with head trauma. Comparison with stable xenon CT for assessment of CBF shows good correlation between $P_{Br}O_2$ and CBF.[25,26] Similarly, the time course of changes in $P_{Br}O_2$ after traumatic brain injury resembles that of CBF.[27,28] Critics of the technique argue that $P_{Br}O_2$ values are highly influenced by the partial pressure of arterial oxygen (Pao_2) and are merely an elaborate indicator of the quality of the patient's ventilation. This view is supported by the observation that increasing the fraction of inspired oxygen (Fio_2) increases $P_{Br}O_2$, but this likely represents an oversimplification.[29] Concurrent microdialysis studies have shown that increasing Fio_2 not only increases $P_{Br}O_2$ but also decreases tissue lactate levels, findings suggesting a true improvement in the metabolic milieu of the brain tissue itself.[30,31]

MONITORS OF NERVOUS SYSTEM FUNCTION

The most commonly used monitors of function are the electroencephalogram (EEG), sensory-evoked responses (SERs), motor-evoked responses, and the electromyogram (EMG). The EEG is a surface recording of the summation of excitatory and inhibitory postsynaptic potentials spontaneously generated by the pyramidal cells in the cerebral cortex. The signals are very small, and each recording electrode records only information generated directly beneath the electrode. Monitoring the EEG is usually directed toward one or more of four perioperative uses. First, the EEG is used to help identify inadequate blood flow to the cerebral cortex that is caused by either surgically induced or anesthetic-induced reduction in blood flow or retraction on cerebral tissue. Second, the EEG may be used to guide an anesthetic-induced reduction of cerebral metabolism either in anticipation of a loss of CBF or in the treatment of high intracranial pressure, when a reduction in CBF and blood volume is desired. Third, the EEG may be used to predict neurologic outcome after a brain insult. Finally, the EEG may be used to gauge the depth of the hypnotic state of the patient under general anesthesia (see Chapter 50).

EEG patterns can correlate with clinical states of the normal and diseased cerebral cortex. The electroencephalographer can accurately identify consciousness, unconsciousness, seizure activity, stages of sleep, and coma. In the absence of significant changes in anesthetic technique, the electroencephalographer also can accurately identify inadequate oxygen delivery to the brain (from either hypoxemia or ischemia). By using high-speed computerized EEG analysis and statistical methods, EEG patterns in the continuum from awake to deeply anesthetized are becoming, with few exceptions, much better understood. In addition, computer advances have made possible high-speed mathematic manipulation of the EEG signal to present the data in a manner more suitable to continuous trends for use during surgical or anesthetic monitoring.

Evoked potentials are electrical activity generated in response to either a sensory or a motor stimulus. Measurements of evoked responses may be made at multiple points along an involved nervous system pathway. The

evoked responses are generally smaller than other electrical activity generated in nearby tissue (muscle or brain) and are readily obscured by these other biologic signals. In the case of SERs, repeated sampling and sophisticated electronic summation and averaging techniques are needed to extract the desired evoked potential signal from background biologic signals. Motor-evoked responses are generally larger and commonly do not require averaging.

SERs are the most common type of evoked potentials monitored intraoperatively. Since the 1990s, much research has been done on the use of intraoperative motor-evoked potentials (MEPs). Although routine use of MEP monitoring is still not widespread, it is becoming more so. The three basic types of SERs are somatosensory-evoked potentials (SSEPs), brainstem auditory-evoked potentials (BAEPs), and visual-evoked potentials (VEPs).

The SSEP is produced by electrically stimulating a peripheral (or rarely cranial) nerve. Responses may be recorded proximally over the stimulated nerve, the spinal cord, and the cerebral cortex. The recorded responses assess the function of the peripheral nerve, the posterior and lateral aspects of the spinal cord, a small portion of the brainstem, the ventral posterolateral nucleus of the thalamus, the thalamocortical radiation, and a portion of the sensory cortex. The BAEP is usually produced by a series of rapid, loud clicks applied directly to the external auditory canal. Responses are most commonly recorded from electrodes applied to the scalp, although more invasive direct recordings from auditory structures and nerves may also be made. BAEPs assess function of the following: the auditory apparatus itself; cranial nerve VIII; the cochlear nucleus; and a small area of the rostral brainstem, the inferior colliculus, and the auditory cortex. The VEP is produced by flash stimulation of the retina. Recordings are made from cortically placed electrodes and assess visual pathways from the optic nerve to the occipital cortex.

MEP responses are generated most commonly by the application of a transcranial train of electrical stimuli, and responses are recorded at various points along the spinal column, peripheral nerve, and innervated muscle. Electrical stimuli to activate motor tracts also may be applied at the level of the spinal cord, but this method of stimulation is controversial (see later). At best, it is a mixed response and at worst primarily a sensory response. MEPs assess the integrity of the descending motor pathway through the internal capsule, the brainstem, the spinal cord, the peripheral nerve, and finally the muscle itself. The ability to record MEPs from some patients with cerebral palsy indicates that normal functional organization of the motor cortex cannot be inferred from MEPs.

Electroencephalogram

Basic Unprocessed Electroencephalogram Concepts. The EEG is produced by a summation of excitatory and inhibitory postsynaptic potentials produced in cortical gray matter. Because the EEG signal is generated only by postsynaptic potentials and is much smaller than action potentials recorded over nerves or from heart muscle, extreme care must be taken when placing electrodes to ensure proper placement and excellent contact with the skin, to avoid significant signal loss. Alternatively,

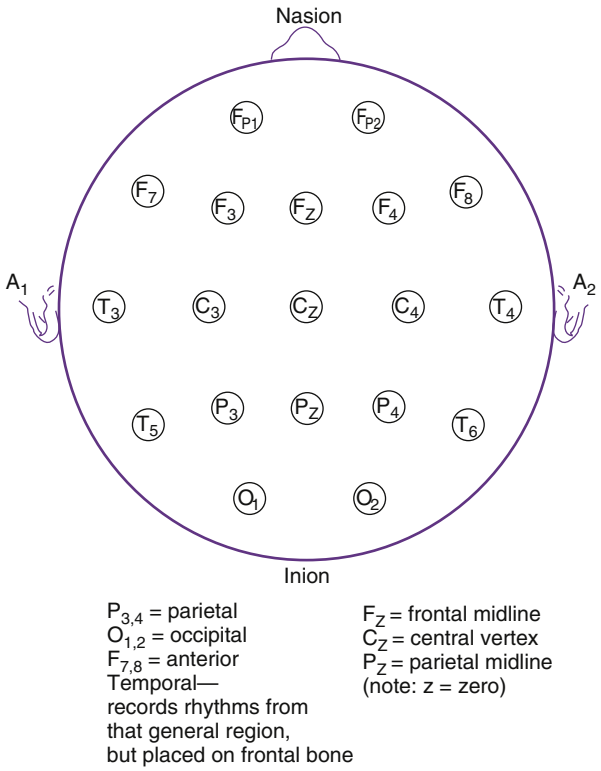

Figure 49-3. International 10-20 system of electrode placement for recording electroencephalogram and sensory-evoked responses. *(From Hughes JR:* EEG in clinical practice, *ed 2, Newton, Mass, 1994, Butterworth-Heinemann.)*

subdermal needle electrodes may be used, particularly when sterile application of an electrode close to a surgical field is necessary. When electrodes are applied directly to the surface of the brain, impedance is minimized by close electrode contact and saturation of the area with an electrolyte solution.

EEG electrodes generally are placed according to a mapping system that relates surface head anatomy to underlying brain cortical regions. The placement pattern of recording electrodes is called a montage. Use of a standard recording montage permits anatomic localization of signals produced by the brain and allows development of normative EEG patterns and comparison of EEG recordings made at different times. The standard EEG "map" is called the 10-20 system for EEG electrode placement (Fig. 49-3). This system is a symmetric array of scalp electrodes placed systematically based on the distance from the nasion to the inion and from the pretragal bony indentations associated with both temporomandibular joints. Based on 10% or 20% of these distances, recording electrodes are placed systematically over the frontal (F), parietal (P), temporal (T), and occipital (O) regions at increasing distances from the midline. Left-sided electrodes are given odd number subscripts, and right-sided electrodes are given even number subscripts. Increasing numbers indicate an increasing distance from the midline. Midline electrodes are designated with a "z" subscript. The standard diagnostic EEG uses at least 16 channels of information,[32] but intraoperative recordings have been reported using 1 to 32 discrete channels.

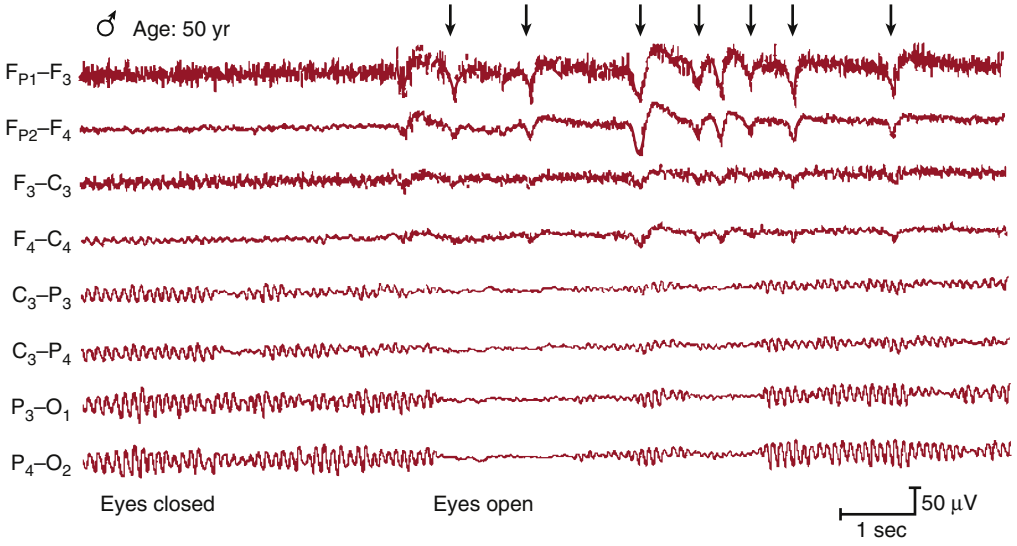

Figure 49-4. The loss and return of alpha activity as the eyes open and close can be seen. The large spikes (*arrows*) are muscle artifact from eye blinks and hence are best visible in channels that incorporate frontal electrodes (designated *F*).

The intraoperative EEG is most commonly recorded from electrodes placed on the scalp. Recordings also may be made from electrodes placed on the surface of the brain (electrocorticography) or from microelectrodes placed transcortically to record from individual neurons (e.g., during surgery for Parkinson disease).[33,34] The EEG signal is described using three basic parameters: amplitude, frequency, and time. Amplitude is the size, or voltage, of the recorded signal and ranges commonly from 5 to 500 μV (versus 1 to 2 mV for the electrocardiogram signal). Because neurons are irreversibly lost during the normal aging process, EEG amplitude decreases with age. Frequency can be thought of simply as the number of times per second the signal oscillates or crosses the zero voltage line. Time is the duration of the sampling of the signal; this is continuous and real time in the standard paper or digital EEG, but it is a sampling epoch in the processed EEG (see later).

Normal Electroencephalogram. Normal patterns seen on the EEG vary among normal individuals, but they are consistent enough to allow for accurate recognition of normal and pathologic patterns. The usual base frequency in an awake patient is the beta range (>13 Hz). This high-frequency and usually low-amplitude signal is common from an alert attentive brain and may be recorded from all regions. With eye closure, higher-amplitude signals in the alpha frequency range (8 to 13 Hz), seen best in the occipital region, appear (Fig. 49-4). This "eyes closed" resting pattern is the baseline awake pattern used when anesthetic effects on the EEG are described. When events occur that lead the brain to produce higher frequencies and larger amplitudes, the EEG is described as activated, and when slower frequencies are produced (theta = 4 to 7 Hz, and delta = <4 Hz), the EEG is said to be depressed. The EEG in a sleeping patient may contain all these frequencies at various times. The slower frequencies occur during deep natural sleep with "sleep spindles" (Fig. 49-5), but during light sleep or rapid eye movement (REM) sleep, the EEG becomes activated, and the eye muscle EMG appears on the EEG.

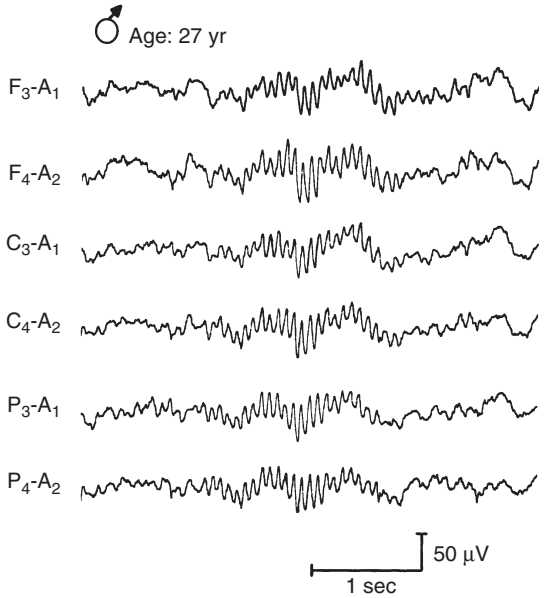

Figure 49-5. Characteristic sleep spindles in normal sleep are shown in the *center*.

In the normal EEG in awake and asleep patients, patterns recorded from corresponding electrodes on each hemisphere are symmetric in terms of frequency and amplitude, the patterns are predictable if clinical states are known, and spike (epileptic) waveforms are absent. In most cases, normal EEG patterns are associated with normal underlying brain function in awake and anesthetized patients.

Abnormal Electroencephalogram. General characteristics of the "abnormal" EEG include asymmetry with respect to frequency, amplitude, or both, recorded from corresponding electrodes on each hemisphere, and patterns of amplitude and frequency that are unpredictable or unexpected in the normal recording. These abnormal patterns reflect either anatomic or metabolic alterations

in the underlying brain. Regional asymmetry can be seen with tumors, epilepsy, and cerebral ischemia or infarction. Epilepsy may be recognized by high-voltage spike and slow waves, whereas cerebral ischemia manifests first with EEG slowing with preservation of voltage. Further slowing and loss of voltage occur as ischemia becomes more severe. Factors affecting the entire brain may produce symmetric abnormalities of the signal. Identifying pathologic abnormal patterns in the global EEG signal is very important, although sometimes quite difficult, in the clinical situation. Many of the normal global pattern changes produced by anesthetic drugs are similar to pathologic patterns produced by ischemia or hypoxemia. Control of anesthetic technique is essential when the EEG is used for clinical monitoring of the nervous system.

Processed Electroencephalogram Concepts. Interpretation of the standard raw EEG tracing is a science and an art. Until the last quarter of the twentieth century, the raw EEG was used during intraoperative monitoring, and the technologist relied on memory of the baseline and on experience to determine when significant EEG changes occurred. This qualitative approach was used simply because the waveforms could not be described mathematically in a time frame that would make such information of any practical use. Computer hardware has dramatically improved in speed and size, and real-time signal processing is now possible and commonly used.

Numerous limitations are introduced when moving from the raw EEG domain to the processed EEG domain. First, artifact is processed in many cases along with desired signal, thus leading to a perfectly believable processed EEG display that is materially incorrect. Second, the standard 16-channel EEG montage provides more information than can be practically analyzed or displayed by most processed EEG monitors and perhaps more than is needed for routine intraoperative use. Most available processed EEG devices used by anesthesiology personnel use four or fewer channels of information—translating to at most two channels per hemisphere. Processed EEG devices generally monitor less cerebral territory than a standard 16-channel EEG. Third, some intraoperative changes are unilateral (e.g., regional ischemia resulting from carotid clamping), and some are bilateral (e.g., EEG depression by bolus administration of an anesthetic drug). Display of the activity of both hemispheres is necessary to delineate unilateral from bilateral changes. An appropriate number of leads over both hemispheres is needed. Most early studies validating intraoperative EEG monitoring used continuous visual inspection of a 16- to 32-channel analog EEG by an experienced electroencephalographer; such monitoring was considered the gold standard.[35,36] Adequate studies comparing the processed EEG with fewer channels with this gold standard across multiple uses and operations have not been conducted, although limited data using processed EEG monitoring during carotid surgery suggest that 2- or 4-channel instruments would detect most significant changes,[37,38] provided the electrodes are appropriately placed over watershed areas of blood supply.

Devices. EEG processing for intraoperative monitoring is typically based on power analysis of a segment of raw EEG, referred to as an epoch (see also Chapter 50). Power analysis uses Fourier transformation to convert the digitized raw EEG signal into component sine waves of identifiable frequency and amplitude. The raw EEG data, which are a plot of voltage versus time, are converted to a plot of frequency and amplitude versus time. Many commercially available processed EEG machines display power (voltage or amplitude squared) as a function of frequency and time. These monitors display the data in two general forms, either compressed spectral array or density spectral array. In compressed spectral array, frequency is displayed along the *x*-axis, and power is displayed along the *y*-axis with height of the waveform equal to the power at that frequency. Time is displayed along the *z*-axis. Tracings overlap each other, with the most recent information in front (Fig. 49-6). Density spectral array also displays frequency along the *x*-axis; time is displayed along the *y*-axis, and power is reflected either by the density of the dots at each frequency or by a spectrum of colors. Each display format provides the same data, and choice depends on the preference of the user.

Many changes that occur during anesthesia and surgical procedures are reflected as changes in amplitude, frequency, or both. These changes can be clearly seen in these displays if adequate and appropriate channels are monitored. Power analysis has been used clinically for many years as a diagnostic tool during procedures with

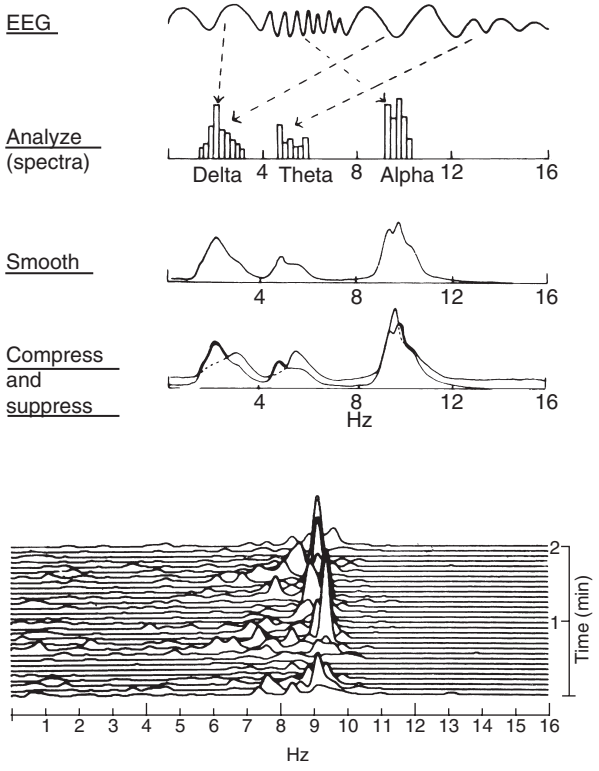

Figure 49-6. Diagram of a technique used to generate compressed spectral array. The example at the *bottom of the figure* shows compressed spectra of the alpha rhythm from a normal subject. *(From Stockard JJ, Bickford RG: The neurophysiology of anaesthesia. In Gordon E, editor:* A basis and practice of neuroanesthesia, *New York, 1981, Elsevier, p 3.)*

risk for intraoperative cerebral ischemia, such as carotid endarterectomy and cardiopulmonary bypass (CPB). Power analysis is a sensitive and reliable monitor in the hands of experienced operators using an adequate number of channels. In addition, parameters obtained from power analysis have been investigated as monitors for depth of anesthesia[39-42] (see Chapter 50).

Data Acquisition Period. An important consideration in the processed EEG is time. Raw EEG is continuous in real time. The processed EEG samples data over a given time period (epoch), processes the data, and then displays information in various formats. A relationship exists between epoch length and spectral resolution. If a long epoch length is chosen, the waveform can be described precisely, but the time required for data processing is long and not real time. If a short length of data is sampled, analysis may be done in near-real time, but the epoch chosen for analysis may not be representative of the overall waveform (i.e., the condition of the patient). Moreover, data points may be insufficient for meaningful Fourier transformation. This issue, as related to the use of intraoperative EEG for analysis of anesthetic depth, was studied by Levy.[43] A longer epoch may produce less epoch-to-epoch variability and allow more precise description of frequency and power; however, the longer epoch increases the delay before new information is processed and displayed, thereby reducing the amount and timeliness of information available for clinical decision making. In studying EEG epochs of 2 to 32 seconds, Levy concluded that 2-second epochs are appropriate during general anesthesia.[43] Many commercially available devices have used 2-second epoch lengths, updated at varying user-selected intervals. With better and faster computers, continuous monitoring of 2-second epochs and now even longer epochs is possible.

Evoked Potentials

Basic Concepts Common to All Modalities. EEG signals provide information about cortical function, but little to no information about subcortical neural pathways crucial to normal neurologic function. Intraoperative monitoring of SERs has gained increasing popularity since the 1980s because it provides the ability to monitor the functional integrity of sensory pathways in an anesthetized patient undergoing surgical procedures that place these pathways at risk. Because motor pathways are often adjacent anatomically to these sensory pathways or are supplied by the same blood vessels, or both, function of motor pathways may be inferred, albeit imperfectly, from function of these sensory pathways. Today, MEPs are ideally monitored together with SERs to provide direct information about function of motor pathways.

Sensory-Evoked Responses. SERs are electrical CNS responses to electrical, auditory, or visual stimuli. SERs are produced by stimulating a sensory system and recording the resulting electrical responses at various sites along the sensory pathway up to and including the cerebral cortex. Because of the very low amplitude of SERs (0.1 to 10 μV), it is often impossible to distinguish SERs from other background biologic signals, such as the EEG or EMG, which may be considered in this case undesirable noise. To extract the SER from the background noise, the recorded signal is digitized, and signal averaging is applied. With this technique, signal recording is time-locked to the application of the sensory stimulus. During intraoperative posterior tibial nerve SER monitoring, after nerve stimulation at the ankle, only signal information occurring less than 90 msec after the stimulus is recorded (Fig. 49-7). The SER occurs at a constant time after the stimulus application; other electrical activity, such as spontaneous EEG, occurs at random intervals after the sensory stimulus. The averaging technique improves the SER signal-to-noise ratio by eliminating random elements and enhancing the SER. This enhancing effect increases directly with the square root of the number of responses added into the averaged response.

SER recordings are of two general types, determined by the distance of the recording electrode from the neural

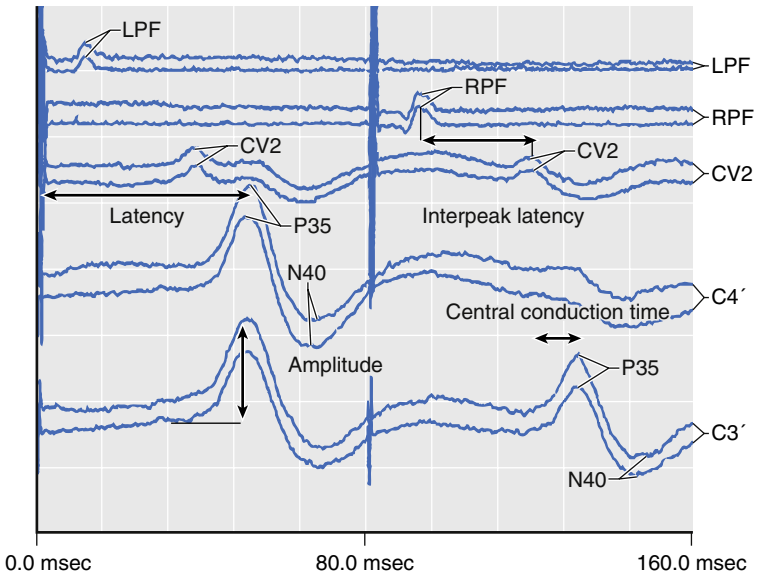

Figure 49-7. Sensory-evoked responses are described in terms of latency and amplitude. Interpeak latency is the measured time between two peaks. Interpeak latency may be measured between two peaks in the same channel or between peaks in different channels (shown in figure). The polarity of peaks is displayed contrary to standard convention (see text). The example shows a recording of posterior tibial somatosensory-evoked potentials. Each tracing is reproduced twice because reproducibility of a waveform helps distinguish signal from artifact. Left and right posterior tibial nerves are stimulated at 0 and 90 msec, respectively. The first evoked response is recorded from the left and right popliteal fossa (LPF and RPF, respectively). The peak labeled CV2 represents the brainstem response recorded at the craniocervical junction. As a far-field potential, the potential looks similar for right- and left-sided stimulation. The primary cortical responses are recorded from the contralateral hemisphere (labeled P35 and N40).

generator of the evoked response. SERs recorded from electrodes close to the neural generators (within ≈3 to 4 cm in the average adult) are termed near-field potentials.[44] Near-field potentials are recorded from electrodes placed very close to the actual signal generator site,[45] and the morphology is directly affected by electrode location.[44] Far-field potentials are recorded from electrodes located a greater distance from the neural generator and are conducted to the recording electrode through a volume conductor (brain, cerebrospinal fluid, and membranes). Because the current spreads diffusely throughout the conducting medium, it is more difficult to locate the source of the recorded signal, and the electrode position has little effect on the morphology of the recorded evoked potential (see Fig. 49-7).[44,45] As the distance between the recording electrode and the neural generator increases, the recorded SER becomes smaller. More responses must be averaged to record far-field potentials (several thousand) than near-field potentials (50 to 100).[44,45]

SERs also may be described as cortical or subcortical in origin. Cortical SERs are generated by the arrival at the cortex of the volley of action potentials generated by stimulating the sensory system. Because these SERs are recorded as near-field potentials, they are typically easy to identify by elapsed time, waveform morphology, and amplitude. Subcortical responses may arise from many different structures depending on the type of response, including peripheral nerves, spinal cord, brainstem, thalamus, cranial nerves, and others. Cortical SERs are usually recorded from scalp electrodes placed according to the standard 10-20 system for EEG recordings (see Fig. 49-3). Subcortical-evoked responses also may be recorded as far-field potentials from scalp electrodes or, as appropriate, from electrodes placed over the spinal column or peripheral nerve.

Evoked potentials of all types (sensory or motor) are described in terms of latency and amplitude (see Fig. 49-7). Latency is defined as the time measured from the application of the stimulus to the onset or peak (depending on convention used) of the response. The amplitude is simply the voltage of the recorded response. According to convention, deflections below the baseline are labeled positive (P), and deflections above the baseline are labeled negative (N). Because amplitude and latency change with recording circumstances, normal values must be established for each neurologic monitoring laboratory and may differ from values recorded in other laboratories.

SERs used for intraoperative monitoring include SSEPs, BAEPs, and, rarely, VEPs. For all these techniques, cortical recording electrodes are placed on the scalp, by using the same standard 10-20 system as for recording the EEG, whereas recordings for subcortical and peripheral signals are placed in various standardized anatomic locations. The surgical incision and the need for sterility may necessitate nonstandard electrode placements. Such deviations must be considered when interpreting baseline and subsequent SERs. In the case of MEPs, stimulating electrodes also are placed according to the 10-20 system of electrode placement, but over motor cortex instead. Recording electrodes may be placed over the spinal column, peripheral nerve, and (most commonly) innervated muscle.

Intraoperative changes in evoked responses, such as decreased amplitude, increased latency, or complete loss of the waveform, may result from surgical trespass, such as retractor placement or ischemia. They may also reflect systemic changes, such as changes in the anesthetic drugs or doses, temperature, or hypoperfusion. If these changes are clinically significant, the surgeon or anesthesiologist can make changes to relieve or lessen the insult to the monitored pathway (and presumably surrounding neural structures). Interventions by the anesthesiologist are directed at improving perfusion to the nervous tissue at risk and include increasing arterial blood pressure, especially if induced hypotension is used or if arterial blood pressure has decreased to less than the preoperative level. In addition, correction of anemia with a blood transfusion, intravascular volume expansion, augmentation of cardiac output, and ensuring that arterial blood gas tensions are adequate all must be considered. Changes in evoked potentials after retractor placement during craniotomy or after compression of the blood supply to the spinal cord from spinal column distraction promptly allow the surgeon and the anesthesiologist to make appropriate changes to the operative procedure and anesthetic management to minimize the chance of a postoperative neurologic deficit (Fig. 49-8).

Tolerance limits for degree of change in evoked response signals or duration of complete loss of waveform before permanent neurologic dysfunction occurs are not clearly defined, especially for transcranial MEPs. Such ambiguity is common among intraoperative monitors. Although we do know that increased frequency and duration of ST-segment depression during coronary bypass surgery are associated with an increased risk of perioperative infarction, exact limits for degree and duration of ST-segment depression for surgery do not exist and likely vary significantly from patient to patient. The same problem may be exhibited with neurologic monitors.

Many centers using intraoperative SER monitoring define decreases in amplitude of 50% or more from baseline associated with a less than 10% prolongation in latency as clinically significant SER changes. If not corrected, such changes are associated in clinical series and in case reports with onset of new postoperative neurologic deficits. As a result, such changes are immediately investigated. In practice, any SER changes directly associated with a surgical event are considered clinically significant, even if the magnitude of change is less than just described. Changes in SER that do not progress to complete loss of the waveform are less likely to be associated with a major new postoperative neurologic deficit. Complete loss of the SER waveform intraoperatively without recovery probably indicates a major new deficit. If the SER recovers either spontaneously or after intraoperative interventions, the likelihood of neurologic injury depends on the procedure, the duration of the SER loss, and whether the SER is mainly used to judge integrity of adjacent unmonitored structures. These problems were illustrated in one study of aortic vascular surgery in which SSEPs were monitored to predict or prevent postoperative motor deficits (i.e., paraplegia or paraparesis). Loss of the SSEP waveform for less than 15 minutes was not associated with a new permanent neurologic deficit, whereas

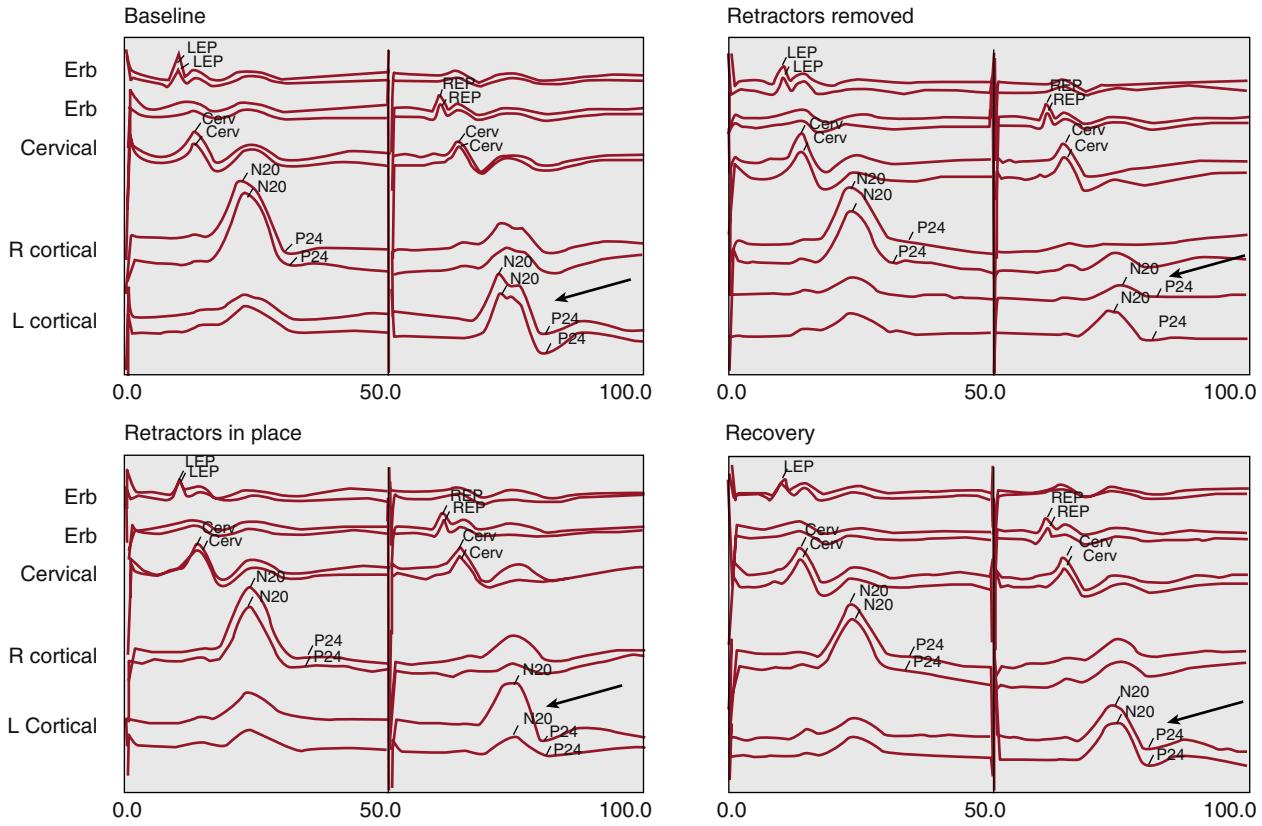

Figure 49-8. Somatosensory-evoked potentials during aneurysm clipping. Responses generated by the cortex at risk are indicated by *arrows*. Baseline, after retractor placement, after retractor removal, and recovery traces are shown. The initial evoked response change occurred 4 minutes after retractor placement. Note loss of voltage of cortical-evoked response caused by inadvertent compression of the middle cerebral artery. *Cerv,* Cervical; *LEP,* left Erb point; *REP,* right Erb point.

complete loss of the SSEP for longer periods was increasingly likely to reflect permanent neurologic injury, even if the response recovered completely to its intraoperative baseline during the surgical procedure.[46]

One of the most important principles of recording SERs intraoperatively is that reproducible, reliable tracings must be obtained at baseline before any intervention likely to cause changes in the evoked response. If good-quality tracings with identifiable waveforms cannot be recorded and reproduced at baseline, evoked response monitoring will be of little use in monitoring the integrity of the CNS intraoperatively. If significant variability exists, or waveforms are difficult to identify, it will be impossible intraoperatively to distinguish SER changes that are clinically significant from a preexisting baseline variability of waveforms. When excellent, reproducible responses cannot be recorded at baseline, monitoring should not be used for clinical decision making.

Somatosensory-Evoked Potentials. SSEPs are recorded after electrical stimulation of a peripheral mixed nerve. Stimulation is provided most commonly with surface electrodes (e.g., electrocardiogram electrodes) placed on the skin above the nerve or with fine needle electrodes. A square wave stimulus lasting 50 to 250 μsec is delivered to the peripheral nerve, and the intensity is adjusted to produce a minimal muscle contraction. Increasing the stimulus intensity beyond the sum of the motor and sensory threshold does not influence the amplitude or latency of the recorded evoked potential. On a practical basis, however, SSEP monitoring is often not initiated until after the patient is already anesthetized and paralyzed. In these cases, stimulus intensity is increased until no further increase in response size occurs at any recording site, typically constant current stimulation of 20 to 50 mA. For comparison, consider supramaximal stimulation used for the neuromuscular blockade monitor, commonly 80 mA. The rate of stimulation varies from 1 to 6 Hz. The common sites of stimulation include the median nerve at the wrist, the common peroneal nerve at the knee, and the posterior tibial nerve at the ankle[47] (see also Chapter 53).

SSEP responses consist of short-latency and long-latency waveforms. Cortical short-latency SSEPs are most commonly recorded intraoperatively because they are less influenced by changes in anesthetic depth. The pathways involved in the generation of upper extremity short-latency SSEPs include large-fiber sensory nerves with their cell bodies in the dorsal root ganglia and central processes traveling rostrally in the ipsilateral posterior column of the spinal cord and synapsing in the dorsal column nuclei at the cervicomedullary junction (first-order fibers), second-order fibers crossing and traveling to the contralateral thalamus through the medial lemniscus, and third-order fibers from the thalamus to the frontoparietal sensorimotor cortex. These primary cortical-evoked responses, which are recordable with most anesthetic

techniques, result from the earliest electrical activity generated by the cortical neurons and probably arise from the postcentral sulcus parietal neurons. The longer-latency secondary cortical waves probably arise in the association cortex. These responses have much greater variability in an awake patient,[45] habituate rapidly on repetitive stimulation,[44] and are only poorly reproducible during general anesthesia. Cortical SSEPs other than the primary cortical response are not monitored or interpreted intraoperatively because they are severely altered by general anesthesia.[44]

Upper extremity evoked potentials are likely conducted rostrally in the spinal cord through dorsal column pathways, and lower extremity SSEPs are conducted substantially by the lateral funiculus.[48] Stimulation of the posterior tibial nerve or common peroneal nerve at or higher than motor threshold activates group I fibers that synapse and travel rostrally through the dorsal spinocerebellar tract. After synapsing in nucleus Z at the spinomedullary junction, the pathway crosses and projects onto the ventral posterolateral thalamic nucleus.[49] Lower extremity SERs are conducted in all quadrants of the spinal cord, but primarily in the dorsal lateral funiculus.[50,51] This pathway difference is important because the dorsal lateral funiculus is supplied primarily by the anterior spinal artery, the artery that also supplies the descending motor pathway and neurons in the spinal cord. Manipulations, such as distraction of the spinal column to correct scoliosis, that may secondarily compress or distort radicular blood supply to the anterior spinal cord should cause changes in the SSEP in the event blood supply is reduced to critical levels. This hypothesis is verified by the very infrequent, but not zero, incidence of postoperative paraplegia on awakening without any intraoperative changes in SSEPs.

For SSEP recordings with median nerve stimulation, recording electrodes (usually electrocardiogram pads) are first placed at the Erb point, just above the midpoint of the clavicle. This point overlies the brachial plexus, and signals recorded here assure the clinician that the stimulus is actually being delivered properly to the patient. The next electrode (either an electrocardiogram pad or a gold cup electrode) is placed midline posteriorly over the neck at level of the second cervical vertebra, relatively near the dorsal column nuclei. Signals recorded here ensure proper transmission of the response from the peripheral nervous system into the spinal cord and rostral along the spinal cord to the lower medulla. The final electrodes (gold cup electrodes, corkscrew, or needle electrodes) are placed on the scalp overlying the sensory (parietal) cortex contralateral to the stimulated limb. Signals recorded here ensure the integrity of the pathway through the brainstem, thalamus, and internal capsule, and they may assess adequacy of CBF in this area of the cortex.[52-56]

To record SSEPs after posterior tibial nerve stimulation, electrodes (electrocardiogram pads) are placed first over the popliteal fossa to ensure proper stimulus delivery to the nervous system. Electrodes also may be placed over the lower lumbar spine to ensure proper transmission of the signal into the spinal cord itself, but this site is not commonly used because of the proximity of sterile surgical incisions. Cervical spine and scalp recording electrodes are placed in a similar fashion as described previously, although different locations may be used as required by the placement of the surgical incision. More invasive recording methods, such as epidural electrodes, also may be used intraoperatively.

Purported generators for short-latency SSEPs are listed in Table 49-1 and are shown in Figure 49-9.[44,47] Induction

TABLE 49-1 GENERATORS OF SOMATOSENSORY-EVOKED POTENTIALS AFTER MEDIAN NERVE STIMULATION

Peak	Generators
N9 (EP)	Brachial plexus*
N11	Posterior columns or spinal roots
N13/P13	Dorsal column nuclei*
N14, 15	Brainstem or thalamus
N19/P22	Parietal sensory cortex*

*Indicates sites commonly recorded during surgical procedures. All other waveforms indicated are not commonly monitored.

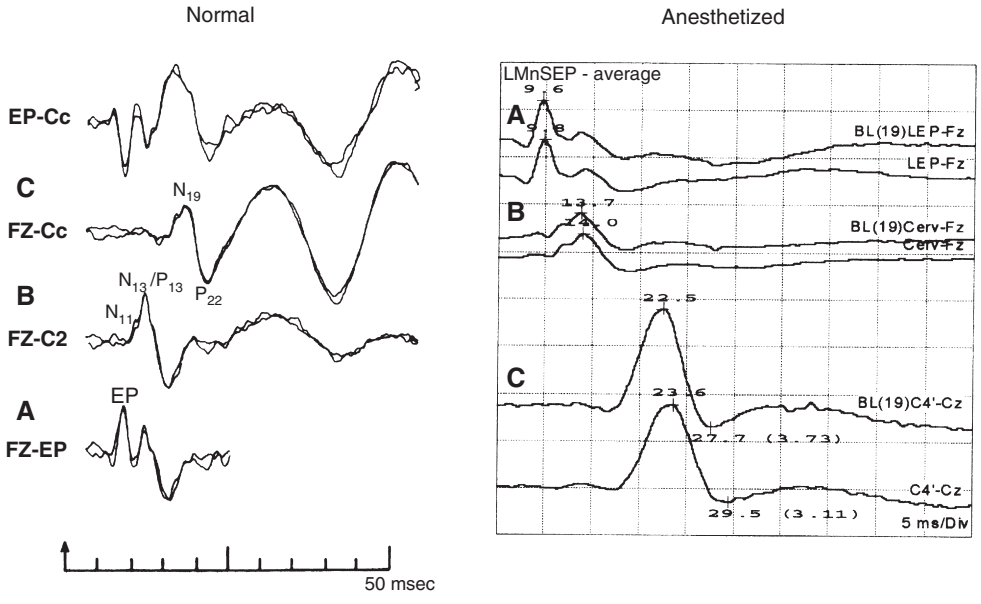

Figure 49-9. Short-latency somatosensory-evoked potentials (SEP) produced by stimulation of the left median nerve (LMn) at the wrist. The ability to identify each of the labeled peaks shown in the tracing from the awake patient is compromised by the anesthetic state and use of different recording electrode locations (*A* to *C*). Corresponding tracings are labeled with the same letter. *(From Chiappa KH, Ropper AH: Evoked potentials in clinical medicine,* N Engl J Med *306:1205, 1982.)*

of anesthesia and use of different recording electrode locations (montage), necessitated by the surgical incision, may significantly alter the appearance of the SSEP. In these cases, attribution of a particular generator to a given wave on the tracing may be quite difficult. During neurologic monitoring, such precision is not needed, and recorded waveforms are compared with tracings obtained at baseline and during earlier portions of the surgical procedure. After lower limb stimulation, absolute latencies are increased because of the greater distance the response to stimulation must travel along the peripheral sensory nerve and spinal cord. Interpeak latencies (see Fig. 49-7) also are evaluated to assess specific conduction times, such as N9 to N14 conduction time, reflecting transmission time from the brachial plexus to brainstem, or N14 to N19 conduction time, reflecting transmission time between the dorsal column nuclei and the primary sensory cortex.[57]

Brainstem Auditory-Evoked Potentials. BAEPs are produced in the diagnostic laboratory by delivering repetitive clicks or tones through headphones. Headphones are not practical for surgical monitoring of neurosurgical procedures, and click stimuli are delivered using foam ear inserts attached to stimulus transducers (Fig. 49-10). Stimulus intensity is usually set at 60 to 70 dB higher than the patient's click-hearing threshold, although, practically speaking, many intraoperative laboratories establish monitoring after induction of anesthesia and instead begin with a stimulus intensity of 90 dB nHL (normal hearing level). The duration of the click is approximately 100 μsec, and the stimulus is given usually 10 to 15 times per second. Clicks are delivered using different "polarities" (i.e., the click may cause initial movement of the tympanic membrane away from the transducer [rarefaction] or toward the transducer [condensation]). Use of these two different methods commonly produces very different waveforms, amplitudes, and latencies in individual patients, and the method that produces the largest reproducible response is chosen. If stimulus artifact is a serious problem, clicks of alternating polarity may be used to decrease the artifact, but the waveforms produced are an average of those produced by either stimulating technique alone and may be more difficult to monitor.

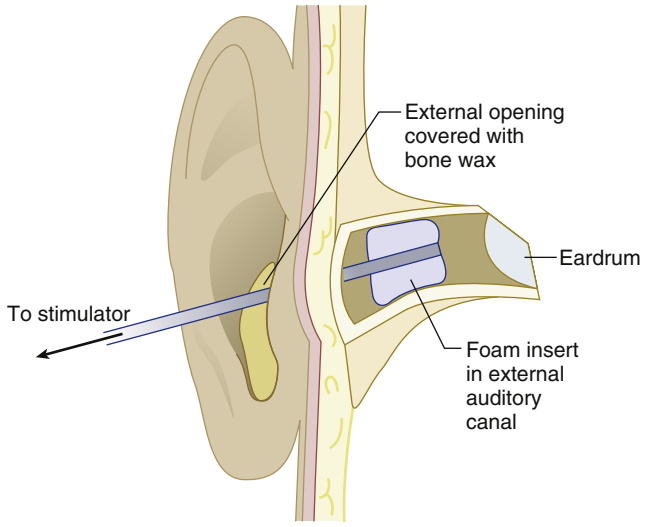

Figure 49-10. Schematic of brainstem auditory-evoked potential–stimulating apparatus. Loud click stimuli are delivered directly to the eardrum through the ear insert.

Rate and intensity of stimulus delivery affect BAEPs.[44,58] Unilateral stimulation is used because responses from the other ear, which may remain normal during surgical procedures, may obscure any abnormal responses from the monitored ear. Recording electrodes are placed on the lobe of the stimulated ear and on the top of the head (vertex).[58] White noise may be delivered to the contralateral ear to prevent bone conduction from stimulation of the monitored ear from producing an evoked response from the contralateral ear. On average, 500 to 2000 repetitions are required because BAEPs recorded from the scalp are far-field potentials and extremely small (often <0.3 μV).[44,58]

Peaks in recordings of BAEPs are labeled I through VII; the purported neural generators for these peaks and the auditory pathway are shown in Figure 49-11. The anatomic auditory pathway would predict that BAEP monitoring would be most useful for surgical procedures in the posterior fossa that risk hearing or structures in the upper medulla, pons, and midbrain. As with other SERs, amplitude, absolute latencies, and interpeak latencies are evaluated to assess integrity of the auditory system, localize the functional defect when it occurs, and assess peripheral and central conduction times. Because waves VI and VII are inconsistent and variable, they are not routinely monitored,[58] and most articles on the use of BAEP for surgical monitoring in the operating room report monitoring waves only up to wave V.[59-61]

Visual-Evoked Potentials. VEPs are recorded after monocular stimulation with recording electrodes over the occipital, parietal, and central scalp.[60] Flash stimulation of the retina using light-emitting diodes embedded in soft plastic goggles through closed eyelids or as needed by contact lenses with built-in light-emitting diodes is provided. VEPs are cortical SERs, which vary with the type of stimulus, part of the retina stimulated, degree of pupil dilation, and patient's attention level.[44] Because some of these factors change commonly and even constantly during the course of every anesthetic regimen, VEPs are highly variable during surgical procedures even when no surgical trespass on the visual system occurs. VEPs are the least commonly used evoked response monitoring technique intraoperatively. However, reproducible intraoperative VEPs have been generated using multiple red light-emitting diodes embedded in a soft silicone disk placed directly on the cornea for stimulating the retina.[62] This technique may allow for further studies that will determine the clinical utility of this modality.

Motor-Evoked Potentials. MEPs are generated most commonly by the application of a transcranial train of electrical stimuli, and responses are recorded at various points along the spinal column, peripheral nerve, and innervated muscle.

Transcranial Motor-Evoked Potentials. Monitoring of the integrity of the motor tracts within the spinal cord is

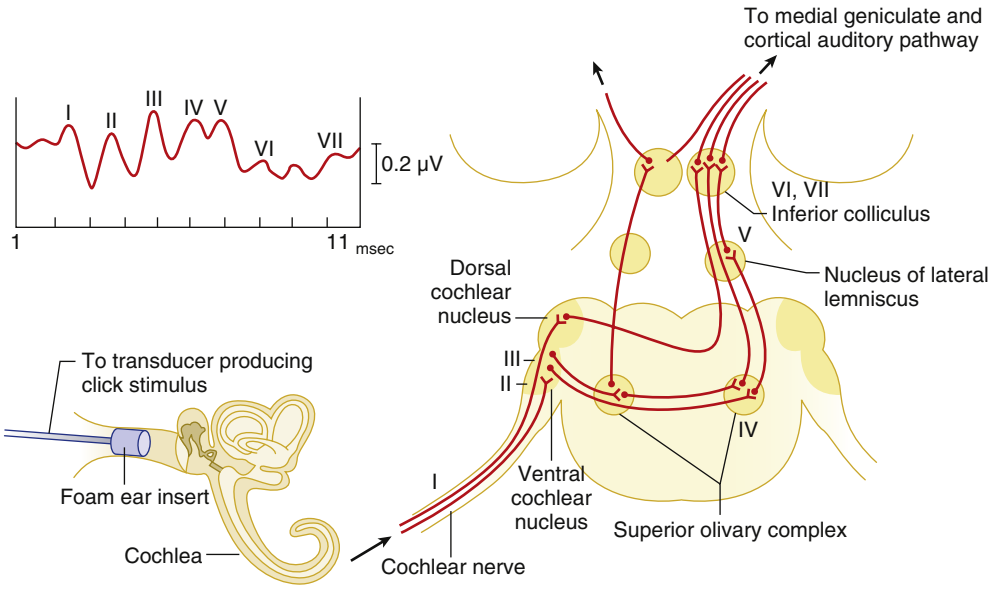

Figure 49-11. Schematic of auditory neural pathway. The brainstem auditory-evoked potential is initiated by stimulation of the cochlea with a broadband click stimulus given through an ear insert in the external auditory canal. Neural generators of the brainstem auditory-evoked potential peaks are shown.

a technique with great potential benefit, and even during the relative short history of MEP monitoring, cases of loss of MEPs with preservation of the SSEP have been reported.[63-68] This technique has potential applications in spinal surgery, in which transmission across the operative field can be assessed, and in aortic surgery, with the potential for impairment of the blood supply to the vulnerable anterior spinal cord. Relative to SER monitoring, MEP monitoring is quite invasive and, in the case of transcranial stimulation, uses much higher stimulus intensity (≥400 V).

Several variants of MEP monitoring exist. The most common method involves transcranial electrical stimulation. During transcranial electrical MEP monitoring, stimulating electrodes (usually small, metallic screw-type electrodes similar to those used in fetal monitoring) are placed into the scalp overlying the motor cortex, and a train of electrical stimuli (usually ≈400 to 500 V) is applied to the scalp. This stimulation definitely activates muscles of mastication, and bilateral bite-blocks must be placed to prevent serious damage to the tongue during stimulation. Alternatively, if the precentral gyrus or motor strip is exposed during the surgical procedure, stimulating electrodes may be placed directly onto the cortex. Because approximately 90% of the transcranial stimulus dissipates across scalp and skull, typical stimulus intensities of direct cortical stimulation are 40 to 50 V.

Both stimulating methods also activate surrounding cortical structures and subcortical white matter pathways (sensory and motor). In fact, transcranial MEPs (tcMEPs) can frequently be recorded from patients with cerebral palsy, despite the disruption of their cortical neuronal architecture. Distal antidromic propagation of the transcranially applied stimulus is blocked by synapses in all the ascending sensory pathways. The stimulus is propagated easily orthodromically through descending motor pathways. The evoked responses may be recorded over the spinal cord, the peripheral nerve, and, most commonly, the muscle itself. To enhance the MEP, these responses may be averaged in the same manner as SERs, but averaging is almost always unnecessary. Activation of the corticospinal tract well below the motor cortex may limit the utility of tcMEP to assess the adequacy of CBF to the motor cortex because activation may be distal to the site of ischemia and may be part of a different vascular bed.

Spinal Motor-Evoked Potentials. Another method of producing the MEP involves electrical stimulation of the spinal cord itself above the area of the spinal cord at risk during the surgical procedure. Responses may be recorded over the distal spinal cord, peripheral nerve, and muscle.[69-71] Responses are recorded distally, usually over the peripheral nerve, and profound surgical muscle relaxation is used to prevent gross movement intraoperatively. This type of MEP is called a neurogenic MEP. Initially, investigators believed that this response, recorded over a peripheral nerve in the lower extremity (typically the tibial nerve in the popliteal fossa), was generated by stimulation of the descending motor tracts, activation of the anterior horn cells, and propagation of the nerve action potential by the peripheral nerve. Multiple clinical trials were conducted using this technique and comparing results of MEP monitoring with the SSEP, with good results.[69-71] These responses also have the advantage that they do not show the same sensitivity to anesthetic drugs that SSEPs do and may be recorded with any anesthetic technique.

Subsequent studies in animals and humans showed that neurogenic MEPs are, at best, mixed responses with a significant component of an antidromically conducted response along the sensory pathway.[72] Stimulation of the dorsal column results in an antidromically conducted recordable signal peripherally because the somesthetic system does not synapse in the dorsal root ganglion, and fibers pass directly from the dorsal column through the cell body in the ganglion into the peripheral nerve. Because of this problem, use of neurogenic MEP monitoring has decreased significantly, replaced by the more invasive transcranial stimulation techniques, which produce responses that are exclusively produced by activation of the motor system.

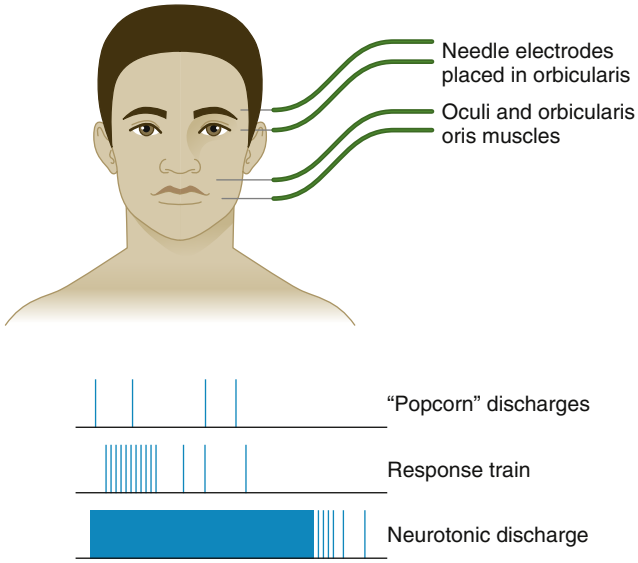

Figure 49-12. Schematic of facial nerve monitoring and typical responses seen during surgical procedures.

Electromyography. Intraoperative monitoring of EMG responses generated by cranial and peripheral motor nerves allows early detection of surgically induced nerve damage and assessment of level of nerve function intraoperatively. In these cases, the ability of a nerve to produce a response in the innervated muscle is used to assess the health of a cranial or peripheral nerve at risk during surgical procedures. Recordings are made from either surface (electrocardiogram or gold cup) electrodes or needle electrodes placed directly in the innervated muscle of interest. Sensitivity of EMG recordings is best, if recordings are made from needles within the muscle itself. Surface electrodes and, to a lesser extent, subdermal needle electrodes may completely miss neurotonic discharges that indicate damage to a nerve.[73] The most experience with this monitoring modality has been obtained during facial nerve monitoring.

EMG monitoring may be either active or passive. During active monitoring, a cranial or peripheral nerve is stimulated electrically, and the evoked EMG (compound muscle action potential) response from the muscle is recorded. Stimulation of the nerve proximal to the operative area or tumor can be used to assess functional integrity of the nerve.[74] Nerve function also may be assessed by noting the intensity of nerve stimulus needed to evoke a muscle response and by the morphology of the compound muscle action potential. Nerve function may be monitored passively during surgical procedures with continuous recording of all generated responses from innervated muscle groups. "Popcorn" EMG discharges are produced by simple, benign contact with the monitored nerve. Response trains are produced with more significant nerve irritation. Neurotonic discharges are produced by significant nerve irritation or damage, or both (Fig. 49-12).[75] When these EMG responses reach a certain voltage threshold, they are usually converted into audible signals that provide immediate feedback to the surgeon and warn of impending nerve damage in real time. Real-time feedback is key because density and frequency of neurotonic discharges may correlate with degree of postoperative nerve dysfunction, as shown by data obtained from patients undergoing resection of acoustic tumors.[74] One caveat of EMG monitoring is that sharp section of a nerve may produce no EMG discharge at all.

Intraoperative monitoring of the motor component of other cranial nerves also has been successfully performed. EMG monitoring of the trigeminal nerve can be accomplished with electrodes placed over or in the temporalis or masseter muscles. Trigeminal nerve motor monitoring has been used during nerve section for tic douloureux to ensure preservation of the motor branch of the trigeminal nerve and in combination with facial nerve monitoring during resection of large posterior fossa lesions.[75] Using recording electrodes placed in or over the trapezius or sternocleidomastoid muscles, the spinal accessory nerve has been successfully monitored during resection of large meningiomas, glomus jugulare tumors, and neck carcinomas.[75] EMG monitoring of the hypoglossal nerve with needle electrodes placed in the tongue has been infrequently used for large posterior fossa lesions and clivus tumors.[75] Although EMG monitoring of the eye muscles can be performed using tiny hook wires for recording, it is rarely used, except at a few centers.

Monitoring of peripheral motor nerves has been performed by placing needle electrodes in or over the muscles innervated by nerves that traverse the operative area and are at risk from the planned surgical procedure. Auditory feedback from EMG monitoring can warn the surgeon of unexpected surgical trespass of the nerve, help locate a nerve within the field (e.g., during untethering of the spinal cord), and localize the level of any conduction block or delay. Because radiculopathies have been reported to occur after surgical procedures of the spine, particularly because of incorrect pedicle screw placement, EMG monitoring of peripheral nerves has been used in patients undergoing spine operations, to decrease the risk of nerve root injury during the procedure.[75] During pedicle screw placement, the surgeon can stimulate the screw directly with a small amount of current. If EMG responses are produced with only a small amount of current, the screw has likely been placed outside the bony pedicle.

CLINICAL APPLICATIONS OF NEUROLOGIC MONITORING

NEUROVASCULAR SURGERY

Extracranial Neurovascular Surgery: Carotid Vascular Surgery (Monitors: Electroencephalogram, Somatosensory-Evoked Potentials, Transcranial Doppler, Cerebral Oximetry)

Electroencephalogram. The use of the EEG as a monitor of the adequacy of CBF during carotid endarterectomy has been established for many years. In a large series of patients undergoing carotid endarterectomy at the Mayo

Clinic in Rochester, Minn.[36] the EEG was compared with regional CBF by using the ^{133}Xe washout method. This study validated the EEG as an indicator of the adequacy of regional CBF.

Normal CBF in gray and white matter averages 50 mL/100 g/minute. With most anesthetic techniques, the EEG begins to become abnormal when CBF decreases to 20 mL/100 g/minute. The threshold for EEG changes apparently is much lower (8 to 10 mL/100 g/minute), however, when isoflurane is used.[76] Cellular survival is not threatened until CBF decreases to 12 mL/100 g/minute (lower with isoflurane). The difference in blood flow between when the EEG becomes abnormal and the blood flow at which cellular damage begins to occur provides a rational basis for monitoring the EEG during carotid surgical procedures. In many cases, prompt detection of EEG changes may allow intervention (e.g., shunting, increasing cerebral perfusion pressure) to restore CBF before onset of permanent neurologic damage. Standard hemodynamic monitoring provides no direct information about the adequacy of CBF. Blood pressure is not a specific indicator of the adequacy of CBF. Significant hypotension is not predictably associated with EEG evidence of cerebral ischemia. Severe anemia and decreases in oxygen saturation also decrease oxygen delivery. EEG activity becomes abnormal when increased blood flow cannot compensate for reduced arterial oxygen content.

Serious intraoperative decrease in cerebral oxygen supply may result from surgical factors (e.g., carotid cross-clamping) that are usually beyond the anesthesiologist's control and from factors that the anesthesiologist can correct. Reduction in CBF produced by hyperventilation, hypotension, or temporary occlusion of major blood vessels may be corrected by reducing ventilation, by restoring normal arterial blood pressure, or in the case of temporary vessel occlusion, by even increasing arterial blood pressure to higher than the normal preanesthetic value. Because the EEG may readily detect cerebral ischemia, continuous EEG monitoring can evaluate the effectiveness of therapy instituted to correct ischemia.

If monitoring of the EEG could be proved scientifically to reduce the incidence of stroke during carotid vascular surgical procedures, EEG monitoring would be established as a standard of care. Such definitive data do not exist because the incidence of stroke is too low to justify a large enough study to achieve statistical significance. So is universal use of EEG monitoring during carotid surgical procedures justified? In a large series of patients undergoing carotid endarterectomy with selective shunting who were monitored with 16-channel unprocessed EEG, no patient awakened with a new neurologic deficit that was not predicted by EEG.[77] Transient, correctable EEG changes were not associated with stroke. Persistent changes were associated with stroke. Unfortunately, this study had no comparison group (i.e., to determine the rate of stroke without EEG monitoring).

In the North American Symptomatic Carotid Endarterectomy Trial and the European Carotid Surgery Trial, retrospective comparison of patients receiving EEG monitoring and patients not receiving EEG monitoring failed to show a significant difference in outcome.[78,79] Because the EEG detects reductions in CBF that would not otherwise be apparent in unmonitored patients and permits intervention that may correct the problem (usually placing a shunt or increasing blood pressure), EEG monitoring should logically be useful in reducing the incidence of stroke when selective shunting is used. Data available from studies at this time bring us no closer to resolving this question, however, than we were in the 1980s. Advocates of monitoring and individuals who believe monitoring is of no value can cite multiple studies supporting each viewpoint.

Even more difficult to prove is that EEG monitoring is useful when all patients undergo shunting during carotid clamping. Such monitoring has detected correctable shunt malfunction, and investigators have described hypotension-related EEG changes in patients with critical stenoses and poor collateral circulation.[80] Advocates of selective shunting based on EEG (or other monitoring) criteria claim that inserting a shunt unnecessarily through a region of diseased vessel would surely increase embolization. A multicenter study of 1495 carotid endarterectomies provides some evidence that shunting in patients without evidence of decreased cerebral perfusion increases the incidence of stroke more than sixfold.[81] Although this study and other more recent studies advocated that selective shunting using some form of monitoring of the adequacy of CBF should improve the perioperative stroke rate,[82-84] an analysis by the Cochrane Stroke Group failed to show sufficient evidence to advocate for routine shunting, selective shunting, or even no shunting at all.[85] In addition, this review failed to demonstrate that any type of monitoring for cerebral ischemia was superior to another. Until compelling studies addressing this issue are done, it is unlikely that EEG monitoring or other forms of CNS monitoring during carotid vascular surgical procedures will become standard practice.

Processed EEG also has been used during carotid vascular surgical procedures. Two issues affect the efficacy and reliability of processed EEG as a monitor for cerebral ischemia. First, what is the minimum number of channels (or areas of the brain) to be monitored? The 16-channel unprocessed EEG is a reliable and sensitive monitor for intraoperative cerebral ischemia during carotid endarterectomy. In a series of more than 2000 patients monitored with 16-channel EEG at the Mayo Clinic, were no false-negative EEGs were found[77]; in other words, no patient had undetected intraoperative cerebral injury. However, in many operating rooms where carotid surgical procedures are performed, 16-channel EEG monitored by a dedicated technician is unavailable. Processed EEG using less than 16 channels is used much more commonly. Clinical experience and clinical investigations suggest that 4 channels (2 per side) are the minimum number of channels for adequate sensitivity and specificity.[37] When a limited number of channels were compared with 16-channel EEG monitoring, 100% sensitivity and specificity were obtained using 2 channels per hemisphere, provided those channels monitored the middle cerebral artery territory. These results were obtained with a frontoparietal channel combined with a frontotemporal channel.[37]

The second issue is the experience level of the observer monitoring the processed EEG. Is a dedicated,

experienced technician or electroencephalographer needed? In a study addressing this question, the 16-channel unprocessed EEG monitored by a dedicated technician was compared with a processed EEG reviewed by 3 anesthesiologists of differing levels of experience with processed EEG.[38] These anesthesiologists interpreted the tracings without knowledge of the case. They were presented only with the written trace with an indication of the point at which the carotid artery was clamped. In these cases, the most important interpretation pitfall to avoid is the "false-negative" pattern. If the clinician interprets the EEG as showing adequate CBF when in fact it does not, the surgeon may fail to place a shunt in an ischemic patient. A false-positive result may be less of a problem because that patient is not ischemic but is given a shunt anyway. In this case, only the risk of emboli from the "unnecessary" shunt is incurred. The positive predictive value of the anesthesiologist correctly interpreting the trace as unchanged after clamping was 91% to 98%; this finding indicates that the device can be used by novice interpreters with fair accuracy to determine the presence of cerebral ischemia at the time of carotid occlusion. In this study, the review by the anesthesiologist was not done during the course of the procedure, but rather "off line," and it did not address the issue of whether an anesthesiologist providing intraoperative anesthetic management of the patient can provide adequate monitoring of the processed EEG simultaneously.

EEG monitoring has limitations. Despite the data available from the Mayo Clinic, immediately evident postoperative strokes have been reported in patients without any evidence of EEG changes intraoperatively. In our experience, such strokes result from emboli through the lenticulostriate arteries to subcortical structures that do not generate or affect the EEG but are critically involved in the descending motor pathway. Overall, such events are rare.

Should the patient undergoing carotid endarterectomy have EEG monitoring? That question cannot be answered based on any available data. EEG monitoring provides information about CBF that would not otherwise be available. The clinician has an opportunity to intervene to increase inadequate blood flow when it occurs. Anecdotally, many clinicians have found such monitoring useful and use it routinely. Population studies do not support routine use, and it is up to the clinician to decide whether to use it.

Somatosensory-Evoked Potentials. SSEP monitoring can gauge the adequacy of CBF to the cerebral cortex and subcortical pathways during carotid vascular surgical procedures.[56,86,87] SSEPs have been found in the laboratory to have a similar but slightly lower threshold for failure compared with the EEG. SSEPs are generally intact until the cortical blood flow decreases to less than 15 mL/100 g/minute.[54] A meta-analysis of shunting during carotid vascular operations concluded that selective shunting based on SSEP monitoring results in a perioperative stroke rate similar to when EEG monitoring is used as the basis for shunting.[88] However, logic also would suggest that changes in SSEP are unlikely, for example, with ischemia involving the anterior portions of either the frontal or temporal lobe, which could readily be detected by an appropriately placed EEG electrode. Even less outcome evidence supports the use of SSEPs than the EEG during carotid surgical procedures, but we and others have found SSEPs to be useful as a simultaneous monitor with EEG to detect subcortical ischemia.

Transcranial Doppler Ultrasound. TCD monitoring during carotid vascular surgical procedures is based on measurement of two primary parameters—blood flow velocity in major conducting arteries leading to the cerebral cortex (most commonly middle cerebral artery) and the number of emboli detected in the same artery. The hypothesis justifying the use of this monitoring during carotid vascular surgical procedures has two components: blood flow velocity correlates with CBF, and increasing numbers of emboli increase the likelihood of emboli-related cerebral ischemia or stroke. The first component has not been well tested and shows variable results. An early study in a small group of patients undergoing carotid operations did not show good correlation between CBF and blood flow velocity.[89] Subsequent studies in patients with varying intracranial diseases yielded mixed results.[90-93]

The correlation between CBF and TCD-measured blood flow velocity remains good over time only when the artery being insonated does not change diameter and when cortical blood flow in the distribution of the measured artery does not have significant collateral sources of blood flow. The relationship between emboli count and stroke is better established with multiple studies conducted in the preoperative, intraoperative, and postoperative periods; these studies indicate that higher emboli counts are associated with higher stroke risk and warrant intervention.[94-100] TCD ultrasound is the only monitor able to detect dangerous hyperemia, also known as normal perfusion pressure breakthrough, after removal of severe, flow-limiting carotid stenosis. Typically, a sustained doubling of flow velocity after unclamping should prompt the anesthesiologist to consider lowering the blood pressure.

Intraoperative TCD monitoring is not often used. Good TCD signals cannot be obtained in many individuals who could benefit from monitoring. In addition, TCD probe motion during surgical procedures causes major problems with loss of signal or with angle of insonance–induced changes in the relationship between blood flow velocity and blood flow. Nonetheless, multiple series of carotid endarterectomies with TCD monitoring have had good success, with a reported critical blood flow velocity reduction of approximately 50% as indicative of inadequate CBF requiring intervention (shunt or increased arterial blood pressure, or both).[94-100] Although outcome data are lacking, emboli count and risk of stroke suggest that if technical issues with probe attachment to the patient can be overcome, TCD ultrasound may be useful as a predictor of impending stroke in the entire perioperative period.

Cerebral Oximetry (Near-Infrared Spectroscopy). Near-infrared spectroscopy (NIRS) is an attractive monitor because of its ease of application and lack of training required for interpretation. The hypothesis governing

its use is very simple: As oxygen delivery to the brain decreases, oxygen extraction from arterial blood increases, and the oxygen saturation in cerebral venous blood decreases. NIRS applied to cerebral monitoring measures the oxygen saturation in the cerebral venous blood in the prefrontal cortex and promptly detects increases in oxygen extraction resulting from decreased oxygen delivery. The use of cerebral oximetry during neurovascular surgical procedures is well documented, but several major questions surrounding use of NIRS during carotid surgical procedures remain unanswered.

What degree of decrease in oxygen saturation can be tolerated before intervention is necessary? Because most interventions involve some risk (e.g., shunt → emboli, increased BP → myocardial ischemia), the answer to this question is important; yet the answer does not exist. In awake patients, the saturation value at which any patient develops symptoms varies.[101,102] An absolute value that required shunting could not be determined. Another study showed that cerebral oxygen saturation decreased before the EEG developed changes; the investigators concluded that NIRS monitoring of the brain should be used during carotid surgery.[103] This finding should not be surprising, however, because function of the brain (in this case, electrical function) does not fail until increased extraction of oxygen no longer meets metabolic demands for the tissue. If metabolic demands are being met by increased extraction, it is unclear that intervention is needed.

Finally, a study by Friedell and colleagues compared NIRS with EEG and SSEP monitoring during carotid surgical procedures.[104] In 24 of 323 patients, significant differences were observed between NIRS and monitors of electrical function. Seventeen patients showed no changes in electrical function with significant decreases in cerebral oxygen saturation. In seven patients, no change in cerebral oxygen saturation occurred despite significant change in the EEG and SSEP. The reason for the latter finding may be that NIRS and EEG or SSEP monitor different vascular territories. These data, in combination with the data from studies in awake patients, suggest that use of NIRS alone during carotid vascular surgical procedures may be inappropriate. In addition, an aggregate of studies and case reports available in the literature suggests that no clear cutoff value of regional oxygen saturation that would mandate the use of shunting or increasing the cerebral perfusion pressure exists.

Intracranial Neurovascular Surgery (Monitors: Somatosensory-Evoked Potentials, Motor-Evoked Potentials)

Somatosensory-Evoked Potentials. SSEPs have been extensively studied during surgical repair of cerebral aneurysms. During these procedures, the surgical incision and brain retraction preclude placement of scalp or brain surface electrodes that could detect cerebral ischemia in at-risk cortex. Recording electrodes placed on the surface of the brain have been used successfully, but they are commonly considered "in the way" by neurosurgeons. Scalp electrodes may be placed easily for SSEP monitoring, although the recording montage is frequently not the same as that used in an awake patient.

For aneurysms involving the anterior cerebral circulation, SSEP monitoring has an excellent, but not perfect, record for predicting postoperative neurologic function. Most patients without surgically induced SSEP changes during the surgical procedure awaken with an unchanged neurologic examination. Patients with significant SSEP changes that do not revert to normal awaken with a new neurologic deficit. Patients with SSEP changes that return to normal after a significant intraoperative change may show at least a transient postoperative deficit, with the severity and duration increasing as the duration of the SSEP change increases. Many authors have reported significant utility of SSEP monitoring in detecting improper aneurysm clip placement (see Fig. 49-8), and in guiding intraoperative arterial blood pressure management, particularly in patients already showing, or at significant risk for, vasospasm after subarachnoid hemorrhage.[55,105-110] The same success cannot be reported, however, for posterior circulation aneurysms. In these cases, many areas of the cortex and subcortical structures are at risk for damage that cannot be monitored by somatosensory pathway function. A significant false-negative monitoring pattern exists for these patients, but changes can still be detected when a surgical insult is sufficiently severe to involve large portions of the brain.[111-114]

Some centers have begun monitoring tcMEPs in addition to SSEPs during surgical clipping of aneurysms. Inclusion of tcMEPs is motivated by the desire to evaluate the integrity of subcortical pathways in the internal capsule more effectively. Anatomically, the motor pathway runs anterior to the sensory pathway in the internal capsule and is at greater risk if the anterior choroidal artery or lenticulostriate perforator vessels are injured during dissection and clip placement. Two concerns must be addressed, if tcMEP is to be incorporated successfully in these cases. First, motion caused by stimulation needs to be minimized, to avoid interfering with the surgical procedure. Second, and more important, stimulus parameters need to be set to limit deep current spread that would activate the corticospinal tract distal to the internal capsule and obscure ischemia of the proximal pathway. The use of longer stimulus trains at intensities close to the motor threshold addresses both concerns.

Supratentorial Intracranial Nonvascular Surgery (Monitors: Awake Patient, Electroencephalogram, Somatosensory-Evoked Potentials)

During supratentorial procedures, neurologic monitoring can contribute to the precise localization of structures that need to be preserved or conversely supplement the anatomic information provided by imaging with functional data. Three techniques fall under this category: (1) awake craniotomy can be a suitable approach for the resection of tumors and seizure foci; (2) intraoperative electrocorticography (i.e., the recording from strategically placed subdural electrodes) is used to target more closely the resection of seizure foci; (3) localization of the central sulcus and, by extension, the precentral motor cortex is

sometimes helpful, if these structures have been displaced by a tumor.

The most comprehensive approach to the problem of functional localization of brain structures that need to be preserved to achieve a good outcome is to perform entire segments of supratentorial craniotomy in an awake patient who is undergoing repeated neurologic examinations targeted to assess the eloquent area at risk. Such procedures are typically divided into exposure, mapping, and resection phases and can be done with the patient entirely awake or awake only during periods when the neurologic examination must be assessed.[115] Common to all these approaches is the need for meticulous locoregional anesthesia of the scalp at the craniotomy site and the pin sites of the head holder.[116] A second requirement is a patient who is well informed about the awake parts of the procedure and is willing and able to cooperate. Dexmedetomidine, propofol, and remifentanil are the drugs most frequently incorporated into the anesthetic regimens for awake craniotomy.[117] Complications of awake craniotomy include nausea and vomiting, respiratory problems, and "tight" brain, but these complications are typically mild and occur in less than 10% of cases in experienced centers. Seizures triggered by cortical stimulation can be stopped by the application of iced saline to the exposed cortex or a small amount of barbiturate or propofol.

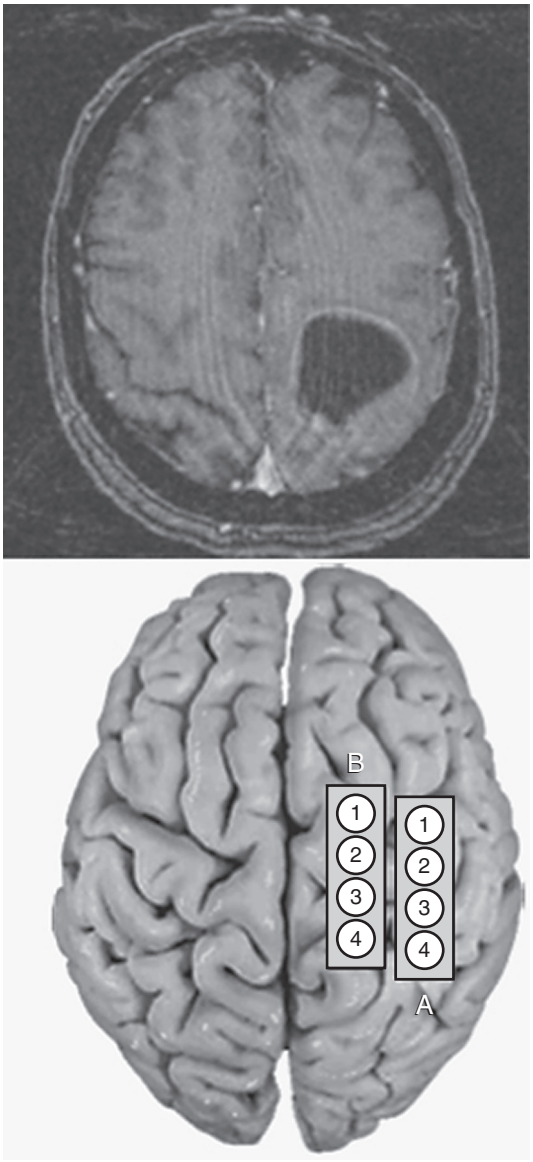
Seizure Focus Localization Surgery

Patients with epilepsy who have seizures that generalize from an anatomically distinct focus may benefit greatly from surgical resection of that seizure focus.[118] Precise localization of a seizure focus is important for achieving the therapeutic objective of seizure control and for minimizing complications from the resection. With sensitive magnetic resonance imaging techniques, neuronavigation, and recordings of typical seizure activity in the awake patient after placement of subdural and depth electrodes, the anatomic location and the appropriate extent of the resection frequently can be determined preoperatively.[119] These developments have diminished the role of intraoperative recordings from the epileptogenic zone with electrocorticography.[120]

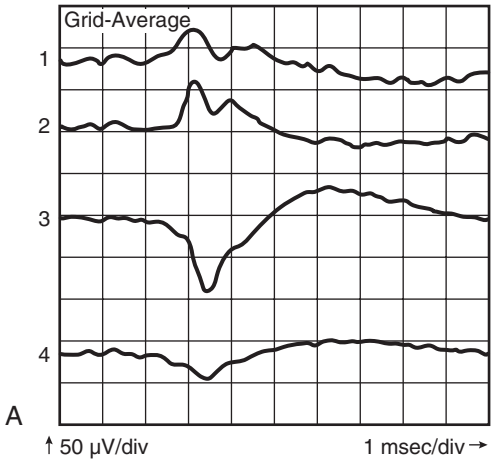
Neurologic monitoring during such a resection is performed using two different techniques. First, activity of the seizure focus can be recorded through electrocorticography. Second, eloquent brain areas next to the seizure focus can be monitored during awake craniotomy as described in the previous section. Electrocorticography is done by placing a grid of subdural electrodes onto the exposed brain surface and recording spontaneous electrical activity. Electrocorticography is constrained by several limitations. The time for such recordings is limited to a few minutes; recordings are limited to interictal discharges, which may not correlate with the epileptogenic focus; and recordings need to be obtained from a brain that is under the effects of general anesthetic drugs, which alter the EEG.

To provide good conditions during the recording, the level of anesthesia is lightened (e.g., by use of a strict nitrousoxide-narcotic technique or low concentrations of volatile anesthetic drugs). Provocative techniques, such as hyperventilation or administration of a small dose of methohexital, may be useful to activate the seizure focus. Intraoperative seizure mapping requires the involvement of an expert electroencephalographer familiar with this technique.

Motor Strip Localization



Electrophysiologic monitoring of the somatosensory system in anesthetized patients can provide a simple anatomic guide to the location of the rolandic fissure, which separates the parietal primary sensory and frontal primary motor cortex. The fissure is located by recording cortical SSEPs from a subdural strip electrode that is placed perpendicular to the presumed location of the fissure. The exact location of the fissure is characterized by a reversal in the polarity of the primary cortical response between the electrodes straddling the fissure, as illustrated in the clinical example in Figure 49-13. Subsequent placement of the electrode strip onto the primary motor area of the precentral gyrus allows subsequent monitoring of the corticospinal tract through direct cortical stimulation.



POSTERIOR FOSSA SURGERY (MONITORS: BRAINSTEM AUDITORY-EVOKED POTENTIALS, CRANIAL NERVE MONITORING, SOMATOSENSORY-EVOKED POTENTIALS, MOTOR-EVOKED POTENTIALS)

Besides the cerebellum, the posterior fossa contains within the narrow space of the brainstem many crucial neural structures, including the following: the ascending and descending sensorimotor pathways; cranial nerve nuclei; cardiorespiratory centers; the reticular activating system; and the neural networks that underlie crucial protective reflexes, such as eye blink, swallowing, gag, and cough. Surgical procedures of the posterior fossa are not undertaken lightly, and even small injuries can leave significant neurologic deficits. Although some of these neural structures, such as the sensory or auditory pathway, can be monitored consistently, intraoperative integrity of other neural structures is frequently only inferred from the well-being of neighboring structures amenable to monitoring.

Microvascular Decompression of Cranial Nerves V, VII, and IX

Microvascular decompression is performed most frequently for trigeminal neuralgia (cranial nerve V) in patients who have acceptable medical risks for posterior fossa craniotomy. More rarely, the same approach is used to treat hemifacial spasm or neurovascular compromise of lower cranial nerves. The surgical procedure entails dissecting along the intracranial portion of the nerve, identifying offending blood vessels that encroach on the nerve, and placing an insulating Teflon pad between vessel and nerve. The operation risks ischemic damage to perforating vessels coming off the offending arteries and cerebellar retraction–related damage to cranial nerves. The facial and vestibulocochlear nerves are at particular risk for stretch-induced injury caused by medial retraction of the cerebellum. Retraction-induced stretch prolongs the interpeak latency between peaks I and V of the BAEP

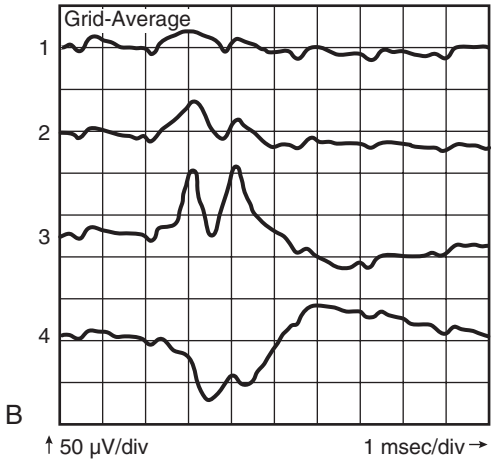


Figure 49-13. Intraoperative localization of the rolandic fissure separating the primary sensory cortex and motor cortex. The clinical example is from a patient with a large parietal tumor shown in the scan. Two of the recordings made from a four-contact subdural electrode strip are shown. The relative positions of the strip electrode are labeled *B* and *A*. In recording *A,* the primary cortical response from the electrodes anterior to the rolandic fissure shows an upward deflection, whereas the response from electrodes posterior to the fissure shows a downward deflection. Moving the strip electrode anteriorly (recording *B*) moves this "phase reversal" between electrodes 3 and 4.

waveform and ultimately leads to complete loss of all waves beyond wave I (Fig. 49-14). Failure to release retraction in a timely manner results in postoperative hearing loss. Such monitoring increases the chances for preserved hearing after microvascular decompression.[121-125]

During microvascular decompression of the facial nerve for hemifacial spasm, more recent developments using EMG monitoring have enabled some centers to document the adequacy of nerve decompression more clearly and lessen the likelihood of persistence or recurrence of hemifacial spasm postoperatively. This newer technique monitors the so-called lateral spread response (LSR) of the facial nerve. A peripheral branch of the facial nerve is stimulated. In the normal patient, this stimulation would not result in a recordable EMG response in a muscle innervated by a different branch of the facial nerve. In patients with hemifacial spasm, EMG responses can be recorded in muscles innervated by a different branch of the facial nerve (LSR) indicating abnormal crossover of electrical activity. Decompression of the facial nerve has been shown in multiple studies to result in a great decrease or elimination of this LSR, and studies have indicated that elimination of the LSR is highly predictive of immediate postoperative relief of hemifacial spasm.[126]

Vestibular Nerve Schwannoma

Vestibular nerve schwannomas are the most common tumors located in the cerebellopontine angle. Because of the common origin of the cochlear component of cranial nerve VIII and the essentially identical intracranial trajectory of the facial nerve, hearing loss and facial nerve palsy are concerns during surgical resection of these tumors.

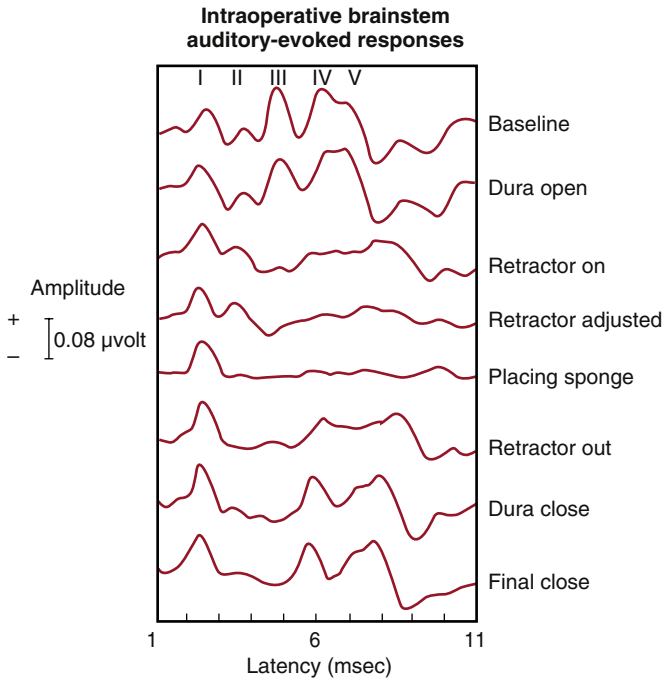

Figure 49-14. Intraoperative monitoring of brainstem auditory-evoked responses during microvascular decompression. The baseline recording shows the typical five waves of the brainstem auditory-evoked potential response. Intraoperative events are designated to the right of each trace. Placement of the retractor causes a severe increase in latency of wave V even after adjustment of retraction. During placement of the sponge, all waves subsequent to wave I, which originates in the inner ear, are nearly completely lost. Removal of the retractor causes brainstem auditory-evoked potentials to revert toward baseline.

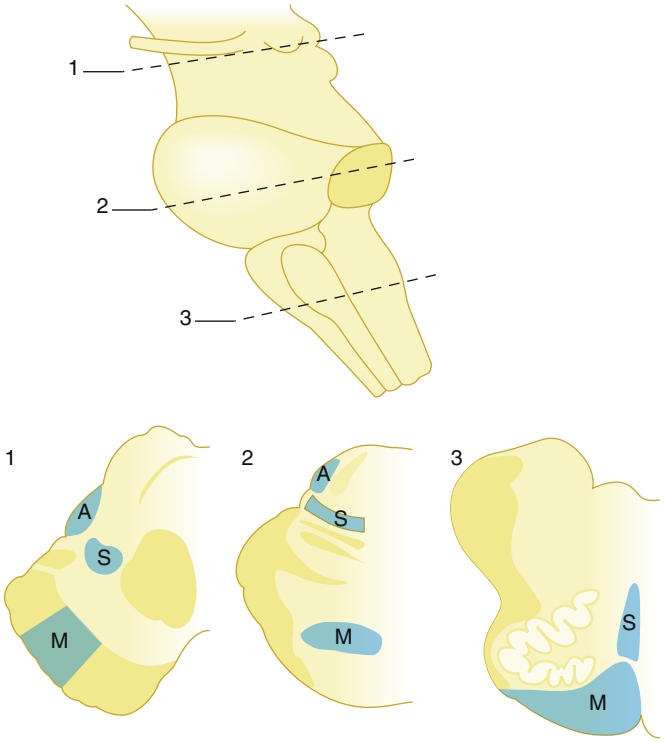

Figure 49-15. Monitoring of the brainstem with evoked potentials. Evoked potentials monitor specific tracts that encompass defined areas in the brainstem. This is shown in three transverse sections approximately at the levels indicated in the drawings. The areas directly monitored by a given modality are indicated in *blue* and are labeled M (motor), S (somatosensory), and A (auditory). Conclusions about the well-being of the remainder of the brainstem are made by inference from the monitored areas.

Size and preoperative auditory function are the best predictors of postoperative hearing.[127] For tumors up to approximately 2 to 3 cm in size, monitoring of BAEPs can increase the chances of preserving hearing.[128] In addition to BAEPs, the facial nerve is monitored through spontaneous and stimulated EMG. Prospective trials have shown a higher percentage of patients with a functional facial nerve 1 year postoperatively when facial nerve monitoring was used as previously described. Tonic discharges warn of impending damage caused by stretch or heat (Bovie procedures). Sharp section of the nerve may elicit no discharge, and neuromuscular blockade may eliminate the ability to monitor. If the course of the nerve is displaced by the tumor, the surgeon can map its course with a handheld stimulator and real-time auditory feedback.

Other Posterior Fossa Neoplasms

Monitoring for operations on other neoplasms located in the brainstem typically is individualized to each particular case or to the particular surgical approach. EMG may be recorded not only from the territory of the facial nerve, but also from the tongue to monitor the hypoglossal nerve, and from the glottis through electrodes embedded into a specialized endotracheal tube to monitor the vagus nerve. Such a setup can be used to map the floor of the fourth ventricle functionally, if it is distorted by a tumor.[129] Such monitoring may be insufficient to preserve vital reflexes because only the efferent limb of these reflexes is monitored by recording EMG from innervated muscle.

Use of neurologic monitoring for brainstem ischemia, although performed in some centers, is not well documented or supported by clinical studies. Global well-being of the brainstem may be monitored by combining multiple modalities of evoked potentials, such as BAEPs, SSEPs, and MEPs. Each modality monitors a function whose integrity would be considered important in its own right for the functional outcome of an individual patient. As illustrated in Figure 49-15, the cross-section monitored by combining all these modalities still leaves out crucial areas. Given that perfusion occurs through perforating vessels, it is easy to see that monitoring may indicate that all is well or, more likely, that a therapeutic intervention was helpful in restoring function when clinically the patient is still left with a significant deficit. This occurrence invalidates neither monitoring nor the therapeutic intervention, but it indicates only that the monitored pathway was not located in an area at risk from the surgical procedure. Because of such obligatory "false-negatives" results, few studies address the utility of such monitoring. Given that each individual monitoring modality comes with its own constraints, such an approach typically requires a dedicated neurophysiologist for interpretation and troubleshooting.

SPINAL COLUMN AND SPINAL CORD SURGERY (MONITORS: SOMATOSENSORY-EVOKED POTENTIALS, MOTOR-EVOKED POTENTIALS, ELECTROMYOGRAM)

Intraoperative monitoring of SSEPs has been used most extensively in patients undergoing surgical procedures involving the spinal column or spinal cord, or both. Extensive experience has been gained in patients who have decompressive laminectomies or who have undergone corrective procedures for scoliosis. Intraoperative changes in SSEPs have been noted in 2.5% to 65% of patients undergoing surgical procedures on the spine or spinal cord.[130-133] When these changes are promptly reversed either spontaneously or with interventions by the surgeon or anesthesiologist (e.g., lessening the degree of spine straightening in scoliosis repair or increasing arterial blood pressure), the patients most often have preserved neurologic function postoperatively. When these changes persisted, however, the patients most often awakened with worsened neurologic function.

False-negative (rare) and false-positive (common) results can occur with SSEP monitoring during spine operations. Patients with intact SSEPs throughout the procedure have awakened with a new significant neurologic deficit, but the total reported incidence of this finding is far less than 1% of all cases monitored. Patients with no postoperative neurologic deficit commonly experience significant changes in intraoperative SSEPs.[133] This monitoring pattern is most commonly caused by failure to control for other, nonpathologic factors that may alter the SSEPs. Overall, the reliability of properly performed SSEP monitoring to predict the postoperative sensory and motor function has been reported to be excellent.[44,132,134] Motor tracts are not directly monitored by SSEPs, however. In addition, the blood supply to the dorsal columns of the spinal cord, which carries all the upper extremity SSEPs and at least a portion of the lower extremity SSEPs, is derived primarily from the posterior spinal arteries. The blood supply to motor tracts and neurons is derived primarily from the anterior spinal artery. A significant motor deficit can develop postoperatively in patients with intact SSEPs throughout the operative course. Such events have been reported.[135,136]

In operations on the spinal column and after acute spinal cord injury, the sensory and motor changes generally correlate well[44]; however, in patients with neurologic dysfunction after thoracic aortic vascular surgical procedures, frequently posterior spinal cord function (proprioception, vibration, light touch) is left intact when motor and other sensory functions (pain, temperature) are impaired. This result occurred in 32% of patients with neurologic injury after aortic aneurysm repair in one series,[137] with similar results in many other series. Intraoperative SSEP monitoring in these patients carries a significant risk for false-negative results, and such monitoring therefore is not widely used.

MEP monitoring during surgical procedures on the spine or its blood supply is very useful. MEPs can decrease without changes in SSEPs. The combined use of SSEP monitoring and MEP monitoring may eliminate false-negative monitoring patterns during spine operations.[138-143] In the case of monitoring paraplegia risk during surgical repair of thoracoabdominal aneurysms, the literature shows improving support for the use of MEP monitoring. Two earlier studies suggested that MEPs may not be as effective as hoped. The first study recorded MEPs from the canine lumbar spinal cord that were produced by transcranial electrical stimulation.[137] Elmore and associates found that these spinally recorded potentials did not accurately predict postoperative motor function.[144] In a second study, Reuter and colleagues recorded MEPs at the spinal cord and the peripheral nerve level that were produced by transcranial electrical stimulation in dogs.[145] These investigators also found that the spinally recorded responses were inaccurate in predicting motor function postoperatively. The peripheral nerve responses disappeared in all animals and were not present 24 hours later regardless of whether the animal could move its lower extremities.

These studies suggest that the spinally recorded MEP likely represents a response generated by the descending corticospinal tract. This white matter pathway is resistant to ischemia compared with the more metabolically active anterior horn cells (gray matter). Recovery of this white matter–generated MEP response could occur after reperfusion of the spinal cord, whereas the gray matter may not recover. Responses recorded from the peripheral nerve would reflect postsynaptic anterior horn cell function, but lower extremity ischemia occurring after aortic cross-clamping may preclude recording this or the response from muscles during surgical procedures.

MEP monitoring during aortic vascular surgical procedures has correctly detected inadequate spinal cord blood flow and improved operative outcome. The technique has proven useful, particularly when operative strategies such as reimplantation of crucial intercostal vessels based on results of MEP monitoring, alteration of spinal cord perfusion pressure (blood pressure increase or cerebrospinal fluid drainage, or both), spinal cord cooling, and other methods are used.[146] Although this monitoring technique holds promise in aortic surgery, its validity has not been verified.

PERIPHERAL NERVE SURGERY (MONITORS: ELECTROMYOGRAM, NERVE ACTION POTENTIAL)

Neurologic monitoring for surgical procedures involving peripheral nerves can be done in two different settings. In the first, the peripheral nerve is intact but threatened by the operation. Examples include an intrinsic nerve tumor, such as a schwannoma, or an extensive soft tissue tumor, particularly if it displaces the normal anatomic course of a nerve. In the second setting there is a preexisting injury involving damage to a nerve and the objective is to explore the site of injury. Monitoring of spontaneous and stimulated muscle responses from muscle groups innervated by the nerve in question can be used to guide the resection. Spontaneous EMG discharges can be generated by stretch or compression of the nerve, by local heating from electrocautery, or from ischemia. Two caveats apply to the monitoring of spontaneous EMG: (1) the neuromuscular junction is part of the monitored pathway, and muscle relaxation decreases or abolishes the sensitivity of monitoring in a dose-dependent manner; and (2) sharp

section of the nerve may not result in a noticeable discharge. To search out the course of the nerve intraoperatively, the surgeon may stimulate the wound area with a handheld probe and listen for stimulated EMG or palpate for muscle contraction. The underlying concept should be familiar to anesthesiologists from the use of nerve stimulators in regional anesthesia.

A variation of this technique of monitoring that is in widespread use, because it is conceptually simple, is monitoring of pedicle screw placement during spinal instrumentation with the aim of avoiding nerve root injuries resulting from malpositioned pedicle screws.[147,148] The aim is to avoid malpositioned screws that weaken the construct or cause postoperative radicular pain. Typically, the pilot hole or, less desirable, the shank of an implanted pedicle screw is stimulated repetitively with increasing current to determine the threshold for eliciting a dermatomal compound muscle potential. The interpretation of responses is complicated by the anatomic relationship between pedicles and nerve roots that depends on the level of the spinal cord because the spinal cord is shorter than the bony spinal column. Thus, a medially misplaced screw in the lumbar region will come to lie next to a nerve root, whereas in the thoracic spine, a medial misplacement puts the screw next to the corticospinal tract, which cannot be activated by single stimuli. Because thresholds vary in the cervical, thoracic, and lumbar spine, as well as between healthy and diseased nerve roots, this technique has limitations but is widely thought to be useful.[149]

In patients with prolonged weakness and sensory loss after nerve injury who undergo nerve exploration monitoring, peripheral nerve activity is very useful.[150] The aim is to determine whether nerve reconstruction may improve outcome. The area of the lesion is determined by preoperative nerve conduction studies. Intraoperatively, the nerve is first stimulated proximal to the lesion, and a recording of the nerve action potential is made directly from the nerve distal to the lesion, as illustrated in Figure 49-16. If nerve conduction occurs across the lesion, lysis of scar is performed, and the incision is closed. Natural recovery by means of axonal regrowth produces the best outcome. If conduction does not occur across the lesion, resection of the damaged nerve and nerve cable grafting are performed.[151-153]

NONNEUROLOGIC SURGERY THAT RISKS DAMAGE TO THE CENTRAL NERVOUS SYSTEM (MONITORS: ELECTROENCEPHALOGRAM, TRANSCRANIAL DOPPLER, CEREBRAL OXIMETRY, JUGULAR VENOUS OXYGEN SATURATION)

Cardiopulmonary Bypass

See also Chapter 67.

Electroencephalogram. In humans, changes that occur with the institution of CPB may alter the EEG by multiple different mechanisms. Plasma and brain levels of anesthetic drugs may be altered by CPB or by anesthetics commonly given during CPB, alterations in arterial carbon dioxide tension and arterial blood pressure may occur, and hemodilution with hypothermic perfusate

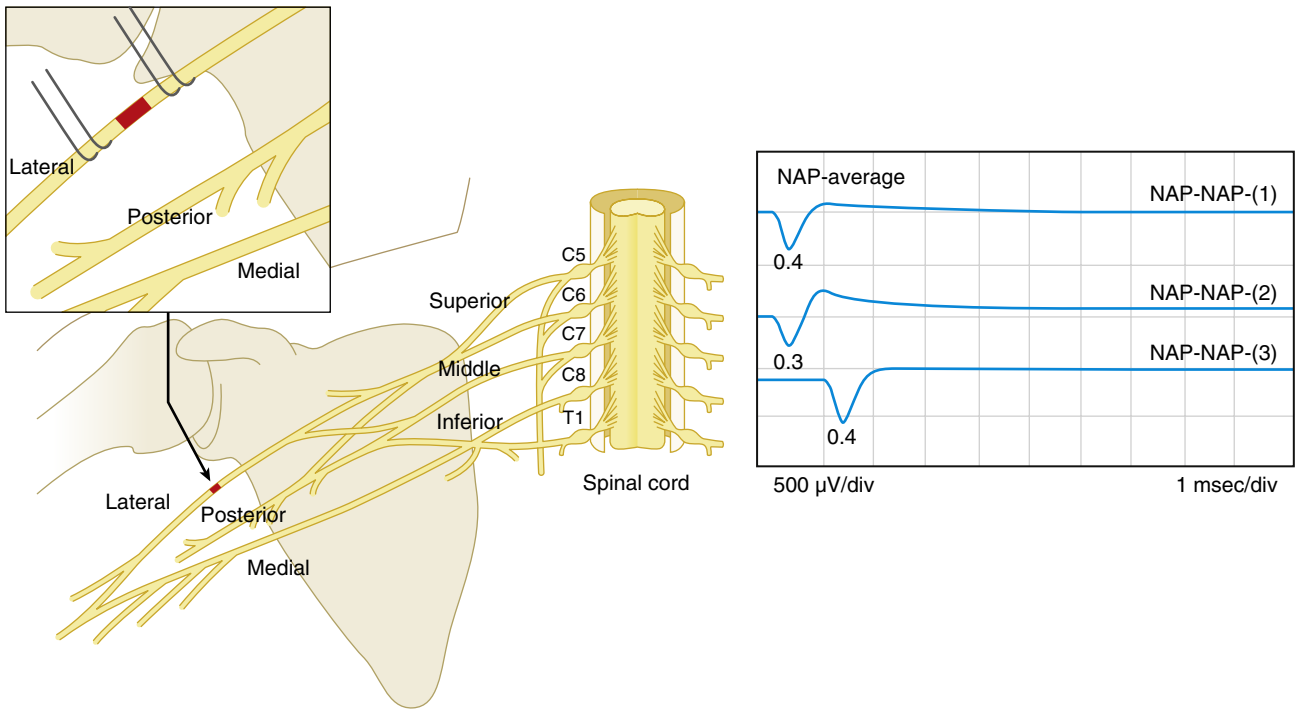

Figure 49-16. Recording a nerve action potential (NAP) during brachial plexus exploration. The site of the injury on the lateral fascicle is indicated in *red*. As shown in the *inset,* the surgeon places hook electrodes on either side of the exposed part of the nerve. If the injury is limited to an axonotmesis, proximal stimulation will result in a distal NAP similar to the ones shown in the recording to the *right.* The delay in the response in the third tracing is simply the result of a change in technical settings.

nearly always occurs. These effects, all of which may produce EEG changes similar to pathologic changes seen with ischemia, make it difficult to interpret EEG changes occurring during CPB.

Levy and others tried to distinguish the normal effects of hypothermia from other events occurring at the institution of and conclusion of CPB.[154,155] Initially, Levy concluded that only a qualitative relationship could be determined, but later, with the use of a much more sophisticated EEG analysis technique (approximate entropy), EEG changes associated with changes in temperature could be quantified.

Chabot and colleagues,[156] as well as Edmonds and colleagues,[157] attempted to use quantitative (processed, multiple-channel) EEG during CPB to detect cerebral hypoperfusion and relate these changes to postoperative neurologic function. In addition, some work has been done with intervention after detection of cerebral hypoperfusion using quantitative EEG. Although the data seem promising, only a few patients have been studied, with very few corroborating studies. In addition, this type of monitoring is extremely costly in time, personnel, and equipment. Given the lack of convincing outcome data, the cost-to-benefit ratio is unclear. Some other investigators failed to show any convincing relationship between intraoperative EEG parameters and postoperative neurologic function, especially in small infants and children[158,159] (see also Chapter 93). Whether the processed, quantitative EEG provides useful information for clinical management of patients during CPB is not clear. An evidence-based justification for routine application of this method is not apparent.

Transcranial Doppler Ultrasound. TCD ultrasound can monitor the cerebral circulation during CPB. Anecdotal reports and case series document the use of TCD for determining adequacy of CBF, detection of emboli, and detection of improper cannula placement.[160] Only very limited outcome data exist, and use of TCD ultrasound during CPB does not stand up to evidence-based examination, primarily because of lack of information. Probe placement instability and inability to obtain signals in some patients also have limited the use of this monitor intraoperatively. Finally, although the hypothesis that cerebral microemboli are at least part of the pathogenesis of postoperative cognitive decline following CPB is attractive, any relationship between CPB counts of presumed emboli and postoperative cognitive dysfunction is not convincing.[161]

Cerebral Oximetry and Jugular Venous Oxygen Saturation. As is the case with EEG monitoring during CPB, the use of NIRS or $Sjvo_2$ has been recommended as an indicator of adequate perfusion of the brain during CPB.[162,163] Incorrect placement of CPB cannulas has been detected clinically and in laboratory studies. One more recent series of patients undergoing CPB for coronary bypass surgery showed a more frequent incidence of major organ system dysfunction and longer hospital stays in patients with lower baseline and intraoperative cerebral oxygen saturation values.[164] The same questions exist for this application of NIRS, however, as do for the use of NIRS during carotid vascular surgical procedures. A systematic review of the use of NIRS during CPB showed that data are insufficient to conclude that interventions based on low cerebral oxygen saturation values prevent either stroke or postoperative cognitive dysfunction.[165] Use of NIRS during CPB does not stand up to evidence-based examination, and much more work is needed before NIRS can be recommended as a standard of care during CPB.

$Sjvo_2$ is very invasive. Although data from case reports and studies suggest that $Sjvo_2$ may have utility in detecting inadequate CBF, lack of outcome data, lack of clearly defined critical values at different temperatures during CPB, and availability of more noninvasive modalities (EEG, cerebral oximetry) have resulted in only limited use of this monitoring method during CPB. Based on current information, no neurologic monitoring techniques, either alone or in combination, are clearly useful in improving outcome during surgical procedures requiring CPB. Further research is needed before the cost in personnel and in equipment of neurologic monitoring during CPB can be justified.

INTENSIVE CARE APPLICATIONS OF NEUROLOGIC MONITORING (MONITORS: ELECTROENCEPHALOGRAM, EVOKED POTENTIALS, TRANSCRANIAL DOPPLER, JUGULAR VENOUS OXYGEN SATURATION)

Secondary injury to the CNS is a major modifiable risk factor in patients with CNS disease (see also Chapter 105). Aneurysmal subarachnoid hemorrhage, stroke, and traumatic brain injury are examples of CNS insults in which secondary injury has important implications for the ultimate functional outcome.[166-168] The same diseases frequently result in a primary insult to the CNS that severely constrains the utility of the clinical neurologic examination because of the need for mechanical ventilation and sedation. Many techniques of neurologic monitoring discussed earlier also have been used in the intensive care unit. Generally, however, techniques that require the continued presence of skilled technologists, such as monitoring of evoked potentials, are prohibitively expensive and of less practical value than techniques that can be performed as a daily examination or techniques that provide data easily integrated into the intensive care frame of mind. Along with monitoring, some of the techniques discussed previously also can provide important prognostic information in comatose patients and can guide decision making.

Cerebral Ischemia

Cerebral ischemia is an important cause of secondary injury to the CNS. It can be difficult to detect in patients who are either comatose or sedated, but it can occur even in patients with adequate cerebral perfusion pressure.[169,170] Three techniques may provide intensivists with additional information about cerebral perfusion. None of the monitors is considered "standard of care." As with all monitors, the impact of the monitor on outcome depends on the quality of the therapeutic interventions

that result from integration of the additional data into the clinical management of a given patient.

$Sjvo_2$ monitoring is used most extensively in the intensive care unit to monitor patients with traumatic brain injury. The data have been used to guide blood pressure and ventilatory management to optimize blood flow. $Sjvo_2$ monitoring has had a major effect on ventilatory management of head-injured patients and has significantly reduced the routine use of hyperventilation in neurosurgical patients.[171-175] $Sjvo_2$ values of less than 50% generally indicate cerebral ischemia. Increases in $Sjvo_2$ may occur in response to therapy, or they may be an ominous sign if the increase is caused by falling demand because of neuronal death.

Similar to $Sjvo_2$ monitoring, monitoring of $P_{Br}o_2$ and blood flow is used most frequently in patients with traumatic brain injury. $P_{Br}o_2$ performs well in clinical practice. Decreases to less than 10 to 15 mm Hg are associated with worsening outcome,[27,175] whereas $P_{Br}o_2$-targeted treatment strategies may improve outcome.[176] The data for thermal diffusion CBF are not as comprehensive, perhaps reflecting the slightly less robust technology.[177] Nonetheless, in the setting of subarachnoid hemorrhage, thermal diffusion CBF of less than 15 mL/100 g/minute showed a sensitivity of 90% and a specificity of 75% for detecting symptomatic vasospasm.[19]

TCD ultrasound is widely used in the intensive care unit to document the presence and severity of cerebral vasospasm after subarachnoid hemorrhage. As the major cerebral arteries narrow, flow velocity within the lumen must increase if blood flow is to be maintained. Such narrowing occurs 12 to 24 hours before the onset of clinical symptoms, thus allowing therapy to be initiated before the onset of clinical symptoms.[178-182] Mean flow velocities of more than 120 cm/second seem to correlate well with angiographic vasospasm,[183,184] although intracranial pressure and concurrent therapy with hypertensive hypervolemic hemodilution modify the flow velocity. The latter two factors result in characteristic changes of the TCD waveform, however, and preserve the utility of the examination.

Prognosis in Coma and Determination of Brain Death. EEG monitoring may help to assess the clinical course and the prognosis of comatose patients. Assessment of prognosis must be separated from the insult that precipitated the coma by more than 24 hours. If not, the EEG may reflect predominantly the effect of the insult and may not predict prognosis. More than 24 hours after the insult, spontaneous sustained burst suppression correlates strongly with severe irreversible brain injury.[185] Absence of EEG variability portends a high likelihood of persistent vegetative state or death,[185,186] whereas spontaneous variability, reactivity to external stimuli, and typical sleep patterns are associated with more favorable outcomes.[187-189]

A specific indication for EEG monitoring is the therapeutic induction of a coma by barbiturate administration. Because neither blood nor cerebrospinal fluid concentration of barbiturates reliably predicts burst suppression and near-maximal reduction in cerebral metabolic rate of oxygen consumption,[190] and because barbiturate administration usually requires an increase in cardiovascular support, documentation of a burst suppression pattern on EEG allows the use of the minimal effective dose of barbiturate.

Similar to EEG, evoked potential studies have a place in predicting prognosis in comatose patients. The presence of normal SSEPs bilaterally is an excellent prognostic sign, whereas the absence of any SSEP cortical response is a poor prognostic indicator. The degree of unfavorable outcome can be predicted by BAEPs. Intact and normal BAEPs with absent cortical SSEPs predict a best outcome of a chronic vegetative state. Outcome may be worse, however, because BAEPs commonly deteriorate later with rostral-to-caudal deterioration. Absent BAEP responses beyond wave I predict a high likelihood of brain death. Present but abnormal SSEPs are associated with outcomes intermediate between good to high function and a chronic vegetative state.[191-200]

TCD ultrasound also has been used in the intensive care unit as an aid to the diagnosis of brain death. As intracranial pressure increases, the pulsatility of the TCD waveform increases, accentuating the systolic peak and diminishing flow during diastole. With further increases in intracranial pressure, a characteristic to-and-fro pattern of flow is established, which is consistent with clinical brain death.[201] TCD studies are easily performed at the bedside and can minimize the need for unnecessary transports of the patient for definitive radiologic studies.

NONSURGICAL FACTORS INFLUENCING MONITORING RESULTS

ANESTHESIA AND THE ELECTROENCEPHALOGRAM

Anesthetic drugs affect the frequency and amplitude of EEG waveforms. Although each drug class and each specific drug have some specific, dose-related EEG effects (Table 49-2), some basic anesthesia-related EEG patterns may be described. Subanesthetic doses of intravenous and inhaled anesthetic drugs usually produce an increase in frontal beta activity and abolish the alpha activity normally seen in the occipital leads in an awake, relaxed patient with the eyes closed. As the patient loses consciousness with general anesthesia, the brain waves become larger in amplitude and slower in frequency. In the frontal areas, small beta activity seen in an awake patient slows to the alpha range and increases in size. In combination with the loss of the occipital alpha activity, this phenomenon produces the appearance of a "shift" of the alpha activity from the posterior cortex to the anterior cortex. Further increases in the dose of the inhaled or intravenously administered anesthetic drug produce further slowing of the EEG. Some anesthetic drugs suppress EEG activity totally (see Table 49-2). Other anesthetic drugs never produce burst suppression or an isoelectric EEG, despite increasing dose, either because they are incapable of completely suppressing the EEG (e.g., opioids, benzodiazepines) or because cardiovascular toxicity of the drug (e.g., halothane) prevents administration of a large enough dose.

TABLE 49-2 **ANESTHETIC DRUGS AND ELECTROENCEPHALOGRAM**

Drug	Effect on EEG Frequency	Effect on EEG Amplitude	Burst Suppression?
Isoflurane, Sevoflurane, Desflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, ↑ frontal beta		
Anesthetic	Frontal 4-13 Hz activity		
Increasing dose >1.5 MAC	Diffuse theta and delta → burst suppression → silence	↓ 0	
Nitrous oxide (Alone)	Frontal fast oscillatory activity (>30 Hz)	↓, especially with inspired concentration >50%	No
Barbiturates			Yes, with high doses
Low dose	Fast frontal ↑ beta activity	Slight	
Moderate dose	↑ Frontal alpha frequency spindles		
Increasing high dose	Diffuse delta → burst suppression → silence	↓ 0	
Etomidate			Yes, with high doses
Low dose	Fast frontal beta activity		
Moderate dose	Frontal alpha frequency spindles		
Increasing high dose	Diffuse delta → burst suppression → silence	↓ 0	
Propofol			Yes, with high doses
Low dose	Loss of alpha; frontal beta		
Moderate dose	Frontal delta; waxing/waning alpha		
Increasing high dose	Diffuse delta → burst suppression → silence	↓ 0	
Ketamine			No
Low dose	Loss of alpha, variability	↓	
Moderate dose	Frontal rhythmic delta		
High dose	Polymorphic delta; some beta	Beta is low amplitude	
Benzodiazepines			No
Low dose	Loss of alpha; increased frontal beta activity		
High dose	Frontally dominant delta and theta		
Opioids			No
Low dose	Loss of beta; alpha slows	None	
Moderate dose	Diffuse theta, some delta		
High dose	Delta, often synchronized		
Dexmedetomidine	Moderate slowing, prominent spindles		No

EEG, Electroencephalogram; *MAC,* minimum alveolar concentration.
*Delta = <4 Hz frequency; theta = 4-7 Hz frequency; alpha = 8-13 Hz frequency; beta = >13 Hz frequency.

Intravenous Anesthetic Drugs

See also Chapter 30.

Barbiturates, Propofol, and Etomidate. Despite widely varying potencies and durations of action, barbiturates, propofol, and etomidate produce similar EEG patterns (Fig. 49-17 shows EEG effects of thiopental). These drugs all follow the basic anesthesia-related EEG pattern described previously with initial EEG activation (see Fig. 49-17, *A*), followed by dose-related depression. As the patient loses consciousness, characteristic frontal spindles are seen (see Fig. 49-17, *B*), which are replaced by polymorphic 1- to 3-Hz activity (see Fig. 49-17, *C*), as the drug dose is increased. Further increases in dose result in lengthening periods of suppression interspersed with periods of activity (burst suppression). With a very high dose, EEG silence results. All these anesthetic drugs can cause epileptiform activity in humans, but epileptiform activity is clinically significant only after methohexital and etomidate when given in subhypnotic doses.

Ketamine. Ketamine does not follow the basic anesthesia-related EEG pattern. Anesthesia with ketamine is characterized by frontally dominant rhythmic, high-amplitude theta activity. Increasing doses produce intermittent polymorphic delta activity of very large amplitude interspersed with low-amplitude beta activity.[202] Electrocortical silence cannot be produced with ketamine. EEG activity may be very disorganized and variable at all doses. This disorganization of the EEG with ketamine is responsible for the failure of the bispectral index (BIS) to be useful in looking at the effect of ketamine on consciousness. Recovery of normal EEG activity even after a single bolus dose of ketamine is slow compared with barbiturates. No information is available about the relationship between emergence reactions after ketamine and the EEG. Ketamine can cause increased epileptiform activity.[202]

Benzodiazepines. Despite varying potencies and durations of action, benzodiazepines also follow the basic anesthesia-related EEG pattern. As a class, however, these drugs are incapable of producing burst suppression or an isoelectric EEG.

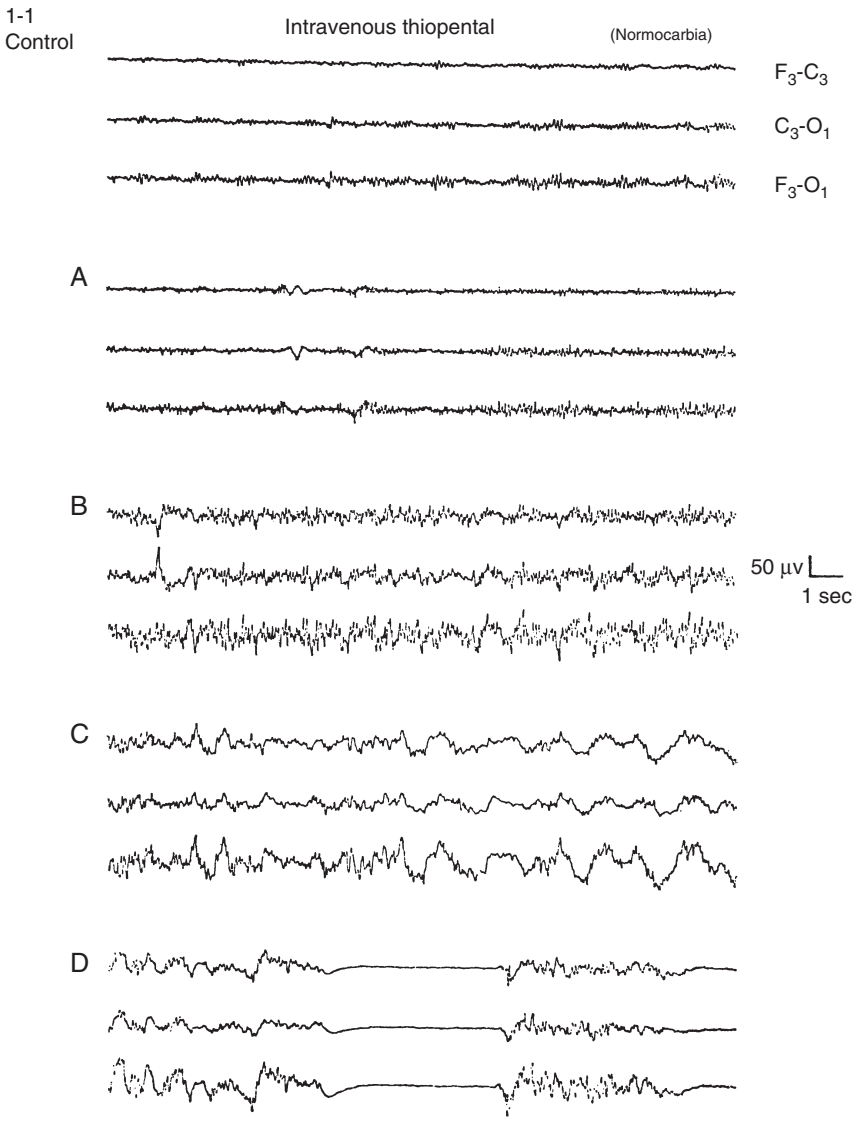

Figure 49-17. Electroencephalogram effects of intravenous administration of thiopental in humans: *A*, rapid activity; *B*, barbiturate spindles; *C*, slow waves; and *D*, burst suppression. *(From Clark DL, Rosner BS: Neurophysiologic effects of general anesthetics,* Anesthesiology *38:564, 1973.)*

Opioids. As a class, opioids do not follow the basic anesthesia-related EEG pattern. Opioids generally produce a dose-related decrease in frequency and increase in amplitude of the EEG. If no further doses of opioids are given, alpha and beta activity return as drug redistribution occurs. The rapidity of return depends on the initial dose and on the drug. Remifentanil is associated with the most rapid return to normal.[203] Complete suppression of the EEG cannot be obtained with opioids. Epileptiform activity occurs in humans and in animals receiving large to supraclinical doses of opioids. Sharp wave activity is common after induction of anesthesia with fentanyl, with 20% of patients showing this phenomenon after 30 µg/kg, 60% after 50 µg/kg, 58% after 60 µg/kg, and 80% after 70 µg/kg. Alfentanil bolus has been used clinically to activate seizure foci during surgical treatment of epilepsy.[204] This epileptiform activity is mainly noted in the frontotemporal region.[205]

Dexmedetomidine. Dexmedetomidine is being increasingly used for sedation in the operating room and in the intensive care unit, and it is also used for sedation during diagnostic EEG studies in children. EEG studies of patients undergoing sedation with dexmedetomidine alone show patterns similar to those seen in normal human sleep, with increased slow-wave activity and sleep spindles prominent.[206] Burst suppression or an isoelectric EEG pattern cannot be produced even with high doses of the drug. The level of sedation with dexmedetomidine can be effectively monitored with processed EEG parameters using BIS and entropy techniques.[207] BIS values at comparable levels of sedation are lower with dexmedetomidine than propofol.[208]

Inhaled Anesthetic Drugs

See also Chapter 25.

Nitrous Oxide. Used alone, nitrous oxide causes a decrease in amplitude and frequency of the dominant occipital alpha rhythm. With the onset of analgesia and depressed consciousness, frontally dominant fast oscillatory activity (>30 Hz) is frequently seen.[209] This activity may persist to some extent for 50 minutes after discontinuation of nitrous oxide. When nitrous oxide is used in

combination with other drugs, it increases the effects that would be associated with the drug alone clinically and with respect to the EEG pattern seen.

Isoflurane, Sevoflurane, and Desflurane. Potent inhaled anesthetic drugs, including halothane and enflurane, which are no longer available, follow the basic anesthesia-related EEG pattern. Isoflurane initially causes an activation of the EEG, followed by a slowing of the EEG activity that is more marked with increasing dose. Isoflurane begins to produce periods of EEG suppression at 1.5 minimum alveolar concentration (MAC), which become longer with increasing dose until electrical silence is produced at 2 to 2.5 MAC. Isolated epileptiform patterns sometimes can be seen during intersuppression activity at 1.5 to 2 MAC isoflurane.[210] Sevoflurane causes similar dose-dependent EEG effects. Equi-MAC concentrations of sevoflurane and isoflurane cause similar EEG changes.[211] Epileptiform activity has been induced by administration of sevoflurane in patients without epilepsy, and seizure activity on EEG, but not clinical seizure activity, has been reported in pediatric patients with a history of epilepsy during induction of anesthesia with sevoflurane.[212,213] Despite these observations, sevoflurane, similar to other inhalation drugs, is not suitable for use during electrocorticography for localization of seizure foci.[214] EEG patterns seen with enflurane are similar to the patterns seen with isoflurane, except that epileptiform activity is considerably more prominent. At 2 to 3 MAC, burst suppression is seen, but virtually all intersuppression activity consists of large spike-wave pattern discharges. Hyperventilation with high concentrations of enflurane increases the length of suppression and decreases the duration of bursts, but it increases the amplitude and main frequency component of the intersuppression epileptiform activity. Frank EEG seizures also may occur with enflurane that produce the same cerebral metabolic effects as pentylenetetrazol, a known convulsant.

Halothane also produces EEG patterns similar to those of isoflurane, but dosages of halothane that would produce burst suppression in the EEG (3 to 4 MAC) are associated with profound cardiovascular toxicity. Desflurane produces EEG changes similar to those seen with equi-MAC concentrations of isoflurane. In limited clinical studies, no evidence of epileptiform activity has been seen with desflurane, despite hyperventilation and 1.6 MAC dosage,[215] and desflurane has been used as a treatment for refractory status epilepticus.[216]

Clinical studies showed that the EEG effects of inhaled anesthetic drugs are influenced by age and baseline EEG characteristics. Older patients and patients with EEG slowing at baseline were more sensitive to the EEG effects of isoflurane and desflurane (see also Chapter 80). As anesthesia was deepened, similar EEG pattern changes occurred, but these changes occurred at lower end-tidal anesthetic concentrations.[217]

ANESTHESIA AND SENSORY-EVOKED RESPONSES

Volatile Anesthetic Drugs

Multiple drugs used in the perioperative period can influence the ability to monitor SERs accurately (Table 49-3). A more recent review provides the interested clinician with a detailed analysis of all drug effects on SERs that is beyond the scope of this chapter.[218] Table 49-3 does not quantify drug effects, but rather lists whether an individual drug is capable of producing a change in any part of an evoked response that could be mistaken for a surgically induced change. A "no" designation in this table does not mean that a given drug has no effects on SERs. The "no" designation indicates that any effects that do occur would not be called clinically significant by *clinicians experienced in intraoperative monitoring*. Several general concepts help the clinician who is trying to determine the best choice of drugs for use during monitored cases (Box 49-1).

The volatile anesthetic drugs isoflurane, sevoflurane, desflurane, enflurane, and halothane have similar effects in differing degrees on all types of SERs. VEPs are the most sensitive to the effects of volatile anesthetic drugs,

TABLE 49-3 **ABILITY OF AN INDIVIDUAL ANESTHETIC DRUG TO PRODUCE A CHANGE IN SENSORY- AND MOTOR-EVOKED POTENTIALS THAT COULD BE MISTAKEN FOR A SURGICALLY INDUCED CHANGE***

*This table is not quantitative in any way. "Yes" or "no" designations indicate whether an individual drug is capable of producing an effect on any portion of the evoked response that could be mistaken for a surgically induced change.

†Increases the anesthetic effect of the drug or drugs with which it is used.

and BAEPs are the most resistant to anesthetic-induced changes. Spinal and subcortical SSEP responses are significantly less affected than are cortical potentials.[219-221]

Because they are the most widely used intraoperative SER technique, SSEPs are the most completely studied with respect to the effects of anesthetic drugs. The effects of the currently used volatile anesthetic drugs on cortical SSEPs are dose-dependent increases in latency and conduction times and a decrease in amplitude of cortically, but not subcortically recorded signals.[219-223] When comparing the different volatile anesthetic drugs, studies are not clear.[219,221] One study suggested that halothane has a greater impact on cortical SSEPs than either isoflurane or enflurane,[221] whereas another published report supported a greater effect produced by enflurane and isoflurane than halothane.[219] None of these differences are clinically important and may be ignored by the practicing clinician. Desflurane and sevoflurane have effects on SERs that are qualitatively and quantitatively similar to those of isoflurane.[224-228] In neurologically normal patients, 0.5 to 1.0 MAC of any of the potent inhaled anesthetic drugs in the presence of nitrous oxide is compatible with monitoring of cortical SSEPs (Figs. 49-18 to 49-20).[219,223]

BOX 49-1 ***Guidelines for Choosing Anesthetic Techniques During Procedures in Which Sensory-Evoked Responses Are Monitored***

1. Intravenous drugs have significantly less effect than "equipotent" doses of inhaled anesthetics.
2. Combinations of drugs generally produce "additive" effects.
3. Subcortical (spinal or brainstem) sensory-evoked responses are very resistant to the effects of anesthetic drugs. If subcortical responses provide sufficient information for the surgical procedure, anesthetic technique is not important, and effects on cortically recorded responses may be ignored.

Neurologically impaired patients may show a significantly greater sensitivity to inhaled anesthetic drugs, even to the point of not tolerating any recordable level of inhaled anesthetic drug. Generally, better monitoring conditions are obtained, however, with narcotic-based anesthetic drugs with less than 1.0 MAC total (nitrous oxide plus potent drug) end-tidal inhaled anesthetic concentration.

The volatile anesthetic drugs result in increases in latency of BAEPs without significantly affecting the amplitude.[223,229-231] Volatile anesthetic drugs cause increases in latency and decreases in amplitude in the early (middle-latency) cortical responses after auditory stimulation,[230]

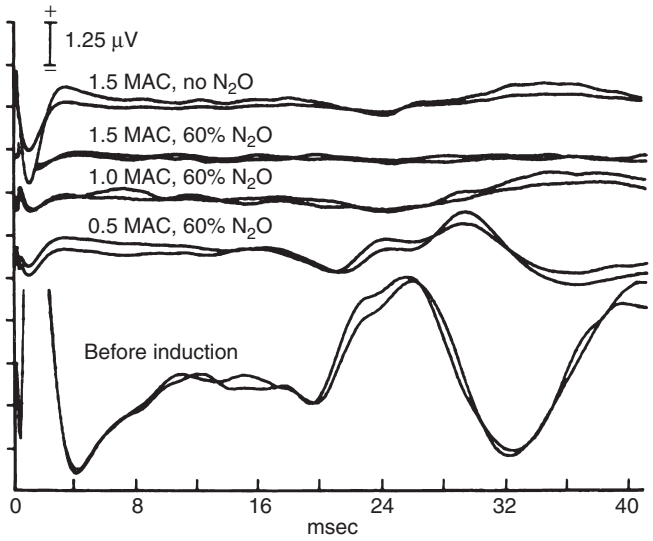

Figure 49-19. Representative somatosensory-evoked potential cortical responses (C-3, or C-4-FPz) at various minimum alveolar concentration (MAC) levels of enflurane. *(From Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans,* Anesthesiology *65:35, 1986.)*

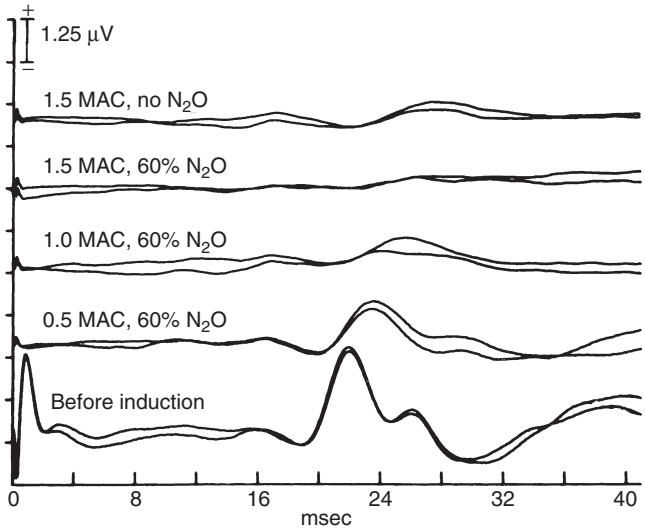

Figure 49-18. Representative somatosensory-evoked potential cortical responses (C-3, C-4-FPz) at various minimum alveolar concentration (MAC) levels of isoflurane. *(From Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans,* Anesthesiology *65:35, 1986.)*

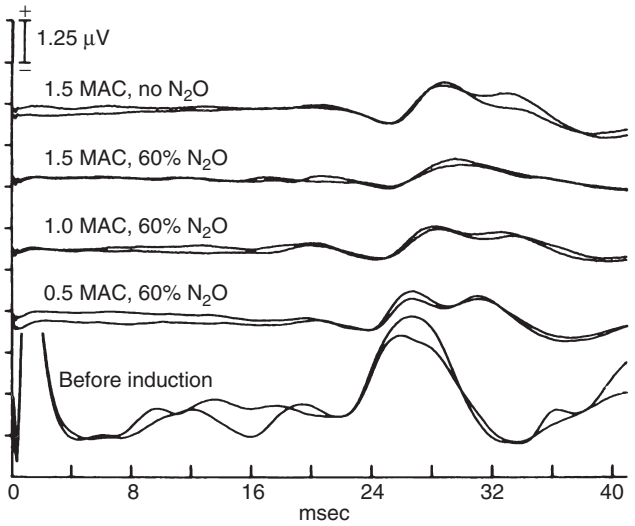

Figure 49-20. Representative somatosensory-evoked potential cortical responses (C-3, C-4-FPz) at various minimum alveolar concentration (MAC) levels of halothane. *(From Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans,* Anesthesiology *65:35, 1986.)*

however, and these middle-latency responses are now used to monitor the hypnotic component of general anesthetic drugs.[32] Adequate monitoring of BAEPs is possible with any clinically useful concentrations of inhaled anesthetic drugs (with or without nitrous oxide) (Figs. 49-21 and 49-22).[223,229-232]

Use of the volatile anesthetic drugs during monitoring of VEPs results in dose-dependent increases in latency with or without changes in amplitude.[223,233-236] Isoflurane results in dose-dependent increases in latency and decreases in amplitude up to 1.8% in 100% oxygen, at which time the waveform is lost.[223,233] Enflurane, in the absence of hypocarbia, also leads to decrease in amplitude.[233] Halothane causes increases in latency without changes in amplitude.[234,235] These results are not clinically relevant because the variability of VEPs in anesthetized patients is so great that satisfactory monitoring, in the opinion of many experts, is impossible using any anesthetic technique.

Although volatile anesthetic drugs cause significant changes in the SER waveforms, adequate monitoring intraoperatively can be provided in the presence of anesthetic doses of volatile anesthetics. Doses of anesthetic drugs causing significant depression of the response to be monitored must be prevented. In our experience, end-tidal concentrations of inhaled anesthetic drugs totaling greater than 1.3 MAC have a dose-related increasing probability of obliterating cortical SSEPs, even in neurologically normal patients. Equally important, anesthetic concentrations should not be changed during the critical periods of intraoperative monitoring. Critical periods are defined as periods in which surgical interventions are most likely to result in damage to neurologic tissue and changes in the SERs. Because the volatile anesthetic-induced changes in SERs are dose dependent, increasing anesthetic dosage at a crucial point in the operative procedure can result in confusing changes in the SERs that potentially may be caused by the anesthetic drug, the surgical procedure, or both. The appropriate intervention is difficult to determine.

As with the volatile anesthetic drugs, nitrous oxide causes differing effects on the SERs, depending on the sensory system monitored. It causes decreases in amplitude without significant changes in latency in SSEPs when it is used alone or when it is added to a narcotic-based or volatile anesthetic drug.[219,220,237] The addition of nitrous oxide to a maintenance volatile anesthetic drug during the monitoring of BAEPs causes no further change.[229] Similarly, use of nitrous oxide alone causes no change in BAEPs, unless gas accumulates in the middle

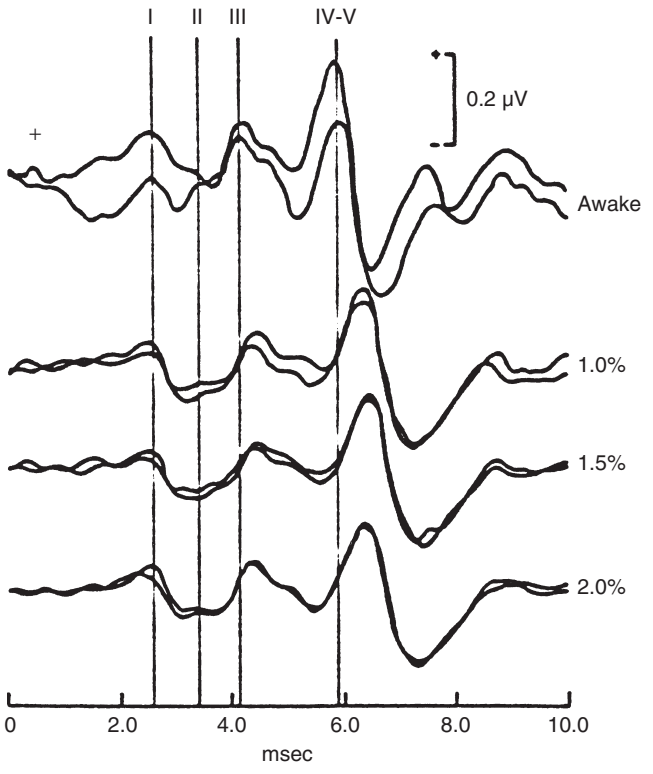

Figure 49-21. Influence of isoflurane alone on brainstem auditory-evoked potential in a typical subject. Latency of peaks III and IV to V increased at 1.0% but stabilized with increasing anesthetic depth. *(From Manninen PH, Lam AM, Nicholas JF: The effects of isoflurane–nitrous oxide anesthesia on brainstem auditory evoked potentials in humans,* Anesth Analg *64:43, 1985.)*

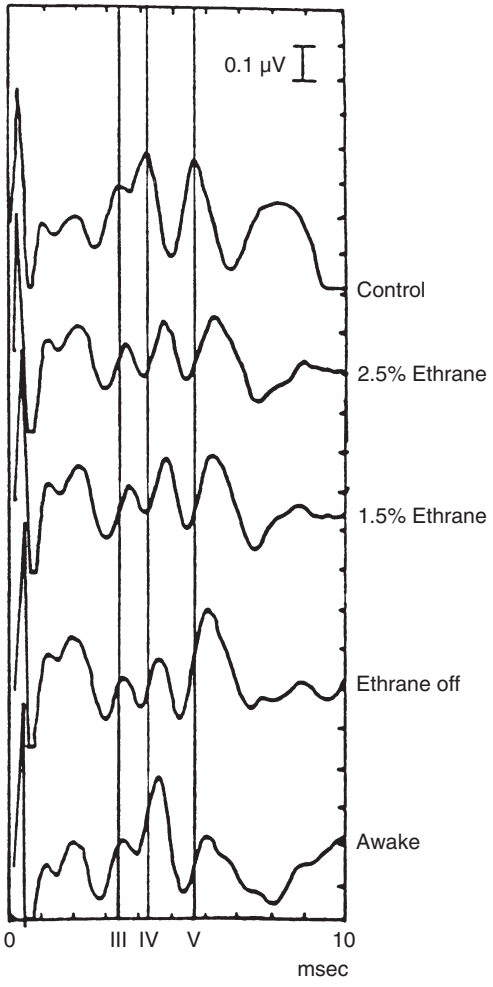

Figure 49-22. Brainstem auditory-evoked potential recording obtained in one patient at different enflurane (Ethrane)–inspired concentrations. *(From Dubois MY, Sato S, Chassy J, et al: Effects of enflurane on brainstem auditory evoked responses in humans,* Anesth Analg *61:898, 1982.)*

ear.[237] Use of nitrous oxide alone results in an increase in latency and a decrease in amplitude in VEPs, but when it is added to a volatile anesthetic technique, it causes no further changes in VEPs.[233,237]

Intravenous Anesthetics

The effects of barbiturates on SERs have been studied in animal models and in humans (see also Chapter 30). Increasing doses of thiopental in patients result in progressive dose-dependent increases in latency, decreases in amplitude of SSEPs, and progressive increases in latency of wave V in BAEPs. The changes in SSEPs are more pronounced than the changes in BAEPs, and waveforms beyond the initial primary cortical response are quickly obliterated. This finding is consistent with the theories that barbiturates affect synaptic transmission more than axonal conduction. Early waveforms in SERs result primarily from axonal transmission, and later waves depend on multisynaptic pathways in addition to axonal transmission. At doses of thiopental far larger than doses producing an isoelectric EEG, adequate monitoring of early cortical and subcortical SSEPs and BAEPs was preserved.[238] Other barbiturate compounds show similar effects. Somatosensory and auditory SERs were never obliterated even at doses larger than those causing complete suppression of spontaneous EEG activity.[239] This observation is important, especially when attempting to monitor the adequacy of CBF during cerebrovascular surgical procedures when the patient has been given large, "protective" doses of barbiturates. The EEG is isoelectric and not helpful for monitoring. The early cortical SSEP waveforms are still preserved, however, and may be very helpful in determining adequacy of CBF. Preserved ability to monitor SSEPs in head-injured patients receiving therapeutic thiopental infusions has been shown.[240] VEPs are much more sensitive to barbiturates. Low barbiturate doses obliterated all except the earliest waveforms. The early potentials persisted with increases in latency even to very high pentobarbital doses.[241] Except for VEPs, adequate perioperative monitoring of SERs is possible even in the presence of large-dose barbiturate therapy as long as the effects of the drug (increased latency with moderately decreased amplitude) are considered.

After bolus administration and intravenous infusions, etomidate causes increases in latency of all waves and prolongation of central conduction time in SSEPs. In contrast to virtually all other commonly used anesthetics, etomidate causes increases in amplitude of the cortical SSEP.[242,243] This effect may result from an alteration in the balance of inhibitory and excitatory influences or an increase in the irritability of the CNS. This effect seems to be present in the cortex, but not in the spinal cord.[243] Etomidate infusions have been used to enhance SSEP recording in patients when it was impossible to obtain reproducible responses at the beginning of intraoperative monitoring because of the patients' pathologic features (Fig. 49-23). Following baseline responses that could not be monitored, the etomidate augmentation of the SSEP allowed adequate monitoring and detection of intraoperative events leading to compromise of the spinal cord.[243] The effects of etomidate on BAEPs are dose-dependent increases in latency and decreases in amplitude that are not clinically significant.[244]

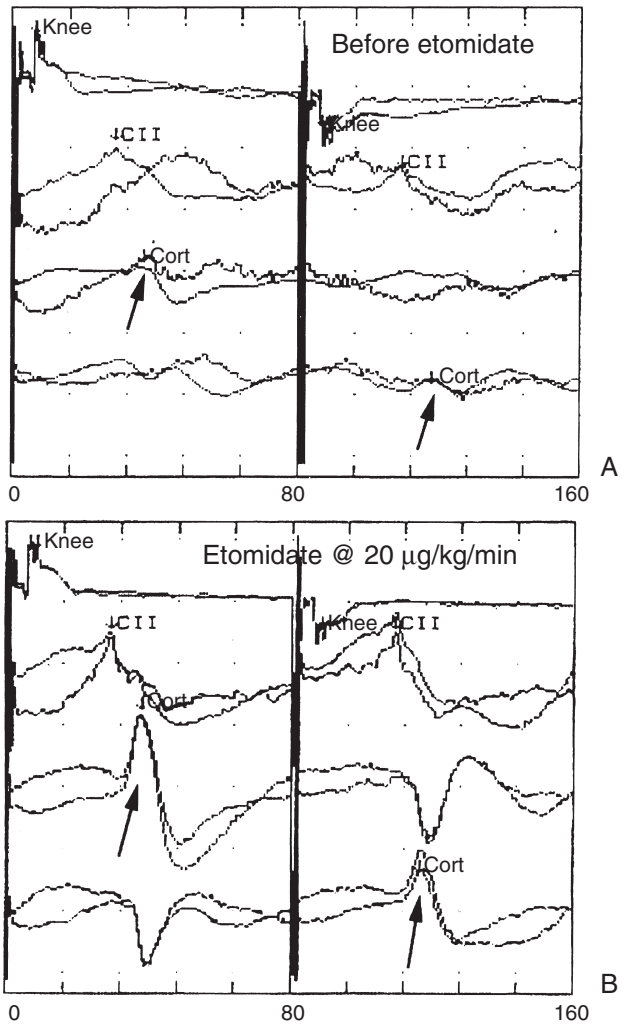

Figure 49-23. Effects of etomidate on somatosensory-evoked potential. **A,** These tracings were obtained from a mildly mentally impaired patient with severe kyphoscoliosis during the early maintenance phase of anesthesia using isoflurane and fentanyl. **B,** These tracings were obtained after discontinuing isoflurane and instituting an etomidate infusion at 20 µg/kg/minute. Note dramatically increased amplitude and clarity of the signal in the cortical (Cort) channels (marked by *arrows*), which both are recorded with the same amplification scale.

Benzodiazepines also can cause changes in SERs.[245,246] Diazepam causes increases in latency and decreases in amplitude of SSEPs, increases in latency in the cortical response after auditory stimulation, and no change in BAEPs.[245,246] Midazolam causes decreases in amplitude without changes in latency of SSEPs.[242]

Generally, opioids cause small, dose-dependent increases in latency and decreases in amplitude of SSEPs. These changes are not clinically significant. Effects on amplitude are more variable than the latency increases.[247,248] Even at large doses of fentanyl (60 µg/kg), reproducible SSEPs can be recorded.[248] Other opioids cause similar dose-dependent changes in SSEPs.[247,249] Opioids can be used even in large doses in patients requiring intraoperative SSEP monitoring without impairment of the ability to monitor neurologic function adequately. Opioid-induced changes must be taken into account, however, when evaluating the recordings. Large intravenous bolus administration of

opioids should be avoided at times of potential surgical compromise to neurologic function, to prevent confusing the interpretation of SEP changes if they develop. BAEPs were resistant to doses of fentanyl of 50 μg/kg with no changes observed in absolute latency, interpeak latency, or amplitude.[250]

Based on several case reports and small series, dexmedetomidine is compatible with all types of evoked potential monitoring, although data regarding MEPs are not entirely consistent. Once study demonstrated significant attenuation of MEPs during surgical treatment of scoliosis when dexmedetomidine was used as an adjunct to propofol and remifentanil.[251] Data are limited, and large studies are lacking. Use of dexmedetomidine currently is not a problem.

ANESTHESIA AND MOTOR-EVOKED POTENTIALS

Effects of anesthetic drugs on tcMEPs recorded from muscle are surprisingly profound (see Table 49-3).[252-257] Anesthetic techniques typically used by most anesthesiologists for surgical procedures of the spine would produce prohibitive depression of the MEP.[258,259] Intravenously administered anesthetic drugs produce significantly less depression, and techniques using any of a combination of ketamine, opioids, etomidate, and propofol have been described.[260-266] We have had excellent experience with a combination of propofol and remifentanil, which also is supported in the literature.

Anesthetic effects on MEP responses recorded at spinal levels seem to be less serious. When responses are recorded from muscle, neuromuscular blocking drugs should be monitored quantitatively, maintaining T1 twitch height at approximately 30% of control values to prevent excessive movement during the operation.[138,253] When responses are not recorded from muscle, profound relaxation is desirable because gross muscle movement produced by MEP stimulation is eliminated, facilitating the surgical procedure. More recent studies using rapid trains of stimuli with transcranial electrical and magnetic stimulus techniques have produced responses that are more resistant to the effects of anesthetic drugs, and more "traditional" techniques using inhaled anesthetic drugs and narcotics may be used.[267-269] Total intravenous anesthesia is preferred to techniques using nitrous oxide or potent inhaled anesthetic drugs, however. Precise control of the anesthetic regimen and avoidance of boluses during critical monitoring periods are more important than for SSEPs, and active cooperation of the anesthesia care team is essential for good, reproducible results. Figure 49-24 shows the dramatic effect of introduction of 0.3 MAC isoflurane to a total intravenous technique using propofol and remifentanil.

PATHOPHYSIOLOGIC EFFECTS ON THE ELECTROENCEPHALOGRAM

Hypoxia

Hypoxia may produce inadequate delivery of oxygen to the cerebral cortex generating EEG, and changes similar to those occurring with ischemia result. Initially, hypoxemia may not cause any EEG changes because the brain can increase blood flow to compensate. When the hypoxemia becomes severe enough, further increases in flow are impossible, and EEG changes occur. "Slowing" of the EEG during hypoxia is a nonspecific global effect. Fast frequencies are lost, and low frequencies dominate. Eventually, the EEG is abolished as the brain shuts down electrical activity and diverts all oxygen delivered to maintenance of cellular integrity.

Hypotension

In a normal, awake patient, significant levels of hypotension are needed to cause the earliest of CNS signs, as measured by discrimination tests such as the flicker-fusion test. This test examines the flicker rate at which the observer perceives the light to be continuous. In the early days of deliberate hypotension, this test was part of the preoperative evaluation to judge how far the pressure could be reduced during the operation. Clear signs of confusion and inability to concentrate or respond properly to simple commands generally represent very low levels of cerebral perfusion when caused by hypotension because the normal cerebral circulation has a large capacity to vasodilate and maintain normal flow in the presence of significant hypotension.

The EEG changes associated with even this level of hypotension are not dramatic, although they are clear by comparison with a previously active recording. Herein lies the problem with using intraoperative EEG to determine whether a given level of hypotension has resulted in brain ischemia. EEG changes are not very pronounced and are bilateral. These changes also are nearly identical to the changes caused by increasing doses of many anesthetic drugs. EEG changes associated with hypotension can be detected, but when the hypotension is induced slowly and is associated with changes in anesthetic drugs (e.g., use of isoflurane to reduce blood pressure), the changes are very difficult to interpret. EEG changes associated with acute, severe hypotension such as may be caused by sudden arrhythmias are easier to read. Many patients undergoing surgical procedures do not have a normal cerebral circulation, however. In these individuals, even mild hypotension may result in significant cerebral ischemia. Monitoring the EEG during planned hypotension may be helpful in these patients, provided other causes of similar EEG changes may be carefully controlled. Although not supported in the literature, when the EEG changes (e.g., during carotid surgical procedures) secondary to hypotension, cerebral ischemia is likely.

Hypothermia

During cooling on CPB, the total power and peak power frequency of the high-frequency band were highly correlated with temperature when using Fourier analysis and spectral edge data; however, significant variability was noted among subjects, especially during cooling.[270] Complete EEG suppression usually develops at 15° C to 18° C. Levy and colleagues showed an improved ability to quantify the effects of hypothermia on the EEG by using an EEG processing technique known as approximate entropy.[155]

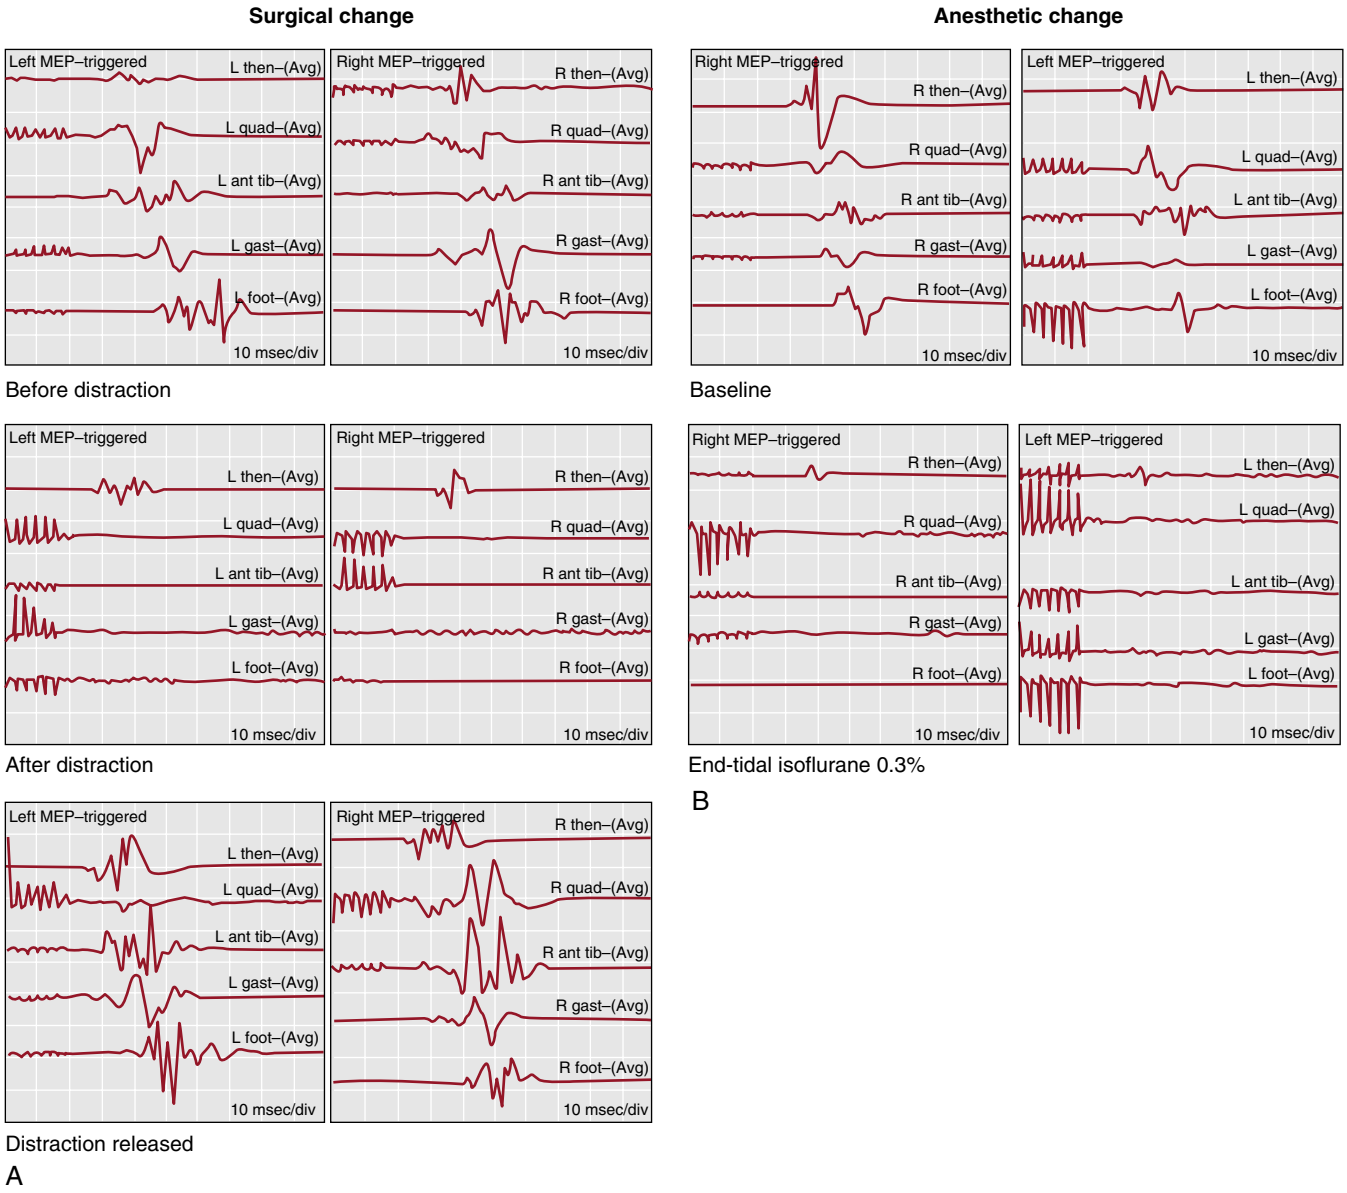

Figure 49-24. A, Transcranial electrical motor-evoked potential recording showing surgically induced change during spine surgery (scoliosis repair). **B,** Motor-evoked potential with an anesthetic-induced change. Note similarity of the change pattern, except that in the anesthetic-induced change, the responses in the upper extremity also changed. Left-sided and right-sided responses are shown on the corresponding panel. A single upper extremity response is shown (*top tracing*) in each panel. Responses from four muscle groups in each lower extremity are shown directly below them. *Ant tib,* M tibialis anterior; *gast,* m gastrocnemius; *L,* left; *quad,* m quadriceps femoris; *R,* right; *then,* thenar.

Hypercarbia and Hypocarbia

Hypocapnia is known to activate excitable seizure foci, and in rare cases it may produce EEG evidence of cerebral ischemia even in awake subjects.[271] Hypercapnia, unless severe and associated with hypoxemia, has only indirect effects secondary to increased CBF. In an anesthetized patient, hypercarbia-associated increases in CBF may have effects similar to those seen with increasing end-tidal tension of volatile anesthetic drugs.[272]

Untoward Events

One of the main reasons for monitoring the brain of an anesthetized patient is to enable detection of injuries to the nervous system that would not be otherwise apparent. Although hundreds of such case reports exist in the literature, as well as many in our experience, the cost effectiveness of such monitoring is unclear. In a more recent case at our institution, severe EEG changes occurred at the beginning of a carotid endarterectomy, before surgical incision, and were unassociated with any other vital sign changes or hypotension. Immediate angiography revealed acute carotid occlusion and completely changed the operation performed on this patient, who recovered completely. Some intraoperative events could lead to CNS insult that, if detected early, could be rapidly reversed or treated to prevent permanent injury. Given the rarity of such events, however, it is extremely unlikely that such monitoring would be shown to be beneficial in

any foreseeable randomized trial. If the "at-risk" patient could be identified preoperatively, perhaps the EEG or other types of neuromonitoring could be useful in detecting untoward CNS events during anesthesia, such as a new stroke after elective general surgical procedures.

PHYSIOLOGIC FACTORS INFLUENCING SENSORY-EVOKED RESPONSES

Numerous physiologic variables, including arterial blood pressure, temperature (local and systemic), and analysis of arterial blood gas values can influence SEP recordings. With decreases in mean arterial blood pressure to below levels of cerebral autoregulation as a result of either blood loss or vasoactive drugs, progressive changes in SERs occur. SSEP changes observed are progressive decreases in amplitude until loss of the waveform with no changes in latency.[273,274] BAEPs are resistant to even profound levels of hypotension (mean arterial pressure of 20 mm Hg in dogs).[273] Cortical (synaptic) function necessary to produce cortical SERs seems to be more sensitive to hypoperfusion than spinal cord or brainstem, nonsynaptic transmission.[274] Rapid decreases in arterial blood pressure to levels higher than the lower limit of autoregulation also have been associated with transient SSEP changes of decreased amplitude that resolve after several minutes of continued hypotension at the same level.[275] Reversible SSEP changes at systemic pressures within the normal range have been observed in patients undergoing spinal distraction during surgical treatment of scoliosis. These changes resolved with increases of arterial blood pressure to slightly higher than the patient's normal pressure; this finding suggests that the combination of surgical manipulation with levels of hypotension generally considered "safe" could result in spinal cord ischemia.[276]

Changes in temperature also affect SERs (see also Chapter 54). Hypothermia causes increases in latency and decreases in amplitude of cortical and subcortical SERs after all types of stimulation.[277-279] Hyperthermia also alters SERs, with increases in temperature leading to decreases in amplitude in SSEPs and loss of SSEPs at 42° C during induced hyperthermia.[280]

Changes in arterial blood gas tensions can alter SERs, probably in relation to changes in blood flow or oxygen delivery to neural structures.[281,282] Hypoxia produces SSEP changes (decreased amplitude) similar to the changes seen with ischemia.[282] Decreased oxygen delivery associated with anemia during isovolemic hemodilution results in progressive increases in latency of SSEPs and VEPs that become significant at hematocrit values lower than 15%. Changes in amplitude were variable until extremely low hematocrit values (≈7%) were reached, at which point the amplitude of all waveforms decreased.[283]

TABLE 49-4 CURRENT PRACTICES IN NEUROLOGIC MONITORING

Procedure	Monitors	Current Practice
Carotid endarterectomy	Awake patient neurologic examination, EEG, SSEP, TCD	NIH recommends use of one of these four available monitors
	CO	Threshold value not determined, inadequate normative population data
Scoliosis surgical treatment	SSEP	Monitoring recommended and may substitute for wake-up testing
	Wake-up test	Largely abandoned in centers using electrophysiologic monitoring; monitoring not continuous, and false-negative monitoring patterns reported
	MEP	Increased clinical use now that transcranial electrical stimulation is FDA approved; useful in combination with SSEP
Acoustic neuroma	Facial nerve monitor	Facial nerve monitoring recommended
	BAEP	BAEP showing some clinical evidence of improved outcome in some procedures
Intracranial aneurysm clipping	SSEP, EEG, tcMEP	Used routinely in some centers; limited clinical data on outcome, but appears clinically useful during anterior circulation procedures
Cranial nerve V decompression	BAEP	Used in some centers; reduces hearing loss
Cranial nerve VII decompression	BAEP, facial nerve monitor	Data from small series showing improved hearing preservation
Supratentorial mass lesions	SSEP, tcMEP	Used in some centers in selected high-risk procedures
Infratentorial mass lesions	BAEP, SSEP, tcMEP	BAEP to detect retractor-related cranial nerve VIII injury; SSEP and tcMEP in rare, high-risk lesions adjacent to ascending sensory or descending motor pathways
Decompression of spinal stenosis	SSEP, tcMEP	Used in some centers in high-risk procedures (more often cervical)
Spinal cord trauma	SSEP, MEP	Used in some centers in high-risk procedures
Cardiopulmonary bypass	EEG, TCD, $Sjvo_2$, CO	Used routinely in some centers; actively studied, but no outcome data yet
Aortic coarctation	SSEP	Used routinely in a few centers; no widespread acceptance
Aortic aneurysm repair	SSEP, MEP	Used routinely in a few centers; no widespread acceptance

BAEP, Brainstem auditory-evoked potential; *CO,* cerebral oximetry; *EEG,* electroencephalogram; *FDA,* U.S. Food and Drug Administration; *MEP,* motor-evoked potential; *NIH,* National Institutes of Health; *$Sjvo_2$,* jugular bulb venous oxygen saturation; *SSEP,* somatosensory-evoked potential; *TCD,* transcranial Doppler; *tcMEP,* transcranial motor-evoked potential.

SUMMARY

Regardless of the type of intraoperative neurologic monitor, several principles must be observed for neurologic monitoring to provide potential benefit to the patient. First, the pathway at risk during the surgical procedure must be amenable to monitoring. Second, if evidence of injury to the pathway is detected, some intervention must be possible. If changes in the neurologic monitor are detected, and no intervention is possible, although the monitor may be of prognostic value, it does not have the potential to provide direct benefit to the patient from early detection of impending neurologic injury. Third, the monitor must provide reliable and reproducible data. If the data have a high degree of variability in the absence of clinical interventions, their utility for detecting clinically significant events is limited.

This chapter reviews the most common clinically used intraoperative neurologic monitors. Ideally, clinical studies would provide outcome data on the efficacy of a neurologic monitor in a given procedure to improve neurologic outcome. Although a wealth of clinical experience exists with many of these monitoring modalities, little is available in the way of randomized prospective studies evaluating the efficacy of neurologic monitoring. Based on clinical experience with neurologic monitoring and nonrandomized clinical studies in which neurologic monitoring is used and generally compared with historical controls, practice patterns for use of neurologic monitoring have developed. In certain procedures, neurologic monitoring is recommended and used by most centers; in other procedures, monitoring is used almost routinely in some centers, but not in others; and in some procedures, no clear clinical experience or evidence indicates that monitoring is useful at all (experimental use). Finally, in some procedures, monitoring is used selectively for patients believed to be at higher than usual risk for intraoperative neurologic injury. Table 49-4 provides a summary of current clinical practice.

Chapter 50

Monitoring Brain State During General Anesthesia and Sedation

EMERY N. BROWN • KEN SOLT • PATRICK L. PURDON • OLUWASEUN JOHNSON-AKEJU

Acknowledgment: The editors and publisher would like to thank Drs. Adrian W. Gelb, Kate Leslie, Donald R. Stanski, and Steven L. Shafer for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Anesthesiologists rely extensively on physiologic signals and anesthetic dosing strategies to track states of the brain and central nervous system under general anesthesia.
- Heart rate and systemic arterial blood pressure changes are the principal physiologic signals used to monitor the anesthetic state of patients receiving general anesthesia.
- Use of the neurologic examination during induction of and emergence from general anesthesia can provide information regarding loss and recovery of consciousness.
- Electroencephalogram (EEG)-based indices are used to track the level of consciousness of patients receiving general anesthesia. The most commonly used EEG-based indices are the bispectral index (BIS), the Patient Safety Index (PSI), Narcotrend, and Entropy.
- Real-time analysis of the unprocessed EEG and the spectrogram (density spectral array) is a highly informative way to monitor brain states of patients receiving general anesthesia.
- Normalized symbolic transfer entropy (NSTE) is a new approach for quantifying how changes in frontoparietal functional connectivity relate to anesthesia-induced changes in consciousness.
- In the future, closed-loop anesthetic delivery (CLAD) systems may provide highly accurate ways to control states of general anesthesia, medical coma, and sedation.
- Obtaining reliable quantitative markers of nociception is an active area of investigation.

General anesthesia is a drug-induced reversible condition composed of four behavioral and physiologic states: unconsciousness, amnesia, analgesia, immobility, and stability of the physiologic systems, including the autonomic, cardiovascular, respiratory, and thermoregulatory systems.[1,2] Continuously monitoring the status of the patient during general anesthesia is crucial for safe and proper delivery of anesthesia care. The physiologic state of the patient under general anesthesia is commonly monitored using the electrocardiogram and an arterial blood pressure cuff, or an arterial catheter, to monitor the cardiovascular system. In more complex cases, a central venous catheter can be used to monitor central venous pressures, and a pulmonary artery catheter can be placed to monitor cardiac output and pressures in the heart and pulmonary circulation. Transesophageal echocardiography can be used intermittently to gain direct visual information about the anatomy and function of the heart. The capnogram provides a continuous readout of the level of expired carbon dioxide and respiration. In intubated patients, more detailed information about the state of the lungs can be acquired from the pressure tracing on the ventilator. The pulse oximeter estimates the level of hemoglobin saturation in the arterial blood, and the thermometer tracks body temperature (see Chapter 54). Muscle relaxation, or immobility, is monitored primarily using a train-of-four stimulation device, and more grossly by observing changes in muscle tone or movement (see Chapter 53).

Monitoring the behavioral states is more challenging. During general anesthesia, amnesia is not monitored directly but implicitly by the extent to which unconsciousness is achieved. If the patient is unconscious and not simply conscious but unresponsive, the patient will also have amnesia. In this chapter, we discuss approaches

for monitoring unconsciousness and analgesia, or more accurately stated antinociception, during sedation and each of the three phases of general anesthesia: induction, maintenance, and emergence. This chapter's focus is on physiologic signs and neurologic examination findings and the electroencephalogram (EEG)-based indices used to track these states of general anesthesia.

INDUCTION OF GENERAL ANESTHESIA

Monitoring of a patient's level of consciousness begins at induction of general anesthesia. Induction is usually achieved by an intravenous bolus dose of a hypnotic drug such as propofol, a barbiturate, ketamine, or etomidate. Unconsciousness usually occurs in 10 to 30 seconds. The brain state of the patient, which in this case is the transition into unconsciousness, is tracked by monitoring the patient's physiologic signs and the EEG-based index.

PHYSIOLOGIC SIGNS OF LOSS OF CONSCIOUSNESS

When a hypnotic drug is administered to induce general anesthesia—usually as an intravenous bolus over a 5- to 10-second period—several physiologic signs are observed. If asked to count backwards from 100, the patient typically does not get beyond 85 to 90. This transition into unconsciousness can be followed easily by asking the patient to perform smooth pursuit of the anesthesiologist's finger.[2] In smooth pursuit, the patient is instructed to move his or her eyes to track the position of the anesthesiologist's finger. As loss of consciousness ensues, the lateral excursions of the eyes during smooth pursuit decrease, nystagmus may appear, blinking increases, and the eyes fix abruptly in the midline. The oculocephalic reflex and the corneal reflex are lost, but the pupillary response to light remains intact. The patient typically becomes apneic, atonic, and unresponsive at the point when the oculocephalic and corneal reflexes are lost.

The oculocephalic reflex is assessed by turning the patient's head from left to right. Before administration of the induction anesthetic, when the reflex is intact in a patient with no neurologic deficits, the eyes move in the direction opposite the motion of the head. When the reflex is lost, the eyes stay fixed in the midline.[3] The oculocephalic reflex requires the circuits of cranial nerves III, IV, and VI to be intact. The motor nuclei associated with cranial nerves III and IV are located in the midbrain, whereas the nucleus of cranial nerve VI is located in the pons. The corneal reflex has traditionally been assessed using a wisp of cotton at the corner of the eye to stroke the cornea. An easier way to assess the reflex is to allow a drop of sterile water to fall on the cornea. Using a drop of sterile water may be safer than using the wisp of cotton, because the former is less likely to cause a corneal abrasion. With either approach, the reflex is intact if the eyes blink consensually, is impaired if there is a blink in one eye and not the other, and is absent if there is no blink. The afferent component of the corneal reflex travels to the sensory nucleus of the cranial nerve V through the ophthalmic branch, whereas the efferent component arises from the motor nucleus of the cranial nerve VII. The nuclei for these nerves associated with the oculocephalic reflex and the corneal reflex lie in close proximity to the arousal centers in the midbrain, pons, hypothalamus, and basal forebrain.[3]

Loss of the oculocephalic reflex suggests that the motor nuclei required for eye movements have been affected by the anesthetic. Similarly, loss of the corneal reflex suggests that the nuclei that control sensation and motor responses to sensation on the eyes and the face have also been affected. Because the loss of the oculocephalic and corneal reflexes occur concomitantly with the loss of responsiveness, the anesthesiologists can also infer that the loss of consciousness is due at least in part to the effects of the anesthetics on the nearby arousal centers.[2-4] Apnea, which commonly occurs on induction of general anesthesia with bolus administration of a hypnotic agent, is most likely due to the inhibitory effects of the anesthetic on the dorsal and ventral respiratory groups in the medulla and pons, respectively.[5] Atonia can be due to anesthetic action at any one of multiple sites in the motor pathways between the primary motor areas and the spinal cord. The most likely brainstem sites are the pontine and medullary reticular nuclei.[2]

Loss of the oculocephalic reflex, the corneal reflex, apnea, and atonia occur concomitantly with loss of consciousness on induction of general anesthesia because the brainstem is one of the first brain sites that the hypnotic drug reaches after an intravenous bolus. Blood containing the anesthetic reaches the brainstem through the basilar artery, which arises from the fusion of the two vertebral arteries and supplies the posterior cerebral arteries that provide the posterior input to the Circle of Willis.[4] Before terminating in the posterior cerebral arteries, the basilar artery runs on the dorsal surface of the brainstem and gives off multiple penetrating arteries that perfuse the brainstem nuclei leading to the observed physiological effects.

ELECTROENCEPHALOGRAM-MARKERS OF LOSS OF CONSCIOUSNESS

Electroencephalogram-based indices are among the most commonly used methods for tracking the loss of consciousness induced by general anesthesia.[6] With induction of general anesthesia, these indices usually change from high values that indicate the awake state to lower values that indicate states of sedation and unconsciousness.

MAINTENANCE OF GENERAL ANESTHESIA: PHYSIOLOGIC SIGNS AND THE NOCICEPTIVE-MEDULLARY-AUTONOMIC PATHWAY

Despite the many advances in anesthesia care, the physiologic signs of changes in heart rate, arterial blood pressure, and movement are the measurements most commonly used to track the anesthetic during maintenance of general anesthesia.[7] When the state of general anesthesia is not adequate for the level of surgical (nociceptive) stimulation, heart rate and arterial blood pressure can increase dramatically. The changes in heart rate and arterial blood pressure that anesthetized patients show

in response to a nociceptive stimulus can be explained in terms of the nociceptive-medullary-autonomic (NMA) circuit comprised of the spinoreticular tract, the brainstem arousal circuits, and the sympathetic and parasympathetic efferent pathways (Fig. 50-1).[2,8] It is important to understand how the NMA circuit works, because it is the most used pathway for monitoring the patient's level of unconsciousness and antinociception. One example is a description of the NMA pathway in a clinical context that is commonly observed in the operating room.

Suppose that a patient is in a stable state of general anesthesia when, to gain better exposure, the surgeon moves the retractor. Suppose also that this maneuver induces an immediate increase in heart rate and arterial blood pressure. Assuming, that there are no occult hemodynamic or respiratory problems or other common issues that increase heart rate and arterial blood pressure, then these increases likely occurred because the level of general anesthesia did not maintain an adequate level of antinociception. By simultaneously monitoring the level of muscle relaxation and oxygen saturation, oxygen delivery, and EEG-based indices, the anesthesia provider can determine that these increases are due to inadequate antinociception and decide to administer more analgesic.

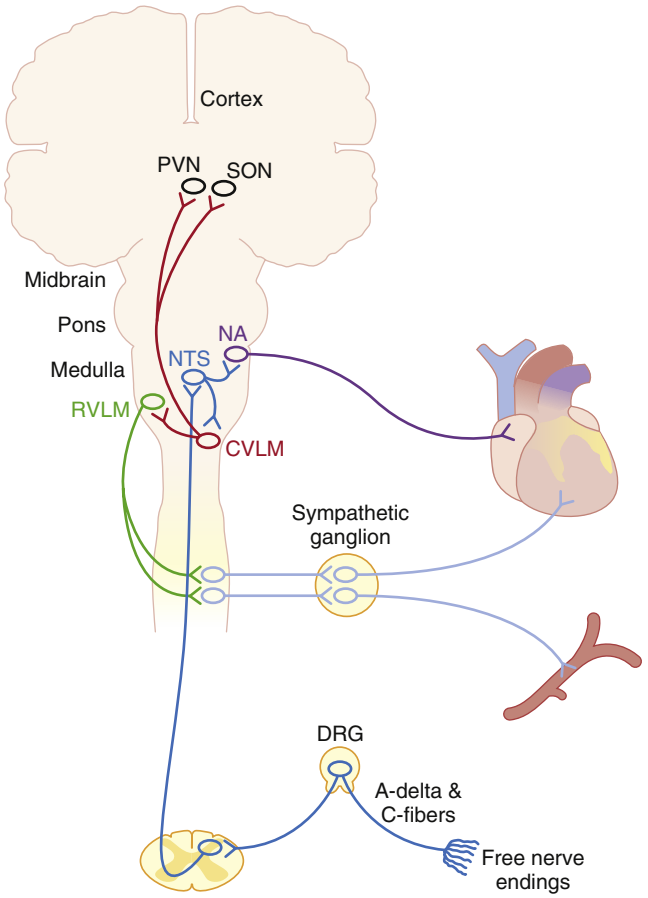

Figure 50-1. Nociceptive medullary autonomic circuit. The ascending nociceptive (pain) pathway starts with C fibers and A-delta peripheral afferent fibers that synapse on projection neurons (PN) in the dorsal horn. The PNs cross the midline, course to the brain where they synapse at several targets, including the nucleus of the tractus solitarius (NTS) in the medulla. The NTS mediates the autonomic response to a nociceptive stimulus by increasing sympathetic output through the rostral ventral lateral medulla (RVLM) and the caudal ventral lateral medulla (CVLM), which projects to the thoracolumbar sympathetic ganglia. The ganglia project to peripheral blood vessels and the heart. The nucleus ambiguous (NA) mediates the parasympathetic output to the sinoatrial node of the heart through the vagus nerve. The NTS projects also to the supraoptic nucleus (SON) and periventricular nucleus (PVN) in the hypothalamus. The NMA circuit is the reason why anesthesiologists use increases in blood pressure and heart rate as markers of increases in nociceptive stimulation and, possibly, a level of general anesthesia that is inadequate. *DRG,* Dorsal root ganglion. *(Redrawn from Brown EN, Lydic R, Schiff ND: General anesthesia, sleep, and coma.* N Engl J Med *363: 2638-2650, 2010.)*

The ascending nociceptive (pain) pathway begins with A-delta and C-fibers whose free nerve endings bring nociceptive information from the periphery to the spinal cord (see Fig. 50-1).[9] In the spinal cord, these fibers synapse in the dorsal horn on projection neurons that travel through the anterolateral fasciculus and synapse at multiple sites in the brainstem, including the nucleus of the tractus solitarius in the medulla.[2,8] The autonomic response to a nociceptive stimulus is initiated from the nucleus of the tractus solitarius, which mediates sympathetic output through the rostral ventral lateral medulla and the caudal ventral lateral medulla to the heart and peripheral blood vessels through projections to the thoracolumbar sympathetic ganglia.[2] The parasympathetic output from the nucleus of the tractus solitarius is mediated through the nucleus ambiguus, which projects through the vagus nerve to the sinoatrial node of the heart.[2] The nucleus of the tractus solitarius also projects to the periventricular nucleus and supraoptic nucleus in the hypothalamus. Thus, the nociceptive stimulus of moving the retractor initiates an increase in sympathetic output and a decrease in parasympathetic output through the NMA circuit that rapidly results in the observed increases in heart rate and arterial blood pressure.

The NMA circuit explains why increases in heart rate and arterial blood pressure are used as a rapid indicator of an inadequate level of analgesia. If unconsciousness is sufficiently well maintained, then no EEG changes will likely be observed. If no acute changes in physiology occur for other reasons, such as bleeding, hypoxemia, disconnection of the breathing circuit, or inadequate dosing of the muscle relaxant, the appropriate treatment is administration of more analgesic medication.

Activity in the NMA circuit can be observed rapidly when a patient is under general anesthesia,[10] because this pathway is a fundamental component of the fight-or-flight response.[11] This circuit is used as a sentinel for detecting nociceptive stimuli that can lead to autonomic, stress, and arousal responses. Heart rate and arterial blood pressure changes are the principal markers of activity under general anesthesia because motor responses are often blocked by muscle relaxation. Neurologists frequently test the NMA circuit with nociceptive stimuli, such as total body pinches, nail bed pinches, and sternal rubs, to evaluate the level of arousal of patients with brain injuries that affect the level of consciouness.[3,12,13]

Other signs of inadequate antinociception are perspiration, tearing, pupil dilation, and return of muscle tone and movement.[7] Changes in muscle tone and movement are not observed if the patient is receiving a muscle relaxant. The galvanic skin response has also been studied as a potentially more objective measure of antinociception;

however, it is not widely used in clinical practice.[14] If the nociceptive stimulus is sufficiently strong and dosing anesthetic is inadequate to ensure maintenance of unconsciousness, then changes in the EEG or in the EEG-based index may warn of return of consciousness.

MAINTENANCE OF GENERAL ANESTHESIA: ELECTROENCEPHALOGRAM-BASED INDICES OF LEVEL OF CONSCIOUSNESS

It is recognized that the EEG changes systematically in relation to the dose of anesthetic drug administered (Fig. 50-2).[2,6,15-17] As a consequence, the unprocessed EEG and various forms of processed EEG have been used to track the level of consciousness of patients receiving general anesthesia and sedation. Several EEG-based index systems have been studied and used in clinical practice. These systems process the EEG and provide an index value or set of values in real time or near real time that can be used to track the level consciousness. In general, the indices are designed to decrease with decreasing level of consciousness and increase as consciousness returns. In this way, the anesthesia provider can use these indices along with the physiological signs to track the patient's state of unconsciousness, and to some degree, antinociception. A summary of the EEG-based indices that have received the most use in clinical practice and clinical studies follows.

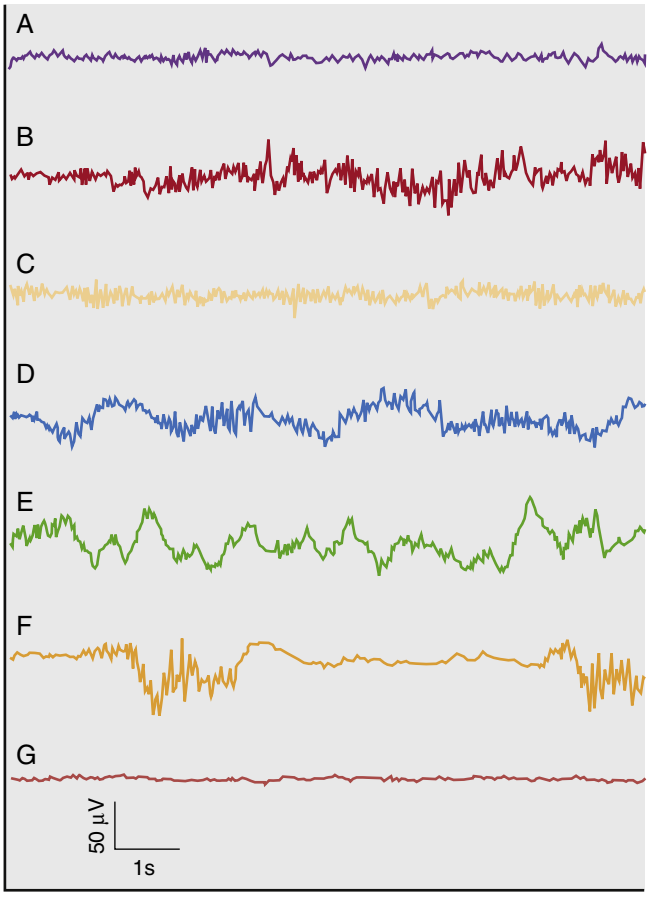

Figure 50-2. Anesthetic states and electroencephalogram signatures of propofol. **A,** Awake electroencephalogram pattern with eyes open. **B,** State of paradoxical excitation. **C,** Alpha (8 to 12 Hz) and beta (13 to 25 Hz) oscillations frequently associated with an arousable state of sedation. **D,** Slow (0.1 to 1Hz), delta (1 to 4 Hz), and alpha oscillations commonly seen during unconsciousness at surgical planes. **E,** Slow oscillations typically recorded during propofol induction and during deep dexmedetomidine sedation (see Fig. 50-8, *D*). **F,** Burst suppression, a state of profound anesthetic-induced brain inactivation, seen commonly in the elderly during normal maintenance, anesthetic induced coma, and hypothermia. **G,** Isoelectric electroencephalogram pattern commonly observed in brief periods during normal maintenance, in anesthetic-induced coma and profound hypothermia.

BISPECTRAL INDEX

The bispectral index (BIS) is an empirically derived scale that was proposed by Aspect Medical Systems (later purchased by Covidien [Boulder, Colo.]) in 1994, as a novel way to monitor level of consciousness among patients receiving general anesthesia and sedation.[18,19] The algorithm processes the EEG in near real time and computes an index value between 0 and 100 that indicates the patient's level of consciousness (Fig. 50-3).[20,21] A value of 100 corresponds to being completely awake, whereas 0 corresponds to a profound state of coma or unconsciousness that is reflected by an isoelectric or flat EEG. The BIS algorithm is proprietary, and the actual computation through which the index is derived is not public knowledge. However, it is known that BIS combines information from three EEG analyses: the spectrogram, the bispectrum, and a time domain assessment of burst suppression.[20-22] The spectrogram is a decomposition of the EEG into its power content by frequency as a function of time.[20] The bispectrum measures as a function of time the degree of nonlinear coupling between pairs of frequencies in the spectrogram.[20] The BIS algorithm works by measuring specific features of the spectrogram, the bispectrum, and the level of burst suppression and uses a predetermined weighting scheme to convert

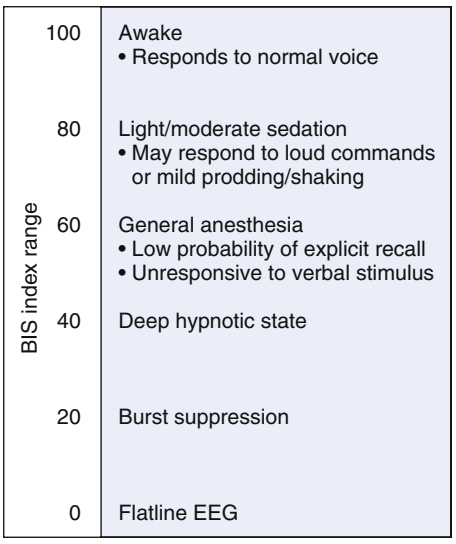

Figure 50-3. Anesthetic states and the bispectral index (BIS). The chart provides a behavioral interpretation of the values of the BIS. *EEG,* Electroencephalogram. *(Redrawn from Kelley SD:* Monitoring consciousness: using the bispectral index, *ed 2. Boulder, Colo., 2010, Covidien.)*

these features into the index value. The EEG also undergoes various artifact corrections. Along with the index value, the unprocessed EEG, the spectrogram and the level of electromyographic activity are displayed on the monitor. The production of the index is computationally intensive, so that there is a 20- to 30-second lag between the time the EEG is observed and the computation of the corresponding BIS value.[23] A patient is considered to be appropriately anesthetized (i.e., unconscious) when the value of the BIS is between 40 and 60 (Fig. 50-3).[21,24] The EEG is recorded from a four-lead frontal montage.

Since its approval by the U.S. Food and Drug Administration (FDA) in 1996, the BIS monitor has been studied extensively in clinical trials and used widely in anesthesiology practice. The changes in the index are correlated with the level of consciousness (Fig. 50-2). Primarily because, for many anesthetics, the EEG shows lower-frequency, higher-amplitude oscillations as patients achieve deeper states of unconsciousness. Three exceptions are the anesthetics ketamine (Fig. 50-6), nitrous oxide, and dexmedetomidine (Fig. 50-7). The dissociative anesthetic state produced by ketamine is associated with prominent high-frequency oscillations rather than slow wave oscillations. As a consequence, patients can be unconscious with ketamine but have unexpectedly high index values.[25] Nitrous oxide increases the amplitude of high-frequency EEG activity[26] and decreases the amplitude of low-frequency EEG activity,[27] yet it has little to no effect on the BIS index.[21,28] In the case of dexmedetomidine, slow oscillations are prominent during sedation,[29-31] (see Fig. 50-7) with BIS values that are typically in the unconscious range. However, the patient can be readily aroused by verbal commands or light shaking because dexmedetomidine does not produce profound unconsciousness. BIS values are also considered less reliable in pediatric patients.

The BIS monitor can be used as a way to prevent intraoperative awareness, which is defined as the patient having explicit recall of events that transpired during the time that he or she was under general anesthesia. Use of the BIS monitor as a way to prevent intraoperative awareness was studied in the B-Aware Trial.[32] This study compared patients at high risk for awareness who were randomly assigned to monitoring with BIS using a target range of 40 to 60 and patients monitored with the standard of care at that particular institution. The patients in the BIS group had a significantly lower incidence of awareness.

The findings from this study were called into question because of several design concerns, and for this reason the B-Unaware Trial was conducted.[33] The B-Unaware Trial was a multicenter investigation that randomly assigned patients to either BIS monitoring or monitoring of end-tidal anesthetic concentration to compare the two approaches for preventing awareness. The end-tidal anesthetic concentration criterion was maintenance of the volatile anesthetic between 0.7 and 1.3 of the age-adjusted minimum alveolar concentration (MAC) of the anesthetic administered to the patient (discussed under End-Tidal Anesthetic Criterion). As in the B-Aware Trial, the objective in the BIS-monitored group was maintenance of the BIS value between 40 and 60. This study found no significant difference in the incidence of awareness among the patients monitored with BIS compared with those monitored with the end-tidal anesthetic criterion. The authors interpreted these findings to mean that BIS monitoring was not more effective than the end-tidal anesthetic criterion in preventing awareness in patients receiving general anesthesia using volatile anesthetics. Several concerns were expressed about the findings of this study as well. The most notable were subject selection and whether the study had sufficient power to detect actual differences had they been present.[34,35]

As a follow-up to this study, the investigators in the B-Unaware Trial conducted a second trial comparing intraoperative awareness in a larger group of patients at high-risk for awareness using BIS and the end-tidal anesthetic criterion used in the first B-Unaware Trial.[36] In this trial, the investigators found that there was a statistically significant greater incidence of definite or possible awareness in the BIS group compared with the end-tidal anesthetic group. These findings suggested that monitoring of patients with BIS was less effective in reducing the likelihood of intraoperative awareness compared with patients who were monitored by the end-tidal anesthetic criterion. Because the two investigations conducted by the B-Unaware group used inhaled anesthetics as the primary anesthetic, their conclusions do not apply to cases in which the BIS is used to monitor level of consciousness in patients receiving total intravenous anesthesia.

Preventing awareness under general anesthesia is a solvable problem if strategies used to monitor the brain states of patients use markers that relate directly rather than indirectly to the mechanisms through which the anesthetics act at specific receptors and neural circuits to alter level of arousal. [2,37,38] Unlike the current EEG-based indices, these markers will most likely need to be different for the different anesthetics. (See Unprocessed EEG and the Spectrogram.)

PATIENT SAFETY INDEX

The Patient Safety Index (PSI) is like the BIS index, a proprietary algorithm that assesses level of consciousness based on the EEG for patients receiving general anesthesia or sedation. The PSI was approved by the FDA in 2000 and was originally produced by Physiometrix (North Billerica, MA), but it is now manufactured and sold by Masimo (Irvine, CA). The development of the PSI was the outgrowth of several years of research conducted by E. Roy John at the Brain Research Laboratory at the New York University School of Medicine.[39] Like the BIS index, the PSI is also scaled between 0 and 100 (see Fig. 50-4). However, the PSI range to ensure that the patient is unconscious is between 25 and 50.[40]

The original formulation of the PSI used an electrode montage that included occipital and frontal EEG leads to monitor the phenomenon of anteriorization as a marker of change in level of consciousness. Anteriorization is the forward shift of spectral power from the occipital area to the frontal area during loss of consciousness and the posterior shift of this power from the frontal areas to the occipital areas during the return of consciousness.[38,41-43] The current formulation of the PSI uses only a four-lead

frontal EEG montage. In addition to displaying the PSI, this monitor also shows in real time the unprocessed EEG and its spectrogram from both the left and right sides of the head, the level of electromyographic activity, an artifact index, and the suppression ratio. The suppression ratio is a number between 0 and 100 that measures the fraction of time the EEG is in burst suppression. The monitor also allows the user to change the viewing screen among various combinations of the unprocessed EEG traces, the spectrogram, and the time series of the index values.

In head-to-head comparisons, the PSI correlates strongly with the BIS readings in terms of tracking a patient's level of consciousness.[44-46] This monitor has been less frequently studied in clinical investigations and has not received the same level of clinical use as the BIS monitor. In our experience, the PSI can also give ambiguous information for ketamine, nitrous oxide, dexmedetomidine, and pediatric patients.

NARCOTREND

The Narcotrend produced by MonitorTechnik (Bad Bramstedt, Germany) is an EEG-based device designed to monitor the level of consciousness in patients receiving general anesthesia or sedation.[47] This monitor was developed at the University Medical School of Hanover, Germany, and has been approved for use in the United States for patient care by the FDA. Like the BIS and PSI, the Narcotrend uses a proprietary algorithm that converts the EEG into different states denoted as *A* to *F* (Table 50-1).[48] Stage A corresponds to the patient being wide-awake, whereas stage F corresponds to increasing burst suppression down to an isoelectric state. The newer version of the Narcotrend monitor includes a Narcotrend Index, which is scaled between 0 and 100.[48] In addition, the Narcotrend monitor displays the unprocessed EEG signal and its spectrogram. This monitor has also been validated with respect to the BIS index and separately. Its performance has been variable.[23,49,50] Narcotrend has received less clinical use than BIS and PSI.

TABLE 50-1 ANESTHETIC STATES, THE NARCOTREND STAGES, AND NARCOTREND INDEX RANGES

	Narcotrend Stage	Narcotrend Index
Awake	A	95-100
	B_0	90-94
Sedated	B_1	85-89
	B_2	80-84
Light anesthesia	C_0	75-79
	C_1	70-74
	C_2	65-69
General anesthesia	D_0	57-64
	D_1	47-56
	D_2	37-46
General anesthesia with deep hypnosis	E_0	27-36
	E_1	20-26
	E_2	13-19
General anesthesia with increasing burst supression	F_0	5-12
	F_1	1-4

The table provides the anesthetic state interpretation of the Narcotrend Stages and the Narcotrend Index values.

ENTROPY

The use of entropy to track the level of consciousness in patients receiving general anesthesia or sedation is a relatively new monitoring approach. The Entropy monitor was developed by Datex-Ohmeda, which is now part of GE Healthcare (Little Chalfont, UK). Entropy is a well-known concept in the physical sciences, mathematics, and information theory. Entropy measures the degree of disorder or the lack of synchrony or consistency in a system.[51] The algorithm in the GE device uses frequency domain analysis, combined with burst suppression to measure the entropy of the EEG in patients receiving anesthetic drugs. Unlike several of the other algorithms

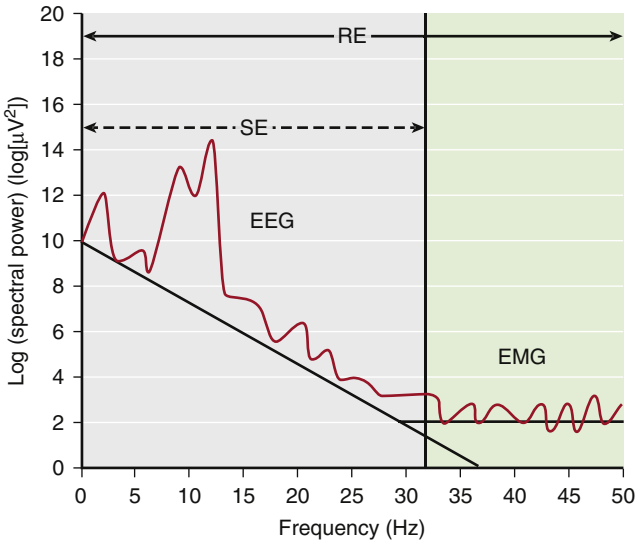

Figure 50-5. Schematic representation of the spectral entropy. The response entropy (RE) is computed from the power in the frequencies between 0 and 47 Hz. The state entropy (SE) is computed from the power in the frequencies between 0 and 32 Hz. The power between 32 and 47 Hz is assumed to represent artifacts coming from the electromyogram (EMG). The difference between the RE and SE allows the anesthesiologist to distinguish between electroencephalogram (EEG) changes related to changes in the anesthetic state and changes that are due to artifact or movement. *(Redrawn from Bein B: Entropy,* Best Pract Res Clin Anaesthesiol *20:101-109, 2006).*

we have discussed, the entropy algorithm used in the GE entropy device is publicly available.[52,53]

A readily apparent feature of the EEG, as patients proceed through deeper levels of unconsciousness induced by general anesthesia, is that the patterns become more regular and ordered (Fig. 50-2). That is, we observe an apparent decrease in the entropy of the EEG signal. The Entropy monitor reports two entropy numbers to aid in interpreting this monitor's EEG analysis (Fig. 50-5).[54] The first is the response entropy (RE) and the second is the state entropy (SE). The RE tracks the changes in the EEG power in the higher frequency range 0.8 to 47 Hz, whereas the SE tracks the changes in the EEG power in the lower frequency range of 0.8 to 32 Hz.[52] The relative changes in the RE and the SE make it possible to distinguish between real brain state changes versus those that are due to muscle activity on the electromyogram.[52] In general, electromyographic activity shows in the higher frequency range tracked by the RE. As a patient becomes more profoundly unconscious, the RE declines faster than the SE, thereby making it possible to distinguish unconsciousness from movement artifacts. Monitoring entropy is consistent with changes with the BIS.[55]

Like the BIS, PSI, and Narcotrend, the Entropy scores correlate with level of consciousness. The Entropy monitor, like BIS and the PSI, can show paradoxically high readings for ketamine and nitrous oxide. The Entropy scores can be misleading when the patient is receiving dexmedetomidine, because the highly ordered slow waves that are present commonly during deep sedation with dexmedetomidine do not necessarily indicate a profound state of unconsciousness (see Fig. 50-8, *B*).

END-TIDAL ANESTHETIC CRITERION

In 1965, Eger and colleagues[56] first introduced the concept of the MAC of inhaled anesthetic required for immobility (defined as lack of movement in response to noxious stimulation). Five years later, Eger's group also introduced the concept of MAC-awake, or the MAC of inhaled anesthetic necessary to ablate response to a verbal command.[57] The median MAC value (i.e., the MAC of inhaled anesthetic required for immobility in 50% of patients) remains the gold standard for dosing inhaled anesthetics, and some modern anesthesia machines calculate age-adjusted MAC values based on the patient's end-tidal anesthetic gas concentration. However, the ratio of MAC to MAC-awake varies widely among general anesthetics,[58] suggesting that MAC cannot be used to define or predict brain states in anesthetized patients. This has been confirmed by animal experiments demonstrating that there is no clear association between anesthetic-induced EEG patterns and immobility,[59] and that inhaled anesthetics produce immobility primarily through their actions in the spinal cord, rather than the brain.[60,61] Nevertheless, the widely accepted concept of MAC has led to the use of end-tidal anesthetic criterion as a way to monitor the level of unconsciousness induced by inhaled anesthetics.

As mentioned previously, this use of MAC has been supported by the B-Unaware Trial that reported no difference in the incidence of intraoperative awareness with an anesthetic protocol that maintained the BIS value between 40 and 60, and a protocol that maintained an end-tidal anesthetic concentration between 0.7 and 1.3 MAC[33] (see Bispectral Index). Similarly, the BAG-RECALL Trial limited enrollment to patients at high risk for intraoperative awareness. Patients with BIS-guided general anesthesia experienced a small but high and statistically significant incidence of intraoperative awareness than patients receiving general anesthesia guided by an end-tidal anesthetic criterion[36] (see Bispectral Index).

Unlike the BIS, PSI, Entropy, and Narcotrend, which provide EEG-based measures of brain activity, the end-tidal anesthetic criterion is related to brain activity through the concentration of anesthetic expired in the lungs. This assumes that the lung anesthetic concentration is in equilibrium with the brain concentration. The end-tidal anesthetic criterion is thus an indirect and less nuanced measure of level of consciousness given that the relevant effects of the anesthetics for inducing unconsciousness are in the brain and not in the lungs. That an EEG-based criterion and a lung-gas criterion are comparable for monitoring the level of consciousness under general anesthesia suggests more of a flaw in the design of the EEG-base marker rather than the superiority of the end-tidal anesthetic criterion. Because it is a more indirect measure of level of consciousness, the success of the end-tidal anesthetic criterion in preventing awareness likely comes at the expense of overdosing some patients. A key drawback of the end-tidal anesthetic criterion is that it cannot be used with total intravenous anesthesia.

OTHER STRATEGIES FOR MONITORING LEVEL OF CONSCIOUSNESS

Other strategies for monitoring level of consciousness during general anesthesia and sedation have been

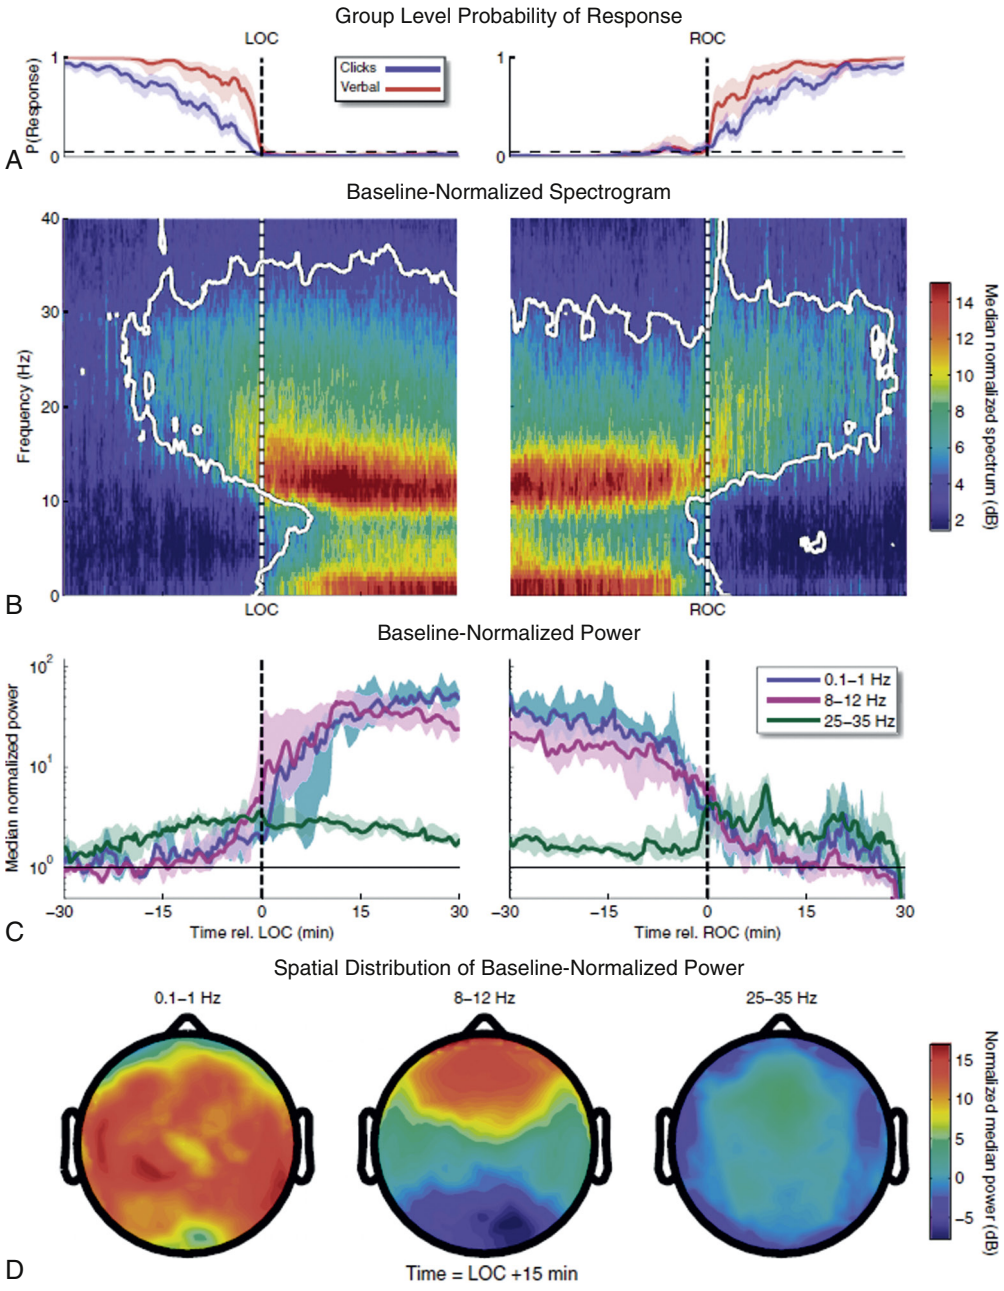

Figure 50-6. Behavioral and electroencephalogram (EEG) dynamics of loss and recovery of consciousness from propofol. **A,** Group-level (10 subjects) click or nonsalient stimulus (*blue*, P_{clicks}) and verbal or salient stimulus (*red*, P_{verbal}) response-probability curves. **B,** Group-level spectrograms computed by baseline-normalization from a frontal channel (approximately *Fz*, using nearest-neighbor Laplacian reference) aligned across subject with respect to loss of consciousness (LOC). Area enclosed within the white borders show where power is significantly different from baseline ($P < 0.05$, sign test) and shows significant power increases spanning slow (0.1-1 Hz) through gamma (25-35 Hz) bands. **C,** Time course of group-level power in slow, alpha (8-12 Hz), and gamma bands aligned with respect to LOC and recovery of consciousness (ROC). **D,** Group-level spatial distribution of slow, alpha, and gamma power during unconsciousness (LOC + 15 min). The frontal increase in alpha power is termed *anteriorization*. These analyses illustrate that changes in broad-band gamma/beta power occur with the behavioral changes before LOC and after ROC, whereas changes in slow and alpha power occur with LOC and ROC. *(From Purdon PL, Pierce ET, Mukamel EA, et al: Electroencephalogram signatures of loss and recovery of consciousness from propofol,* Proc Natl Acad Sci U S A *110:E1142-E1151, 2013.)*

studied. For example, the Cerebral State Monitor,[62] the SNAP Index,[63] and the AEP Index[64] are other EEG-based approaches that have been studied and applied in clinical practice.

EMERGENCE FROM GENERAL ANESTHESIA

ELECTROENCEPHALOGRAM-BASED INDICES AND RETURN OF CONSCIOUSNESS

As stated earlier, the EEG-based indices typically specify a range for maintenance of unconsciousness under general anesthesia (see Figs. 50-3 to Fig. 50-5 and Table 50-1). When delivery of the anesthetic drugs is decreased or terminated, the indices increase toward values that are consistent with the awake state. As the values of the indices increase, the patient is more likely to become conscious. In this way, the EEG-based indices can be used to monitor the transition from unconsciousness to return of consciousness during emergence from general anesthesia. Although the values of the indices increase during emergence, none of the indices has a value at which the patient is certain to regain consciousness. The reason for this lack of perfect correlation between the values of the EEG-based index and the return of consciousness may be due to imprecision in the definition of the indices in that many different anesthetic states are presumed to map to the same index value. Kelz and colleagues found that neural inertia can play a role with inhaled anesthetics.[65,66]

BOX 50-1 *Phases of Emergence From General Anesthesia and States of Coma Recovery*

General Anesthesia
Stable administration of anesthetic drugs
Arousal not possible, unresponsive; eyes closed, with reactive pupils
Analgesia, akinesia
Drug-controlled blood pressure and heart rate
Mechanically controlled ventilation
EEG patterns ranging from delta and alpha activity to burst suppression

Emergence, Phase 1
Cessation of anesthetic drugs
Reversal of peripheral-muscle relaxation (akinesis)
Transition from apnea to irregular breathing to regular breathing
Increased alpha and beta activity on EEG

Emergence, Phase 2
Increased heart rate and blood pressure
Return of autonomic responsiveness
Responsiveness to painful stimulation
Salivation (CN VII and IX nuclei)
Tearing (CN VII nuclei)
Grimacing (CN V and VII nuclei)
Swallowing, gagging, coughing (CN IX and X nuclei)
Return of muscle tone (spinal cord, reticulospinal tract, basal ganglia, and primary motor tracts)
Defensive posturing
Further increase in alpha and beta activity on EEG
Extubation possible

Emergence, Phase 3
Eye opening
Responses to some oral commands
Awake patterns on EEG
Extubation possible

Brain-Stem Death
No respiratory response to apneic oxygenation test
Total loss of brain-stem reflexes
Isoelectric EEG pattern

Coma
Structural brain damage to both cerebral hemispheres, with or without injuries to tegmental midbrain, rostral pons, or both
Isolated bilateral injuries to midline tegmental midbrain, rostral pons, or both
Arousal not possible, unresponsive
Functionally intact brain stem, normal arterial blood gases
EEG pattern of low-amplitude delta activity and intermittent bursts of theta and alpha activity or possibly burst suppression

Vegetative State
Spontaneous cycling of eye opening and closing
Grimacing and nonpurposeful movements
EEG pattern of high-amplitude delta and theta activity
Absence of EEG features of sleep
Usually able to ventilate without mechanical support

Minimally Conscious State
Purposeful guarding movements, eye tracking
Inconsistent communication, verbalizations
Following oral commands
Return of sleep–wake cycles
Recovery of some EEG features of normal sleep–wake architecture

From Brown EN, Lydic R, Schiff ND: General anesthesia, sleep, and coma, N Engl J Med *363:2638-2650, 2010.*
EEG, Electroencephalogram.
General anesthesia is a drug-induced, reversible coma. The physiological signs observed in the phases of emergence from general anesthesia can be related to changes in activity in specific brainstem nuclei. Emergence from general anesthesia has similarities and differences with recovery from coma due to a brain injury.

Neural inertia is the extent to which equal brain concentrations of anesthetic on induction and emergence often yield different behavioral states. In other words, the history of the brain states helps determine arousability.

PHYSIOLOGIC SIGNS AND RETURN OF CONSCIOUSNESS

The state of the patient during emergence from general anesthesia can be tracked reliably by monitoring the patient's physiologic signs and performing neurologic examinations.[2] Many of these physiologic changes relate to the return of brainstem function (Box 50-1). Therefore, by relating the physiologic signs and the findings from the neurologic examinations to the brainstem centers responsible for them, anesthesia providers can map the return of function to specific brainstem sites during emergence from general anesthesia. Once neuromuscular blockade has been reversed (see Chapter 35), the patient may breathe unassisted. As the level of carbon dioxide in the cerebral circulation becomes sufficiently high, most patients begin to breathe spontaneously. As the patient emerges from general anesthesia, the respiratory pattern can transition from one that is irregular with small tidal volumes to one that is regular with full normal tidal volumes.[2] Return of spontaneous breathing is a distinct indicator of return of function in the medulla and lower pons, as these are the locations of the dorsal and ventral respiratory groups, respectively.[5]

Over the ensuing several minutes and often concomitant with the return of spontaneous respiration, a series of other clinical signs begin to appear (see Box 50-1). These signs include swallowing, gagging, salivation, tearing, and grimacing.[2] The signs represent return of a specific center in the brainstem and their associated sensory and motor pathways. Swallowing, gagging, and coughing represent

return of the motor nuclei of the cranial nerves IX and X located in the medulla and the sensory afferent of these nerves arising from the trachea, larynx, and pharynx.[9] These physiologic signs appear because with the progressive decrease in the hypnotic and antinociceptive effects of the anesthetics, the endotracheal tube becomes a progressively more noxious stimulus. Salivation reflects the return of the inferior salivatory nucleus in the medulla and superior salivatory nucleus in the pons. Both are part of the parasympathetic nervous system. The efferent pathways from these nuclei travel in cranial nerves VII and IX, respectively.[9] Tearing also reflects the return of function in the superior salivatory nucleus. Grimacing, the use of muscles of facial expression, represents the return of function to the motor nucleus of cranial nerve VII, located in the pons.[9] Return of muscle tone to the upper and lower extremities is another important clinical sign that clearly reflects return of function in a number of circuits including the spinal cord, the reticulospinal tract, the basal ganglia, and the primary motor tracts.[2] In addition, as the endotracheal tube is perceived as more noxious and motor tone has returned, the patient may commonly exhibit defensive posturing indicated by reaching for the endotracheal tube.

These physiologic signs are often present in advance of the patient responding to any verbal commands. The patient need not respond to commands to be extubated. Tracheal extubation only requires that the patient have sufficient return of airway reflexes and motor function to ventilate and oxygenate adequately with spontaneous breathing. To meet the criteria for extubation of the trachea, a patient can be in a vegetative state as defined by the criteria used by neurologists and rehabilitation specialists to assess the brain states of patients recovering from coma (see Box 50-1).[12,13,67]

The corneal and oculocephalic reflexes typically return at the same time or after the patient begins to grimace (see Box 50-1).[2] Return of the corneal reflex reflects return of function in the sensory nucleus of cranial nerve V and the motor nucleus of cranial nerve VII.[3] The afferent pathway in the corneal reflex is the ophthalmic branch of cranial nerve V that projects to the trigeminal (cranial nerve V) nucleus, whereas the efferent pathway arises from the facial nerve (cranial nerve VII) nucleus. The consensual response in the corneal reflex indicates bilateral return of the sensory and motor components of this pathway. The trigeminal nucleus and the motor nucleus of cranial nerve VII lie in the pons. Return of the oculocephalic reflex indicates return of activity in the oculomotor (III), trochlear (IV), and abducens (VI) cranial nerves, which control movement of the eyes.[3] The cranial nerves III and IV nerve nuclei are located in the midbrain, whereas the cranial nerve VI nerve nucleus is in the pons. Return of the oculocephalic and corneal reflexes provides indirect evidence that the arousal centers in the nearby pons, midbrain, hypothalamus, and basal forebrain, may have also recovered function.[2] The pupils can remain pinpoint if the patient has received a substantial dose of narcotic. The pupillary light reflex can remain intact even when the patient is profoundly unconscious under general anesthesia[3]; therefore, the presence of the pupillary light reflex might not indicate a change in the level of consciousness while under general anesthesia.

Responding correctly to verbal commands, a criterion that is commonly used to assess the extent to which a patient has recovered from general anesthesia, and hence the patient's readiness for extubation, suggests a return of integrated function between the brainstem, the thalamus and cortex, and among cortical regions is a necessary condition.[2,68,69] Responding correctly to verbal commands means that the patient is correctly interpreting auditory information and that the cranial nerve VIII nuclei located in the pons and the auditory pathways from the pons to the cortex and the relevant effector pathways have regained substantial function. If the patient inconsistently follows motor commands, then he or she is classified as being in a minimally conscious state by the criteria neurologists use in examining patients recovering from coma (see Box 50-1).[12,13,67] With emergence, the physiologic signs and neurologic findings can be related to changes in activity in specific brainstem centers. Although the EEG shows the resumption of high-frequency activity consistent with the return of cognitive processing, normal brainstem-cortical, brainstem-thalamic, thalamocortical and intracortical communication must clearly return for full return of consciousness.[38,69-72] Current clinical monitoring approaches do not allow us to monitor these changes adequately.

Opening of the eyes is typically one of the last physiologic signs observed in patients emerging from general anesthesia. In particular, patients may respond reliably to verbal commands, have substantial return of motor functions, yet not necessarily open their eyes.[2] Generally, patients tend to keep their eyes closed even when consciousness has returned. In contrast, during coma recovery, patients can have their eyes open in a vegetative state (see Box 50-1).

EMERGING STRATEGIES FOR MONITORING THE BRAIN STATES OF GENERAL ANESTHESIA AND SEDATION

In the last several years, there has been strong growth in neuroscience of general anesthesia research. As a result, there are several reports of new approaches to monitoring the brain states under general anesthesia.

UNPROCESSED EEG AND THE SPECTROGRAM

Different anesthetics have different receptor targets[73] and neural circuit mechanisms of action.[2,37] These differences in targets and neural circuits translate into different patterns of activity in the brain that are readily visible in the unprocessed EEG or its spectrogram. The spectrum for a segment of EEG is the decomposition of the EEG signal into its power content by frequency. Power is typically expressed in decibels as the logarithm of the square of the amplitude of a given frequency component. When the spectrum is computed on successive nonoverlapping or overlapping segments of EEG data, it is termed the *spectrogram*; the *compressed spectral array* when the spectrogram is plotted in three dimensions[74]; and the *density spectral array* when it is plotted in two-dimensions.[75]

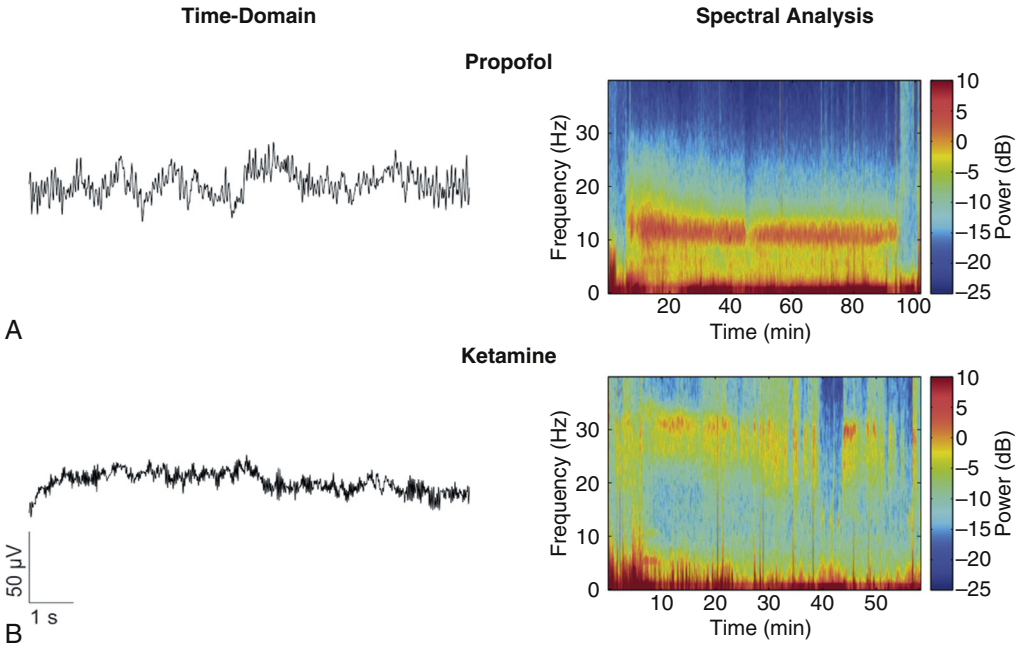

Figure 50-7. Time-domain and spectral electroencephalogram (EEG) signatures of common anesthetics. The left column shows a 10-second time-domain (unprocessed) segment of the EEG for each anesthetic. The right column shows several minutes of the spectrogram (density spectral array) computed from the EEG for each anesthetic. **A,** The spectrogram of propofol shows its characteristic alpha (8-12 Hz) and slow-delta (0.1-4 Hz) oscillation pattern. **B,** The ketamine spectrogram shows high frequency oscillations in the high beta (20-24 Hz) and low gamma (25-35 Hz) range.
