Many of the risks of aggressive intravascular fluid administration just summarized are related to dilution of the circulating blood volume. Recognition of this fact and continued improvement in the safety of donated blood led to increased use of blood products in the management of early hemorrhagic shock (see also Chapter 61). The risk for systemic ischemia is decreased by the maintenance of an adequate hematocrit, and the potential for dilutional coagulopathy can be decreased by the early administration of plasma. The composition of resuscitation fluids may be as important as the rate and timing of administration. A 4-year retrospective review of a cohort of critically injured patients who underwent emergency surgery examined the outcomes of short-term care based on the number of units of blood transfused.[159] One hundred forty-one patients received massive blood transfusions (≥20 units of RBCs) during preoperative and intraoperative resuscitation. The number of blood units did not differ between survivors (30%) and nonsurvivors (70%). Eleven variables were significantly different: aortic clamping for control of arterial blood pressure, use of inotropic drugs, time with a systolic blood pressure higher than 90 mm Hg, time in the OR, temperature less than 34° C, urine output, pH lower than 7.0, PaO_2/FiO_2 ratio less than 150, $Paco_2$ more than 50 mm Hg, K^+ more than 6 mM/L, and calcium less than 2 mM/L. Of these, the presence of the first three variables in the face of transfusion of more than 30 units of packed RBCs was invariably fatal. Total blood loss and the amount of transfused blood were less critical than the depth and duration of shock. These concerns led to the concept of damage control surgery, which emphasizes rapid control of active hemorrhage.[160]

RBCs are the mainstay of treatment of hemorrhagic shock. With an average hematocrit of 50% to 60%, a unit of RBCs will predictably restore O_2-carrying capacity and expand intravascular volume as well as any colloid solution. RBCs of blood type A, B, or AB carry major incompatibility antigens that may precipitate a lethal transfusion reaction if given to a patient with the opposite blood type. Because RBCs also carry dozens of minor antigens that can cause reactions in susceptible patients, crossmatching is desirable when time allows (typically approximately 1 hour from the time a sample reaches the blood bank until the RBCs reach the patient). Type-specific blood requires less time for delivery from the blood bank

(usually ~30 minutes) and may be an appropriate alternative in some situations. Type O blood—the universal donor type—can be given to patients of any blood type with little risk for a major reaction.[161] This is the preferred approach for patients who arrive at the ED in hemorrhagic shock. If O-positive blood is given to a Rhesus-negative woman who survives, prophylactic administration of anti-Rh_0 antibody is indicated.

Risks of RBC administration include transfusion reaction, transmission of infectious agents, and hypothermia (see also Chapter 61 for details). For example, RBCs are stored at 4° C and will decrease the patient's temperature rapidly if not infused through a warming device or mixed with warmed isotonic crystalloid at the time of administration.

Plasma requires blood typing but not crossmatching; delay in availability of plasma is caused by the need to thaw frozen units before they can be administered. Busy trauma hospitals will often maintain a supply of prethawed plasma (thawed fresh plasma as opposed to FFP) that can be issued quickly in response to an emergency need; in smaller hospitals it is important to request plasma early in resuscitation if it is likely to be needed. Very busy centers are experimenting with keeping 2 to 4 units of prethawed type AB (universal donor) plasma available in the trauma resuscitation unit. Units are kept ready in this way for 2 days at a time; if not used on an emergency basis, the units are returned to the blood bank and released to the next patient needing plasma. Whether this approach improves outcomes has not yet been studied.

Platelet transfusion should normally be reserved for patients with clinical coagulopathy with a documented low serum level (>50,000 per high-power field). When the patient is in shock, however, and blood loss is likely to be substantial, platelets should be empirically administered in proportion to RBCs and plasma (1:1:1), as discussed earlier for DCR. Transfused platelets have a very short serum half-life and should be administered only to patients with active coagulopathic bleeding. Platelets should not be administered through filters, warmers, or rapid infusion systems because they will bond to the inner surfaces of these devices, thereby reducing the quantity of platelets actually reaching the circulation (see also Chapter 61).

Rapid transfusion of banked blood carries the risk for inducing citrate intoxication in the recipient. Harvested blood units are treated with citrate to bind free Ca^{2+} and thus inhibit the clotting cascade. Consecutive administration of multiple units of banked blood leads to a correspondingly large dose of citrate, which may overwhelm the body's ability to mobilize free Ca^{2+} and have a profound negative inotropic effect on the heart. Unrecognized hypocalcemia is a cause of hypotension in patients after massive transfusion and persists despite an adequate volume of resuscitation. Ionized Ca^{2+} levels should be measured at regular intervals in a hemorrhaging patient, and Ca^{2+} should be administered as needed (in a separate IV line from transfusion products) to maintain serum levels greater than 1.0 mmol/L.

RESUSCITATION EQUIPMENT

Intravascular fluid resuscitation of any kind is impossible in the absence of IV access. Immediate placement of at least two large-bore catheters (16 gauge or larger) is recommended during the primary assessment of any trauma patient.[17] Practitioners should have a low threshold for placement of a large-caliber central line in any patient in whom antecubital or other peripheral placement attempts have been unsuccessful. Potential sites for central line placement include the internal jugular, subclavian, and femoral veins, each of which has its own benefits and potential risks. The internal jugular approach, though familiar to most anesthesiologists, will require removal of the cervical collar and manipulation of the patient's neck and is not recommended in the acute setting unless other options have been exhausted. The femoral vein is easily and rapidly accessed and is an appropriate choice in patients without apparent pelvic or thigh trauma who require urgent drug or fluid administration. Caution should be used in patients with penetrating trauma to the abdomen because fluids infused via the femoral vein may contribute to hemorrhage from an injury to the inferior vena cava or iliac vein; these patients should have IV access placed above the diaphragm if possible. Femoral vein catheterization carries a high risk for the formation of deep venous thrombosis (DVT),[162] thus limiting use of this approach to the acute setting. Femoral lines should be removed as soon as possible after the patient's condition stabilizes. The subclavian vein is the most common site for early and ongoing central access in a trauma patient because the subclavian region is easily visible and seldom directly traumatized. This approach carries the highest risk for the development of pneumothorax, although many patients will already have indications for tube thoracostomy in one or both chest cavities; when possible, this is the preferred side for placement of a subclavian line. Placement of an arterial line facilitates frequent laboratory analysis and allows close monitoring of blood pressure; this should be undertaken as soon as possible but should not impede other diagnostic or therapeutic maneuvers.

The anesthesiologist should work to maintain thermal equilibrium (see also Chapter 54) in any trauma patient. Although deliberate hypothermia has been suggested as a management strategy for both hemorrhagic shock[163] and TBI,[164] insufficient evidence exists to support this approach. Hypothermia will potentiate dilutional coagulopathy and systemic acidosis, and shivering and vasoconstriction in response to cold will demand an additional metabolic effort that may predispose the patient to myocardial ischemia. Hypothermia also greatly increases the subsequent risk for sepsis. Because many trauma patients arrive at the ED cold from exposure to the elements, early active warming measures are required. All IV fluids should be prewarmed or infused through a warming device. The patient should be kept covered with warmed blankets whenever possible, and the environment should be kept warm enough to make the patient comfortable. If hypothermia has already developed, the use of forced hot air warming is strongly indicated to restore normothermia. Even though all these measures are routine and obvious in the OR, the anesthesiologist can perform a valuable service by ensuring that they are available and applied in the ED, CT scanner, and angiography suite as well.

Commercial rapid-infusion devices are of great benefit in trauma care, particularly in the presence of hemorrhagic

BOX 81-6 ***Benefits of a Fluid Infusion System in Resuscitation from Hemorrhagic Shock***

- An active mechanical pump enables fluid administration rates up to 1500 mL/minute
- Compatible with crystalloid, colloid, packed red blood cells, washed salvaged blood, and plasma (*not* platelets)
- Reservoir allows for mixing of products in preparation for rapid blood loss
- Fluids infused at a controlled temperature (38° to 40° C)
- Able to pump simultaneously through multiple intravenous lines
- Fail-safe detection systems to prevent infusion of air
- Accurate recording of fluid volume administered
- Portable enough to travel with patient between units

BOX 81-7 ***Goals for Late Resuscitation****

- Maintain systolic blood pressure higher than 100 mm Hg
- Maintain hematocrit above individual transfusion threshold
- Normalize coagulation status
- Normalize electrolyte balance
- Normalize body temperature
- Restore normal urine output
- Maximize cardiac output by invasive or noninvasive measurement
- Reverse systemic acidosis
- Document decrease in lactate to normal range

*Fluid administration should be continued until adequate systemic perfusion is restored.

shock. These machines offer benefits when large quantities of fluid resuscitation are likely (Box 81-6). Early experience with these devices demonstrated higher patient temperature and reduced acidosis at the conclusion of the initial surgery,[165] although rapid infusers may contribute to overinfusion of fluids, inappropriately increased arterial blood pressure, and contribute to rebleeding.[108] Application of the principles described earlier can prevent this complication; basal fluid administration should be kept low (200 to 500 mL/hr), with small fluid boluses given in response to measured systolic blood pressure less than 80 to 90 mm Hg. In practice, fluid boluses are given alternately with anesthetics, with the goal of reaching a normal depth of anesthesia without increasing systolic arterial blood pressure.

LATE RESUSCITATION

Box 81-7 summarizes end points for late resuscitation, and Figure 81-10 presents an algorithm for management. IV fluid administration is an integral, mandatory component. The adequacy of resuscitation should not be judged by the presence of normal vital signs, but by restoration of organ and tissue perfusion. The role of the anesthesiologist-intensivist is to recognize the presence of ongoing shock after traumatic hemorrhage and to resuscitate the patient with the appropriate type and amount of fluids intravenously at the appropriate time.

Late resuscitation begins once bleeding is definitively controlled by surgery, angiography, or the passage of time. The goal at this time is to restore normal perfusion to all organ systems while continuing to support vital functions. Hypoperfusion caused by hemorrhagic shock triggers a predictable cascade of biochemical events that will cause physiologic derangements persisting long after adequate blood flow is restored. The extent of hypoperfusion—the depth and duration of shock—dictates the magnitude of subsequent organ system failure. Unfortunately, traditional vital sign markers such as arterial blood pressure, heart rate, and urine output are insensitive to the adequacy of resuscitation. Occult hypoperfusion syndrome is common in postoperative trauma patients, particularly young ones.[166] This syndrome is characterized by a normal blood pressure maintained by systemic vasoconstriction; decreased intravascular volume and cardiac output; and organ system ischemia. The patient will be at frequent risk for MOSF if the hypoperfusion is not promptly corrected.

The search for the optimal end point of resuscitation has led to several different hemodynamic, acid-base, and regional perfusion targets. Table 81-5 summarizes modalities that are available to gauge the adequacy of resuscitation, along with the shortcomings of each technique. Although the flow of blood to tissue beds is a determinant of tissue perfusion, pressure should also be an important consideration. The left ventricular stroke work index is a variable that accounts for both flow and pressure. Furthermore, left ventricular power output has been used to quantify left ventricular performance. These indices were compared with purely flow-derived hemodynamic and O_2 transport variables as markers of perfusion and outcome in critically injured patients during resuscitation.[167] A consecutive series of 111 patients were monitored with a volumetric pulmonary artery catheter during the first 48 hours of resuscitation. The ability to clear lactate in less than 24 hours and survival were studied. Survivors exhibited significantly higher stroke work and left ventricular power output than did nonsurvivors. In addition to heart rate, these were the only variables that were significantly related to lactate clearance and survival. The higher stroke work and left ventricular power output in survivors were related to better ventricular-arterial coupling and therefore more efficient cardiac function.

Monitoring resuscitation with invasive monitors is gradually changing to noninvasive approaches that assess the return of adequate metabolism, respiration, and O_2 transport in peripheral tissue beds. One such technique is tissue O_2 monitoring (skin, subcutaneous tissue, or skeletal muscle). Skeletal muscle blood flow decreases early in the course of shock and is restored later during resuscitation, thus making the skeletal partial pressure of O_2 a sensitive indicator of decreased flow.[168,169] Early goal-directed treatment of septic shock,[170] with an emphasis on measurement of mixed-venous O_2 saturation, has influenced the care of trauma patients, and many ICUs are now using continuously measured venous oxygenation to guide resuscitation. Stroke volume variation, the change in arterial pressure driven by the respiratory cycle, is emerging as another less invasive measure of fluid volume status; increased variation in arterial pressure during positive-pressure ventilation is a reliable predictor of decreased intravascular volume.[171]

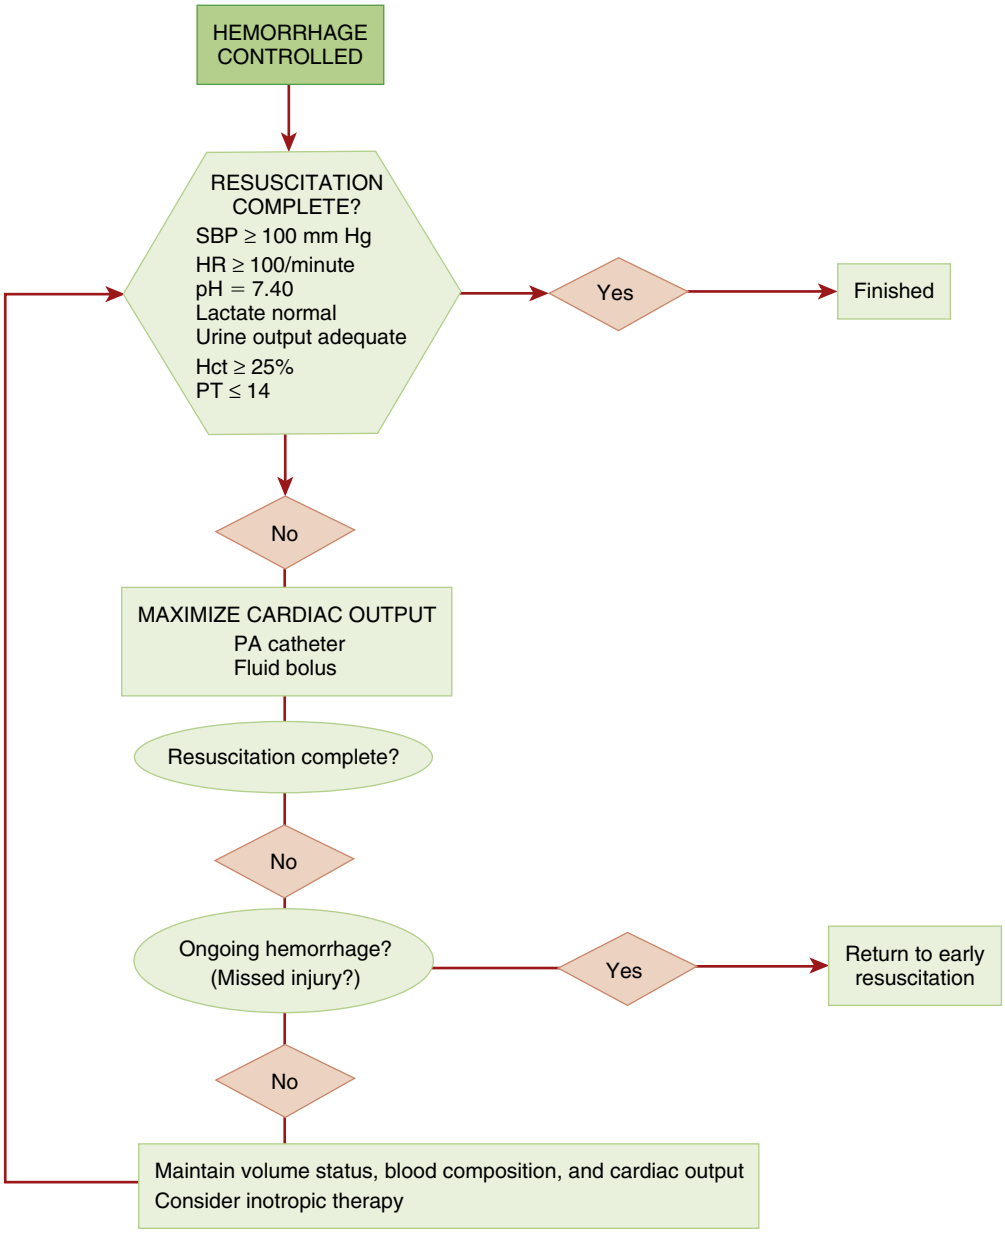

Figure 81-10. Algorithm for management of late hemorrhagic shock. *Hct,* Hematocrit; *HR,* heart rate; *PA,* pulmonary artery; *PT,* prothrombin time; *SBP,* systolic blood pressure.

Tissue hypercapnia may be a universal indicator of critically reduced perfusion. Measurement of gastric Pco_2 by gastric tonometry may be a reliable monitor in trauma patients as an indicator of restoration of splanchnic blood flow, and distal gut pH is also a reliable indicator.[172] The most proximal area of the gastrointestinal tract, the sublingual mucosa, is a useful site for measurement of Pco_2 ($Pslco_2$).[173] When $Pslco_2$ exceeded a threshold of 70 mm Hg (normal, 45.2 ± 0.7 mm Hg), its positive predictive value for circulatory shock was 100%.[174] Inadequate tissue perfusion, as indicated by these specific monitors or by the traditional systemic markers of serum lactate, base deficit, and decreased pH, must be treated promptly once ongoing hemorrhage is controlled. The rate at which lactate returns to normal after shock is strongly correlated with outcome; failure to normalize within 24 hours is associated with a greater risk for MOSF and eventual death.[166,175]

TRAUMA TO THE CENTRAL NERVOUS SYSTEM

CNS trauma accounts for almost half of all trauma death postmortem examinations in population-based analyses[176] or after trauma center admission (see also Chapter 70).[177] In addition, more than 90,000 Americans are disabled by TBI[178] and 8000 to 10,000 by SCI[179] each year. As with hemorrhagic shock, CNS trauma consists of both the primary injury, in which tissue is disrupted by mechanical force, and a secondary response, in which the body's reaction to the injury plays an important role. Mitigation

TABLE 81-5 **MODALITIES FOR ASSESSMENT OF SYSTEMIC PERFUSION**

Technique	Shortcomings
Vital signs	Will not indicate occult hypoperfusion
Urine output	May be confounded by intoxication, diuretic therapy, circadian variation, or renal injury
Systemic acid-base status	Confounded by respiratory status
Lactate clearance	Requires time to obtain laboratory result
Cardiac output	Requires placement of a pulmonary artery catheter, or use of noninvasive technology
Mixed-venous oxygenation	Difficult to obtain, but a very accurate marker
Gastric tonometry	Requires time to equilibrate, subject to artifact
Tissue oxygenation	Emerging technology, appears beneficial
Stroke volume variation	Emerging technology, requires an arterial line
Acoustic blood flow	Investigational technology, unproved

of secondary CNS injury depends on prompt diagnosis and early, goal-directed therapy. Although primary CNS injuries cannot be minimized other than with preventive strategies, secondary injury accounts for much of the death and disability that follows trauma.[180] The initial management of these patients can significantly affect outcome. Attention to the ABCDE approach is paramount to successful resuscitation, and the trauma anesthesiologist should be intimately involved in this process. Critical care management of TBI patients is covered elsewhere in this volume (see also Chapter 105). What follows is a brief discussion of the early management of these patients.

Trauma produces shear forces that result in primary damage to neuronal cell bodies and axons and to the vasculature. The pathophysiologic processes of secondary injury includes metabolic failure, oxidative stress, and a cascade of biochemical and molecular events leading to both delayed necrotic and apoptotic cell death.[181] Secondary injury is often exacerbated by tissue hypoxia or ischemia and by inflammatory responses, and outcomes from TBI are influenced by a large number of interacting factors. Individual drugs such as free radical scavengers, antiinflammatory agents, and ion channel blockers have been effective in animals but have had little impact or yielded disappointing results in human trials.[182] Long-term outcome cannot be predicted from TBI; thus, full resuscitative efforts should be initiated and continued, even in the most severely injured. In a recent review of the Trauma Registry of the German Society for Trauma Patients looking at over 50,000 patients, outcome prediction was most accurate using the GCS motor score and pupil reactivity. In patients with bilateral fixed and dilated pupils, a good outcome was still seen in 8% of patients.[183]

Patients with mild TBI (GCS score of 13 to 15) who maintain a stable GCS score for 24 hours after injury are very unlikely to deteriorate further, although they are at risk for several postconcussive effects, including headache, memory loss, emotional lability (including aggressive behavior and violence), and sleep disturbance.[184] Currently, recognition of long-term effects of mild TBI—and a better understanding of the pathophysiologic processes—have led to prevention strategies and interventional programs for these patients. Specifically, soldiers returning from battle and athletes who experience repetitive mild brain injuries—and even those with a single episode—are at risk. The most frequently proposed cellular mechanism is diffuse axonal injury, associated with alterations in many physiologic processes. As early as 2 hours after severe TBI, increased levels of soluble amyloid β–peptide and deposition of amyloid plaques are evident in brains of 30% of survivors, regardless of their age. An acute, single-incident TBI occurs in 20% to 30% of patients with Alzheimer disease or parkinsonism but in only 8% to 10% of control subjects. TBI researchers and the U.S. National Football league have now identified chronic traumatic encephalopathy (CTE), a condition typically seen in retired or aging athletes, in younger patients. CTE may be caused by large accumulations of τ proteins in the brain that kill cells in the regions responsible for mood, emotion, and executive functioning.[185,186]

Moderate TBI (GCS score of 9 to 12) may be accompanied by intracranial lesions that require surgical evacuation, and early CT is strongly indicated. Early tracheal intubation, mechanical ventilation, and close observation may be required in the management of patients with moderate TBI because of combative or agitated behavior and the potentially catastrophic consequences of respiratory depression or pulmonary aspiration occurring during diagnostic evaluation. Extubation of the trachea can be undertaken if the patient is hemodynamically stable and appropriately responsive after the diagnostic workup. Treatment of secondary brain injury is accomplished by early correction and subsequent avoidance of hypoxia, prompt intravascular fluid resuscitation, and management of associated injuries. The timing of indicated noncranial surgery in these patients is highly controversial because early surgery can increase the episodes of hypoxia and hypotension.[187] Whereas neurologic outcomes can decrease after early surgery,[188,189] delayed surgery can increase the incidence of pulmonary and septic complications in orthopedic and soft tissue surgeries.[190,191] An increased risk has not been described with early surgery, although a definitive prospective trial has not yet been reported.

Neurologic monitoring of patients with moderate TBI consists of serial assessment of consciousness and motor and sensory function (see also Chapter 49). Deterioration of the GCS score is an indication for urgent CT to establish the need for craniotomy or invasive monitoring of ICP. If frequent neurologic monitoring is not possible because of general anesthesia continuing longer than 2 hours, aggressive analgesia, or prophylaxis against delirium tremens, invasive ICP monitoring is indicated.[148] Although mortality from moderate TBI is infrequent, almost all patients will have significant long-term morbidity.

Severe TBI is classified as a GCS score of 8 or less at the time of admission and carries a significant risk for mortality. Patients with severe TBI have mortality three times that of patients with other types of traumatic injury.[192] Early,

rapid management focused on restoration of systemic homeostasis and perfusion-directed care of the injured brain will produce the best possible outcomes in this difficult population. Guidelines for all aspects of the management of patients with severe TBI have been published by the American Association of Neurological Surgeons and Brain Trauma Foundation, now in the third edition.[148] The clinical pathway in place at the R. Adams Cowley Shock Trauma Center in Baltimore appears in Figure 81-11.

A single episode of hypoxemia (PaO_2 < 60 mm Hg) occurring in a patient with severe TBI can double the incidence of mortality.[193] Prehospital tracheal intubation is controversial. Previously, intubation of the trachea before arriving at the hospital was advocated because providing

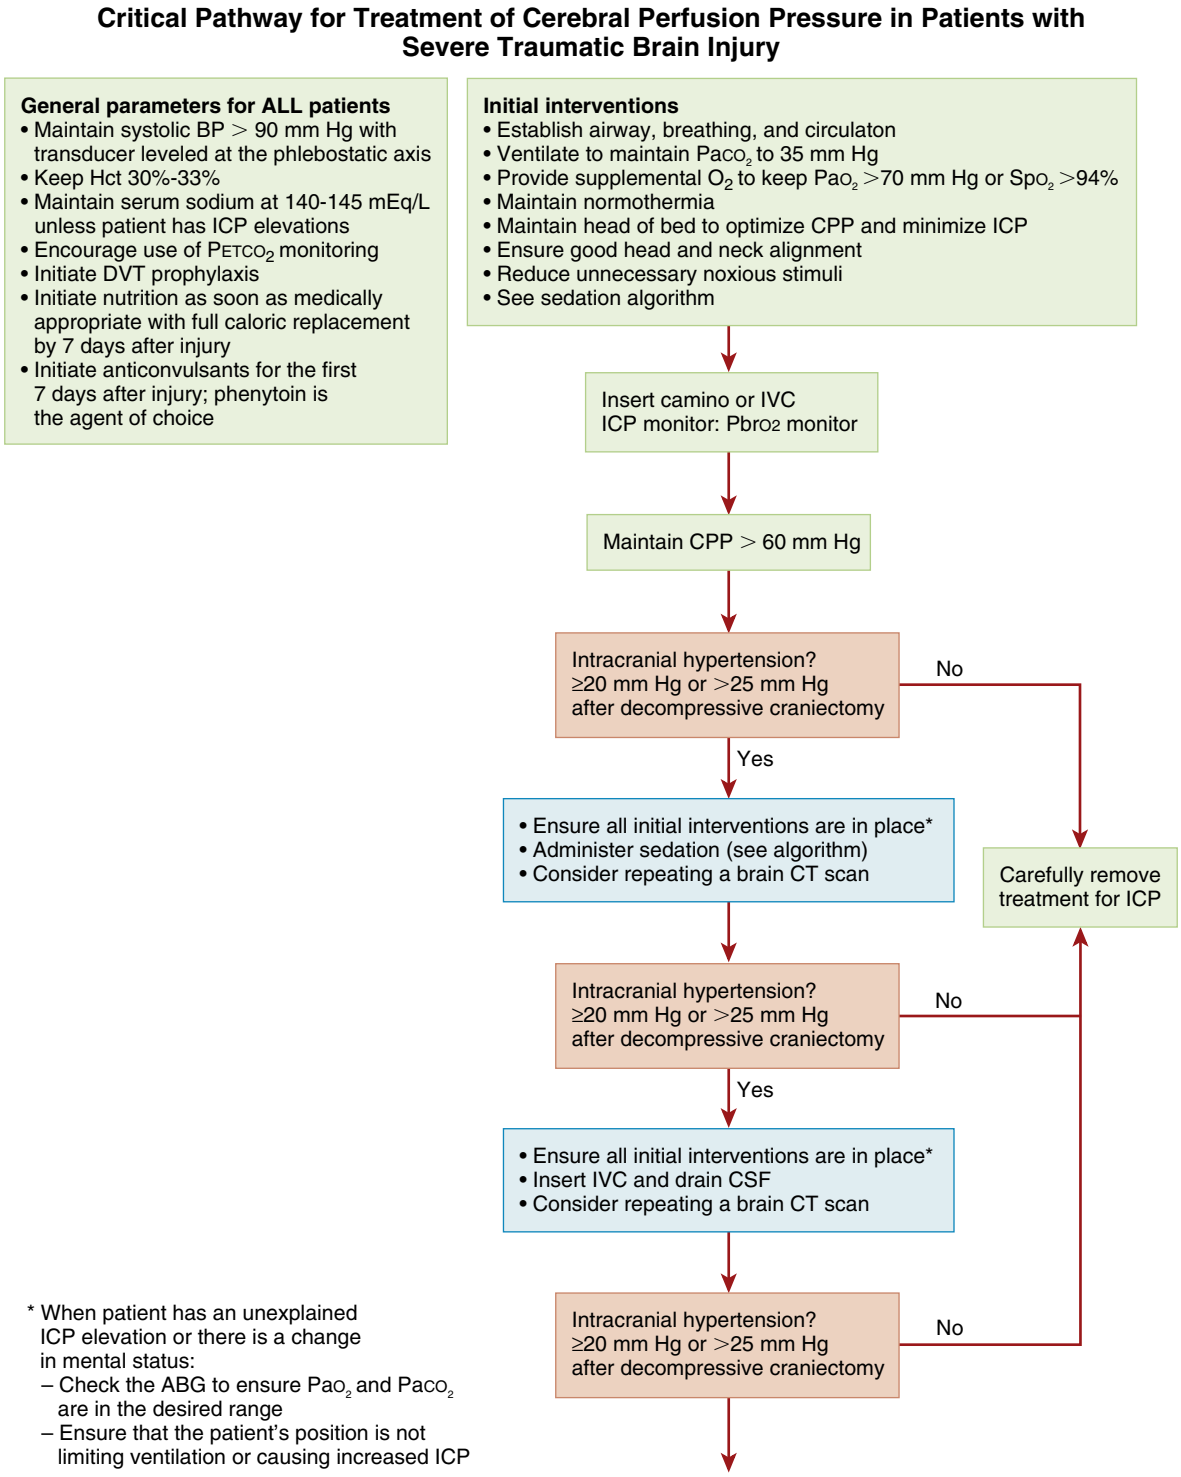

Figure 81-11. Clinical pathway for management of severe traumatic brain injury. The goal of therapy is to maintain cerebral perfusion pressure above 60 mm Hg by support of the circulation and control of intracranial pressure. Progressively more intensive therapies are added until this goal is achieved. *ABG,* Arterial blood gas; *BP,* blood pressure; *CBF,* cerebral blood flow; *CPP,* cerebral perfusion pressure; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *DVT,* deep venous thrombosis; *Hct,* hematocrit; *ICP,* intracranial pressure; *IVC,* intraventricular catheter.

a definitive airway allowed adequate O_2 to be delivered to the brain, benefiting the patients. Yet worsened neurologic outcomes have been described with attempts at prehospital tracheal intubation in adult trauma patients.[194,195] The first prospective trial of prehospital intubation, conducted in urban Australia, randomized patients with severe TBI—defined as evidence of head trauma and GCS of less than 9—to intubation by paramedics in the field or by physicians on the arrival to hospital.[196] Of 312 patients, the proportion with favorable outcome was 51% in the paramedic group, compared to 39% in the hospital tracheal intubation group (P = .046). Because no international standard or consensus exists, the patient should be transported as rapidly as possible to a facility capable of managing severe TBI or to the nearest facility capable of tracheal intubation of the patient and initiation of systemic resuscitation. The sine qua non is adequacy of systemic oxygenation, by whatever means this can best be accomplished.

The patient with TBI will frequently require perioperative monitoring to include ICP, brain temperature, arterial pressure, and cerebral oxygenation (see also Chapter 49). ICP may be monitored through the use of an intraparenchymal probe or intraventricular catheter and should be maintained at less than 20 mm Hg. A variety of monitoring devices have been used to assess adequacy of cerebral oxygenation, including jugular venous O_2 saturation, positron emission tomography, near-infrared spectroscopy, and direct brain tissue oxygenation ($Pbto_2$) monitoring.[197] Brain tissue hypoxia, may be corrected by increasing FiO_2, blood transfusion, inotropic support, or sedation, if increased ICP results in decreased cerebral blood flow.[198-201] Small studies suggest an improvement in

Glasgow Outcome Score (GOS) and mortality with brain O_2–targeted strategies, but no overall consensus exists.

Finally, patients with severe TBI are also at risk for non-CNS organ failure. A retrospective review of patients with isolated TBI found a frequent incidence of subsequent organ failure: 89% developed dysfunction of at least one nonneurologic organ system. Takotsubo cardiomyopathy may develop in the setting of severe TBI and lead to severe myocardial dysfunction in the patient with brain injury.[202] The reasons for development include interplay between the neuroendocrine system and the injured brain. A catecholamine surge that occurs after TBI may manifest as subendocardial ischemia, leading to biventricular heart failure, even in young, previously healthy patients. This cycle may be exacerbated during OR procedures when vasoactive drugs might be administered. β-Adrenergic blockade may be protective in human studies in patients with brain injuries. Retrospective database reviews have indicated improved neurologic outcome and reduced morbidity and mortality in patients receiving periinjury β-adrenergic blockade.[203-206]

TRAUMATIC BRAIN INJURY AND CONCOMITANT TRAUMA

Patients with isolated head injuries can be managed with traditional ventilatory strategies, but those with chest trauma, aspiration, or massive resuscitation after shock are at high risk for the development of acute lung injury (ALI) (see also Chapters 70 and 101). The classic teaching of no or low-level positive end-expiratory pressure (PEEP) to prevent increased ICP is inappropriate because hypoxemia may not be corrected. With adequate intravascular volume resuscitation, PEEP does not increase ICP or decrease cerebral perfusion pressure (CPP)[207] and may actually decrease ICP as a result of improved cerebral oxygenation.[208] Patients who develop ALI after TBI are at risk for cerebral hypoxia.[209] A double-hit model has been proposed as the cause of ALI secondary to CNS trauma—severe TBI leads to a systemic inflammatory response, which then primes the lungs to be more susceptible to injurious ventilator strategies or other mediators of lung injury. ALI and cardiac insufficiency after TBI may lead to compromised systemic oxygenation and therefore a decrease in cerebral O_2 delivery.[210] Hyperventilation therapy (e.g., at a $Paco_2$ of 25 mm Hg), long a mainstay in the management of patients with TBI, is no longer recommended as a prophylactic treatment. A range of $Paco_2$ between 30 and 35 mm Hg should be induced with hyperventilation to 30 mm Hg only for episodes of increased ICP that cannot be controlled with sedatives, drainage of cerebrospinal fluid, neuromuscular blockade, osmotic drugs, or barbiturate coma.[147] Hyperventilation during the first 24 hours is of particular concern because of the critical reductions in perfusion during this timeframe. However, these recommendations should be taken in context and modified in the face of unstable clinical circumstances such as an expanding mass lesion or signs of imminent herniation.[211]

The most challenging of all trauma patients are those with severe TBI and coexisting hemorrhagic shock. A single episode of hypotension, defined as systolic blood pressure lower than 90 mm Hg, is associated with an increase in morbidity and doubled mortality after severe TBI.[193] Hypotension together with hypoxia increases mortality 30-fold. Current recommendations are to maintain a patient with severe TBI in a euvolemic state. Therefore, *fluid resuscitation is the mainstay of therapy,* followed by vasoactive infusions as needed. The ideal fluid has not been defined, but perhaps hypertonic saline solutions are optimal. Correction of anemia from acute blood loss is the first priority; however, an optimal target hematocrit has not been defined. Animal models and healthy human subjects support maintaining a hemoglobin lower than 7 g/dL because impaired brain function may occur with lower values, yet a hemoglobin lower than 10 g/dL may be detrimental to recovery from TBI.[212] At this time it is not clear what optimal transfusion trigger should be used (see also Chapter 61). After the initial ABCDE management of a patient with severe TBI, a stepwise approach to maintenance of CPP is initiated, with a currently recommended goal range of 50 to 70 mm Hg, as discussed in Chapter 70.

Decompressive craniectomy is a surgical procedure used to control severely increased ICP and prevent herniation after stroke, and it is now used for the same indications after severe TBI.[213] Decompressive craniectomy is indicated for selected anatomic patterns of TBI, such as when CPP cannot be maintained despite vigorous application of the previously described therapies, including barbiturate coma. Relieving ICP by removal of a piece of cranium and use of a dural patch may improve mortality and morbidity in patients who might not otherwise survive.[214] Decompressive laparotomy may be indicated in patients with severe TBI if coexisting injuries or vigorous intravascular volume infusion have increased intraabdominal compartment pressure to greater than 20 mm Hg. Increased abdominal pressure worsens pulmonary mechanics, thus necessitating higher MAP to maintain arterial O_2 saturation. This increase in ventilating pressure will increase intrathoracic pressure and impair venous drainage from the head and consequently decrease CPP. The use of decompressive celiotomy as a therapy to reduce ICP was recently described.[215] The concept of multiple compartment syndrome in patients with severe TBI has been proposed.[216] Fluid therapy, ALI, or both may increase intraabdominal pressure and intrathoracic pressure, thereby increasing ICP. Further fluid administration to support cerebral perfusion or increasing ventilatory support to treat ALI further exacerbates this problem. This can create a cycle that ultimately produces multiple compartment syndrome and necessitates opening of the abdomen, even in the absence of primary abdominal trauma. Isolated TBI can thus become a multisystem disease.

Like hyperventilation therapy, the use of hypothermia to treat severe TBI has changed. Early studies demonstrated that moderate, systemic hypothermia reduces both the rate of cerebral edema and mortality after cortical injury in laboratory animals.[217,218] Small clinical series in humans also suggested improved outcome in patients with TBI when hypothermia was maintained for 24 or 48 hours.[219,220] However, a multicenter, randomized trial of hypothermia (33° C) versus normothermia

demonstrated no improvement in outcome in a population of patients with severe TBI.[221] Patients who were hypothermic on admission and then were randomized to the normothermia group had a worse outcome than those who were left hypothermic, thus leading to the recommendation that patients with severe TBI who are hypothermic on admission not undergo active rewarming. Current Brain Trauma Foundation guidelines present only level III evidence suggesting decreased mortality if target temperatures are maintained for more than 48 hours and that prophylactic hypothermia is associated with better long-term neurologic outcomes.[148]

MANAGEMENT OF INTRACRANIAL PRESSURE IN THE OPERATING ROOM

Although most interventions for management of a patient with severe TBI will occur in the ICU, urgent cranial or noncranial surgery can be indicated (see also Chapter 49).

The previously described therapies should be continued throughout the perioperative period, including positional therapy (when possible), aggressive hemodynamic monitoring and resuscitation, administration of osmotic agents (with attention to maintaining euvolemia), and deep levels of analgesia and sedation. Appropriate anesthetic choices include opioids and low concentrations of volatile anesthetics. Pharmacologic management of TBI is the mainstay of the anesthesiologist's role in the operating room. Intraoperative management of elevated ICP may be accomplished with osmotic diuretics or hypertonic saline. No difference was noted in long-term outcomes between mannitol and hypertonic saline on outcomes at 6 months, although hypertonic saline may potentiate small short-term improvements is cerebral blood flow and CPP.[222,223] A meta-analysis of common drugs used in intraoperative management of patients with TBI, including propofol, barbiturates, opioids, benzodiazepines, and corticosteroids showed corticosteroids to be the only drug associated with an increase in mortality. The other drugs had acute benefit in reductions in ICP and sedation, but no appreciable long-term benefit.[182,224]

SPINAL CORD INJURY

SCI after trauma affects some 10,000 Americans each year.[179] Blunt trauma accounts for the majority of SCI: 40% from motor vehicle collisions, 30% from falls, and 15% as a result of penetrating trauma.[225] Cervical spine injuries occur in 1.5% to 3% of all major trauma. Half of all SCIs involve the cervical spine, usually between the C4 and C7 levels. Complete quadriplegia occurs in half of SCI cases. It is important to realize that more than 40% of trauma patients who have SCI may also have other significant injuries, including TBI.

Most spinal injuries are in the lower cervical spine, just above the thorax, or in the upper lumbar region, just below the thorax. Blunt SCI is most common in the regions of the cord that are most flexible, especially at the junctions between flexible and inflexible segments. The vertebral column is divided longitudinally into three columns: anterior, middle, and posterior; injuries to any two of these three columns suggest biomechanical instability. These are the patients who will often require urgent surgical stabilization. Patients with unstable cervical spine injuries who meet criteria for emergency intubation, should undergo rapid-sequence induction (see section on protection of the cervical spine). SCI at midthoracic levels is less common because of the rotational stabilization provided by the rib cage and intercostal musculature.

SCI is commonly accompanied by radiographically visible injury to the bony spine and concomitant disruption of the muscles, ligaments, and soft tissues that support it. However, clinically significant injury to the cervical spinal cord can occur in the absence of visible skeletal injury. This entity, known as spinal cord injury without radiographic abnormality (SCIWORA) is more common in children and is presumably the result of temporary hyperdistraction or torsion of the neck insufficient to disrupt the bony skeleton.[226]

Primary injury to the spinal cord sustained at the moment of trauma may be exacerbated by secondary factors (Fig. 81-12). The combination of biochemical changes, vascular disruption and electrolyte abnormalities can lead to cellular changes and worsening of SCI lesions up to 3 days after injury.[227] SCI includes sensory deficits, motor deficits, and both. Incomplete deficits may be worse on one side than the other and may improve rapidly in the first minutes after injury. Complete deficits—representing total disruption of the spinal cord at one level—are much more ominous, with generally little improvement seen over time. Spine injuries above the level of T4-6 are accompanied by significant hypotension because of inappropriate vasodilatation, loss of cardiac inotropy, and bradycardia resulting from denervation of the cardiac accelerator fibers (neurogenic shock). (Note the distinction between *neurogenic shock* and the incorrect term *spinal shock,* which refers to a loss of reflexes.) Functioning of the lower cord will gradually return, along with restoration of normal vascular tone. Diagnosing cervical spine instability can be difficult. The Eastern Association for the Surgery of Trauma has published guidelines regarding which patients require cervical spine radiographs, which views and studies should be obtained, and how to determine the absence of significant ligamentous injury in an unconscious patient.[228] The need for magnetic resonance imaging versus the adequacy of CT to diagnose SCI is not clear. The most commonly missed cervical fractures are at the C1-2 and C7-T1 levels, usually because of the result of inadequate imaging.

Early intubation of the trachea is almost universally required for patients with cervical spine fracture and quadriplegia. Ventilatory support is almost always required for patients with a deficit above C4, because they will lack sufficient diaphragmatic function. Patients with levels from C6 to C7 may need support because of impairment in respiratory muscle function resulting from (1) loss of chest wall innervation, (2) paradoxical respiratory motion, (3) inability to clear secretions, and (4) decreased lung and chest wall compliance. Early tracheal intubation is recommended and, if elective, often can be accomplished by awake fiberoptic bronchoscopy or video laryngoscopy before hypoxia renders the patient anxious and uncooperative.[229,230] Also, two retrospective studies have evaluated the need for tracheal intubation

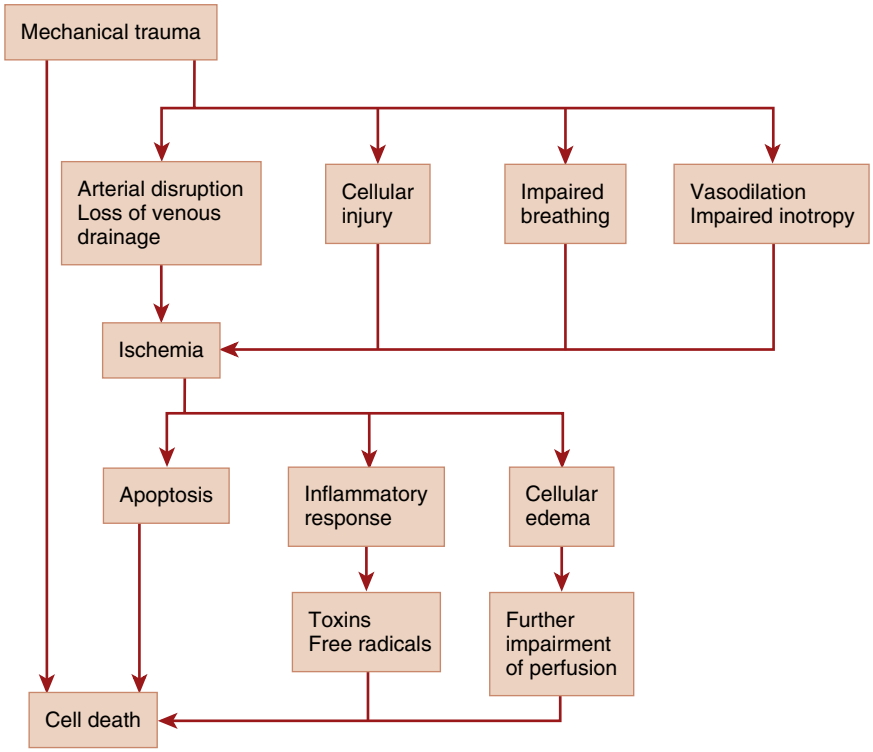

Figure 81-12. Mechanisms of spinal cord injury. Mechanical trauma to the spinal cord is exacerbated by systemic hypoperfusion or hypoxia. *(Reprinted with permission from Dutton RP: Spinal cord injury,* Int Anesthesiol Clin *40:109, 2002.)*

in patients with cervical SCI. Como and colleagues[231] identified 119 patients, 45 of whom had complete SCI. All patients with injuries at C5 and above required intubation, and 71% of these progressed to tracheostomy. A second study of 178 patients with complete cervical SCI showed 70% of patients required tracheostomy, particularly those with an injury between C4 and C7.[231] Spontaneous ventilation and extubation of the trachea are possible after surgical stabilization and resolution of neurogenic shock, although pneumonia is a common and recurrent complication that frequently necessitates tracheostomy to facilitate pulmonary toilet.[230]

Although administration of a glucocorticoid steroid bolus in patients with blunt SCI and deficit was recommended, current guidelines suggest caution. Large-dose glucocorticoid therapy has resulted in a small, but statistically significant, improvement in neurologic level after SCI in two large multicenter trials: the National Acute Spinal Cord Injury Study (NASCIS) II and III.[232,233] However, the NASCIS results have been challenged for several reasons.[234-236] The positive benefits seen with high-dose steroid administration were driven by results in a few subpopulations and were not present in a majority of patients. The improvement in spinal level seen after steroid administration has not been shown to lead to increased survival or improved quality of life, and the results have not been reproducible in other studies of acute SCI. Current recommendations by the American Association of Neurological Surgeons and the American College of Surgeons state that steroid administration is an *option* and should be undertaken with the knowledge that harmful side effects are more consistent than any proved benefit.[237]

INTRAOPERATIVE MANAGEMENT OF SPINAL CORD INJURY

A patient about to undergo surgical reduction and fixation of a spinal column fracture presents challenges for the anesthesiologist. First and foremost is the need for intubation of the trachea in a patient with a known injury to the cervical spine (see also Chapter 55). Direct laryngoscopy with in-line stabilization is appropriate in the emergency setting and in unconscious, combative, or hypoxemic patients when the status of the spine is not known.[238] Tracheal intubation can occur in the OR, in an awake, alert, and cooperative patient by several methods known to produce less displacement of the cervical spine, presumably with less risk for worsening an unstable SCI. A common technique in current clinical practice is awake fiberoptic intubation. Although the nasal route is associated with an easier path to intubation in most patients, it can lead to an increased risk for sinusitis in the ICU if the trachea is not extubated at the end of the procedure. Oral intubation may be more challenging technically but will be of greater value if the patient remains mechanically ventilated. Blind nasal intubation, transillumination with a lighted stylet, and use of an intubating LMA, GlideScope, or Bullard laryngoscope, or any of a variety of other instrument systems for indirect laryngoscopy are acceptable. Again, in comparative studies of direct laryngoscopy, video laryngoscopy, fiberoptic examination, blind nasal intubation, or cricothyrotomy in patients with known cervical cord or spine injuries, no difference is seen in neurologic deterioration with technique used and no clear evidence exists that direct laryngoscopy worsens outcome. Clinicians are

advised to use the equipment and techniques with which they are most familiar. The important concept is to successfully achieve tracheal intubation while minimizing motion of the cervical spine and preserving the ability to assess neurologic function after positioning.[48]

A patient with a partial deficit and visible spinal canal impingement on imaging studies is considered an emergency because of the potential for regaining neurologic function after decompression. Patients with either no deficit or complete deficit may require surgical stabilization to facilitate mobilization, but are less urgent cases. Hemodynamic instability may complicate urgent and emergent spinal surgery. Hypotension from neurogenic shock is characterized by an inappropriate bradycardia resulting from loss of cardiac accelerator function and unopposed parasympathetic tone. However, this situation can be difficult to distinguish from hypotension resulting from acute hemorrhage, and a trial of fluid administration is still indicated, subject to the end points of resuscitation listed earlier. Once hemorrhage has been controlled or ruled out, patients who have maintenance of an increased MAP more than 85 mm Hg for 7 days after SCI may have improved functional recovery. This approach is highly controversial and remains an option in treatment according to the American Association of Neurological Surgeons.[237]

ORTHOPEDIC AND SOFT TISSUE TRAUMA

Musculoskeletal injuries are the most frequent indication for operative management in most trauma centers (see also Chapter 79). Orthopedic trauma, like TBIs and SCIs, can be associated with long-term pain and disability. In addition to physical handicaps that these patients may endure, orthopedic injuries incurred in both civilian and military settings lead to long-term psychological trauma.[239-241] The length of many procedures, particularly in patients with multiple extremity injuries, necessitates attention to body positioning, maintenance of normothermia, fluid balance, and preservation of peripheral blood flow.

For the last 15 years, the emphasis in trauma management of a multiply injured patient has included early stabilization of long-bone, spine, pelvic, and acetabular fractures. Failure to do so results in increased morbidity, pulmonary complications, and length of hospital stay.[242] In one study, only 2% of patients with femoral shaft fractures stabilized within the first 24 hours of injury had pulmonary complications, in contrast to 38% of patients in whom fracture stabilization was delayed for more than 48 hours.[243]

SPECIFIC CONDITIONS

Hip fracture is a common, morbid, and costly event among older adults (see also Chapter 80). Frequently, patients with isolated hip fracture present to the OR for urgent repair. Regional anesthesia is associated with decreased odds of inpatient mortality and pulmonary complications among patients with hip fracture in contrast to general anesthesia.[244] A retrospective cohort of 18,158 patients undergoing surgery for hip fracture in 126 hospitals showed that 5254 (29%) received regional anesthesia. Although unadjusted rates of mortality and cardiovascular complications did not differ by anesthesia type, regional anesthesia was associated with a decreased adjusted odds of mortality (odds ratio: .710, 95% confidence interval [CI] .541, .932, $P = .014$) and pulmonary complications (odds ratio: .752, 95% CI .637, 0.887, $P < .0001$) relative to general anesthesia.[245]

Dislocation of the hip is common after high-energy trauma and is frequently accompanied by fracture of the acetabulum. Whereas the fracture itself can be safely managed on a delayed basis or nonoperatively, the dislocation is a medical emergency that must be promptly addressed if the patient is to have a good functional outcome. Failure to promptly diagnose and reduce a dislocated hip joint is a significant risk factor for avascular necrosis of the femoral head. Reduction typically requires a very deep level of sedation, which may be facilitated by nondepolarizing neuromuscular blockade (see also Chapters 34 and 35). For this reason the anesthesiologist is commonly involved.[246] Although a dislocated hip can be reduced in a spontaneously breathing sedated patient, an acutely injured patient is at high risk for aspiration of gastric contents. Any patient who will be undergoing surgery in the near future (such as for an open long-bone fracture or exploratory laparotomy) should be tracheally intubated at the time of reduction and maintained with appropriate sedation and analgesia until reaching the OR. Other patients who may require intubation even for uncomplicated reductions include those who are inebriated or uncooperative, hemodynamically unstable, or suffering from pulmonary dysfunction. Additionally, successful postoperative fracture reduction is more difficult to achieve in morbidly obese patients (see also Chapter 71) than in those with normal body mass index.[247]

Unlike acetabular fractures, fracture of the pelvic ring requires immediate recognition and management by the trauma team. Hemorrhage, even exsanguination, is common after a major pelvic ring fracture and is a leading contributor to early death after motor vehicle collisions. Bleeding occurs from multiply disrupted venous beds in the posterior pelvic bowl; if the pelvis as a whole is unstable, no anatomic barrier exists to continued expansion of this retroperitoneal bleeding. Surgical exploration by way of the peritoneum is usually unrewarding because the bleeding vessels are not easily accessed.[248] In the past, therapy consisted of supportive volume resuscitation, external fixation of the unstable pelvis, and angiography. Despite this multidisciplinary approach, mortality remained frequent in these patients, partially because of the inability of angioembolization to control venous bleeding from the rich venous plexuses associated with the most severe fractures. The technique of preperitoneal packing has been adopted by many U.S. trauma centers. Preperitoneal packing via laparotomy is a rapid method for controlling pelvic fracture–related hemorrhage that can supplant the need for emergent angiography and reduces transfusion requirements and mortality.[249] Endotracheal intubation is usually undertaken on an emergency basis in a hypotensive patient, and the anesthesiologist may remain with the patient throughout the initial hours of stabilization to manage sedation, analgesia, transport, and ongoing

resuscitation needs. In the absence of an orthopedic specialist, temporary stabilization and tamponade of some pelvic fractures can be accomplished with use of a specially made pelvic binder, the pelvic portion of military antishock trousers, or a bed sheet knotted tightly around the bony pelvis.[250] Mechanically unstable pelvic ring fractures are associated with increased fluid and blood resuscitation volumes, significantly more frequent presence of concomitant injuries, and increased ventilation and ICU stay, rate of MODS, sepsis, and rate of mortality.[251]

Open fractures should be pulse-lavaged and debrided as soon as possible after injury to minimize the risk for infectious complications. If ongoing resuscitation or unstable TBI precludes the patient from early management in the OR, this procedure can be performed at the bedside. Despite the frequency of open fractures, their management remains one of the greatest and most debated orthopedic challenges. Timing of surgical fixation in open fractures is often surgeon-specific or center-specific, because little consensus exists among orthopaedic surgeons as to optimal treatment.[252]

The advantages and disadvantages of regional and general anesthesia are summarized in Boxes 81-8 and 81-9. Regional anesthesia seems to decrease postoperative morbidity and mortality[245,253,254] (including cognitive measures of function), but clinically measurable benefits may not be seen in patients receiving combined general and regional techniques.[255-257]

One prevalent concern in the management of an orthopedic trauma patient is the concomitant use of regional anesthesia, analgesia, or both and prophylaxis for venous thromboembolism, as discussed in Chapter 79.

Intraoperative transesophageal echocardiography (TEE) has shown that most patients undergoing long-bone fracture manipulation experience microembolism of fat and marrow.[258] Most patients suffer no discernible clinical impact from this phenomenon, but some will experience a significant acute inflammatory response. After long-bone fractures, some lung dysfunction occurs in almost all patients, ranging from minor laboratory abnormalities to full-blown fat embolism syndrome (FES). A lack of universally accepted diagnostic criteria combined with concomitant pulmonary and cardiovascular dysfunction accounts for the varying incidence reported in the literature. Clinically significant FES occurs in 3% to 10% of patients but is likely underdiagnosed in patients with multiple injuries or a high ISS.[259] Patients with coexisting lung injury are at additional risk for FES. Signs include hypoxia, tachycardia, mental status changes, and, classically, a petechial rash on the axillae, upper arms and shoulders, chest, neck, and conjunctivae. FES should be considered whenever the alveolar-arterial O_2 gradient deteriorates in conjunction with decreased pulmonary compliance and CNS deterioration. Under general anesthesia, the CNS changes will not be apparent but may be manifested as failure to awaken after surgery. If central hemodynamic monitoring is available, pulmonary artery pressure is elevated, often accompanied by decreases in the cardiac index. Diagnosis in the OR is largely based on the clinical findings after ruling out other causes of hypoxemia. Fat globules in urine are nondiagnostic, but lung infiltrates seen on chest radiography confirm the presence of lung injury and the need for appropriate ventilatory management with O_2, higher PEEP, and possible longer-term mechanical ventilatory support.[260,261] Treatment includes early recognition, administration of O_2, and judicious fluid management.[262] A change in the orthopedic procedure may be indicated, such as converting intramedullary nailing of the femur to external fixation.

Acute compartment syndrome of the extremities is defined as a "condition in which increased pressure within a limited space compromises the circulation and function of the tissues within that space."[263] The most common cause of compartment syndrome is edema secondary to muscle injury and associated hematoma formation. Although most commonly associated with traumatic injuries, compartment syndrome also can occur as a result of causes associated with trauma, including reperfusion injury, burns, drug overdose, and prolonged limb compression (Box 81-10). The most common fractures associated with the development of compartment syndrome are those of the tibial shaft (40%) and forearm (18%).[264,265] Forearm compartment syndrome requiring fasciotomy predominantly affects males and can occur after either a fracture or soft-tissue injury. A further 23% of cases are caused by soft tissue injuries without fracture.[266] Although no randomized, prospective trials

BOX 81-8 *Advantages and Disadvantages of Regional Anesthesia for Trauma*

Advantages

Allows continued assessment of mental status
Increased vascular flow
Avoidance of airway instrumentation
Improved postoperative mental status
Decreased blood loss
Decreased incidence of deep venous thrombosis
Improved postoperative analgesia
Better pulmonary toilet
Earlier mobilization
Lower incidence of long-term pain syndromes

Disadvantages

Peripheral nerve function difficult to assess
Patient refusal common
Requirement for sedation
Hemodynamic instability with placement
Longer time to achieve anesthesia
Not suitable for multiple body regions
May wear off before procedure(s) conclude

BOX 81-9 *Advantages and Disadvantages of General Anesthesia for Trauma Patients*

Advantages

Speed of onset
Duration: Can be maintained as long as needed
Allows multiple procedures for multiple injuries
Greater patient acceptance
Allows positive-pressure ventilation

Disadvantages

Impairment of global neurologic examination
Requirement for airway instrumentation
Hemodynamic management more complex

BOX 81-10 *Risk Factors for the Development of Compartment Syndrome*

Orthopedic
Fractures and operative repair

Vascular
Reperfusion injury
Hemorrhage with hematoma formation
Ischemia from arterial and venous injuries

Soft Tissue
Crush injury
Burns
Prolonged compression in immobile state

Iatrogenic
Casts and circular dressing
Use of pneumatic antishock garment
Intraosseous fluid replacement in infant or child
Pulsatile lavage with extravasation
Extravasation from venous or arterial puncture site

Miscellaneous
Snakebite
Acute exertion

have been conducted, regional anesthesia does not blunt detection of compartment syndromes as long as there is not an associated dense motor block.[267]

Fasciotomy is usually indicated when compartment pressure approaches 20 to 30 mm Hg below diastolic pressure in any patient with a worsening clinical condition, a documented rising tissue pressure, major soft tissue injury, or a history of 4 to 6 hours of total ischemia of an extremity. Prophylactic fasciotomy may be indicated in patients with warm ischemic time in excess of 2 hours, ligation of the major veins in the popliteal region or distal part of the thigh, and crush injuries. Early or prophylactic fasciotomy decreases subsequent muscle loss.[268]

Crush syndrome is the general manifestation of crush injury caused by continuous prolonged pressure on one or more extremities[269] and is commonly found in patients who have been trapped in one position for an extended period. Muscle injury secondary to ischemia causes myoglobinuria, which can lead to acute renal failure and subsequent profound electrolyte disturbances. The most critical treatment consists of crystalloid fluid resuscitation; a total body fluid deficit of 15 L may occur in severe rhabdomyolysis.[270] Osmotic diuresis with mannitol and alkalinization of urine with sodium bicarbonate to prevent precipitation of myoglobin in the renal tubules are controversial.[271,272] The preferred therapy for renal failure secondary to rhabdomyolysis at the shock trauma center is continuous renal replacement therapy and hemofiltration.[273] Most of these patients eventually have full recovery of native renal function.[274]

SOFT TISSUE TRAUMA

Assessment of soft tissue injury is critical in the management of a trauma patient. Muscular coverage is necessary for the viability of any orthopedic repair, but it may be jeopardized by avulsion at the time of injury, ischemia from elevated compartment pressure, and ongoing bacterial infection in open wounds. Acute surgical management of soft tissue injury is straightforward: all dead or devitalized tissue must be debrided and the wound thoroughly irrigated to reduce the load of bacterial contaminants. When muscle or fascia involvement is significant, serial debridement at frequent intervals is necessary to establish a margin of completely viable tissue. Vacuum dressings for large soft tissue wounds are gaining in popularity because continuous negative pressure over the wound surface removes contaminants and encourages blood flow.[275] When serial debridement establishes viable tissue at all margins of the wound, arrangements for definitive closure can be made. Closure may be as simple as a split-thickness skin graft or as complex as free tissue transfer of muscle and fascia from an uninjured portion of the body, with attendant arterial and venous anastomoses.

A degloving injury results in significant soft tissue loss, usually in the extremities. Multiple plastic surgery and reconstructive procedures may be necessary. General anesthesia is usually required, although combining it with epidural or regional block analgesia may confer the benefits of both techniques. Close consultation with the surgical teams is suggested.

Superficial vacuum dressings can be changed at the bedside under light sedation, but patients with deep wound dressings may require general anesthesia. The need for repeated surgeries is an important consideration for the anesthetic technique. Anesthesia for free tissue transfer surgery requires meticulous attention to detail because these operations can be quite protracted. Every effort should be made to facilitate perfusion of the grafted vessels, including keeping the patient warm, euvolemic, and comfortable and maintaining the hematocrit in the rheologically favorable range of 25% to 30%. The use of epidural anesthesia and analgesia is controversial, with some surgeons favoring it for its vasodilatory effects and others being concerned that it will induce a steal phenomenon that will actually limit flow in the denervated free tissue.[276] The use of vasopressors in microsurgery is generally avoided. Yet in one study, the vasopressor used did not cause more complications.[277]

OTHER TRAUMATIC INJURIES

HEAD AND NECK SURGERY

With the exception of emergency exploration of penetrating trauma to zone II of the neck (from the clavicles up to the angle of the mandible), most surgical repair of head and neck trauma will occur in the subacute phase, after complete resuscitation and secondary diagnostic studies (see also Chapter 85). Anesthetic management of these patients is not substantially different from that for similar elective procedures, although coexisting injuries may influence patient positioning, airway management, and ventilator settings.[278,279] Surgery on the mandible and maxilla will be facilitated by nasotracheal intubation, but a secure airway should be not jeopardized by attempting to switch from an oral to a nasal tube in a

patient in whom visualization of the larynx might be difficult because of traumatic swelling or body habitus. It is safer in these cases for the surgeon to either work around an oral tube secured behind the second molar (to allow dental occlusion) or place a tracheostomy if the need for intubation and mechanical ventilation is likely to be protracted. Surgery on the zygoma and the nasal, orbital, and ethmoid bones will be possible with an oral endotracheal tube. Securing the endotracheal tube to the molar with a fine-gauge wire will help stabilize it through the operation. All of these surgeries will lead to significant soft tissue swelling in the immediate postoperative period, often necessitating several days of continued intubation and sedation until sufficient venous drainage has occurred to allow safe extubation of the trachea. Though not by itself definitive, the presence of an air leak when the endotracheal tube cuff is deflated is suggestive that the airway will remain patent once the tube is removed.

CHEST INJURIES: PULMONARY

Injuries to the lung parenchyma that produce pneumothorax can be managed by tube thoracostomy to relieve tension, drain accumulated blood, and apply suction to the pleural space until the air leak spontaneously resolves (see also Chapter 66). Bleeding from the low-pressure pulmonary circulation is usually self-limited. Thoracostomy is uncommon but becomes necessary when evidence exists of mediastinal injury, chest tube output exceeds 1500 mL in the first hours after injury, tracheal or bronchial injury and massive air leak are apparent, or the patient is hemodynamically unstable with evident thoracic pathology.[17] Blood collected from the pleural space is generally free of clotting factors and can be directly reinfused with any of several commercial systems.[280] Hemorrhage necessitating surgery may be from injured intracostal or internal mammary arteries or from the lung parenchyma. Staple resection of injured lung or even anatomic lobectomy is not uncommon, particularly after penetrating trauma.

Although double-lumen endotracheal intubation is desirable during urgent thoracotomy, this should not be the initial approach. Rapid-sequence induction with a large-caliber (at least 8.0 mm in internal diameter) conventional endotracheal tube will allow diagnostic bronchoscopy and protect the patient from aspiration until passage of a gastric tube can reduce the stomach contents. The change to a double-lumen tube can then be made under controlled conditions in the presence of adequate oxygenation, anesthesia, and muscle relaxation. Tolerance of single-lung ventilation is variable in the trauma population and depends in large part on the absence of significant pathologic findings in the ventilated lung. Many patients with blunt thoracic injury have bilateral pulmonary contusions and will require increased FiO_2 and high levels of PEEP to maintain adequate oxygenation, even when both lungs are ventilated.

Although chest trauma requiring pneumonectomy has historically resulted in mortality approaching 100%, a recent multicenter retrospective review reported on a series of survivors of this surgery.[281] Intraoperative deaths are the result of uncontrollable hemorrhage, acute right ventricular failure, and air embolism. Patients who survive the initial procedure are at risk for early postoperative morbidity and mortality. Fluid management may be complicated by the need to weigh ongoing resuscitation against the treatment of right ventricular failure. Blunt thoracic trauma requiring pneumonectomy is often associated with abdominal and pelvic trauma. Volume replacement must be judicious, and the use of a pulmonary artery catheter (placed with care in a postpneumonectomy patient) or TEE may be beneficial. Echocardiography will also play an important role in assessing right ventricular function and pulmonary hypertension (see also Chapter 46). Treatment of right ventricular failure after traumatic pneumonectomy is difficult.[282] During hypovolemic shock a disproportionate increase occurs in pulmonary vascular resistance with respect to systemic vascular resistance,[283] as well as frequent mortality with combined hemorrhagic shock and pneumonectomy.[284] With severe right heart dysfunction it is desirable to maintain a higher preload than normal. Several therapeutic approaches have been used to treat right ventricular failure, including close monitoring of pulmonary artery pressure, the use of diuretics for volume overload, and administration of pulmonary vasodilators. Because this injury is rare and the number of patients reported in the literature is small, the best therapy is difficult to identify. A recent case report describes the use of nitric oxide to successfully treat pulmonary hypertension after posttraumatic pneumonectomy[285] (see also Chapter 104). Extracorporeal support also has been used to sustain patients through the perioperative period, although the technical challenges are substantial and successful weaning may require days to weeks on bypass. Early initiation has been beneficial in our experience, with a recent survival rate of approximately 60%.

Tracheobronchial injury can result from either blunt force or penetrating trauma. Penetrating injuries are usually more promptly diagnosed and treated. Blunt trauma most commonly results in an injury to the tracheobronchial tree within 2.5 cm of the carina and may initially be unrecognized. The presence of subcutaneous emphysema, pneumomediastinum, pneumopericardium, or pneumoperitoneum, without apparent cause, should alert the practitioner to possible tracheobronchial injury.[286] Despite bronchoscopy and helical CT scanning, a small injury may never be delineated. If the resultant injury is an incomplete tear, it may heal with stenosis, subsequent atelectasis, pneumonia, pulmonary destruction, and sepsis. When surgery is required for a delayed, incomplete tracheobronchial injury, pulmonary resection may be required if significant tissue destruction has occurred, whereas complete transection may be amenable to reconstruction with preservation of pulmonary tissue. The level of injury dictates the surgical approach. Cervical injuries are approached through a transverse neck incision, left bronchial injuries via a left thoracotomy, and tracheal or right main bronchial injuries via a right thoracotomy. In the cervical region it is sometimes possible to access a longitudinal tear of the posterior membranous trachea by opening the anterior trachea and operating around the endotracheal tube.

CHEST INJURIES: TRAUMATIC AORTIC INJURY

Traumatic aortic injury (TAI) must be ruled out in any patient with a high-energy injury, such as occurs with a motor vehicle accident or a fall from a height. The incidence of TAI has decreased in recent years because of the increased presence of airbags in motor vehicles; a majority of cases in the past decade have been caused by side-impact collisions.[287] Aortic injury occurs most commonly just distal to the left subclavian artery and is the result of sheer forces between the mobile heart and aortic arch and the immobile descending thoracic aorta. TAI is manifested as a continuum of injury from a small intimal flap to free transection contained by the surrounding mediastinum and pleura. The diagnosis is made by screening chest radiography, followed by definitive angiography, CT, or TEE. Surgical or endovascular repair is indicated for most patients with TAI because of the high risk for rupture in the hours and days after injury.[288] Various techniques have been described for this highly morbid surgery, with the best results attributed to partial bypass techniques using inflow from the left atrium, a centrifugal pump, and outflow to the descending aorta.[289] Selective nonoperative management of high-risk patients with TAI has been described.[290,291] Treatment is similar to that in patients with uncomplicated type B aortic dissection and consists of β-adrenergic blockade to minimize the cardiac rate–pressure product. Endovascular repair is the evolving standard for TAI with a decreased mortality and morbidity rate.[292-294]

CHEST INJURIES: RIB FRACTURES

Rib fractures are the most common injury resulting from blunt chest trauma. The fracture itself generally requires no specific treatment and will heal spontaneously over a period of several weeks. Therapy is directed at minimizing pulmonary complications secondary to these fractures, such as pain, splinting, atelectasis, hypoxemia, and pneumonia. Of particular concern are rib fractures in older adults (older than 55 years of age). Older patients with rib fractures have twice the mortality and thoracic morbidity of younger patients with similar injuries. Epidural anesthesia should be used liberally in patients with severe pain, older adults, and patients with preexisting compromised pulmonary function. Data support a 6% decrease in morbidity and mortality in older patients when epidural anesthesia is used[295]; however, a recent meta-analysis failed to identify a reduction in mortality.[296] Epidural analgesia may minimize or avoid complications of splinting and pain such as hypoxemia, hypoventilation, the need for tracheal intubation, and the possibility of pneumonia. Endotracheal intubation is reserved for patients who are unable to oxygenate or ventilate or who require protection of the airway.

Fracture of multiple neighboring ribs will result in the flail chest syndrome, characterized by paradoxical chest wall motion during spontaneous ventilation. Not all patients with a flail chest require positive-pressure ventilation, and endotracheal intubation should be reserved for those who meet the usual criteria. Patients who are not initially intubated should be observed closely in the ICU for signs of worsening respiratory function. Increasing cases have been reported of the use of noninvasive positive-pressure ventilation (NIPPV) for lung injury secondary to trauma.[297] For these patients who subsequently require intubation for a surgical procedure, the anesthesiologist will need to determine the safety of extubation postoperatively. NIPPV is associated with fewer cases of pneumonia, which may lead to fewer tracheostomies and decreased ICU length of stay. A successful technique has been early extubation to a mask delivering continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP).[298] Concomitant pulmonary injury, especially lung contusion, is commonly associated with flail chest. Pulmonary contusion will cause shunting, which will lead to hypoxemia. This syndrome may progress rapidly in the hours and days after injury. An initially clear chest radiograph does not exclude the possibility of a pulmonary contusion, and, again, close observation is warranted if signs of significant chest wall trauma are present. As with all patients after traumatic injury, a high degree of suspicion along with a continuous search for missed injuries is warranted. No specific therapy exists for a pulmonary contusion, and therapy is directed at the associated injuries or resultant hypoxemia. Early and aggressive implementation of a lung-protective strategy is crucial in the treatment of patients with significant pulmonary contusion to minimize progression to ARDS or concomitant ventilator-associated lung injury.

CHEST INJURIES: CARDIAC INJURY

Blunt cardiac injury is a rare and poorly understood phenomenon that must be considered in any patient who has sustained a frontal impact to the chest. Bruising or edema of the myocardium is functionally indistinguishable from myocardial ischemia and may be causally related in that the pathophysiology of cardiac contusion may involve forcible dislodgement of unstable atherosclerotic plaque. If the patient is hemodynamically stable and the ECG does not demonstrate conduction disturbances or tachyarrhythmias, blunt cardiac injury can be safely excluded.[299] If either a new tachyarrhythmia or conduction disturbance subsequently develops or the patient has unexplained hypotension, other causes (hypovolemia, renal failure) should be ruled out first. If the workup is negative, transthoracic echocardiography (TTE) should be performed. Right ventricular dysfunction resulting in hypotension may be overlooked while more common causes of hypotension in the trauma patient are being evaluated. TEE is superior to TTE in obese patients or those with injuries to the chest wall that make it difficult to obtain adequate acoustic windows, but it will generally require intubation and deep sedation to perform (see also Chapter 71). Once diagnosed, blunt cardiac injury should be managed as ischemic cardiac injury, with completion of resuscitation and then careful control of fluid volumes, administration of coronary vasodilators, and monitoring and symptomatic treatment of rhythm disturbances. Anticoagulation with aspirin or heparin should be approached on a case-by-case basis as determined by the patient's other injuries. Cardiology consultation is appropriate if the patient may benefit from coronary angiography followed by angioplasty or stenting of stenotic vessels.

Patients with penetrating cardiac trauma and blunt trauma causing rupture of one or more chambers (usually the atria) are often not seen by the trauma center because of a frequent rate of prehospital mortality.[300] Those who do not die immediately of free exsanguination into the thoracic cavity will have pericardial tamponade and can be extremely unstable in the first minutes after admission. This condition is diagnosed by clinical suspicion, focused assessment with sonography for trauma (FAST), and direct inspection during ED thoracotomy. Relief of the tamponade and clamp or suture control of the cardiac injury may allow restoration of spontaneous circulation and necessitate urgent transition to the OR for definitive hemostasis and chest closure. Cardiopulmonary bypass may be required for support during repair of cardiac injuries.

ABDOMINAL INJURY

The need for exploratory laparotomy, once the mainstay of the trauma surgeon, has declined because FAST and high-resolution CT have reduced the incidence of negative abdominal explorations, whereas angiographic embolization of hemorrhaging vessels in the liver and spleen has reduced the need for open procedures. Urgent celiotomy, when it does occur, will typically follow the principles of damage control, as described earlier.[160] The abdomen is opened and packed tightly in all four quadrants. Systematic exploration is undertaken in each quadrant in turn, with time taken only for control of hemorrhage and rapid staple closure of open gastrointestinal injuries. The abdomen is packed open at the conclusion of the procedure, a sterile drape is used to cover exposed viscera, and the patient is moved to the ICU to complete resuscitation. Definitive treatment of nonlethal injuries and restoration of bowel continuity are deferred until a second operation 24 to 48 hours later.

Anesthetic management of emergency celiotomy should follow the principles of early resuscitation outlined earlier. Adequate IV access is required, as well as continuous arterial pressure monitoring. Use of cell salvage devices can reduce the patient's exposure to banked blood, although reinfusion is generally deferred if there has been significant contamination by bowel contents. A rapid infusion system is advantageous for preservation of intravascular volume and normothermia during periods of heavy bleeding. Subsequent abdominal surgeries will be needed in hemodynamically stable patients and should not present unusual anesthetic challenges. Subsequent reconstructive procedures can become technically difficult as scarring and adhesions develop; the anesthesiologist should be prepared for a long anesthetic procedure with the potential for significant hemodynamic compromise.

SELECTED PATIENT POPULATIONS

TRAUMA AND PREGNANCY

Trauma to pregnant patients is associated with a frequent risk for spontaneous abortion, preterm labor, or premature delivery, depending on the location and magnitude of the mother's injury (see also Chapter 77). Early consultation with an obstetrician is desirable for any pregnant trauma patient, for both immediate management and long-term follow-up. The best treatment of the developing fetus consists of rapid and complete resuscitation of the mother. Trauma patients in the first trimester of gestation may not realize that they are pregnant; for this reason human chorionic gonadotropin testing is part of the initial laboratory studies for any injured woman of childbearing age. Serious trauma occurring during the period of fetal organogenesis may induce birth defects or miscarriage because of the effects of medications, pelvic irradiation, or hemorrhage leading to placental ischemia. Indicated radiologic tests should not be deferred, but shielding of the pelvis should be provided whenever possible.[301] Patients who do not spontaneously miscarry should be advised of the potential risks for birth defects and be referred for counseling if desired.[302] Dilatation plus curettage of the uterus is advisable after miscarriage to avoid toxicity arising from retained products of conception.[303]

Trauma occurring in the second or third trimester of pregnancy necessitates early ultrasonographic examination to determine fetal age, size, and viability. Monitoring of the fetal heart rate is indicated if the pregnancy is sufficiently advanced that the fetus would be viable if delivered. Preterm labor is very common in this population and should be treated with β-adrenergic agonist drugs or magnesium at the direction of the obstetrician. Delivery should be delayed as long as the fetus is not an unacceptable metabolic stress on the mother. Delivery by cesarean section is indicated if the mother is in extremis, if the uterus itself is hemorrhaging, or if the gravid uterus is impairing surgical control of abdominal or pelvic hemorrhage.[304] Placental abruption can occur in response to substance abuse or abdominal trauma and can precipitate life-threatening uterine hemorrhage. Emergency cesarean section is indicated in these cases. The Kleihauer-Betke blood test can be used to determine if fetal blood has leaked into the maternal circulation[304]; if positive, administration of anti-Rh_0 immune globulin is recommended for any Rh-negative mother carrying an Rh-positive fetus. By the third trimester the uterus is sufficiently enlarged to compress the inferior vena cava when the patient is positioned supine, thereby impairing venous return to the heart and contributing to hypotension. Left lateral uterine displacement is indicated to treat this problem. If the patient is immobilized on a long spine board because of concern for a thoracic or lumbar spinal fracture, the whole board can be tipped to the left. Because the gravid uterus displays abdominal contents upward, elevating the head of the bed may also be required to improve ventilation.

OLDER TRAUMA PATIENTS

Equivalent traumatic injuries will have a markedly more serious outcome in older adults than in younger victims (see also Chapter 80).[305] Decreased cardiopulmonary reserves lead to a higher incidence of postoperative mechanical ventilation in older trauma patients and a much greater risk for MOSF after hemorrhagic shock. Greater care must be taken with intraoperative positioning to avoid pressure injuries. A higher hematocrit achieved by tighter control of administered fluid is generally recommended

to maintain maximized tissue O_2 delivery. Posttraumatic myocardial dysfunction is a significant risk, particularly if the heart rate is elevated secondary to blood loss, pain, or anxiety. Complex operations or large blood loss should encourage the use of TEE, invasive arterial monitoring, and noninvasive monitors of cardiac output and volume status to guide fluid and inotropic therapy.[149] Although prophylactic β-antagonist therapy has been recommended for older patients undergoing major elective surgery,[306] its role in the early management of older trauma patients is unknown. Older patients will have diminished requirements for postoperative analgesia and may respond to sedative medications with inappropriate agitation. Prophylaxis against DVT is important in patients who cannot be immediately mobilized in the postoperative period, as is aggressive pulmonary physiotherapy.

JEHOVAH'S WITNESS PATIENTS

A trauma patient who refuses blood products requires special management. Early identification and control of hemorrhage are obviously important (see also Chapter 61). Deliberate hypotension to limit bleeding may be helpful. Preoperative and intraoperative phlebotomy should be minimized. The use of salvaged red cells (from intraoperative collection or from a chest drainage system) should be discussed with the patient because some Jehovah's Witness patients will allow the use of salvaged blood provided that the entire system remains in continuity with the vasculature.[307] The use of albumin and other substances derived from circulating proteins should be addressed. Early hemodynamic monitoring is indicated to help determine the role of colloid therapy, pressors, and inotropes in maintaining tissue O_2 delivery at the highest possible level. Case reports have described the successful use of rFVIIa and hemoglobin-based O_2 carriers in Jehovah's Witness patients to rapidly correct bleeding and support O_2 delivery, but these agents are not approved for these uses and large case series are not available.[308] In the postacute phase, the use of erythropoietin to promote red cell growth will shorten the period of relative anemia.[309]

POSTOPERATIVE CARE

EMERGENCE AND TRACHEAL EXTUBATION

Initial surgery in a trauma patient is followed by a period of monitoring and ongoing treatment in which the anesthesiologist is closely involved, either in the postanesthesia care unit (PACU) or in the ICU (see also Chapter 96). The adequacy of posttraumatic resuscitation must be confirmed, as outlined earlier, and diagnostic studies of the secondary survey completed. Rapid termination of general anesthesia is highly desirable, particularly in patients with an altered level of consciousness or other evidence of TBI before surgery. Change in mental status from the preoperative baseline is an indication for repeat cranial CT and a search for possible metabolic or toxic derangements.

Although neurologic function should be assessed postoperatively, early extubation of a trauma patient should not be taken for granted. Many patients will require continued ventilator support because of CNS trauma, direct pulmonary or chest wall trauma, massive transfusion, upper airway edema, or ongoing intoxication. Box 81-11 lists the criteria for extubation after urgent or emergency trauma surgery. If any doubt exists about the patient's ability to meet these criteria, the patient should be transported to the PACU or ICU with the endotracheal tube in place. Appropriate analgesic medication should be administered, with sedation if necessary. Twelve to 24 hours of support allows confirmation of successful resuscitation and surgical repair, hemodynamic equilibration, titration of appropriate analgesia, and resolution of intoxication. Many patients can be tracheally extubated easily and safely at this time; those who cannot are at high risk for the development of MOSF—heralded by the development of posttraumatic ARDS—and will usually require days to weeks of subsequent intensive care (see also Chapter 101).

ACUTE PAIN MANAGEMENT

Trauma patients present significant pain management challenges to the clinician because of multiple sites of injury, protracted episodes of care, complicating psychological and emotional issues, and prior or ongoing substance abuse (see also Chapter 98). As with pain management practice in other diseases, trauma patients are frequently undertreated, thus creating a significant source of dissatisfaction. Because trauma patients run the gamut of physiology from healthy young athletes to debilitated older adults, anesthesiologists providing pain management for trauma patients must be prepared for a wide range of needs.

Individual trauma patients will have widely varying requirements for pain medication, so induction of analgesia must be titrated carefully, ideally in a closely monitored environment such as the PACU. Administration of rapidly acting IV agents in small doses at frequent intervals until pain relief is achieved is recommended. This allows the practitioner to determine the patient's basal requirements before starting long-acting medications or

BOX 81-11 *Criteria for Operating Room or Postanesthesia Care Unit Extubation of the Trachea in a Trauma Patient*

Mental Status

Resolution of intoxication
Able to follow commands
Noncombative
Pain adequately controlled

Airway Anatomy and Reflexes

Appropriate cough and gag
Ability to protect airway from aspiration
No excessive airway edema or instability

Respiratory Mechanics

Adequate tidal volume and respiratory rate
Normal motor strength
Required FiO_2 less than 0.50

Systemic Stability

Adequately resuscitated (see earlier)
Small likelihood of urgent return to the operating room
Normothermic, without signs of sepsis

patient-controlled analgesia. Hypotension in response to analgesics is most commonly indicative of hypovolemia and should prompt a search for occult hemorrhage while further resuscitation occurs.

The need for analgesic medication and the duration of requirement for analgesics will be minimized if a comprehensive emotional support system is available to the patient. Trauma, because of its unexpected nature, carries with it a strongly negative psychological overlay that can have a profound effect on how anatomically based pain is perceived by the brain[310] and on how the patient reacts. After an injury the patient may have legal, financial, and family-based concerns, without the ability to immediately address them. The availability of counselors—religious, financial, or legal—who can help the patient and family with these issues is of enormous benefit. The anesthesiologist can help by communicating to the patient a clear description of the injuries, the probable time required for recovery, and the plan for managing pain throughout the course. The anesthesiologist should refer the patient to counseling services as needed and should be alert to the potential for posttraumatic stress disorder (PTSD) in any traumatized patient.[311] Referral to an experienced psychiatrist or psychologist is appropriate if PTSD is hindering the patient's recovery.

The need for analgesic medication is also influenced by the schedule of physical therapy prescribed for the patient. In general, the more active a patient can be after traumatic injury, the lower the risk for pulmonary complications, venous thrombosis, and decubitus ulcers. Though painful in the short term, the sooner the patient is mobilized, the lower are the analgesic requirements in the long term. Early mobilization demonstrates to the patient the path to recovery and contributes to an improved emotional state. One of the goals of analgesia, therefore, is provision of adequate medication to facilitate physical therapy without so sedating the patient that participation is impossible.

Neuropathic pain arises when direct injury occurs to a major sensory nerve and is common after spinal cord trauma, traumatic amputations, and major crush injuries. Neuropathic pain is characterized by burning, intermittent electrical shocks, and dysesthesia in the affected dermatomal distribution. Neuropathic pain must be identified because it responds poorly to the analgesics used for somatic pain. This diagnosis should be considered whenever pain control is poor or the patient has a rising requirement for medications unexplained by anatomic injuries. First-line therapy for neuropathic pain has been revolutionized by the widespread use of gabapentin, an antiepileptic drug with very strong specificity for this problem.[312] Gabapentin therapy is typically initiated at a dose of 200 mg three times daily, with daily titration upward to a maximum of 2 to 3 g/day. If neuropathic pain persists, selective regional anesthesia or analgesia may be indicated in an effort to break the cycle of spinal cord receptor recruitment.[313]

Regional analgesia (see also Chapters 56 and 57) provided through an epidural or brachial catheter should be considered for any trauma patient with a potential to benefit from this approach because it will spare the use of systemic opioids and facilitate early mobilization. Epidural analgesia produces high levels of patient satisfaction and improved pulmonary function after major thoracoabdominal and orthopedic surgery in elective populations[314]; this is very likely true for the trauma population as well. Regional techniques are less useful when the patient has multiple sites of injury or when fractures or open wounds make placement difficult. Although epidural placement in anesthetized patients is relatively contraindicated because of the potential for occult SCI, the risk-to-benefit ratio in many trauma patients favors placement during surgery, when general anesthesia facilitates appropriate positioning and patient cooperation.

SUMMARY

Trauma touches all ages and classes of patients, from young and vigorous to older and frail. Because of its great prevalence, practicing anesthesiologists will encounter trauma patients throughout their careers. Increased public recognition of the consequences of injury has sparked interest in trauma research and education, with the result that diagnostic and therapeutic techniques have evolved rapidly in recent years. The anesthesiologist, as a perioperative physician, is in the ideal position to understand and apply these new techniques.

Chapter 82

Anesthesia and Prehospital Emergency and Trauma Care

PETER NAGELE • MICHAEL HÜPFL

Key Points

- After World War II, the subspecialty of prehospital emergency medicine evolved with anesthesiology's leadership. In many countries, prehospital emergency medicine is considered the fourth pillar along with anesthesiology, critical care, and pain therapy.
- Emergency medical service (EMS) systems differ between and within countries. When these differences are put together, two primary models have evolved. In the United States, paramedics provide prehospital care for all patients (single-tiered system). In many European countries, EMS-physicians lead the prehospital care for patients requiring advanced life support (two-tiered system).
- The core approach of managing prehospital emergencies involves basic life support (BLS) and advanced life support (ALS).
- Prehospital endotracheal intubation and rapid sequence induction of anesthesia are critical skills in prehospital care. Yet prehospital advanced airway management may be too challenging for inexperienced providers and is associated with increased mortality and poor neurologic outcomes, especially after traumatic brain injury.
- In major trauma, prehospital care must limit the time spent on the scene, controlling hemorrhage, and expediting transport to a trauma center, often ideally via a rescue helicopter. Although this approach has been used both in the military (e.g., Vietnam) and in civilian locations, it is not always possible. Prehospital intravenous fluid resuscitation for major trauma varies in approach. Patients with penetrating torso injuries and hemorrhagic shock may benefit from limited intravenous fluid resuscitation and permissive hypotension, in particular in urban settings. Prevention of the lethal triad of hypothermia, acidosis, and coagulopathy is of paramount importance.
- In acute coronary syndrome (ACS) and stroke, achieving rapid reperfusion of the ischemic tissue is the priority. Because only specialized centers provide 24-hour cardiac catheter service or stroke teams, rapid transport to acute myocardial infarction (MI) or stroke centers is critical. In response to an MI, morphine, oxygen, nitrates, and aspirin (MONA) are the main components of prehospital therapy. Fibrinolysis for MI has been used with significant success in the prehospital setting but requires very close supervision by EMS physicians.

The goal of this chapter is to provide a concise overview of prehospital emergency trauma care and to define the important roles anesthesiologists often play in prehospital medicine.

INTRODUCTION AND HISTORICAL BACKGROUND

In many regions of the world, anesthesiologists serve as the backbone of physician-staffed prehospital emergency medical service (EMS) systems,[1-3] and emergency medicine is considered the fourth pillar, along with anesthesiology, critical care, and pain therapy. The specialty of anesthesiology was also instrumental in the creation of modern prehospital emergency medicine.[4,5]

After World War II, the inadequacy of the civilian ambulance service became all too apparent for wartime-experienced physicians, as vehicle traffic–related injuries and deaths sharply increased and ambulances provided only transport to the hospital. In Germany, this inadequacy led to a call to "bring the doctor to the patient," rather than the more traditional converse arrangement.[1,5] As a consequence, the first surgeon-staffed ambulance,

the *klinomobil*, was implemented 1957 in Heidelberg and functioned as a mobile operating room,[5] a concept that was soon abandoned in favor of physician-staffed ambulances, sometimes referred to as *mobile intensive care units* (ICUs).[6] Similar developments occurred throughout Europe, including Prague, Mainz, Munich, Moscow, and in several Scandinavian countries where physicians began to staff ambulances to respond to vehicle crashes and other accidents.[3,4] In Belfast, Ireland, Frank Partridge was the first to implement a mobile coronary care unit (CCU) that brought a defibrillator to prehospital patients in cardiac arrest attributable to ventricular fibrillation.[7] Over the next decades, several European countries, such as France, Germany, Austria, and Norway, implemented nationwide physician-staffed ambulance services often complemented with the physician-staffed helicopter emergency medical service (HEMS) system.[1-3,8,9] Anesthesiology is currently the dominant medical specialty providing EMS physicians in Europe, and many anesthesiology departments are in charge of staffing ambulances and helicopters with physicians.[3,10]

In the United States, a different development took place. For various reasons, physician-staffed ambulances were not considered an option, so specifically trained emergency medical technicians (EMTs) and paramedics, became the mainstay of the EMS system in North America. A landmark event for the creation of modern EMS systems was the publication of the report *Accidental Death and Disability: The Neglected Disease of Modern Society*, commonly referred to as *The White Paper*, published by the National Academy of Sciences in 1966.[11] Among several remarkable physicians, two anesthesiologists, Peter Safar in Pittsburgh, the father of modern cardiopulmonary resuscitation (CPR), and Eugene Nagel in Miami, were most influential in creating the first paramedic-based EMS system in the United States in the 1960s. Before emergency medicine became its own medical specialty, anesthesiologists were often involved in prehospital emergency care based on their unique expertise in resuscitation, airway management, and critical care. This involvement has dwindled over the last two decades, although it appears that anesthesiology could still play an important role in prehospital emergency care in the United States based on what the recent, widely cited Institute of Medicine report *Emergency Medical Services: At the Crossroads* identified as the major problems in prehospital care, such as prehospital airway management, intravenous fluid resuscitation, rapid sequence induction of anesthesia, and pain therapy[12] (also see Chapters 59, 61, 81, 83, 98, and 101).

ORGANIZATIONAL MODELS OF PREHOSPITAL EMERGENCY CARE

LEVELS OF CARE

Originally, the terms *basic life support* (BLS) and *advanced life support* (ALS) were used only to describe the two different levels of care for CPR (see Chapter 108) but were then expanded to all emergency situations including trauma and pediatric emergencies. Currently, these terms denote the level of care in an organized EMS system and are, which is divided into the BLS and ALS levels. First responders, such as police officers and firefighters, are not part of an EMS system and only provide first aid, operating at a level less than the formal BLS level.

BASIC LIFE SUPPORT

Prehospital care at the BLS level is usually provided by EMTs and does not include advanced and invasive techniques and skills.[13] BLS is focused on the classic ABCs (Airway, Breathing, Circulation) and includes simple airway maneuvers, such as chin lift or jaw thrust, oral and nasal airways, bag-valve-mask ventilation, hemorrhage control, and the administration of oxygen (Box 82-1). During CPR, the use of an automated external defibrillator is considered a BLS skill. BLS-only ambulances are often found in rural areas where the incidence of emergencies is low and volunteer EMTs frequently staff the ambulances.

ADVANCED LIFE SUPPORT

ALS is usually provided by paramedics and flight nurses with a rigorous educational background and includes the use of advanced and invasive techniques (see Box 82-1). In many countries, ALS-level providers are allowed to work somewhat independently, often with only indirect physician control through the use of standing orders and protocols issued by the EMS medical director. The use of drugs is tightly regulated, and physician permission from the emergency department must be sought in cases where drugs outside the approved list are to be administered. Most urban EMS systems use ALS units to provide prehospital care. In EMS systems without EMS physicians responding directly to the scene, the scope of practice of ALS-level providers is usually greater and they are allowed to work more independently. Combat medics in the military frequently operate at the ALS level. EMS physicians, flight nurses, and critical care EMTs provide a level of care above and beyond ALS.

MODELS

A high degree of variability exists on how prehospital care is organized and staffed among different countries. Providing a description of all the nuances of the different EMS systems worldwide is beyond the scope of this chapter. Consequently, this chapter outlines the differences between the two models that primarily differ by their level of direct physician involvement in prehospital emergency care: EMT-based models versus physician-based models. These two models are also known as the U.S. paramedic model and the Franco-German EMS-physician model.[14] Although controversy exists on which model provides superior patient care and outcomes, the design of the EMS system is dictated by tradition and fiscal constraints.

EMT- AND PARAMEDIC-BASED EMS SYSTEMS

In North America, EMTs provide organized prehospital care[15]; only rarely will physicians be directly involved in out-of-hospital patient care on the scene.[16] By U.S.

BOX 82-1 ***Skill Set for Basic Life Support and Advanced Life Support Providers and Prehospital Emergency Physicians***

BASIC LIFE SUPPORT (BLS)

- Basic patient evaluation
- Vital signs and basic monitoring (noninvasive blood pressure, pulsoximetry, heart rate)
- Hemorrhage control via direct pressure or pressure dressing
- Cardiopulmonary resuscitation (CPR) (BLS level) with the use of an automatic external defibrillator
- Bag-valve-mask ventilation
- Oral and nasal airway
- Oral suctioning
- Administration of oxygen
- Basic patient rescue, positioning, and transport skills
- Cervical spine stabilization
- Fracture splinting
- Assisting a patient taking prescribed medication (e.g., albuterol inhaler)

ADVANCED LIFE SUPPORT (ALS)

- Venous access and fluid therapy
- Administration of selected drugs*
- Advanced monitoring (ECG, capnography)
- CPR (ACLS level)
- Manual defibrillation
- Basic 12-lead ECG interpretation
- External pacing
- Endotracheal intubation* (without drugs; some EMS systems allow rapid sequence induction)
- Cricothyroidotomy
- Sedation*
- Needle decompression of tension pneumothorax
- Knowledge of mass casualty incident management and triage
- Knowledge of biologic, chemical, and nuclear agents

PREHOSPITAL EMERGENCY PHYSICIAN

- Unlimited administration of emergency drugs
- Use of narcotics and controlled substances (e.g., fentanyl)
- Prehospital rapid sequence induction and anesthesia
- Advanced airway management
- Chest tube placement
- Advanced 12-lead ECG interpretation
- Advanced techniques (ultrasound, noninvasive ventilation)
- Emergency surgery
- Can assume role of medical incident commander in mass casualty event

ACLS, Advanced cardiac life support; *ECG,* electrocardiogram; *EMS,* emergency medical service.
*Not available in all ALS-level EMS systems.

law, physicians are required in most states to oversee the medical operations of EMS systems, either *online* through direct communication or *offline* as EMS medical directors responsible for developing and implementing standardized treatment protocols. Besides developing standard operating procedures, EMS medical directors are responsible for quality control and improvement and are an integral part of EMT education.[17] In the United States, EMS medical directors are often emergency physicians working in the emergency department of the local hospital.

In the United States, three levels of EMTs can be distinguished by their educational background: EMT-basic (EMT-B), EMT-intermediate (EMT-I), and EMT-paramedic (EMT-P). EMT-B providers usually have between 80 and 120 hours of training and are only allowed to perform BLS skills. The EMT-B level is the minimum level required to work in an organized ambulance service. Often, EMT-B providers staff nonemergent ambulance transport but may also respond to nonemergent calls. EMT-I providers are regulated differently among the individual states, and their skills range between BLS and ALS. Although most states do not allow EMT-I providers to perform endotracheal intubation or administer drugs (except for drugs deemed extremely safe, such as albuterol for asthma), they do allow them to insert an intravenous line. EMT-P providers, on the other hand, are the most advanced level of EMTs who undergo intensive 1- to 2-year training in all the different aspects of advanced prehospital emergency care. Their scope of practice is ALS, and they can perform advanced techniques such as endotracheal intubation, administration of selected drugs, and manual defibrillation. Most developed countries have training requirements for their EMT workforce similar to the United States model.

PHYSICIAN-BASED EMS SYSTEMS

Germany and France represent two well-known examples of countries where physicians are an integral part of prehospital emergency care.[14] These integrated EMS systems combine BLS-level ambulances with physician-staffed ALS ambulances and helicopters in a noncompetitive but complementary fashion. Physician-based EMS systems are always part of a *multi-tiered system* and often use what is referred to as a *rendezvous system* to dispatch two units simultaneously to the scene, one unit staffed with EMTs (BLS or ALS level) and one ambulance carrying the physician. Often, the physician-staffed vehicle is a nontransport vehicle that provides quick response to emergencies without having to move a large and slow truck through traffic. EMS physicians are licensed physicians from various medical specialties who undergo a specialized training in prehospital emergency care. The level of mandatory education varies from country to country. With direct physician involvement in prehospital care, anesthesiologists comprise the largest fraction of physicians and often assume the role of chief emergency physician and medical director.[18,19]

HELICOPTER EMERGENCY MEDICAL SERVICE SYSTEM

In most countries, the HEMS system has become an integral component of the EMS system. With its ability to reach remote locations and cover a wide area rapidly, the HEMS system is a perfect supplement to the ground-based EMS system. Although most are privately organized and funded in the United States, several European countries have implemented a nationwide HEMS network that is strategically distributed to respond to emergency calls from every location in the country. Particularly in rural areas, helicopter rescue is now considered a vital ALS-level responder for all emergencies, including trauma and medical emergencies.[20] EMS helicopters are usually staffed with experienced personnel, typically a paramedic plus a flight nurse or an EMS physician.[9,21] In mass-casualty

incidents, all helicopters from a large area can be concentrated at the scene of the accident within a short period and provide several highly trained ALS teams to support local rescue operations and quickly transport the victims to trauma centers (Figure 82-1). Another area where the HEMS system has become the most important means of evacuation is in mountain rescue operations. Pioneered in the Alps, helicopter evacuation by ALS teams specially trained in mountain rescue techniques is now considered the standard of care in countries such as Switzerland, Austria, Germany, and France (Figure 82-2). In major trauma, transport by helicopter is associated with a significantly increased rate of survival, compared with ground-based EMS system.[22,23] For over 50 years, helicopter evacuation has been dominant in the military, including the Vietnam conflict.

Figure 82-1. Train accident in Wampersdorf, Austria. Mass-casualty incident with 6 fatalities and 17 injured individuals. In addition to more than 50 EMS personnel and EMS physicians on the ground, 5 EMS-physician–staffed helicopters provided invaluable EMS-physician level–backup and transport capacity.

Figure 82-2. In a mountain rescue, HEMS systems have become the standard of care for evacuating individuals from alpine accidents and emergencies. In this rescue, a rescue helicopter supported a complex mock rescue operation from a ski lift in alpine Austria.

COMMUNICATION

Starting with the emergency call, communications is a vital aspect of prehospital emergency care. The implementation of a universal emergency telephone number (9-1-1 in the United States and Canada, 1-1-2 in several European countries, 0-0-0 in Australia, and 9-9-9 in the United Kingdom)[17] was a milestone in prehospital care. Currently, the location of the caller can be automatically identified by the system, often via Global Positioning System (GPS). Mobile phones, including applications for specific conditions, will undoubtedly play an ever-increasing role in the prehospital care of the future.[24-28]

Emergency medical dispatchers determine the type and priority of the response, based on standardized questionnaires, and provide invaluable prearrival instructions to the caller to start potentially lifesaving interventions before the ambulance arrives. For example, dispatcher-assisted CPR improves survival after cardiac arrest.[29,30]

BASIC TECHNIQUES AND SKILLS

PATIENT EXAMINATION AND INITIAL ASSESSMENT ON THE SCENE

Patients in an emergency situation may show a wide range of symptoms, challenging the prehospital care team to obtain a quick tentative diagnosis and start a specific treatment. In contrast to the emergency department, fewer diagnostic tools are available in the prehospital setting. The classic approach, "look, listen, and feel," is still the most important aspect of the patient examination. Most commonly, patients are triaged according to their chief complaint, such as chest pain, rather than by a definitive diagnosis obtained on the scene. The most common chief complaints encountered in the prehospital setting are dyspnea or respiratory distress, cardiac or circulatory problems, altered level of consciousness, and trauma. A rapid assessment of potential hazards on the scene is critical before approaching the patient.

Vital Signs

The initial survey uses the well-known ABCDE mnemonic from advanced cardiac life support (ACLS)[31,32] (also see Chapter 108). The first step is to use acoustic and tactile stimuli to rule out unconsciousness in the patient. The next step is to identify airway (A) obstruction and, if necessary, to secure the airway. While maintaining an open airway, breathing (B) is assessed by observing the respiratory effort and chest rise.[33,34] Respiratory rate, efficacy, work, and pattern of breathing are also assessed. If indicated, supplemental oxygen or assisted ventilation should be administered to support oxygenation and ventilation. Circulation (C) is initially assessed by centrally feeling the pulse at the carotid artery and can be extended to feel pulses proximally and distally on the extremities. The pulse should be assessed for rate, quality, and regularity. To complete C, the capillary refill time should be measured, particularly in children.[35,36] The level of responsiveness and consciousness, disability (D), should

be determined according to the Glasgow Coma Scale (GCS), and a quick pupil check should be performed to determine size and reaction to light. The GCS is a reliable prognostic tool for head trauma[37,38] and other forms of nontraumatic altered levels of consciousness.[39] For children under the age of 3 years, the verbal component of the GCS score has to be adjusted. In case of trauma, exposure and environment (E) are assessed to complete the primary survey. At this point, the patient should be checked from head to toe, including the back after performing a log-roll maneuver.[40]

MONITORING AND EQUIPMENT

Similar to standard monitoring in the surgical department and ICU, monitoring in the prehospital setting has now become considerably standardized and consists of pulse oximetry, noninvasive arterial blood pressure monitoring, electrocardiography (ECG), temperature monitoring, and capnography (also see Chapters 44, 47, and 101).

Pulse Oximetry

After the first prehospital uses in the 1980s,[41] pulse oximeters have become the universal, easy-to-attach and easy-to-use monitor for the patient in the prehospital setting. The improvement of the devices have led not only to smaller machines but also to pulse oximeters with better quality even while in motion and when in the cold.[42,43] Additionally, new features, such as the detection of methemoglobin and carboxyhemoglobin,[44,45] can help diagnose conditions such as carbon monoxide poisoning.

Arterial Blood Pressure

Noninvasive arterial blood pressure measurement is the most common form of blood pressure monitoring in the prehospital setting. Automatic or manual cuffs are mostly applied and use an oscillometric technique with its known limitations.[46] The precision and accuracy of noninvasive oscillometric blood pressure monitoring is reduced by movement during transport. During interhospital transfer of a patient who is critically ill, ICU monitoring with invasive arterial blood pressure monitoring is frequently used.

Electrocardiogram

ECG monitoring has two major goals in the prehospital setting. A 3- or 4-lead ECG or an ECG rhythm obtained from defibrillator paddles is sufficient for a rapid and crude ECG rhythm check (i.e., to distinguish a shockable rhythm from a nonshockable rhythm during CPR).[31] On the other hand, to identify myocardial ischemia or myocardial infarction (MI), a 12-lead ECG is required. When prehospital 12-lead ECGs support the diagnosis of acute MI, patients can then be rapidly directed toward a hospital capable of providing percutaneous coronary interventions (PCIs) with a substantial improvement in door-to-reperfusion time[47-49] (also see Chapter 47).

Temperature Monitoring

Oral, esophageal, and some tympanic thermometers[50-52] are generally reliable tools in the field, considering the more extreme weather conditions in which they have to operate. The most important aspect of measuring body temperature on the scene is to identify hypothermia. Special temperature probes are required to assess severe hypothermia (<28° C) because most commercially available instruments become unreliable at these low temperatures. Patients who have experienced trauma, who are disabled (stroke, coma), or intoxicated, as well as patients in the pediatric or older adult populations, are especially vulnerable to hypothermia, especially during the winter months. Even relatively mild outside temperatures can result in hypothermia with long exposure times[53] (also see Chapter 54).

Capnography

Colorimetric, mainstream, or sidestream capnographs are primarily used in the prehospital setting to identify the correct positioning of the endotracheal tube.[54-56] Continuous monitoring of end-tidal carbon dioxide ($ETCO_2$) allows the monitoring of cardiac output and the efficacy of resuscitation,[57] but capnography is not yet universally used in the EMS system. In cardiac arrest, low carbon dioxide (CO_2) levels are a predictor of a fatal outcome.[58] Hyperventilation may also contribute to a poor outcome[59] and may be prevented by controlling ventilation with the aid of $ETCO_2$ monitoring[60,61] (also see Chapter 51).

Prehospital Point-of-Care Testing

Currently, only point-of-care blood glucose testing is routinely performed by EMS providers. Cardiac troponin, lactate, and blood gas analysis are examples of tests that may have potential utility.[62,63]

Ultrasonography

Small and portable ultrasound machines are applicable in the prehospital setting.[64,65] Diagnostic ultrasound requires a physician on the scene (or online through medical oversight if adequate transmission of the image can be achieved) but offers very interesting possibilities. Focused abdominal sonography for trauma (FAST) is a rapid and reliable technique even in inexperienced hands in the emergency department and could be used in the field.[66] FAST has the potential to improve the triage and management of patients with trauma.[67] During resuscitation from cardiac arrest, cardiac activity is a predictor for return of spontaneous circulation (ROSC)[68] (also see Chapter 58).

PREHOSPITAL AIRWAY MANAGEMENT AND VENTILATION

Swift and safe airway management and ventilation are life-saving interventions that are central to prehospital emergency and trauma care (also see Chapter 55). For anesthesiologists who perform advanced airway management on a daily basis, the reasons why airway management is such a contentious issue in prehospital emergency medicine, particularly in the United States, is difficult to comprehend.[69-75] The reasons are many. The major difference from the operating room environment is, as an EMS saying goes, *"There is no easy airway in the field."* Challenges include a nonstandard environment; difficult access to the patient's head; bad weather and lighting conditions; and blood, vomitus, secretions,

and foreign bodies obstructing the airway. In a patient who is critically ill and who has limited oxygen reserves with increased baseline oxygen consumption, all of these factors contribute to a significantly more difficult prehospital airway management, compared with the operating room, even for the experienced anesthesiologist.[76-81]

Airway Management at the Basic Life Support Level

At the BLS level, in addition to simple airway opening maneuvers, the administration of supplemental oxygen and ventilation via a mask are the most important components in prehospital airway management (also see Chapter 108). Emergency medical technicians are trained and qualified to administer supplemental oxygen, often via a nonrebreather facemask, which creates a significantly higher fraction of inspired oxygen concentration (FiO_2). Furthermore, EMTs are allowed to use nasopharyngeal or oropharyngeal airways to maintain a patent airway and to ventilate the lungs with bag-mask-valve ventilation. The ability to use the Combitube (EasyTube), which is a double-lumen tube with a proximal and distal balloon that was initially developed for ventilation during CPR, is considered a BLS skill.[82,83] The use of other alternative supraglottic airways, such as the King LT (laryngeal tube) or laryngeal masks, is increasingly recommended at the BLS level if adequate training and experience are provided.[84] These alternative airways are safe and easy to apply and have excellent success rates when used by EMTs and paramedics.[85-88] The limitations of these alternative airways are the inability to ventilate if misplaced in the larynx and the lack of airway protection, compared with a cuffed endotracheal tube. Ironically, many anesthesiologists who do not work in EMS medicine are currently unfamiliar with many new alternative airway devices used in prehospital care, such as the King-LT, which has become the standard airway in the field for EMTs, replacing older oropharyngeal devices.[84] Nevertheless, the gold standard for prehospital airway management is still endotracheal intubation, which is associated with improved outcomes, compared with supraglottic devices during CPR.[89]

Ventilation in the prehospital setting is most commonly achieved by bag-mask-valve ventilation. Although fairly common in Europe, only a few EMS services in the United States currently use portable field ventilators to ventilate intubated patients. The major disadvantage of relying on bag-mask-valve ventilation is that minute ventilation and tidal volumes are uncontrolled, often leading to significant hyperventilation that is detrimental in cardiac arrest[59,90,91] and in patients with head trauma.[92-96]

Airway Management at the Advanced Life Support Level

Endotracheal intubation is considered the standard of care in prehospital airway management and a standard intervention for paramedics and EMS physicians; it provides a definitive airway and protection from aspiration of gastric contents (also see Chapter 108). Compared with standard endotracheal intubation in the surgical unit, several differences exist. First, most prehospital tracheal intubations (50% to 70%) are performed in patients with cardiac arrest, obviating the need for induction of anesthesia or paralysis.[97] Most other tracheal intubations in spontaneously breathing patients require sedation or induction of a general anesthesia, which is most commonly performed as rapid sequence induction (RSI). Particular emphasis should be placed on adequate *preoxygenation* since these patients who are critically ill have little to no oxygen reserves.[81,98] The recommended approach is direct, oral laryngoscopy and endotracheal intubation. Recently, the application of cricoid pressure during RSI has become controversial because its use may increase the difficulty of visualizing the glottis.[99] Endotracheal intubation in the field requires confirmation by auscultation and $ETCO_2$ monitoring.

Airway management in the field has a significantly more frequent rate of difficult airway management[78,100,101] and of unrecognized esophageal or endobronchial intubation.[79] Every prehospital provider performing advanced airway management should also be trained in the management of a difficult airway, including the use of alternative airways and the creation of an emergent surgical airway (cricothyroidotomy).[102] Having experienced anesthesiologists as EMS-physicians can significantly reduce the complication rates after prehospital endotracheal intubation.[103-106]

SEDATION, ANESTHESIA, AND PAIN CONTROL IN THE PREHOSPITAL SETTING

The general focus of this section is on the accepted strategies for providing prehospital sedation, induction, and maintenance of anesthesia, and pain control. Drugs commonly used in the field are discussed with an emphasis on the differences with in-hospital use (also see Chapters 30, 31, and 98).

Drugs Commonly Used for Prehospital Sedation, Anesthesia, and Pain Control

In general, not all drugs routinely used in the surgery department for general anesthesia are safe in the prehospital setting.[107] Nonanesthesia personnel, such as paramedics and nurses, are significantly less experienced than anesthesiologists in the use of these drugs; patients who are critically ill often require a special titration of drugs. Therefore drugs used for analgesia, sedation, and anesthesia in the field should have the following desirable properties:

- Wide safety margin, even for inexperienced providers
- Hemodynamic stability
- Minimal respiratory depression
- Ease of administration via different routes (e.g., intravenous [IV], intramuscular [IM], intraosseous [IO], rectal)
- Rapid onset and minimal side effects[108]

Benzodiazepines, such as midazolam (0.05 to 0.2 mg/kg IV) and diazepam (3 to 10 mg IV), are well suited for sedation in adult and pediatric patients, have a wide safety margin, and can be administered via several different routes. However, the lack of analgesic properties usually requires the concurrent administration of a potent analgesic in patients with pain. *Ketamine*, on the other hand, is closer to an ideal agent for prehospital sedation

and analgesia (0.5 to 1 mg/kg IV) and in larger doses for induction of anesthesia (1 to 2 mg/kg IV; 4 to 8 mg/kg IM); it is also ideally suited to provide analgesia and sedation for entrapped patients with trauma during extrication.[109] Ketamine provides potent analgesia and sedation, maintains hemodynamic stability in patients with hypovolemic shock, is a potent bronchodilator, and causes minimal respiratory depression. Because of its hallucinogenic properties, benzodiazepines should be co-administered. Traditionally, the use of ketamine in the patient with a traumatic brain injury has been controversial but, in fact, may be a good choice as an induction of anesthesia in patients with head injuries.[110-112] The new isoform, S(+) ketamine, is twice as potent but otherwise has a similar profile as a racemic drug. *Etomidate* is rarely used for sedation but is often administered as an anesthetic induction agent for RSI in the field (0.2 to 0.3 mg/kg IV). It maintains hemodynamic stability but frequently produces myoclonus, rendering intubating conditions less favorable. Furthermore, etomidate causes adrenocortical suppression and should not be used in patients with sepsis,[113] but the effects of a single dose have not been sufficiently studied in nonseptic patients in the EMS setting.[114,115] Although *propofol* is routinely used in the operating room, it has several disadvantages when used in the prehospital setting. Propofol causes significant hemodynamic instability and respiratory depression, both highly undesirable properties in patients who are critically ill. Barbiturates, such as *thiopental*, have pharmacologic properties and side effects similar to those of propofol and should only be used by experienced providers and only in selected patients, for example, in patients with status epilepticus. The prehospital muscle relaxant of choice for RSI is still *succinylcholine* (1 to 1.5 mg/kg IV),[116] although rocuronium has been successfully used by anesthesiologist in the EMS system.[117] For control of acute pain in the prehospital setting, *opioids* are the drug of choice because of their rapid onset and ability to control severe pain.[118] *Morphine* is considered the gold standard in acute coronary syndrome (ACS) (0.1 to 0.2 mg/kg IV), but in trauma, other opioids such as *fentanyl* (1 to 3 μg/kg IV), *piritramide* (0.1 to 0.2 mg/kg IV), which is currently not available in the United States but is widely used in Europe, and sometimes *tramadol* (50 to 100 mg bolus IV) are more frequently used. Nonopioid analgesics are infrequently used in the prehospital setting, although parenteral formulations of acetaminophen, ibuprofen, and ketorolac have recently become available.

Induction of Anesthesia—Rapid Sequence Induction

The prehospital induction of anesthesia is typically performed as RSI, also known as drug-assisted intubation (DAI) in EMS literature (also see Chapter 55). The goal of prehospital induction of anesthesia is twofold: (1) the safe and swift provision of a definitive airway and ventilation control and (2) the ability to provide potent analgesia and sedation. The actual principles of RSI do not differ from RSI in the emergency department, operating room, or ICU; only the environment in which it is applied is different, as discussed earlier.[71] A standard RSI sequence consists of the steps presented in Box 82-2. As discussed earlier, the usefulness of applying cricoid pressure has been repeatedly questioned. Even more important than in the operating room, a backup plan needs to exist in the event that endotracheal intubation fails. Bag-mask-valve ventilation, the placement of an alternative airway such as a laryngeal mask airway (LMA) or intubating LMA, and a laryngeal tube are all acceptable options. EMS providers must understand that prehospital RSI is not trivial and is associated with significant morbidity and mortality if improperly performed.[119] Life-threatening hypoxemia will ensue if endotracheal intubation is prolonged and ventilation difficult (Figure 82-3).

BOX 82-2 ***Prehospital Rapid Sequence Induction***

1. Preparation of necessary equipment—suction equipment, oxygen, laryngoscopes, endotracheal tube (ETT), Ambu-Bag plus masks, and stylet)
2. Preoxygenation with 100% oxygen (at least 3 minutes)
3. Pretreatment (optional) with small dose of a nondepolarizing neuromuscular-blocking agent such as vecuronium (0.01-0.015 mg/kg IV)
4. Pretreatment (optional) with sedative (midazolam) and/or opioid analgesic (fentanyl)
5. Induction agent (ketamine 2-3 mg/kg IV or etomidate 0.3 mg/kg IV) plus succinylcholine (1-1.5 mg/kg IV)
6. Manual in-line stabilization for patients with trauma (optional) and with suspected cervical spine injury
7. Direct laryngoscopy with oral intubation (use of stylet is recommended)
8. Confirmation of correct ETT placement: bilateral auscultation plus end-tidal carbon dioxide ($ETCO_2$) confirmation

Note: the administration of cricoid pressure (Sellick maneuver) is controversial and is no longer recommended by many authorities.

PREHOSPITAL TRAUMA CARE

The management of a patient who is severely injured is one of the most difficult challenges in prehospital care. The potential for saving lives is probably nowhere more prevalent in the EMS system than in major trauma, which was historically also the driving force behind the creation of the modern EMS systems (see also Chapter 81). Ironically, the details of prehospital trauma care are derived from wars. An analysis of the history of prehospital care closely correlates the military conflict of the time ranging from World War II, Korea, Vietnam, and the Middle East. Accordingly, current experience from combat casualty care during the wars in Iraq and Afghanistan has substantially changed the core strategies in prehospital trauma care in areas such as intravenous fluid resuscitation and the prevention of trauma-induced coagulopathy. These newly gained insights have resulted in major changes in the trauma guidelines over the last years. The most commonly used guideline for prehospital trauma care is Prehospital Trauma Life Support (PHTLS) developed by the National Association of Emergency Medical Technicians (NAEMT) in cooperation with the American College of Surgeons Committee on Trauma (ACS COT).[40] PHTLS is based on the Advanced Trauma Life Support (ATLS) concept that is used as the standard for inhospital trauma

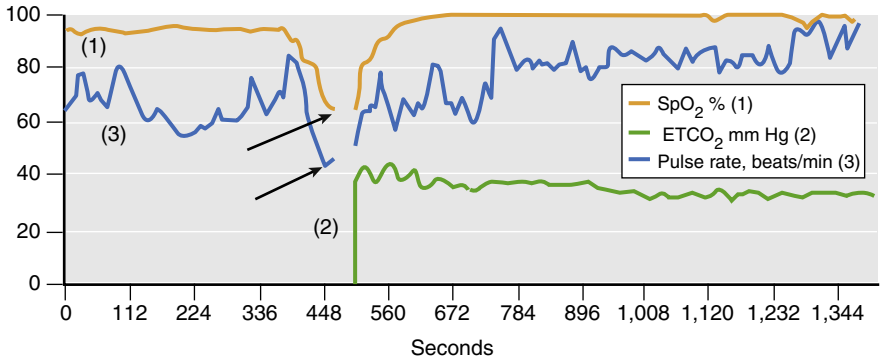

Figure 82-3. Potentially life-threatening desaturation and bradycardia after out-of-hospital rapid sequence induction (RSI) and endotracheal intubation. *$ETCO_2$*, End-tidal carbon dioxide; *SpO_2*, saturation of peripheral oxygen. *(Modified from Dunford JV, Davis DP, Ochs M, et al: Incidence of transient hypoxia and pulse rate reactivity during paramedic rapid sequence intubation,* Ann Emerg Med *42(6):721-728, 2003.)*

care.[120] What are the major changes in ATLS and PHTLS? Trauma life support now places more emphasis on the team approach, advocates for a balanced fluid resuscitation with limited crystalloids (1 L instead of 2 L for initial volume), and recommends the early use of blood products and massive transfusion protocols in patients with hemorrhagic shock (also see Chapters 59 through 62).

The challenges for EMS providers responding to major trauma begin with scene assessment—safety, number of injured individuals, mechanism of injury, injury severity, environmental hazards—and coordination with other first-responder services, such as the police and fire department. Significant pressure exists to minimize on-scene and transport times, based on the "golden hour" and the "platinum 10 minutes" concepts in trauma.[121]

PATIENT EVALUATION ON THE SCENE AND INITIAL MANAGEMENT

Before turning their attention to the individual with trauma, EMS providers must ensure that the accident scene is safe. Crew protection is paramount, particularly in hazardous accidents involving fire, chemicals, electricity, or on busy highways. Motor vehicle accidents often involve more than one person; therefore the EMS team must perform a quick but thorough scan of the entire accident scene and triage all victims. The overarching goal of the initial patient assessment on the scene is to identify life-threatening injuries, which usually follows the well-known ABCDE (**A**irway, **B**reathing, **C**irculation, **D**isability, and **E**xposure or environment) mnemonic. Treatment is immediately initiated if a life-threatening condition is identified—*Treat what kills first,*—which often involves emergent airway management for airway protection, hemorrhage control for major bleeding, or needle thoracostomy for tension pneumothorax. Supplemental oxygen via nonrebreathing facemask should be started on the scene, as well as standard monitoring (ECG, pulse oximetry, arterial blood pressure, capnography) applied. The goal is to maintain oxygen saturation (SpO_2) above 90%. If the respiratory status deteriorates or if the patient is unable to protect his or her airway (e.g., unconsciousness, intoxication, hypoperfusion, direct trauma), then establishing a definitive airway is indicated. Endotracheal intubation after RSI is the recommended approach.

Hemorrhage control is probably the most critical aspect of prehospital trauma care, particularly in combat casualty care. A large fraction of early deaths in trauma can be attributed to exsanguination.[122] The recommended first step in controlling bleeding is the application of direct pressure to the wound, including an appropriate pressure dressing. Compressing the major artery proximal to the wound at pressure points is the next step. In military trauma, the use of tourniquets has been accredited with saving many lives[123,124] and has become the standard of care in major extremity bleeding. Not recommended for decades in civilian trauma, tourniquets have undergone a reappraisal and several organizations now advocate for their use.[125-127] In patients with hemorrhagic shock, two large-bore intravenous lines should be started through which a fluid bolus of 1 liter of a warm crystalloid solution should be administered.[40] This practice, however, has been repeatedly questioned, particularly for penetrating trauma in an urban setting.[128,129] Newer concepts, such as permissive hypotension in the setting of uncontrolled hemorrhage, are advocated and currently under investigation.[130] Despite the initial enthusiasm, small-volume resuscitation with either hypertonic saline or hypertonic-hyperoncotic hydroxyethyl starch solution does not improve clinical outcomes.[131,132] Actually, these starch solutions may cause harm (also see Chapters 59 and 61). The controversy regarding optimal fluid therapy in the field goes hand in hand with the ongoing discussion of whether a "scoop-and-run" (evacuate the site) or a "stay-and-play" (resuscitate on site) or the BLS versus the ALS approach is superior in major trauma.[133] Strong evidence supports minimalistic on-the-scene management (BLS only) for penetrating trauma to the torso; the injury can only be treated by emergent surgery, and aggressive fluid management could actually increase the risk of coagulopathy and blood loss. Irrespective of the current controversy regarding fluid resuscitation in major trauma, the goal is to minimize on-scene time and transport time in major trauma. Helicopter transport has been advocated for patients with major trauma; its expediency reduces mortality[23] and facilitates treatment in a trauma center (Box 82-3).[134] In major head trauma (also see Chapter 70), a modified approach is required in the field:

- Provide adequate oxygenation and avoid hypoxemia (SpO_2 >90%)
- Maintain an adequate cerebral perfusion pressure of >70 mm Hg with a systolic blood pressure (SBP) of at least 90 mm Hg with isotonic or hypertonic fluids

BOX 82-3 *On-scene Triage Criteria for Major Trauma Necessitating Transport to a Trauma Center*

Mechanism of Injury

- Extrication time >20 minutes
- High-speed crash with:
  - Intrusion into passenger compartment >20 cm
  - Speed >40 mph
- Ejection
- Death of another passenger in the same motor vehicle
- Rollover
- Pedestrian or bicyclist hit by motor vehicle
- Motorcycle crash >20 mph or with separation of rider from motorcycle
- Falls >3 m (9.8 feet)

Physiologic Criteria

- Systolic blood pressure <90 mm Hg
- Respiratory rate <10 or >29 breaths per minute
- Glasgow Coma Scale score <14
- Pregnancy

Anatomic Criteria

- Flail chest
- Two or more proximal long bone fractures
- Pelvic fracture
- Penetrating injury to the head, neck, torso, or extremities proximal to the elbow or knee
- Open or depressed skull fracture
- Amputation proximal to the wrist or ankle
- Paralysis

Discretion of Emergency Medical Technician

At the discretion of the emergency medical technician, a person can be declared as having a major trauma. In addition, preexisting conditions of the individual can lead to an upgraded status, such as coronary artery disease, congestive heart failure, severe chronic obstructive pulmonary disease, morbid obesity, or bleeding disorders.

From O'Connor RE: Trauma triage: concepts in prehospital trauma care, Prehosp Emerg Care *10(3):307-310, 2006.*

- Institute endotracheal intubation for patients with a GCS score lower than 9
- Maintain normoventilation ($ETCO_2$ 35 to 40 mm Hg)
- Avoid hyperventilation or hypoventilation

These steps are considered the mainstays of prehospital therapy in traumatic brain injury.[135] However, if cerebral herniation is suspected, then moderate hyperventilation ($ETCO_2$ 30 to 35 mm Hg) and hyperosmolar therapy with mannitol or hypertonic saline should be instituted.

ADULT MEDICAL EMERGENCIES

Most textbooks on prehospital emergency medicine discuss adult medical emergencies under the patient's final diagnosis, such as congestive heart failure, MI, or chronic obstructive pulmonary disease (COPD). This is not, however, how individuals present themselves to the EMS team on the scene. Rather, they usually first express a chief complaint (or lead symptom), such as dyspnea or chest pain. Therefore adult medical emergencies are presented in this text according to the chief complaints. Most adult medical emergencies fall into one of only three separate chief complaints: (1) dyspnea or respiratory distress, (2) cardiac or circulatory problem, and altered level of consciousness.

BOX 82-4 *Common Nontraumatic Causes of Acute Shortness of Breath in Adults*

- Exacerbated chronic obstructive pulmonary disease
- Asthma
- Cardiogenic pulmonary edema (from congestive heart failure)
- Noncardiogenic pulmonary edema (inhalational, related to sepsis)
- Pneumonia
- Pulmonary embolism
- Foreign body obstruction
- Aspiration

Modified from Fowlkes TD: Shortness of breath. In National Association of EMS Physicians, Kuehl AE, editors: Prehospital systems and medical oversight*, Dubuque, Ia, 2002, Kendall and Hunt, pp 665-671).*

DYSPNEA OR RESPIRATORY DISTRESS

Dyspnea is one of the most common presenting symptoms in prehospital care and is associated with a significant mortality rate of 12% to 18%.[136] Each year in the United States alone, 2 million patients with respiratory distress are transported by EMS. As reported in the large Canadian outcome study, Ontario Prehospital Advanced Life Support (OPALS), prehospital ALS decreases mortality in these patients.[136] In adults, acute shortness of breath is most commonly caused by either bronchospasm or pulmonary edema, secondary to congestive heart failure (CHF), but other differential diagnoses such as pulmonary embolism, pneumonia, foreign body obstruction must also be considered[137] (Box 82-4). Identifying the correct diagnosis on the scene is not easy[138-140]; the cause of dyspnea can be multifactorial, for example, the individual with severe COPD and CHF who develops pneumonia.

Patient Evaluation

The most important aspect of the initial evaluation in a patient with acute dyspnea is to identify whether the condition is life threatening with imminent respiratory failure that requires immediate treatment. Physical signs and symptoms indicating a life-threatening condition are cyanosis, tachypnea (respiratory rate >30 per minute), stridor, tachycardia, inability to speak in full sentences (<5 to 6 words), and the use of accessory respiratory muscles.[141] The use of pulse oximetry has quickly become the standard of care in diagnosing hypoxemia and adds an objective measurement of the severity of the respiratory distress. Irrespective of the underlying cause, all patients with respiratory distress should receive high-flow oxygen, ideally through a nonrebreathing facemask. Two of the most common causes of respiratory distress in adults, (1) bronchospasm attributable to asthma and COPD and (2) pulmonary edema attributable to congestive heart failure, are discussed in this text.

Prehospital Management

Bronchospasm: Chronic Obstructive Pulmonary Disease and Asthma. Bronchospasm as a cause for dyspnea is often suggested by the patient's medical history and current medications. Patients with asthma and COPD often use inhaled β-adrenergic agonists and corticosteroids and, in severe cases, also systemic agents. These patients tend to have frequent encounters with the EMS system and emergency departments. In addition to the clinical signs of dyspnea, wheezing and coughing are classic symptoms of bronchospasm. In extreme forms of bronchospasm, no breath sounds can be auscultated, resulting in a "silent chest." A long-standing myth in EMS system states that patients with severe COPD should not receive high-flow oxygen to prevent respiratory arrest.[137] However, these patients often die as a result of hypoxemia and thus should be given the same oxygen therapy as any other patient in respiratory distress.

On-the-scene management of patients with asthma attacks or acute COPD exacerbations is similar and follows the recommended guidelines.[142-144] Besides providing oxygen to prevent hypoxemia, the first line of treatment is inhaled β-agonists plus an anticholinergic agent such as albuterol or salbutamol plus ipratropium, either via nebulized aerosol or a metered-dose inhaler. Often, these patients have already used their inhalers before calling the EMS system; therefore in moderate-to-severe exacerbations, the use of systemic corticosteroids (methylprednisolone, 60 to 125 mg IV bolus dose) is indicated. In life-threatening asthma and COPD exacerbations, intravenous β-agonists (epinephrine, 100 to 200 μg IV bolus dose) are particularly helpful. In the case of impending or actual respiratory arrest, endotracheal intubation is warranted, often after RSI with ketamine as the preferred drug because of its favorable bronchodilating properties. The EMS crew must be vigilant for additional conditions that add to the severity of hypoxemia, such as pneumonia, pneumothorax, anaphylaxis, and pulmonary embolism.

Pulmonary Edema Precipitated by Congestive Heart Failure

Often, acute heart failure is precipitated by additional events such as ACS. Therefore a 12-lead ECG should be obtained to guide prehospital therapy for patients with acute pulmonary edema and rule out acute MI. The treatment consists of three components: oxygen (noninvasive positive-pressure ventilation [NIPPV]), diuretics, and vasodilators.[145] NIPPV, such as continuous positive airway pressure (CPAP), has become a standard therapy in the treatment of acute pulmonary edema in the prehospital setting.[146] NIPPV should be used for most patients with acute pulmonary edema.[147] The subsequent therapy should be guided by the patient's SBP:

- **SBP higher than 140 mm Hg:** NIPPV plus nitrates; nitroglycerin spray or continuous IV infusion is recommended with a starting dose of 10 to 20 μg per minute.
- **SBP 140 to 100 mm Hg:** NIPPV plus nitrates and a diuretic agent (furosemide) are recommended if signs of systemic fluid retention are present.
- **SBP lower than 100 mm Hg:** If hypoperfusion is predominant and signs of cardiogenic shock are present, then these patients require inotropic agents such as dopamine and dobutamine and a carefully titrated volume challenge.
- **Pulmonary edema with signs of ACS:** These patients require ACS-specific management in addition to NIPPV plus nitrates.[147]

The treatment goals are to stabilize the patient, improve oxygenation and perfusion, and reduce dyspnea.

CARDIAC AND CIRCULATORY EMERGENCIES

Acute chest pain and circulatory conditions (e.g., syncope, hypertension) are frequently encountered in the prehospital setting. Significant emphasis has been put on the role of the EMS providers in the management of ST-elevation myocardial infarction (STEMI), but other conditions such as pulmonary embolism, hypertensive emergencies, or dysrhythmias require significant diagnostic and therapeutic skills by the providers in the field (also see Chapter 67). In this overview, the focus is on the most common emergencies resulting in chest pain: ACS, pulmonary embolism, and hypertensive emergencies. ACS is defined as an umbrella term for all ACSs and includes STEMI, non–ST-elevation myocardial infarction (NSTEMI), and unstable angina. Cardiac arrest and CPR are discussed in a separate chapter (new CPR guidelines were published in 2010[31,32,148,149]).

Patient Evaluation

The most important goal in evaluating a patient with acute chest pain or an urgent circulatory condition is to rule out a life-threatening condition such as ACS or pulmonary embolism. Because chest pain is a common complaint, identifying patients who are at high risk among all of the patients with benign conditions such as back spasm, gastroesophageal reflux, or other gastrointestinal disorders, is difficult. History and a physical examination, as well as a 12-lead ECG, often guide the diagnosis. A prehospital 12-lead ECG can be quickly performed by the EMS crew and transmitted to a physician oversight if required; it offers a high sensitivity and specificity for detecting myocardial ischemia and MI. ECG interpretation for ACS may prove difficult in patients with left bundle branch block, ventricular paced rhythm, isolated posterior MI, or an ST-elevation in the ECG lead aVR (augmented ECG lead from the right arm). Assessing the type and quality of the chest pain—stabbing versus burning, radiation, severity, and provocation—is critical in determining the differential diagnosis (Box 82-5). However, up to 30% of patients with ACS have atypical pain symptoms (epigastric discomfort, jaw pain) or no pain at all in the case of silent myocardial ischemia in patients with diabetes.

Prehospital Management Acute Coronary Syndrome

The primary goal for a patient with suspected ACS is to minimize the time to diagnosis and potential reperfusion therapy while maintaining hemodynamic stability on scene and during transport. If STEMI is suspected, then

access to rapid reperfusion therapy is paramount. According to the most recent guidelines, primary PCI is the preferred reperfusion strategy compared with thrombolysis, but a combination of the two may provide additional benefits.[150,151]

Patients with suspected ACS should be immediately monitored by a continuous ECG in addition to arterial blood pressure and oxygen saturation. Rapid access to a defibrillator is mandatory, especially for patients with STEMI, because patients with an acute MI have a high risk of ventricular fibrillation. The most recent guidelines recommend starting supportive therapy on the scene consisting of morphine (pain control), high-flow oxygen, nitrates (if the patient is not hypotensive), and oral aspirin, easily memorized by the well-known MONA acronym—**m**orphine, **o**xygen, **n**itrates, and **a**spirin.[152-153] β-Adrenergic blockers can be considered if the patient exhibits tachycardia and/or is hypertensive. The goal is to reduce myocardial oxygen demand while improving oxygen supply. The 12-lead ECG is a vital component of prehospital care for ACS because it is the only tool that can reliably identify patients who may benefit from prehospital reperfusion therapy (Figure 82-4). The overarching goal is to minimize myocardial ischemia time. If prehospital fibrinolysis is considered, then the "contact to needle" time should be less than 30 minutes. If primary PCI is considered, then the "door to balloon" time should be less than 90 minutes. Out-of-hospital fibrinolysis reduces mortality in patients with STEMI or new onset left bundle branch block[154] but is no longer recommended if the patient can undergo primary PCI within 1 hour. If the 1-hour time limit for primary PCI cannot be met, then prehospital fibrinolysis may improve outcomes.[151] Several fibrinolytic drugs are available, and the choice is often based on the institution. Yet fibrinolytic therapy has several contraindications (Box 82-6) and also has the risk of intracranial hemorrhage resulting in major disability or death in 1% to 2% of the patients.

BOX 82-5 ***Differential Diagnosis of Acute Chest Pain in Adults***

- Acute coronary syndrome (unstable angina, myocardial infarction)
- Pulmonary embolism
- Gastroesophageal reflux
- Peptic ulcer disease
- Gastritis or esophagitis
- Aortic dissection
- Pericarditis
- Pneumonia
- Pneumothorax
- Pleurisy
- Boerhaave syndrome (esophageal rupture)
- Pancreatitis
- Musculoskeletal pain

Pulmonary Embolism. A definitive diagnosis of pulmonary embolism is difficult to establish on the scene because signs and symptoms are nonspecific and no rapid objective test comparable with the 12-lead ECG in ACS is available for on-site diagnosis. Often, the patient's medical history is revealing (e.g., immobilized leg and signs of a preexisting deep venous thrombosis; unilateral and tender swelling in one extremity). The severity of pulmonary embolism directly relates to the size of the clots and ranges from mild symptoms of dyspnea to acutely life-threatening states of cardiogenic shock attributable to acute right-sided heart failure. Classic symptoms of pulmonary embolism include distended neck veins, hypoxemia, tachycardia, tachypnea, and chest pain. More objective, but nevertheless

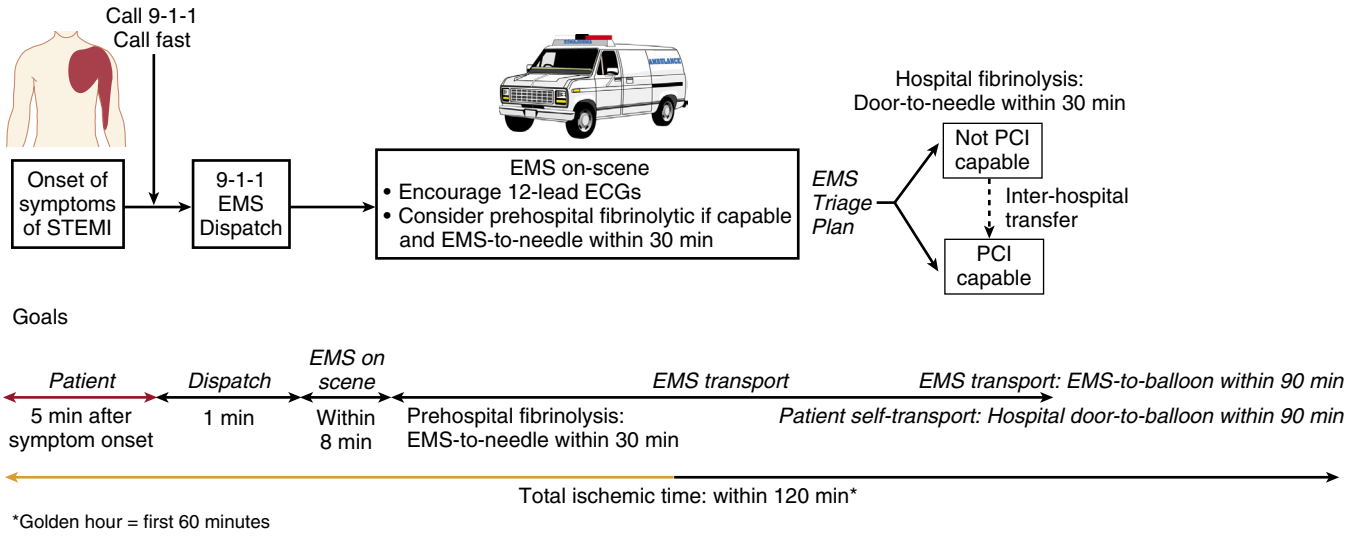

Figure 82-4. Prehospital management priorities in patients with ST-elevation myocardial infarction (STEMI). *ECG,* Electrocardiogram; *EMS,* emergency medical service; *PCI,* percutaneous coronary intervention. *(Data from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of patients with acute myocardial infarction],* J Am Coll Cardiol *44:E1-E211, 2004; and Armstrong PW, Collen D, Antman E: Fibrinolysis for acute myocardial infarction: the future is here and now,* Circulation *107:2533-2537, 2003.)*

BOX 82-6 ***Contraindications of Fibrinolytic Therapy in ST-Elevated Myocardial Infarction (EMI)***

Absolute Contraindications

- Any prior intracranial hemorrhage
- Known structural cerebral vascular lesion (AVM)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed head trauma or facial trauma within 3 months

Relative Contraindications

- History of chronic, severe, poorly controlled hypertension
- Severe uncontrolled hypertension on presentation (SBP >180 mm Hg or DBP >110 mm Hg)*
- History of prior ischemic stroke <3 months, dementia, or known intracranial pathologic condition not covered in the contraindications
- Traumatic or prolonged (>10 minutes) CPR or major surgery (<3 weeks)
- Recent (within 2 to 4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase or anistreplase: prior exposure (<5 days ago) or prior allergic reaction to these agents
- Pregnancy
- Active peptic ulcer
- Current use of anticoagulants (the higher the INR, the higher the risk of bleeding)

*Could be an absolute contraindication in low-risk patients with myocardial infarction.

unspecific findings, are new right bundle branch block, symmetric T-wave inversion in the anterior leads (V1-V4), and S_IQ_{III} pattern in the 12-lead ECG.[155] Often the 12-lead ECG is more useful to rule out other conditions such as MI than ruling in pulmonary embolism.

In the absence of an objective means to diagnose pulmonary embolism reliably in the prehospital setting, the management is largely supportive.[156] Applying standard monitoring, administering high-flow oxygen, establishing an intravenous line, and controlling pain with opioid analgesics are considered standard therapy. In severe pulmonary embolism that is usually accompanied with systemic hypotension (SBP <90 mm Hg), circulatory support with inotropic drugs is often required. The prehospital use of heparin in pulmonary embolism is not universally recommended and must be determined on a case-by-case basis, taking into account the likelihood of pulmonary embolism and the severity of symptoms. Prehospital fibrinolysis in pulmonary embolism is not recommended, although it has been successfully used *in extremis*.[157]

BOX 82-7 ***Classification of Acute Hypertensive Episodes***

1. Hypertensive emergency: Also termed *hypertensive crisis.* Hypertension with acute end-organ dysfunction
2. Hypertensive urgency: Hypertensive episode with high risk of imminent end-organ damage that has not yet occurred
3. Acute hypertensive episode: Systolic blood pressure (SBP) >180 mm Hg or diastolic (DBP) >110 mm Hg without signs of evolving or imminent end-organ dysfunction
4. Transient hypertension: Related to anxiety or primary complaint

Modified from Chobanian AV, Bakris GL, Black HR, et al: Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, Hypertension *42(6):1206-1252, 2003.*

Hypertensive Emergencies. The EMS often responds to patients with acute hypertensive episodes, but these are rarely true hypertensive emergencies. The classification of hypertensive episodes is very helpful in determining the urgency of a prehospital intervention (Box 82-7). The combination of acute hypertension plus end-organ damage (hypertensive emergency), such as hypertensive encephalopathy, stroke, pulmonary edema, MI, aortic dissection, acute renal failure, and preeclampsia, must be immediately treated, and the progression must be stopped. The goal is to decrease the arterial blood pressure by 20% to 25% within 30 to 60 minutes.[158] However, in the setting of cerebral infarction, arterial blood pressure should be slowly decreased since the ischemic territory may be critically dependent on collateral perfusion pressure. Evidence for benefits of acute antihypertensive treatment is scant; perhaps only very high SBP or diastolic blood pressure (DBP) should be treated.[159] On the other hand, patients with an aortic dissection require swift and aggressive treatment with a target arterial blood pressure of SBP less than 120 mm Hg and a DBP less than 80 mm Hg.[160] The choice of antihypertensive should take into account the underlying pathophysiologic condition. For example, patients with acute hypertension plus ACS and tachycardia might benefit from β-adrenergic blocker and nitroglycerin, whereas in intracranial hemorrhage, labetalol is probably the preferred drug. Depending on availability and approval, urapidil, an α-adrenoceptor antagonist is extremely helpful.

ALTERED LEVEL OF CONSCIOUSNESS

Altered level of consciousness is often encountered in prehospital care. The differential diagnoses are vast, treatment options are limited, and therefore most patients receive only supportive care in the field. The overarching goal is to stabilize vital signs, quickly identify and treat potentially life-threatening conditions, and determine a likely cause.[161] For example, severe hypoglycemia in an unconscious patient can be rapidly detected by point-of-care testing and reversed by the administration of an intravenous glucose bolus. Although this section focuses on general principles, it briefly mentions a few specific conditions, such as stroke or seizure.

Patients with an altered level of consciousness should immediately receive high-flow oxygen and intravenous access, be undressed, and undergo standard monitoring.

BOX 82-8 ***Causes of Altered Level of Consciousness in Adults: Mnemonic AEIOU-TIPS***

Alcohol and airway (hypoxia)
Epilepsy, electrolytes, encephalopathy
Insulin—hypoglycemia
Opioids or overdose
Urea (metabolic)
Trauma or tumor
Infection
Psychiatric
Shock, subarachnoid hemorrhage, or snake bite

Adapted from Wolfe RE, Brown DFM: Coma and depressed level of consciousness. In Marx JA, Hockberger RS, Walls, RM, editors: Rosen's emergency medicine: concepts and clinical practice*, ed 6, Philadelphia, 2006, Mosby–Elsevier.*

The addition of continuous capnography (when available) is helpful to assess adequate ventilation. The level of unconsciousness and a determination of the GCS score should be performed. In the prehospital setting, distinguishing whether the patient is alert (i.e., responsive to verbal commands), is only responsive to painful stimuli, or is completely unresponsive (i.e., unconscious) is often sufficient.[162]

Because patients with impaired consciousness are at risk for pulmonary aspiration of gastric contents, the need for airway protection needs to be assessed. Recommended diagnostic steps on the scene include determining the pupil size and reaction to light, measuring core body temperature and point-of-care blood glucose levels. During the initial neurologic examination, EMS providers must determine whether the main neurologic symptoms are global or whether a focal neurologic deficit is present. Nasal or oral airways may be inserted to keep the airway patent and to test for a gag reflex. Once these basic steps have been accomplished, the EMS team should try to obtain as much information as possible about the patient and the circumstances to narrow the probable causes for the patient's unconsciousness (Box 82-8). Often, this can only be accomplished by involving bystanders and family members. Important aspects are onset and progression of unconsciousness (immediate or delayed), fever, the patient's status before the onset of symptoms, headache, medications and medical history (e.g., hypertension, diabetes, depression), signs of intoxication (e.g., open drug containers, needles, drug paraphernalia), and signs of trauma.

For patients with *hypoglycemia*, the recommended treatment is to administer dextrose ($D_{50}W$, 50 mL = 1 amp) immediately. If an intravenous line cannot be established, then intramuscular glucagon (1 to 2 mg) is a viable alternative. On average, blood glucose levels increase between 100 and 150 mg/dL after this treatment, and patients are fully awake within a few minutes. In patients in whom opioid overdose is suspected (meiosis, respiratory rate <10 per minute), the opioid antagonist naloxone should be administered. The recommended starting intravenous dose is between 0.1 to 0.4 mg, but it should be titrated to clinical effect; that is, to the restoration of spontaneous ventilation and not to complete awakening. A wide range of required dosages may be needed, sometimes requiring as little as 0.2 mg and sometimes up to 10 mg.[162] If too much naloxone is administered, then severe opioid withdrawal symptoms may result. Similarly, if patients with benzodiazepine overdose are aggressively treated with the antagonist, flumazenil, then generalized seizures can result that may be unresponsive to further benzodiazepine treatment.

Only recently have patients with acute stroke received similar attention in prehospital care as patients with acute MI. It is now clear that a comparable "golden hour" exists in acute stroke treatment.[163] Stroke is a leading cause of death in the United States and the number-one cause for disability in adults. Both the rapid identification and the treatment of stroke limit brain damage and improve survival.[164] Classic symptoms of stroke are hemiparesis, aphasia, and altered level of consciousness. Formal prehospital screening tools such as the Cincinnati Prehospital Stroke Scale are useful and should be used.[165]

The goal in prehospital emergency care is the quick identification of stroke and the expeditious transport of the patient to a stroke center with 24-hour computed tomography (CT) scanner availability.[164,166] An emergent CT scan is mandatory to distinguish between hemorrhagic and ischemic stroke. Because of the inability to clinically distinguish between ischemic stroke (85% of cases) and hemorrhagic stroke (15%), prehospital thrombolysis cannot be performed and is contraindicated until hemorrhagic stroke is ruled out. Thus supportive care to stabilize the patient's vital signs and to avoid risk factors that negatively influence outcome, such as hypoxia, hypotension, and hyperglycemia, are the primary treatment goals in stroke in the prehospital setting.[167] Patients with a stroke require supplemental oxygen, intravenous access, continuous ECG, and arterial blood pressure monitoring. Hypoglycemia, as well as hyperglycemia, frequently occurs in patients with a stroke; therefore prehospital blood glucose measurement is mandatory. Arterial blood pressure management in patients with stroke is controversial; aggressive decreasing of SBP can worsen the outcome; some hypertension in a patient with an acute stroke might actually be beneficial. If, on the other hand, end-organ dysfunction is apparent, such as myocardial ischemia or a SBP higher than 220 mm Hg, then cautious antihypertensive treatment should probably be started on the scene.

Seizure is a common disorder observed in the EMS practice. Often, the seizure has abated when the EMS team arrives, and the patient is found in a postictal state that seldom requires intervention. If ongoing, however, the seizure requires aggressive treatment, which typically includes the intravenous administration of benzodiazepines and the prevention of secondary complications such as hypoxemia.[168] Intravenous access is difficult to establish during a generalized seizure, and an intraosseous or intramuscular approach may be required. High-flow oxygen should be administered via a nonrebreathing facemask. Status epilepticus is a state of ongoing, refractory general seizure activity and is a true life-threatening emergency that often requires the induction of general anesthesia.[169]

PEDIATRIC EMERGENCIES

Pediatric emergencies are a major challenge in prehospital care. Between 5% and 8% of EMS calls are pediatric

emergencies.[170,171] During the first years of life, common pediatric emergencies are respiratory problems and febrile seizures. The incidence of trauma increases in older age groups.[170] In this section, the main differences in causes, diagnostic procedures, and treatments between pediatric and adult emergencies are reviewed (also see Chapter 93).

DYSPNEA AND RESPIRATORY DISTRESS

Respiratory distress is one of the most common pediatric emergencies, particularly among young children under the age of 6 years, and is the leading cause for cardiac arrest in children. Airway anatomy, a smaller respiratory reserve attributable to a smaller residual capacity, as well as a higher baseline oxygen consumption, make children more vulnerable to hypoxic events. Infections or foreign body airway obstruction are most prevalent in younger age groups; in older children respiratory disorders such as asthma predominate.

Patient Evaluation

The initial assessment of a child in respiratory distress can be more difficult since children are often agitated and frightened. Important physical signs and symptoms indicative of respiratory distress are tachypnea and intercostal, sternal, and subcostal retractions. Children use accessory muscles to support breathing, which may be demonstrated as head bobbing and nasal flaring. An early sign of respiratory distress is the use of chest wall muscles. Paradoxical breathing movements of the chest and abdomen (see-saw respiration) indicate decompensated respiration.

Prehospital Management

Pediatric respiratory support includes the administration of supplemental oxygen, assisted bag-mask-valve ventilation, or controlled ventilation with a secured airway. Prehospital airway management in children is difficult and significantly more challenging than in the controlled environment of an operating room. As a consequence, the risk of encountering a difficult airway in a child in the field is likely.

Infection. Laryngotracheobronchitis (croup) is a typical emergency of the young child, 6 months to 3 years of age at presentation. Because of its dramatic onset, usually during the night, and combined with sudden loud inspiratory stridor, laryngotracheobronchitis frightens both the child and the parents. Except for a recent minor infection of the upper respiratory tract, the medical history is usually noncontributory.

On-the-scene management of mild croup (without retractions) consists of psychologic support by the EMS team, humidified oxygen via facemask, and transport to a pediatric emergency department. More severe cases with retractions and/or neurologic signs such as apathy or agitation require the administration of oral dexamethasone (0.6 mg/kg once [16 mg max]) and, as a next step, nebulized epinephrine (0.5 mL of 2.25% racemic epinephrine or 5.0 mL of epinephrine 1:1000, irrespective of the weight of the child).[172] The need for prehospital endotracheal intubation is rare.

Epiglottitis, another upper airway infection observed in children, is very dangerous but fortunately very rare. Epiglottitis usually occurs in children aged 2 to 7 years and is characterized by inspiratory stridor, hypersalivation, a high fever, and an inability to swallow. The child's voice sounds muffled. Any anxiety-provoking maneuvers such as excessive examination or establishing an intravenous access should be avoided. Complete airway obstruction can rapidly occur and emergent airway management may become necessary including cricothyroidotomy.[173]

Asthma. Acute asthma exacerbation is a common emergency in children. The prevalence of asthma among children ranges from 5% to 10% and acute exacerbation, an *asthma attack*, is a frequent complication. Asthma is the third most frequent cause of hospitalization among children younger than 15 years of age. Although a severe asthma exacerbation often presents itself with loud wheezing, tachycardia, and a SpO_2 between 92% to 95%, children in a life-threatening asthma attack lose the ability to speak, become quiet, and develop a paradoxical breathing pattern with SpO_2 <92%, pseudonormalization of the heart rate that may progress to bradycardia, and ultimately cardiac arrest. Recent guidelines recommend supportive therapy in mild cases and inhaled β-adrenergic agonists as first-line treatment (albuterol or salbuterol, 2 puffs every 2 minutes; up to 10 puffs) and corticosteroids (oral prednisolone, 1 mg/kg once daily).[174] In life-threatening asthma, intravenous epinephrine may be administered, and patients may require general anesthesia and endotracheal intubation; ketamine is the anesthetic drug of choice because to its favorable broncholytic properties.

Foreign Body Airway Obstruction. Foreign body airway obstruction is a common accident among children younger than 3 years of age, particularly boys. It is characterized by the sudden onset of respiratory distress associated with coughing, gagging, or stridor in a child with no other signs of illness. Foreign body airway obstruction has a prominent place in the current pediatric BLS guidelines.[175] With mild foreign body airway obstruction, when the child can still effectively cough, no immediate action to remove the foreign body by EMS team is necessary. The child should be encouraged to expel the foreign body by coughing. If the obstruction is severe and coughing is ineffective, urgent intervention is required. For children older than 1 year of age, abdominal thrusts (Heimlich maneuver) are recommended (up to five times until the foreign body is expelled) whereas in infants, a series of five back blows in turn with chest thrusts is recommended. If the child becomes unconscious, standard BLS must be initiated.[175] ALS units may inspect the airway with direct laryngoscopy to remove the foreign body under visualization.

CARDIAC EMERGENCIES AND SHOCK

Life-threatening pediatric cardiac emergencies in prehospital emergency care are rare. Yet hypovolemic shock attributable to acute blood loss or diarrheal diseases does occur and requires urgent treatment.

Patient Evaluation

In addition to standard assessment, including mental status assessment, heart rate, pulse quality, and particularly capillary refill time, are good indicators of the volume status of the child.

Prehospital Management

Arrhythmia. Most arrhythmias encountered in the prehospital setting in pediatric patients are secondary; that is, most are the result of an underlying disease and not a primary disease. Bradycardia in children is an ominous sign and often the result of hypoxia or poisoning. If the heart rate is lower than 60 beats per minute and the child shows signs of inadequate end-organ perfusion (e.g., unconsciousness), BLS measures must be initiated and the underlying cause for bradycardia identified and treated. Most tachyarrhythmias, on the other hand, are supraventricular and compensatory and seldom require treatment in the field. If treatment is required, then supraventricular tachycardia can nearly always be controlled by vagal maneuvers, such as carotid sinus massage, or intravenous adenosine. Ventricular tachyarrhythmias are rare in children but clearly more dangerous and typically occur as a consequence of one of two conditions—inherited long-QT syndrome and commotio cordis. In inherited long-QT syndrome, torsade de pointes, which is a special case of ventricular tachycardia, is triggered and may result in cardiac arrest. However, most cases of torsade de pointes are self-limiting and do not require ALS measures, defibrillation, or drug therapy (magnesium is the drug of choice). Commotio cordis describes a scenario during which the chest of a child is struck by an object, such as a baseball or puck, during the critical phase of cardiac repolarization; as a result, ventricular fibrillation is triggered. The fatality rate tends to be high (up to 70%), and defibrillation appears to be the only effective therapy (also see Chapters 45 and 47).

Shock. Hypovolemic shock attributable to acute blood loss or acute diarrheal disease is the most common type, followed by septic, cardiogenic, and distributive shock.[176,177] The top priority in children who developed shock is obtaining rapid vascular access and initiating aggressive fluid resuscitation. Venous access is the first choice; however, if it cannot be rapidly established, then intraosseous access is the next alternative. Intraosseous access provides quick and reliable access, through which intravenous medications and fluids can be administered. An initial fluid bolus of 20 mL/kg of balanced crystalloid, such as lactated Ringer solution, is recommended.[178]

ALTERED LEVEL OF CONSCIOUSNESS

Chief neurologic complaints, such as meningitis, encephalitis, febrile seizure, and coma, are not infrequently encountered in prehospital medicine. Neurologic examination of children is difficult and treatment on the scene is often only symptomatic.

Patient Evaluation

After an evaluation of breathing and circulation, a quick neurologic assessment should be made. A pediatric GCS has been developed that provides age-appropriate responses for neurologic assessment (see Chapter 97).[179] The motor score of the GCS has a good predictive value for outcome after traumatic brain injury.[180] Blood glucose measurement is mandatory on the scene to rule out severe hypoglycemia.

Prehospital Management

Infection. Bacterial meningitis accounts for approximately 30% of the children with meningeal irritation, whereas viral or aseptic meningitis is the cause in approximately 13% of cases managed by EMS providers.[181] Identification of this potentially life-threatening disease is an important challenge for the prehospital provider. Independent predictors of bacterial meningitis obtained from the patient's history and physical examination are the duration of the primary complaint, history of vomiting, and meningeal irritation, cyanosis, petechial bleeding, and altered consciousness.[182] Airway management and fluid resuscitation may be necessary before transferring the child to a pediatric emergency department. If the diagnosis of bacterial meningitis is confirmed, then antibiotic prophylaxis of all individuals who had direct contact with the patient is mandatory.

Seizures. Febrile seizures are the most common seizure disorder in childhood, occurring in 2% to 5% of children, typically between the ages of 6 months and 5 years.[183] Usually the seizure has already terminated when the EMS team arrives and the patient is in a postictal state. An antipyretic therapy may prevent a recurrence of the seizure.

To rule out other underlying conditions for a seizure such as hypoxia, intoxication, infectious reasons, metabolic disorders, trauma, or heatstroke, the child should be hospitalized after the vital signs are stabilized. If seizures recur or are still ongoing (status epilepticus), then the initial assessment should follow the airway, breathing, circulation (ABC) principle. High-flow oxygen should be given and blood glucose tested. For those children in whom intravenous access can be immediately established, a benzodiazepine such as lorazepam 0.05-0.1 mg/kg should be given intravenously. If intravenous access cannot be rapidly established, then the rectal diazepam (0.5 mg/kg) (or intraosseous access) is a good alternative. A second dose of lorazepam (0.1 mg/kg) may be given if the seizure is recurring.[184]

TRAUMA

Among children, trauma is the leading cause of death between ages 1 and 18 years. Boys are more at risk than girls. More than 90% of injuries are blunt and 10% penetrating. The prehospital approach in pediatric trauma, including patient evaluation and management, is very similar to adult trauma; therefore the focus of this text is limited to the pertinent differences between pediatric and adult traumas.

Because of the anatomic differences, children experience different injury patterns, compared with adults. Children have proportionately larger heads and are thus at a higher risk for head injury.[185] Bone fractures involving the growing ends of bones are predominantly observed in children. Softer, more flexible ribs decrease the risk for rib fractures, yet increase the risk for pulmonary contusion. The large body surface area predisposes children to hypothermia with all the associated negative consequences in trauma such as traumatic coagulopathy. Prehospital management of a severely injured child

TABLE 82-1 **DEFINITIONS IN DISASTER MEDICINE**

	Definition	Level of Prehospital Medical Care Possible	Examples
Emergency	Incident that demands urgent action Impact: minutes to hours	Individual medicine	Patient with bicycle accident Stroke Angina
Mass casualty	Large number of casualties in a short period that initially exceeds local logistic support capabilities Impact: hours to days	Triage Increasing level of medical treatment dependent on resources	Airplane crash Train collision Mass poisoning
Disaster	Large number of casualties and destroyed infrastructure; exceeds local response capabilities Supraregional (national) forces are needed to solve the problem Impact: damage and interruption may last long-term (weeks to years)	Triage First aid Significant delay until professional medical help is available, which is usually only after temporary infrastructure is set up	Hurricane Earthquake Tsunami Nuclear disaster (e.g., Chernobyl)

is generally more challenging than that of a severely injured adult. Obtaining rapid intravascular access is difficult in a volume-depleted child, and prehospital providers often resort to intraosseous access in these instances. Airway management in a pediatric patient with trauma is also significantly more difficult compared with adults and carries a higher risk of complications such as esophageal intubation and severe hypoxemia.

THE ABUSED CHILD

Child abuse is common and poses a major challenge for prehospital providers.[186] Typical injuries consistent with child abuse include injuries of different ages, atypical burns, abrasions and hematomas reflecting the form of the beating hand or instrument, shaken baby syndrome, and injuries at unusual locations (e.g., femur fracture in a toddler). A delayed or inconclusive patient history should arouse suspicion. The management goal is to guarantee the well-being of the child. In suspected cases of child abuse, the appropriate authorities must be informed and the child transferred to a hospital or another safe facility (also see Chapter 93).

PREHOSPITAL MASS CASUALTY INCIDENT MANAGEMENT AND DISASTER MEDICINE

Prehospital providers are often faced with incidents during which the number of patients exceeds the capabilities of the rescue squad or local rescue forces; examples are multiple vehicle accidents, fires, and train collisions. These incidents are called *mass casualty incidents* and are defined as having an inadequate ratio of rescuers to victims. Mass casualty incidents are different from disasters; the former can be managed by local and regional resources, whereas *disasters* can only be managed on a national level. Examples of mass casualty incidents are train collisions, and examples of disasters are hurricanes or large earthquakes or tsunamis (Table 82-1). Paramount for both is that in these mass casualty situations, the concept of *triage* must be used; that is, trying to save as many people as possible without being able to provide individual one-on-one care. This approach is necessary to identify those critically injured individuals who can benefit from immediate, life-saving interventions and to conserve resources[187] (also see Chapter 83).

The most important duty of the first team to arrive at the scene is to conduct a quick assessment of the scene including hazards, number of victims, and other pertinent aspects and to communicate this assessment rapidly to the EMS dispatch. During mass casualty events, the EMS dispatch is a crucial resource because it provides accurate and good communication that is required to mobilize adequate additional back-up resources. The initial phase of mass casualty incidents is often chaotic, and overreacting or underreacting is common. Frequent assessment errors include having multiple communicators on site (38%), misidentifying the number of victims (56%), and having unclear information for the resource physician (43%).[188] Prehospital triage information has been deemed appropriate in only one third of mass casualty events.

Concurrent with the individual EMS provider and team's rescue, triage, and treatment efforts, the EMS system will deploy logistics, coordination, and communication teams to the scene of the mass casualty incident to provide on-site local command and control abilities. Typically, this on-site control involves triage areas, where EMS physicians often play an important role in coordinating triage and medical treatment of the victims. In disasters such as hurricanes, national resources such as disaster medical assistance teams (DMAT) or National Guard troops are deployed.

In field triage, different strategies (Simple Triage and Rapid Treatment [START], CareFlight Triage, modified START) show comparable results in correctly identifying the severely injured patients (Table 82-2). In most circumstances, triage cards are used to register and classify triaged patients (Figure 82-5). Triage implies constant reevaluation of victims as conditions of the victims and of available resources continually change.[189] Patients whose injuries are so grave (i.e., traumatic cardiac arrests) that their prognosis is dismal are often classified as *expectant*, and no further medical resources are diverted to their

TABLE 82-2 **TRIAGE GROUPS IN MASS CASUALTY INCIDENTS**

With the aid of triage tags or colored flags, the patients are sorted into four groups.

Triage Tag	Assessment of Treatments Needed	Types of Injuries
Green (minor)	Minor injuries with no immediate need of treatment Psychologic support is needed Patients can walk	Wounds Minor fractures
Yellow (delayed)	Urgent treatment is needed No vital threat is present	Fractures, joint injuries Amputation, major blood loss Burns
Red (immediate)	Vital threat is immediate	Respiratory insufficiency, shock Brain trauma Burns with immediate vital threat Abdominal trauma
Black (expectant)	Patients are dead or moribund	Respiratory arrest, cardiac arrest Head injuries with dismal prognosis

Figure 82-5. Triage tag, front and back, used in field triage. Patients are assigned to one of four categories, according to the severity of their injuries and the need for immediate intervention or rapid transport to a trauma center.

care. Otherwise, these patients would likely consume large quantities of much-needed resources in a futile resuscitative effort.[190] Adequately triaged patients are then either immediately treated on the scene or transported to a hospital. The goal is to not overwhelm the closest local hospital with all victims from the scene but to intelligently, appropriately, and efficiently transfer the victims to multiple surrounding health care facilities.

Chapter 83

*The Role of the Anesthesia Provider in Natural and Human-Induced Disasters**

DAVID J. BAKER

83A *The Role of the Anesthesia Provider in Natural Disasters*

Key Points

- Disasters may be natural or human-made. Both types produce a surge of casualties that involve both anesthesia providers and intensivists.
- Of the range of natural disasters, earthquakes produce the most casualties requiring an emergency and anesthesiologic response.
- Natural disasters may affect anesthetic practice either directly, as a result of effects on hospital operation and resilience, or indirectly because of the workload from excessive casualties.

For more than 30 years, *Miller's Anesthesia* has been recognized as the most complete single resource regarding modern anesthesia. During these years, the expanding role and responsibility of anesthesia care have required a scholarly analysis of many aspects of medical care overall. In the seventh edition, the potential role of anesthesia in rare major threats to society resulted in David J. Baker's chapter, "Chemical and Biological Warfare Agents: The Role of the Anesthesiologist." This editor's memory is imprinted with radio accounts of the New York City and Washington, DC, September 11, 2001 terrorist attacks and wondering if San Francisco would be the next target. That morning, I was in charge of the operating rooms, and I and others deliberated on how to proceed and whether to leave some operating rooms open—just in case. Fortunately, San Francisco was not hit, and our decision to carry on as usual with our operating room schedules proved to be the right one. This personal experience convinced me that this chapter was and continues to be necessary. My overriding premise, shared by the associate editors, was that although most anesthesia providers will never be exposed to a terrorist attack, they should be familiar with the basic principles of anesthetic care for those "just in case" scenarios.

When planning for this eighth edition, the editors concluded that the chapter in the seventh edition was excellent, but one major component needed to be added—the role of anesthesia in natural disasters such as earthquakes and tsunamis. Some areas are known to be susceptible to natural disasters (e.g., Chile with earthquakes, the Philippines with typhoons, or the Gulf Coast of the United States with hurricanes) and, as we have experienced more recently, other locations are subject to unexpected severe weather, floods, or fires. Because of the unpredictability and magnitude of these events, anesthesia providers can be caught off guard, and for many, it may be the first time they have been called on to provide anesthesia under the strenuous conditions in a natural disaster.

The editors have concluded that this revised and updated chapter by the same author, David J. Baker, provides a global baseline of information for anesthesia providers who may be required to provide clinical emergency care in the face of these unexpected disasters and in locations with limited resources.

Ronald D. Miller

*The views expressed in this chapter are solely those of the author and do not necessarily represent those of Service d'Aide Médicale Urgente (SAMU) de Paris.

INTRODUCTION

The exact definition of disaster medicine is difficult and depends not only on the event but the nature and number of casualties. The working definition used by the World Health Organization (WHO) is "a sudden ecological phenomenon of sufficient magnitude to require external assistance." Such events can exceed a given response system.[1] A better medical approach more suited to the impact of disaster on anesthesia is a potential mass injury or event that causes illness.[1] This definition is gradually gaining acceptance. Eric K. Noji, MD, Consulting Medical Epidemiologist, Centers for Disease Control and Prevention at Johns Hopkins University, has suggested an alternative definition of disaster as "any community emergency that seriously affects people's lives and exceeds the capacity of the community to respond effectively to the emergency."[2]

Dr. Patrick Guérisse of the Emergency Department at CHU Brugmann-Brien, Brussels, has discussed several definitions of a medical disaster[3] and suggests that the term should best be reserved for situations in which the social and medical infrastructure is so damaged by the event that it places extraordinary burdens on fundamental societal functions such as law and order, communication, transportation, and water and food supply.

CLASSIFICATION

Disasters can be classified as natural or human-induced. Both affect anesthesiology and intensive care in terms of the volume of casualties with both injuries and infection. Natural disasters occur regularly and involve mechanisms related to climate and seismic activity. Human-induced disasters, however, involve the accidental or deliberate release of toxic substances and pathogens, explosions, and fire. The anesthesiologic management of conventional trauma and burns is considered in other sections of this book (see also Chapter 81). This chapter deals with the implications for anesthesia in natural disasters and of chemical and biologic agent release as human-induced disasters.

Natural disasters are events produced by meteorologic and geologic causes. These events can sometimes happen with a certain degree of warning (e.g., hurricanes) or with little or no warning (e.g., earthquakes). Natural disasters occur in both developing and developed countries but the impact on poorer nations where the medical infrastructure is already fragile magnifies the effect.

Natural disasters include the following:

- Flooding
- Heat wave
- Fires
- Storms
- Tsunamis
- Earthquakes

Of these, earthquakes are the events that produce most casualties with mass physical trauma that requires an emergency surgical response.

RESPONDING TO NATURAL DISASTER

Natural disasters affect anesthetic practice either directly, because of effects on the local hospital service, or indirectly, as a result of the excess flow of casualties to the degraded hospital facility. The consequences of natural disaster may affect services and infrastructure in developed and developing nations alike, but the effects in developing nations are usually greater and provide the biggest challenge for mounting an emergency medical response.

For anesthesia providers involved with foreign medical teams (FMTs) in nations with limited resources, special understanding and preparation are necessary for an effective intervention. Lind and associates[4] defined a framework necessary for FMTs to be regulated and organized. In the context of earthquakes, the authors define four phases of development.

- Phase 1 (approximately 72 hours): FMTs are not present; therefore, any aid has to be sourced locally during this acute phase.
- Phase 2 (4 to 21 days): FMTs arrive, establish services, and carry out operations for trauma. During the first weeks after an earthquake, trauma workload increases and nontrauma workload decreases.
- Phase 3 (4 to 12 weeks): A slow return to the usual burden of disease. FMTs are established by this phase, but the pressure of local health needs begins to predominate.
- Phase 4 (3 to 6 months): A gradual return occurs to normal functioning of the health services to predisaster levels. The length of time for return to normalcy depends on the magnitude and severity of the earthquake.

Within these phases of disaster, three levels of care are recognized:

- Basic (primary) and immediate emergency care
- Secondary (intermediate level of health care), which includes diagnosis and treatment in hospital
- Tertiary, which involves specialized highly technical care up to state-of-the art standards

Note that individual countries have very different levels of care at the predisaster level. Within this framework a cycle of disaster onset, response, and recovery has been described.[5]

THE IMPACT OF NATURAL DISASTER ON THE WORK OF THE ANESTHESIA PROVIDER

Within the phases of disaster, anesthesia providers are involved as part of the emergency surgical response teams. The overall stages in the deployment of such teams are as follows:

1. Planning and training: Establishing techniques for the use of unfamiliar equipment that is not used in everyday practice in developed nations
2. Response: The provision of anesthesia and high-dependency care at a field level
3. Recovery: Dealing with the chronic effects of trauma and reestablishing the normal local anesthetic practice

In practical terms, natural disasters have considerable implications for the anesthesia provider, including the following:

- The impact on the normal social infrastructure: Natural disasters disrupt communications and essential services, such as water and power supplies. This disruption creates a challenging background through which emergency medical services, including anesthesia, must be mobilized before any organized medical response can be mounted. The 1995 Kobe, Japan earthquake effectively cut off access to the city's main hospital by staff and casualties, because the hospital was located on a separate island from the city.[6]
- Effects on the prehospital response: After natural disasters, anesthesia providers may be involved in prehospital care as part of a standing emergency medical system (EMS), as in France, where the EMS is medicalized,[7] or as part of an onsite surgical intervention to free entrapped patients.[8] In addition, anesthesia providers may be required to provide high-quality anesthesia for the severely injured in a field hospital, where facilities may be basic and often very different from those available in the normal place of work.
- Effects within the hospital: At the hospital, mass casualties will occur requiring initial emergency care and often early surgical intervention. Time for resuscitation, investigation, and preparation of such casualties for surgery is often limited, and resources may be stretched.
- Further management of casualties in critical care: The problems caused by natural disasters are further complicated by the need for the provision of postoperative critical and high-dependency care in normal hospital surroundings, which have themselves been affected by the disaster. The complex equipment in such units depends on power and gas supplies, all of which may be disrupted by the effects of the disaster. Nevertheless, critical care must still be provided for victims of both physical and toxic trauma alike.[9]

It is essential that emergency medical response by national teams be part of a coordinated international response, preferably at the request of the nation affected by the disaster. A piecemeal, "disaster tourism" approach with a short stay and no postoperative patient follow-up presents problems that have been highlighted by van Horning and colleagues.[10]

RESPONDING TO A NATURAL DISASTER: PRACTICAL CONSIDERATIONS

PREPARATION AND PLANNING

Anesthesia providers, including nurse anesthetists, will be involved in phase 2 of disasters as members of the field surgical teams. Planning and preparation of necessary equipment is essential, preferably as part of an existing special response plan that was established before a disaster occurs. The Haiti earthquake of 2010 provided lessons for emergency responders, including that a coordinated effective field response can be created quickly from a major academic center with no special planning for a disaster response in another country.[11] In addition to the preparation logistics, the anesthesia provider must be familiar with the manifesting pathophysiology of victims of natural disasters, which include crush injury, penetrating and blunt trauma, acute lung injury, burns management, drowning, and near drowning. These are characteristics of the specialty of disaster medicine.[12]

TRAINING

Apart from the need for disaster management planning, EMS teams require special training and experience on the available equipment used in disaster situations and the techniques involved in anesthetic care, which are very different from those used in everyday practice in developed countries. For those with military and humanitarian aid experience or who have worked in developing nations where facilities are often basic, the transition to emergency circumstances will be familiar. However, many anesthesia providers have never worked outside the setting of a sophisticated modern hospital with facilities and abilities to support complex high-technology equipment. This group will require training that familiarizes them with the relatively basic equipment and facilities of field anesthesia.

The practical aspects of field anesthesia are discussed later in this chapter.

PREHOSPITAL ON-SITE EMERGENCY CARE

Anesthesia providers may be involved in the onsite management of casualties. This may be as a result of entrapment (such as after earthquakes and collapsed buildings) in which anesthesia may be required for extraction (emergency amputation). Usually, specialist teams are deployed for this purpose. In France, special teams that are part of the prehospital emergency response system, the Service d'Aide Médicale Urgente, are deployed for disaster management as part of their national policy of bringing the hospital to the patient.[13] The equivalent in a paramedical system is the United Kingdom's Hazardous Area Response Team and Urban Search and Rescue Teams (USARs),[14] which can be supplemented by medical teams as required. Also, military medical teams are usually qualified. Such teams are able to provide immediate triage; assessment; and medical care, including surgery.

EARTHQUAKES: A SPECIAL DISASTER SITUATION

Earthquakes are a major cause of death and injury. Over 1 million deaths as a result of seismic activity have been recorded over the past 40 years.[15] Earthquakes affect both developed and developing nations, and in both cases social and medical infrastructure are affected. The effects on developing nations with an often fragile infrastructure are potentially greater. Earthquakes are sudden-impact disasters that strike quickly and without warning. These

are caused by shifts in the plates that form the crust of the earth, known as tectonic plate shift. Where plates meet, fault lines occur that determine the sites of potential earthquakes.[16]

The factors affecting the outcome of an earthquake are as follows[16]:

- Strength of the earthquake
- Degree of planning and preparation
- Local geologic conditions
- Building design
- Demographics: Many densely populated areas exist along fault lines

The strength of an earthquake is measured using the Richter scale. This scale is logarithmic between 1 and 10. A change of one unit on the Richter scale is equivalent to a 10-fold change in ground motion and a 32-fold change in radiated energy. Earthquakes are measured using instrumentation, observation of human effects, or both. Earthquakes above 5 on the Richter scale cause damage. Those above 7 are regarded as major earthquakes. The 2011 northern Japan earthquake registered 8.9 on the Richter scale and triggered a massive tsunami with 30-foot waves that swept inland for 3 miles resulting in the loss of 15,000 people and creating a nuclear meltdown at Fukushima.

THE PREHOSPITAL RESPONSE AFTER AN EARTHQUAKE

Earthquakes can cause injury from the direct effects of the release of energy leading to structural damage and secondary effects from sequelae such as fires, landslides, floods, tsunamis, and the release of toxic substances. Also, health care facilities may be damaged. They must be inspected immediately, before care is given.

The key problems in prehospital casualty management are as follows:

- Hospital autoreferral: Earthquake casualties who are not trapped often take themselves to the nearest hospital, which can rapidly overwhelm the available medical facilities. At times, inappropriate referral (e.g., many patients without significant injury may autorefer to major trauma centers), leads to the inappropriate use of resources.[17]
- Communications: Early breakdown or overload of standard communications systems such as mobile telephones and the internet may occur. Often an overreliance on these systems is seen, and they have not proved resilient under disaster conditions. A further identified problem is the lack of standardization of radiofrequencies among emergency responders.
- Transportation and social infrastructure: Earthquakes may cause direct effects on links to major regional hospitals as was the case in the 1995 Kobe earthquake.[7] In addition, in poorer countries, airport and air traffic capacities may rapidly be overrun as in the 2010 Haiti earthquake.[18] This had a major impact on teams trying to enter the country to provide emergency medical help.
- Entrapment: Most of the fatalities from earthquakes are a result of injury from collapsing buildings or entrapment in the ruins. Death rates rise 67-fold and injury rates rise 11-fold for trapped victims in contrast to those not trapped but injured. Ninety percent of deaths in earthquakes occur as a result of structural collapse.[19] Survival rate decreases with entrapments longer than 24 to 48 hours after the earthquake. A study of more than 3000 earthquake survivors after the 1980 earthquake in Irpinia, Italy showed that 93% of those who were trapped and survived were extricated within the first 24 hours. In contrast, 95% of those who died did so before they could be extricated.[20] The provision of advanced life support in airway, ventilation, and circulatory management is an essential part of the primary rescue response for casualties. In entrapment cases, the anesthesia provider not only administers anesthetics but also general anesthesia and sedation to aid extrication.
- Triage: Triage of earthquake casualties is essential, particularly in settings where medical care is limited. Several systems of triage have been developed, and the anesthesia provider should be familiar with these. Of these, the Simple Triage and Rapid Treatment (START) system is probably the most familiar and has been evaluated.[21] This system emphasizes essential lifesaving measures, but rescuers are instructed not to provide any definitive care procedures at the scene.
- Delays in the delivery of emergency care: Many victims from earthquakes die because of delays in the delivery of lifesaving emergency medical care. Special urban search and rescue teams (USARs) have now been set up around the world and are ready for immediate response in their home country and for rapid deployment elsewhere. The problem still remains in the delays associated with dispatching the teams. Studies have shown that USAR teams require 24 hours for deployment within the United States and longer for international missions. As an example, the first U.S. team to deploy in Turkey after the 1999 earthquake required 48 hours to begin operations.[16]

HOSPITAL RESPONSES

Earthquakes have a direct impact on hospital services,. aggravating an initial imbalance of demand for medical care and surge capacity,[7] particularly evident in a developed country, Japan, with the 2009 Kobe earthquake.[7] All operating services are disrupted, including anesthesia, with loss of power, water, piped gas supplies, and internet technology systems. Most major hospitals around the world now have a general disaster plan. For hospitals within earthquake zones, this plan should be specially modified. It is important that hospital sustainability be a part of any disaster plan.

Other major obstacles delaying the immediate response in hospital include being able to contact off-site staff and arranging their transportation to the facility.

PATIENT MANAGEMENT

In both the developed and developing nation settings, a patient identification and tracking system should be started as soon as possible. In the early stages, identification numbers may have to be assigned until true identities

can be established. Anesthesia providers and surgeons should be aware of the patient flow pattern to hospital, to plan the best use of operating facilities. The following pattern of patient flow to hospital is described by Schutz and Deynes.[16]

- Thirty to 60 minutes after the tremor: Walking wounded with minor injuries and lacerations. These patients should be quickly evacuated to an observation area. Treatment should be postponed until a more detailed appraisal is available.
- More than 60 minutes after the tremor: Victims with more serious injuries such as crush. These patients will be accompanied by paramedical staff or other emergency medical responders and may have received some treatment in the prehospital zone. This wave of casualties may rapidly overwhelm the available hospital resources, and further triage is essential at this stage. The START system mentioned previously will not discriminate between those injured who will consume large quantities of limited supplies and those whose prognosis will remain poor, despite aggressive treatment. To overcome this problem a modified system of triage, Secondary Assessment of Victim Endpoint (SAVE), has been introduced. The objectives of this system are to reduce victim mortality and ensure that resources will be allocated only to those who will benefit from them.[22]

SPECIFIC INJURIES AND ANESTHETIC IMPLICATIONS

Earthquakes will produce a wide range of traumatic injury. Major injuries include skull fractures and intracranial hemorrhage, spinal injuries, and intraabdominal and pelvic trauma. Studies of previous earthquakes have revealed the following major medical complications of trauma:

- Hypothermia
- Wound infection
- Gangrene
- Sepsis
- Acute respiratory distress syndrome (ARDS)
- Exacerbations of chronic pulmonary disease, such as asthma
- Myocardial infarction
- Multiple organ failure
- Crush syndrome

Crush injuries are a major cause of fatality after earthquakes. The mortality from crush syndrome among those requiring renal dialysis may reach 40% or more.[23]

The following life-threatening conditions may arise as a result of crush injury:

- Hypovolemic shock
- Lactic acidosis
- Rhabdomyolysis
- Acute renal failure
- Hypocalcemia
- Hyperkalemia
- ARDS
- Disseminated intravascular coagulation
- Fatal cardiac arrhythmias

The possibility of hyperkalemia is of particular importance given the need in some cases for rapid sequence intubations using suxamethonium (succinylcholine).

FIELD ANESTHESIA

Natural disasters can challenge anesthesia providers because of the need to manage large numbers of casualties over a short period. In essence, standard anesthetic practice has to be followed but in an abbreviated and simplified format in terms of assessment of the patient and the anesthetic techniques used.

RESUSCITATION AND TRIAGE

Disaster anesthesia providers must be familiar with systematic standardized trauma management systems (e.g., Advanced Trauma Life Support [ATLS]),[24] which are used to provide a unified system of care to the victims. Box 83A-1 presents the conventional guidelines for resuscitation and triage of mass casualties (also see Chapters 81 and 108).

PREOPERATIVE ASSESSMENT

History

In the management of mass casualties in the field, a basic and consistent system of preoperative anesthetic management is required. If the patient is conscious, a rapid history can be taken following the AMPLE mnemonic, as follows[11]:

- **A**llergies/Airway problems
- **M**edications (either taken or given on site)
- **P**ast medical history
- **L**ast meal
- **E**nvironment/event

Every patient to undergo emergency anesthesia in the field must be considered to have a full stomach. Injury causes delayed gastric emptying, and normal gastric clearance times may not be appropriate.

BOX 83A-1 ***Primary Responses for Casualties of a Natural Disaster***

RESUSCITATION

Airway maintenance with cervical spine protection
Breathing and ventilation (including the management of chest injury)
Circulation with control of hemorrhage
Disability or neurologic status (AVPU scale)
Exposure (undress the patient for full examination of primary and secondary injuries)
Environment (avoidance of hypothermia and security of the working area)

TRIAGE

P1 Requiring immediate lifesaving surgery
P2 Surgery can be delayed up to 2 hours
P3 Ambulant injured: Treatment can be delayed by several hours
P4 Expectant

AVPU, Acronym for alert, voice, pain, unresponsive.

Physical Examination

Little time may be available for a complete physical examination of the patient before anaesthesia. Instead, an abbreviated essential examination should be used as a basic response. This examination involves the following:

- Measurement of vital signs
- Airway evaluation
- Examination of the heart and lungs
- Evaluation of hemorrhage and hypovolemia
- Assessment of chest, abdominal, and other injuries

FIELD ANESTHETIC EQUIPMENT AND TECHNIQUES

Sophisticated anesthetic workstations typical in developed nations are unlikely to be available or usable at or near the disaster site because of damage to the infrastructure. Therefore, the need exists to be familiar with basic anesthetic equipment designed to work in extreme conditions and equally basic and safe anesthetic techniques. Resources such as bottled gases and power may be in very short supply or nonexistent, so equipment must be used that takes this into account. Anesthetic equipment to be used in natural disasters must meet the following standards:

- Simple to operate
- Rugged and reliable
- Easily transportable

Anesthesia providers in the nineteenth century used simple inhaled anesthetic techniques that could be used in the hospital or outside. Field anesthetic equipment has developed along the lines of simplicity and preservation of the approaches of the early anesthesia providers. Development has been driven by the military, which has a requirement to provide safe general anesthesia in battlefield surroundings.[25] However, providing care in remote areas away from mainstream hospitals presents problems because many anesthetic providers do not have the experience with the equipment or techniques of field anesthesia; also, the equipment used is absent from standard hospital practice and thus, providers are not likely to have acquired necessary skills.

USING FIELD ANESTHETIC EQUIPMENT

Field anesthetic equipment sets should be assembled and used for training before disasters occur. This practice may raise complications with current hospital procedures and regulations where the daily practice is to use sophisticated modern equipment. However, it is necessary that anesthesia providers be completely familiar with the equipment and adept at field techniques before deploying to the site of a disaster.

Field anesthetic equipment sets should contain at minimum the following items:

- Torches and emergency lighting
- Airway management
  - Handheld wide-bore suction device
  - Laryngoscopes: Conventional and visualization devices (see also Chapter 55)
  - Endotracheal tube and laryngeal mask airway
  - Cricothyroidotomy sets
- Essential monitoring
  - SpO_2, electrocardiogram, end-tidal carbon dioxide, and noninvasive blood pressure monitoring devices. These devices are available in a portable form suitable for use in field anesthesia.

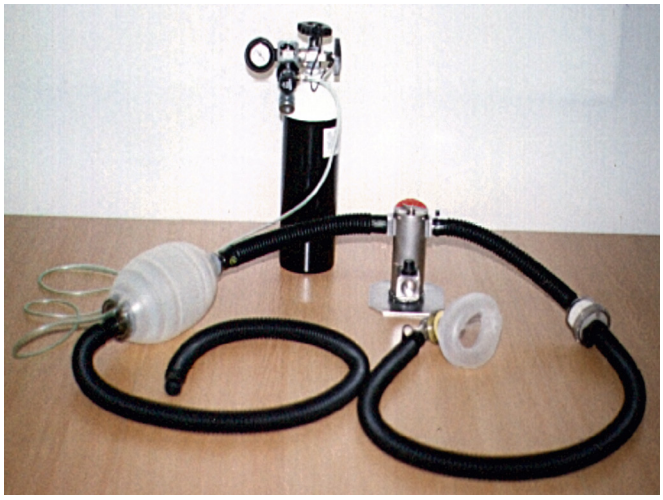

Figure 83A-1. The British Triservice anaesthetic apparatus (TSA). The TSA achieved great success, notably during the Falklands War.

FIELD ANESTHESIA SYSTEMS

A number of field anesthetic systems have been developed (see also Chapter 29). Only two will be mentioned here as representative of the origins and development of field anesthesia. The British Triservice anaesthetic apparatus (TSA) was developed over 35 years ago (Fig. 83A-1). In its simplest form, the circuit relies on draw-over of air as a carrier gas. Originally two vaporizers containing trichloroethylene and halothane were placed in series. Oxygen from a compressed source was supplemented via a regulator and a T-piece. Later the circuit was modified to be used in a ventilatory mode with a self-inflating bag placed distal to the vaporizers. The discovery in 1992 that the vaporizers performed equally well in the draw-over and plenum modes allowed the circuit to be modified with a portable ventilator driving air across a single vaporizer containing isoflurane.

The TSA anaesthetic apparatus achieved great success, notably during the Falklands War[26] and is still widely used around the world. However, it suffers from the disadvantage that the Oxford Miniature Vaporiser 50 (OMV 50, Penlon, Abingdon, United Kingdom) cannot be used with modern anesthetics such as sevoflurane because of the physical characteristics.

A more recent field anesthetic system that uses standard plenum vaporizers is the Magellan machine (Oceanic Medical Products, Atchison, Kan.) (Fig. 83A-2). The Magellan can supplement the level of O_2 in the anesthetic gas using a bottled source or an O_2 concentrator. In this way, precious gas resources are conserved. The main driving gas used in the system is again air, but there is a field anesthetic ventilator (ComPac,

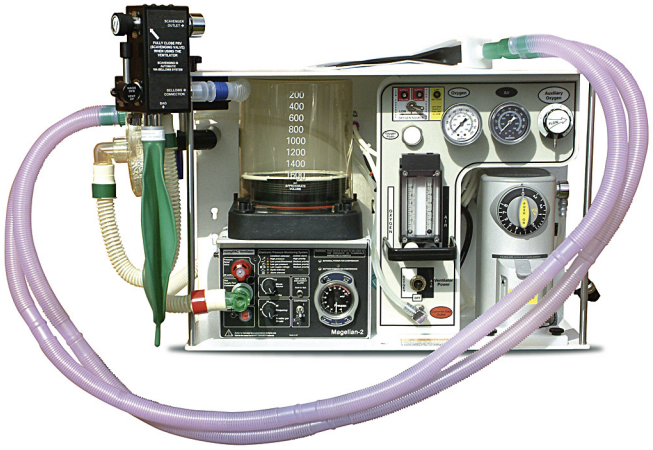

Figure 83A-2. The Magellan anesthesia machine. *(Courtesy Pneupac Ventilation, Smiths Medical International, Luton, United Kingdom.)*

Pneupac, Smiths Medical International, Luton, United Kingdom) built-in that can run from a variety of power sources, including a 28-V vehicle supply (Fig. 83A-3). This turns the Magellan into a plenum system using standard vaporizers without the need for a compressed gas supply

ANESTHETIC TECHNIQUES FOR USE IN NATURAL DISASTERS

No set rules exist for which technique of general anesthesia should be used in disasters. The following factors are used in making the choice:

- Familiarity of anesthesia providers with basic equipment and the ability to train on it in their standard daily practice
- Circumstances and infrastructure
- Availability of anesthetics and equipment that are found in both the developed world and developing nations and, therefore, are familiar to anesthesia providers who may find themselves responding to disasters in developing countries
- Considering the potential workload and the requirement in mass casualty management to provide the greatest good for the greatest number

In general, in extreme disaster conditions only a limited role exists for local analgesic procedures and for epidural and spinal anaesthesia given the collapsed preoperative condition of many of the patients and the nonsterile conditions that often apply. However, in some situations, regional anesthesia techniques have been used successfully before general anesthetic capability is established.[27]

All patients receiving field general anesthesia should be regarded as having a full stomach; therefore, a full rapid sequence induction of anesthetics is required followed by tracheal intubation. Thereafter, a balanced technique should be employed with muscle relaxant, opioid, and ventilation. The actual choice of anesthetics to be used will depend on circumstances and national availability. Drugs requiring refrigerated storage (e.g., suxamethonium chloride/succinylcholine) may not be usable, and

Figure 83A-3. The CompPac portable gas-powered emergency and transport ventilator for use in contaminated environments. *(Courtesy Pneupac Ventilation, Smiths Medical International, Ltd, Luton, United Kingdom.)*

alternatives that are stable at room temperature should be sourced.

The anesthesia technique should be designed to minimize the time spent in postoperative recovery and should aim for awake extubation of the trachea at the end of the surgery. Sufficient analgesia should be given until this can be continued by nursing care.

Anesthesia providers working in developing nations may find that modern anesthetics with suitable rapid induction and emergency profiles may not be available, even in normal practice. Here basic inhaled anesthetics such as ether or halothane, often long since discarded in developed nation practice, may be in daily use. A revision of the properties of such anesthetics should therefore be part of disaster training for anesthesia providers.

INDUCTION OF GENERAL ANESTHESIA IN FIELD ANESTHESIA

The use of intravenous anesthetics depends on availability and experience. Propofol, which has achieved dominance over intravenous barbiturates such as thiopental in recent years, may not be the ideal drug of choice in disaster settings. It is dispensed in solutions that can easily become contaminated in the potentially nonsterile conditions that may prevail in disaster management. However, where circumstances of sterility and storage permit, propofol may be appropriate for rapid procedures such as wound dressing change and burn debridement. Because

BOX 83A-2 *Properties and Administration of Ketamine*

Advantages

Can be given intramuscularly or intravenously as a bolus or infusion
Stable and does not require refrigeration
Basic airway management often can be used with the need for assisted ventilation
Bronchodilator
Analgesic
Rapid recovery

Disadvantages

May be associated with laryngospasm
Increased secretions
Risk for emergence hallucinations (author's note: These are rare in extreme disaster conditions and with children, and they can be controlled using benzodiazepines)

Duration of Anesthesia

Clinical effect up to 30 minutes from bolus depending on dose
Elimination half-life: 2 to 3 hours

Dosage (Adult)

Intravenous induction dose: 1 to 2 mg/kg
Maintenance doses: 0.1 to 0.5 mg/min or half the initial induction dose
Continuous infusion: 10 to 30 mcg/kg/min

of cost, propofol may not be readily available in certain developing nations.

Ketamine, a short-acting but potentially hallucinogenic anesthetic that has been in service for several decades, still remains one of the most useful and safe anesthetics for field anesthesia. Its properties and use are shown in Box 83A-2.

VENTILATION IN THE FIELD AND WHERE HOSPITAL FACILITIES ARE DISRUPTED

Ventilation in the austere conditions that surround disaster requires planning before entering the situation. Ventilation is required as part of emergency balanced anesthesia and for postoperative care in some cases. Consideration must be given to the use of ventilators that are suitable for disaster conditions where main power and compressed gas supplies may be absent. Most hospital ventilators, including those in anesthetic workstations, are not suitable for this setting.

Anesthesia providers should therefore be familiar with portable gas or battery-powered ventilators suitable for use in disaster conditions. A wide range are available, and the following factors are important to consider: (1) Familiarity. Is the device used or known in standard practice? (2) Simplicity of operation. Does the ventilator have the absolute essentials for field use? In disaster anesthesia, most ventilation is part of balanced anesthesia to ensure a rapid recovery and throughput of cases. Thus, complex ventilation modes used in hospital practice are not required. Pneumatic portable ventilators that offer flow generation, time cycling, and preset volume delivery have been tried and tested in field conditions and have been widely used by the military in recent battlefield operations. The Pneupac ComPac ventilator (Pneupac Ventilation, Smiths Medical International, Luton, UK) shown in Figure 83A-3 is a good example of a device that will function without the requirement for compressed O_2 and with a variety of field available power sources.[28]

83B *The Role of the Anesthesia Provider in Chemical and Biologic Warfare Injuries*

Key Points

- The management of chemical and biologic warfare (CBW) injury is a continuing process from the site of release to the hospital. The anesthesia provider may be involved at all stages from the provision of essential early life support through intensive care unit care.
- CBW management requires advanced life support and other specialized skills that are part of the anesthesia provider's sphere of operation.
- CBW injury should not be approached in isolation from the many clinical lessons that already exist from accidental hazardous materials (HAZMAT) releases and natural epidemic infections. CBW release poses a risk to the medical responder, and he or she should be trained and equipped to operate safely in a contaminated or infected zone.
- Chemical and biologic hazards form part of a continuous hazard spectrum. Agents from different parts of the spectrum may have common effects on susceptible somatic systems. Because detection of a released agent may not be immediate, response should be passed on presenting signs and symptoms and may require the provision of life support.

KEY POINTS—cont'd

- Each hazard in the spectrum has four key properties: toxicity, latency, persistency, and transmissibility. The first two determine the management of the patient, and the second two determine the management of the incident.
- A wide range of suggested potential hazards (often loosely described as threats) have been suggested in a climate of apprehension because of the possibility of terrorist attack. On the basis of preexisting military and intelligence information, these potential hazards can be refined down to provide a framework of genuine hazards and management protocols that can be applied across the hazard spectrum.
- CBW agents should not be regarded medically as weapons of mass destruction; instead, they are agents that may cause mass injury. Early life support and specific therapy can break the link between mass injury and mass loss of life.
- Most of the toxic hazards likely in civil life are part of the U.N. HAZMAT classification. Planning for accidental industrial releases is relevant to the management of deliberated CBW release.
- Toxic agents have been used in both military and civil releases over the past 35 years and currently should be regarded as a potential terrorist threat.
- Management of exposed patients depends on the protection of medical responders, early provision of life support, and specific antidote and antimicrobial therapy. Decontamination of patients may cause delays in starting treatment and is not always necessary. Essential advanced life support for acute toxic injury (TOXALS) should be given during decontamination if required. Mass ventilation capability in the hospital is important in the management of respiratory failure from accidental and deliberate chemical and biologic causes.
- Military chemical warfare agents, such as nerve agents, vesicants, pulmonary edemagens, cyanides, and certain toxins, pose the greatest hazard in civil releases. Many industrial chemicals are equally hazardous.
- Classic biologic warfare agents, such as anthrax and plague, manifest as a deliberately induced epidemic with far longer latencies than chemical warfare attack. Anesthetic involvement is usually at the intensive care stage.
- Lessons learned from the current fears of deliberate toxic release will have value for the management of the increasing number of accidental individual and mass toxic exposures that form the greater risk for human life in the twenty-first century.

INTRODUCTION

Until recently, the effects of exposure to chemical and biologic warfare (CBW) agents was a remote area of clinical practice that concerned military specialists, microbiologists, and toxicologists. Since the World Trade Center attack in New York City in September 2001, the level of concern has increased about the possible impact of CBW agents released by terrorists on a civilian population. The attacks in London in July 2005 involved the use of high-explosive devices in a confined space. Toxic effects occurred, and the use of a chemical device by the terrorists was considered by the emergency responders. Anesthesia providers from the helicopter emergency service were among the first to treat the injured onsite.[29] With the continuing real threat of the use of CBW agents by terrorists, anesthesia providers have become more involved in the prehospital and hospital management of CBW injuries. As a result, CBW casualty management, previously dominated by considerations of toxicity and pathogenicity, now includes considerations of modification of outcome by provision of early and continuing life support.

This section discusses the anesthesia aspects of management of casualties who may have been injured or infected after a deliberate exposure to CBW agents. Important lessons for management of CBW incidents can be taken from plans for accidental toxic releases. In some countries, anesthesia providers are part of the initial emergency medical response and are trained in the essentials of personal protection and decontamination.[30] They also may be involved in the initial reception of contaminated casualties at the hospital itself, particularly when autoreferral occurs.[31] Casualties with toxic injuries also may have conventional injuries requiring surgery, and this brings a whole new dimension to the management of operative anesthesia, modified by the effects of a toxic agent. Finally, many of the victims from a CBW attack require immediate and long-term ventilation and other intensive care, which is an area in which anesthesia providers and intensivists are actively involved.

In this chapter, the nature and management of chemical and biologic hazards will be approached first by considering their definition and classification and second by discussion of the properties of key representative agents in terms of pathophysiologic effects. A wide range of potential CBW hazards exist that have been the subject of exhaustive literature, and it is not the intention here to repeat specialized information. Instead, key features of representatives of various classes of hazard are discussed from the standpoint of anesthetic and intensive care practice. Finally, the practical aspects of the involvement of the anesthesia provider and intensivist in management of CBW agent release will be considered. This discussion covers the management of the patients and safe operation during the incident, including detection of release, protection of responding personnel, and decontamination.

APPROACHES TO THE LITERATURE

Many different specialties—both scientific and clinical—have been involved in the study of CBW for over a century. The literature is very extensive and covers a wide clinical range. Of the specialties involved, toxicology, microbiology, and occupational health have been the most dominant and have left their particular influences. Much of the literature relevant to CBW agents predates the Medline era and is not readily accessible from this source. Fortunately many reviews and books exist, particularly in the exhaustively studied area of cholinergic transmission, which makes the careful and relevant work of early researchers still easily accessible to modern anesthetists.[32-38] The reader is advised to consult these resources to gain a working background of the nature of CBW agents.

EVIDENCE-BASED STUDIES

The study of CBW agents in humans has been less extensive than human studies in other areas of clinical medicine. This is understandable because prospective studies that involve exposure of human subjects either willingly or otherwise have been strictly controlled or proscribed by international convention. Despite this, a large amount of information exists in the literature from early clinical volunteer studies and from accidental exposures to chemical warfare agents and many unpublished or previously inaccessible reports are now openly available.[36] In the biologic warfare field, recent reviews are available,[39-41] along with valuable continuing clinical study in the parallel field of accidental (rather than deliberate) infection together with literature on the development of antimicrobial and antiviral agents, which is of immediate relevance to biologic warfare release.

SECRECY

Although considerable information about the pathophysiology and management of CBW cases exists in the open literature, it is highly likely that far more information is still classified by governments involved in the subject and is not easily accessible.[36] Nevertheless, much historical information is available from time-declassified government sources[42] and from searching the sources provided by the *Freedom of Information Act* in the United States. Other nongovernmental organizations, such as the Stockholm International Peace Research Institute, have published extensive information, although this information may have a political bias.[43] By far the most research on CBW agents was carried out by the Soviet Union (Union of Soviet Socialist Republics [USSR]) during the Cold War, and large amounts of this remain unpublished. However, Soviet scientists involved in programs such as Mikrobioprom[44] and the application of genetic engineering to CBW openly published many articles on techniques; these can be accessed through the databases because the major part of the Soviet program started after the signing of the 1972 biologic warfare Treaty,[45] which led to the discontinuation of biologic warfare research by the West.

DEFINITIONS

CLASSIC DEFINITIONS OF CHEMICAL AND BIOLOGIC AGENTS

The accepted classic definition of a chemical warfare agent is a chemical substance that is intended for use in military operations to kill, seriously injure, or otherwise incapacitate people through pathophysiologic effects.[46] Traditionally, riot control agents and herbicides were excluded from this definition, although they have frequently been used in a way that would be compatible with the definition of a chemical warfare agent. Biologic agents were defined by the 1972 biologic warfare treaty as living organisms, whatever their nature, or infective material derived from them, intended to cause disease or death in humans, animals, or plants.[45] Toxins, which are essential part of the pathophysiologic process in bacterial infection, were excluded from the biologic warfare treaty and are regarded essentially as chemical agents.

THE CHEMICAL-BIOLOGIC HAZARD SPECTRUM

Although chemical and biologic agents have traditionally been separated, it is appropriate medically to regard them as part of a continuous spectrum of hazards; this is shown diagrammatically in Figure 83B-1.[47] Agents in Figure 83B-4 are arranged in ascending order of molecular weight through chemical toxic agents through to self-replicating agents such as bacteria and viruses, on the right. The spectral approach to hazards is useful in emphasizing that agents from different parts of the line act in a similar way on the body. The failure of the neuromuscular junction caused by nerve agent anticholinesterases and botulinum toxin is a good example. Bacteria exert their toxic effects through toxins that may affect various somatic systems. The spectral approach serves as a reminder that medical management of CBW injury should respond primarily to system dysfunction rather than to specific etiologic factors.

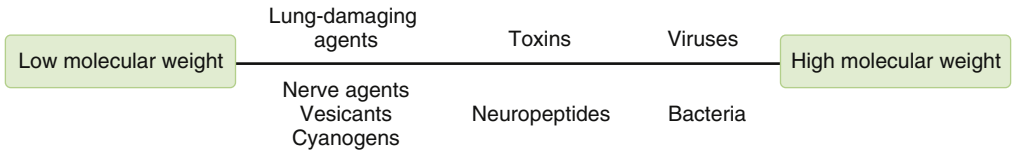

Figure 83B-1. The chemical-biologic hazard spectrum. Agents originally classified as chemical or biologic are arranged in order of ascending molecular weight. Toxins, originally classed as biologic agents, occupy the middle of the spectrum, together with neuropeptides, which normally act as transmitters in the central nervous system. These agents, sometimes called agents of biologic origin, can be synthesized using genetic engineering techniques. *(Modified from Baker DJ: Anesthesia in extreme environmental conditions. Part 2. Chemical and biological warfare. In Grande CG, editor:* Textbook of trauma anesthesia and critical care, *St. Louis, 1993, Mosby–Year Book, p 1331.)*

ESSENTIAL PROPERTIES OF CHEMICAL AND BIOLOGIC WARFARE AGENTS

The four essential properties of hazards within the CBW spectrum are toxicity, latency, persistency, and transmissibility.[38] These four characteristics are common to both chemical and biologic agents and determine the degree of risk and the appropriate response. Toxic effects of CBW agents appear to have a specific latent period. In general, chemical agents and toxins have short periods of latency before the appearance of specific signs and symptoms. In contrast, classic biologic warfare agents have extended latency periods (usually familiar as incubation periods) before the effects of the induced disease begin to appear. Persistency relates to the ability of a toxic agent to remain in the environment into which it was released and is a function of the physicochemical properties of the agent. For chemical agents, the persistency may vary, but for most biologic warfare agents, with the exception of spore-forming agents such as anthrax, persistency is usually very short. Finally, transmission of a hazard may take place as a result of the physical contamination of the victim from a persistent chemical agent or as a result of infection in the case of an airborne agent. Chemical transmission can be contained by decontamination, but biologic warfare agent transmissibility is more difficult to control because of continuing activity.

In summary, toxicity and latency determine the management of the casualty, and persistency and transmissibility determine the management of an incident involving the release of a CBW agent.

TOXICITY AND ITS MODIFICATIONS

Toxicity is usually expressed in terms of median lethal dose (LD_{50}) or LCt_{50}, where C is the concentration of agent inhaled for time (t) required to produce lethality in 50% of the exposed population. LD_{50} usually relates to toxicity via injected routes. In the case of most chemical agents, the inhaled route is usual, so expressions of concentration and time are used.

Haber defined a *lethality coefficient* as follows:

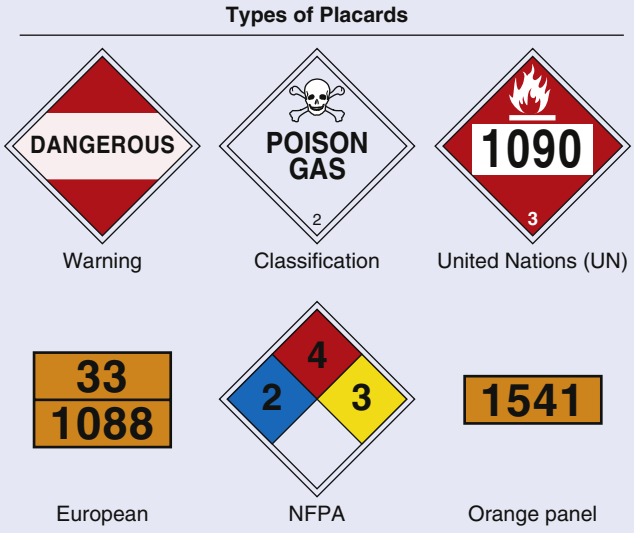
$$W = C \times t$$

where C is the inhaled concentration of toxic agent and t is the time of exposure. In practice, the absorbed amount of agent depends on the respiratory minute volume of the exposed person. This is just one factor modifying the expression of toxicity. Others include life support responses in the case of respiratory failure and the effects of antidotes. The reader is referred to specialized texts for a more detailed discussion.[36]

THE NUCLEAR, BIOLOGIC, AND CHEMICAL WEAPONS CLASSIFICATION

Since the end of World War II, nuclear, biologic, and chemical weapons have by convention been classified together as "NBC" agents, giving rise to a new subsection of warfare, which was developed by both sides during the Cold War. Although all three components are "toxic," the classification ignored the very intense level of physical damage caused by nuclear explosions. Over the years, the term *weapons of mass destruction* (WMDs) has been applied to NBC agents, although the term was originally used by the United Kingdom at the end of World War II.[42] Recently, the term NBC has been altered to reflect the threat perception from the use of explosive devices that can spread radioisotopes (rather than create them as in a fission process) into chemical, biologic, radiologic, and nuclear (CBRN) hazards. CBW agents are defined by their effects after mass release on large populations. The term is not usually applied to the use of such agents for individual or small group poisonings.

MYTH AND REALITY OF CHEMICAL AND BIOLOGIC WARFARE AGENTS AS WEAPONS OF MASS DESTRUCTION



At the end of World War II, the Tizard report[42] appeared, which looked at the future potential of nuclear and biologic weapons, both of which had been used during that conflict. The term *weapons of mass destruction* appears to have been used for the first time in this report because it was thought that both agents would cause mass loss of life. Chemical weapons were added to this group during the 1950s, when the equilibrium of international power depended on analysis of the possession of the three WMD agents. In retrospect, however, the WMD classification is (at least medically) inappropriate. Consideration of the events of World War II showed that nuclear weapons should be classified with conventional weapons systems that cause mass loss of life and destruction to material and the environment, such as the conventional high explosive and firebombing of Germany in the latter part of the war.

CIVIL TOXIC HAZARDS (HAZMAT)

Parallel to the definitions of CBW agents is a classification of hazardous materials used in everyday industrial life. These are usually released by accident. Many of these are as toxic as chemical warfare agents. Such toxic substances are classified as hazardous materials (HAZMAT) and are covered by the U.N. convention controlling the use and transportation of such materials (Box 83B-1).[48,49] A HAZMAT material is defined as that which causes mass injury and death if released from a confined state. The civil equivalent of biologic warfare agent release is natural infection expressed as an epidemic. Another term for HAZMAT is toxic industrial chemicals (TICs). TICs are substances that could be used as improvised chemical agents in a terrorist attack.

BOX 83B-1 *HAZMAT System of Classification*

The U.N. hazardous materials classification for toxic substances (HAZMAT) defines nine classes of hazard. These are identified during production and transportation by a class number and a hazard identification number. Vehicles carrying compounds controlled by HAZMAT must display a plate (the Kemler plate) that carries this essential information for the use of emergency responders. The form of the Kemler plate varies internationally.

Class	Subclass	Hazard Type
1		Explosives
	1.1-1.5	Mass explosion hazard Very sensitive substances
2	2.1	Flammable gases
	2.2	Nonflammable nontoxic gases
	2.3	Toxic gases
3		Flammable liquids
4	4.1	Flammable solids
	4.2	Spontaneous combustion
	4.3	Dangerous substances when wet
5	5.1	Oxidizing substances other than organic peroxides
	5.2	Organic peroxide
6	6.1	Poisons
	6.2	Infectious substances
7		Radioactive substances
8		Corrosive substances
9		Other dangerous substances

NFPA, National Fire Protection Association.

AGENTS OF CHEMICAL AND BIOLOGIC WARFARE: BACKGROUND AND DEVELOPMENT

WORLD WAR I

Chemical agents were used from 1915 to 1918 in World War I. Their use was catalyzed by the battlefield stalemate of trench warfare. They do not fit well with the tactics of a mobile war, which was the case in World War II. Large-scale releases of chlorine and phosgene in 1915 had considerable effects against unprotected troops and caused large numbers of casualties and deaths. It was these early attacks that probably gave rise to the notion of CBW agents being weapons of mass destruction. In fact, chemical weapon injury produced the lowest ratio of dead to wounded of all the arms used during the war at less than 4%,[42] whereas explosive shells had the highest ratio at over 15%. Artillery caused 59% of the overall mortality on all sides. Many different chemical agents were tried during the war, delivered usually by shell fills, but the difficulty was in building sufficiently high concentrations of agent to be lethal and the continuing countermeasures meant that better trained troops with masks were less affected. Although phosgene easily could be regarded as the most lethal of the agents used, causing untreatable toxic pulmonary edema, mustard gas, a vesicant disabling agent, caused the most injuries and removed many from the field of battle (usually temporarily). One overlooked feature of the casualties from World War I is the possibility of mixed toxic and physical trauma. The exact figures are not available, but of 546 American soldiers who died after exposure to chemical warfare agents during the period March to November 1918, 6% also had ballistic injuries.[50] The figures for dead and wounded do not reveal the true extent of the disability caused by exposure to toxic agents, and it is likely that the long-term pathology was high, particularly given the limited postwar medical facilities at that time.

DEVELOPMENT AND USE OF CHEMICAL AND BIOLOGIC WARFARE AGENTS DURING WORLD WAR II

Organophosphate pesticide research by Gerhard Schrader in 1936 led to the development of anticholinesterase "nerve agents" by Germany under conditions of the strictest secrecy during World War II. Although never used in action during that time, nerve agents became the major toxic hazard faced by armies during the Cold War and beyond.[42] A major nerve agent plant was captured by the Russians and rebuilt in the Soviet Union in 1945, giving the USSR a "mass destructive" capability long before it possessed nuclear weapons. A lesson for both military and civil anesthesia providers is that mixed casualties can be expected after the

use of toxic agents, because Soviet commanders saw the use of chemical weapons as part of a normal armamentarium, rather than being exceptional weapons.[51]

Some evidence exists of the use of biologic warfare agents in China by the Japanese, who had a secret unit devoted to the subject since the early 1930s.[42] Plague and clostridia were used in tests on prisoners and against civilian populations. The considerable knowledge gathered was passed on to the United States by the head of the section after his capture and formed the basis of an offensive biologic warfare development program that was terminated in 1972 with the signing of the biologic warfare treaty.

COLD WAR DEVELOPMENT

It is now known that a major Soviet biologic warfare program began in the early 1970s that used genetic engineering and other techniques to develop a whole new range of possible agents, including toxins and "agents of biologic origin," which are probably deployed at the present time.[44] Development of nerve and other agents also continued during the Cold War, along with extensive research into an antidote-based approach to the management of the wounded.

With the end of the Cold War, much of the expertise in USSR laboratories may have moved to other countries, increasing the risk that developed CBW agents and delivery technology may be more easily available to terrorist groups.

THE IRAN-IRAQ WAR

The Iran-Iraq War during the 1980s saw the sustained use of chemical agents and the first application of modern medical techniques to chemical warfare injuries (Box 83B-2). Extensive U.N. investigations established that sulfur mustard and lewisite, both vesicant agents, had been used together with the nerve agent tabun and a toxin agent, mycotoxin.[52,53] Casualties were almost exclusively on the Iranian side and numbered approximately 27,000, with a mortality rate less than 1%. This continued the trend noted during World War I of the low mortality rate for chemical warfare compared with other weapons, and almost certainly reflects the impact of organized medical care for the casualties and techniques of protection. In comparison, the Iraqi attack in 1989 against civilians in the unprotected Kurdish village of Halabja, which had few or no medical facilities, produced 5000 dead.

TERRORIST CHEMICAL AND BIOLOGIC WARFARE RELEASES DURING THE LAST PART OF THE TWENTIETH CENTURY

In 1995, the first recorded terrorist use of a chemical warfare agent against a civilian population occurred with the use of the nerve agent sarin in attacks in Matsumoto and Tokyo, Japan, and for the first time, hospital medical teams were brought into direct contact with a chemical

BOX 83B-2 *Iran-Iraq War Experience With Chemical Warfare Agents*

During the Iran-Iraq War, modern medicine was applied to the treatment of injuries caused by sulfur mustard, tabun, lewisite, and the biologic agent mycotoxin.*,† Although data are limited, there are lessons that should be noted. The most unexpected was the surprisingly low mortality: fewer than 1% of the estimated 27,000 Iranian chemical casualties.‡

Troops with organophosphate exposure fell into four categories. Those with the greatest exposure died in the field. The number appears to have been very small, even though most of the Iraqi attacks were made against unprotected Iranian troops. Those most severely injured who reached medical aid were unconscious, unresponsive, and often in respiratory arrest. The seriously intoxicated had symptoms of dizziness, disorientation, anxiety, salivation, and respiratory difficulty. Those with relatively mild symptoms were often physically difficult to manage because of their disorientation. By far the largest number of casualties required no treatment other than decontamination.

Treatment of mustard exposure during the Iran-Iraq War reflects the experience gained in the management of burn wounds during the 80 years since World War I. Treatment begins with early and thorough decontamination. Early in the course of injury, blistering may not be present. Still, removal of contaminated clothing is important to limit contact time with the agent. Shaving of the affected areas followed by washing mechanically removes and dilutes the agent. Aspiration of blisters, removal of necrotic tissue, and treatment of the skin lesions with silver sulfadiazine cream forms the basis for treatment of skin injury. Respiratory exposure to mustard creates its own set of problems. Depending on the degree of injury, the treatment must be adjusted to the degree of injury. Humidified air or oxygen helps prevent airway obstruction. Bronchodilators, mucolytics, and expectorants are useful. In cases of serious injury, mechanical ventilation with positive end-expiratory pressure and acid-base balance control are used to support the patient until the injuries resolve.

Injury to the eyes was treated with irrigation and antibiotic cream. Pain is treated with systemic medications. Because of weight loss, often in excess of 10 kg (22 lb), nutritional support is instituted to help reduce the significant mortality associated with negative nitrogen balance. Once the patient reaches a setting for definitive care, therapy is divided into two parts: a general supportive treatment for sepsis and dehydration and treatment to eliminate toxins from the body.*

Significant observations from the Iran–Iraq War include the following:

- Decontamination, using soap and water and shaving body hair, was done early. This protected medical personnel and simplified further treatment.
- Comatose casualties of nerve agents who did not have cardiovascular problems were treated with large doses of atropine 50 to 200 mg administered intravenously. Most casualties received 2 mg every 8 hours. Comatose casualties with significant cardiovascular deterioration (such as bradycardia after 2 mg of intravenous atropine) were most often found not to survive.
- Mustard, although it dates from World War I, continues to be an important chemical agent. It is a vesicant but also has effects on multiple organ systems.

warfare incident during the initial and continuing management of the casualties.[31,54] Unfortunately, because of lack of experience, casualties occurred among the attending emergency staff, but the number of fatalities was low. The incident brought home lessons for medical responders, including anesthesia providers. The first was that the use of a hitherto military chemical warfare agent was possible by a terrorist group. Second, the incident management underlined all the lessons taught by the HAZMAT system, in that secondary casualties occurred among the attending staff as a result of lack of control, protection, and decontamination. Third, fatalities that occurred at the release site were essentially caused by lack of onsite resuscitation. Fourth, the well-documented clinical management of the many thousands of cases that were admitted to hospital provided for the first time a significant clinical database for a population exposed to a nerve agent.[55]

HAZARDS AND THREATS

Confusion between the concept of a hazard and a threat is common. CBW agents are, by definition, hazardous. The term *threat* is usually used in the military context if a hazard has been weaponized and the assailant has the capability and the intention to use the weapon. The relationship may be expressed by the simple equation:

$$\text{Threat} = \text{Hazard} + \text{Capability} + \text{Intention}$$

For a balanced medical response to CBW attack, the reality is that many of the CBW hazards causing public concern are very difficult to weaponize and deliver. This understanding is important for the medical responder because it reduces the likelihood of encountering casualties from CBW attack to a restricted number of agents, the properties and pathophysiology of which can be considered before casualties present.

MODES OF RELEASE OF CHEMICAL AND BIOLOGICAL WARFARE AGENTS

CHEMICAL AGENT RELEASE

Military Release

In warfare, the release of CBW agents is a deliberate action achieved through the use of shells or missiles or through spraying. Aerosol release is the essential technique that allows attack through the respiratory route, but for more persistent agents designed to deny terrain, the use of spray devices is more common. By the end of World War I, delivery of chemical warfare agents was almost exclusively through explosive shells, and at that time nearly 40% of the fills were chemical, indicating the effectiveness of chemical warfare agents on the battlefield.[42] The rise of aerial bombardment before World War II brought great fears that cities would be wiped out by gas attacks, but these fears were never substantiated and it is now realized that dissemination of chemical warfare agents over a wide area (rather than a limited tactical area) by explosion is not easy. During the Cold War, the Russians developed considerable expertise in the use of BM21/24 multiple rocket launchers (Stalin organs) that could rapidly deliver a high concentration of nonpersistent agents, such as hydrogen cyanide, and then allow their dispersal and the entry of nonprotected troops. Missiles such as the Scud were also developed for chemical warfare release at this time, and it was feared that they had been developed for chemical warfare use by Iraq before the Gulf War of 1991.

In the military context, release of toxic agents may be revealed or concealed. Attack, by whatever means, is usually predicted and detectable with the considerable resources that the military can bring to bear in this area, for both chemical and biologic agents. Tuned detection systems are employed wherever there is perceived to be a threat, and the threat itself is usually supported by intelligence information about the hazards concerned, which means that the systems can be tuned. Broad detection systems such as mass spectrography are also employed by CBW reconnaissance units in the field (Box 83B-3).

Release on a Civilian Population

In civil life, toxic agent release is usually accidental and is usually revealed by the circumstances. Road and other transportation accidents, particularly when vehicles carrying HAZMAT identification plates are involved, give an immediate warning about the nature of the problem.[48] Accidental releases, particularly in nations with poor emergency response resources, can be catastrophic, as in the case of the mass release of methyl isocyanate in the Indian city of Bhopal in 1984, which caused over 5000 deaths and 50,000 casualties.[56] Civil populations, unlike their military counterparts, are usually untrained and unprotected against toxic agent release. In addition, the panic induced by the fear of the actions of CBW agents compounds the flexibility of the emergency medical response.

BIOLOGIC WARFARE AGENT RELEASE

The deliberate release of classic biologic warfare agents, such as bacteria or viruses, may not be as easy as the

BOX 83B-3 *Detection Techniques*

Detection: Detecting the presence of a chemical or biologic weapon agent in a contaminated environment. Specific detection techniques include the following:

Agent-specific chemistry
Generic chemical detection techniques
Mass spectrography
Ion current devices
Bioluminescence
Microbial techniques
Chemical and pathologic studies on an affected patient after the attack
Internal versus external detection

Monitoring: Detecting contamination on an exposed patient. Monitoring is important to determine the risk for transmission and the effectiveness of decontamination.

media have led the public to believe. Effective mass release implies aerosol release, and very few of the biologic warfare agents are capable of withstanding the environmental stresses involved. Some, such as anthrax spores, have long been recognized as being sufficiently robust and have therefore attracted the most research attention. The only other bacteria that have probably been used as biologic warfare agents are *Francisella tularensis,* which is spread through infected fodder and causes tularemia, and *Yersinia pestis,* which causes plague and was said to have been used by the Japanese during the World War II campaign against China, and where the vector used was the traditional one of the ratborne flea.[42]

Considerable research work was carried out by the USSR during the Cold War to try to find new ways of delivering biologic agents and for their modification using genetic engineering.[44] This work also developed agents of biologic origin that lie in the middle of the CBW spectrum and produce subtle pathophysiologic effects and are difficult to detect postmortem in the body. In military terms, biologic warfare has always been seen as a debilitating weapon, self-propagating, and of long latency, that could be used to degrade the capability of static enemy formations or key formations operating behind front lines, such as airfields. In the civil context, biologic warfare agents have yet to be used in a terrorist attack, evidence of continued interest exists.[57]

AGENTS

Numerous reviews[34-39,41,45] are available giving details of agents that are regarded as CBW hazards. This section concentrates on selected hazards that can be regarded as being potential threats and that are likely to be encountered by the responding anesthesia provider.

AGENT-SPECIFIC CLINICAL APPROACH: WHAT IS IMPORTANT TO THE ANESTHESIA PROVIDER

In the management of CBW casualties, the anesthesia provider acts as part of a clinical team. To provide a safe and effective response, the following are required:

- Physical, pharmacologic, and immunologic methods of individual protection
- Immediate measures for life support
- Specific antidote therapy
- Consideration of latent effects

In the following section, specific agents have been selected that are representative of classes of hazards and in some cases have been used as weapons of warfare. They are hazards that either can be synthesized relatively easily or are potentially available from stockpiles or reference laboratories.

NERVE AGENTS

Nerve agents are members of a very large group of chemical compounds called organophosphates (OPs), known since the nineteenth century but first examined in detail in the 1930s.[35,36,58] More than 50,000 OP compounds have been synthesized, and several are in regular use as insecticides around the world, including parathion, malathion, and fenthion.[59] Although OPs were originally developed as insecticides, certain highly toxic members of the class—known as nerve agents—have been developed since before World War II specifically for military use. As a result of development by Germany, and later by Russia, the United States, and Great Britain, at least five nerve agents have been produced. The formulae of the more common nerve agents are shown in Figure 83B-2. Tabun (military designation GA) was the first nerve agent to be produced, followed during World War II by sarin (GB) and soman (GD). 2-(Diisopropylamino)ethyl-O-ethyl methylphosphonothioate (VX), N,N-diethyl-2-(methyl-(2-methylpropoxy) phosphoryl) sulfanylethanamine (VR), and cyclosarin (GF) were developed during the Cold War. Cyclosarin (in which the isopropyl group in sarin is replaced by a cyclopropyl group) was found stockpiled in Iraq during the First Gulf War in 1992. Currently the most important nerve agent hazard likely to face the anesthesia provider is sarin (isopropyl methyl phosphonofluoridate), which has been widely produced, stockpiled, and also synthesized and used by terrorists.[31,55]

In terms of physical properties, tabun, VX, and VR are persistent and sarin, soman, and cyclosarin are not. However, soman may be made in a thickened form that is persistent. The relevance of the physicochemical data to the clinical situation is that the nonpersistent agents generally pose a respiratory risk and the persistent agents

are a danger because of absorption through the skin. This means that different agents pose specific risks both to victims and medical attendants.

Nerve agents were originally termed nerve gases, but are in fact liquids with volatilities varying between those of petrol and heavy lubricating oil. None freezes until –40° C (–40° F). They are pale yellow to colorless, odorless, and soluble in water, in which they undergo slow hydrolysis. However, in the presence of strong alkalis and hypochlorite solution, the hydrolysis is rapid and this is the basis of the decontamination of the G agents. Decontamination of V agents with hypochlorite can produce toxic products and is not recommended. Nerve agents can penetrate clothing, skin, and leather. Rubber and synthetic materials, such as polyethylene and butyl rubber, are more resistant. The physical properties of the nerve agents are shown in Table 83B-1.

Actions of Nerve Agents

The main effect of nerve agents is inhibition of acetylcholinesterase (AChE) and butaryl cholinesterase in the cholinergic nervous system (see also Chapter 18). These enzyme systems include the carbamate anticholinesterase and neostigmine, to reverse the action of nondepolarizing neuromuscular blocking drugs. OPs also inhibit other enzymes, notably neurotoxic esterase (NTE). This inhibition causes long-term neurologic effects unrelated to cholinergic changes (organophosphate-induced delayed neuropathy [OPIDN]). The interaction of OPs with AChE is complex and is analogous to the interaction of the enzyme with the natural substrate acetylcholine (Fig. 83B-3).[32] Inhibition of AChE causes a buildup of acetylcholine at muscarinic and nicotinic synapses of the cholinergic nervous system. Thus, central and peripheral signs and symptoms occur that can be directly explained from the classic pharmacologic knowledge of how the cholinergic system operates.

Although the classic effects of OPs are essentially cholinergic, important effects on other receptor systems

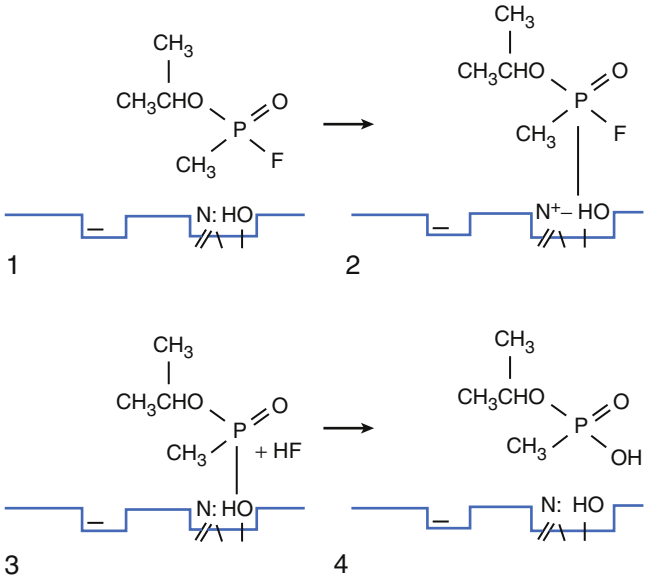

Figure 83B-3. Reaction of acetylcholine and sarin with acetylcholinesterase. *(From Baker DJ: Anesthesia in extreme environmental conditions. Part 2. Chemical and biologic warfare. In Grande CG, editor:* Textbook of trauma anesthesia and critical care, *St. Louis, 1993, Mosby–Year Book, p 1341.)*

occur, notably γ-aminobutyric acid (GABA) and *N*-methyl-D-aspartate, which gives rise to central excitation, causing the initial seizures seen in acute OP poisoning.

The interaction of OPs with AChE is nonreversible after a certain time depending on the nerve agent. The formation of an irreversible complex is known as aging. Each nerve agent has an aging half-life. For sarin, this is about 5 hours, whereas for soman it is only 2 minutes. Tabun and VX both have aging half-lives of 40 hours. After five half-lives, more than 95% of the enzyme AChE has aged and cannot be reactivated. This has important consequences on the window of clinical opportunity[59] for treatment to try to reverse the AChE inhibition (see later section on Oximes).

TABLE 83B-2 SYMPTOMS AND SIGNS OF NERVE AGENT POISONING BY TYPE OF CHOLINERGIC RECEPTOR AND TARGET ORGAN

Receptor	Target Organ	Symptoms and Signs
Muscarinic	Iris muscle ciliary muscle	Miosis; spasm leading to failure of accomodation and pain in the eyes; nausea and vomiting; headache
	Conjunctival vessels	Vasodilation and hyperemia
	Nasal glands	Rhinorrhea and hyperemia
	Bronchial glands	Increased secretion
	Bronchial muscle	Bronchoconstriction; tightness in the chest; expiratory wheezing; dyspnea
	Gastrointestinal tract	Anorexia; nausea; vomiting; abdominal cramps; diarrhea; tenesmus; involuntary defecation
	Sweat glands	Increased activity
	Salivary glands	Increased activity
	Lacrimal glands	Lacrimation (not usually marked)
	Heart	Bradycardia; occasionally tachycardia
	Bladder	Frequency; involuntary micturition
Nicotinic	Skeletal muscle	Weakness; fatigue; fasciculations; cramps; flaccid paralysis (early effects on respiratory muscles may produce dyspnea)
	Autonomic ganglia	Pallor; occasional elevation of blood pressure
Muscarinic and nicotinic	Central nervous system	Anxiety; giddiness; restlessness; headache; withdrawal and depression; memory failure; impaired concentration; slurred speech; depression of respiratory and cardiovascular centers; Cheyne-Stokes respiration

From Baker DJ: Anesthesia in extreme environmental conditions. Part 2. Chemical and biologic warfare. In Grande CG, editor: Textbook of trauma anesthesia and critical care, *St. Louis, 1993, Mosby–Year Book, pp 1320-1354.*

Signs and Symptoms of Nerve Agent Poisoning

The classic signs and symptoms of nerve agent poisoning are shown in Table 83B-2. Poisoning is caused by the accumulation of acetylcholine and not by the OP itself. As a result of stimulation of muscarinic synapses, miosis; ciliary body spasm causing pain[60]; glandular hypersecretion, including salivary, bronchial, and lachrymal; sweating; cardiac effects, including bradycardia (or tachycardia due to the effects on the anomalous sympathetic system), atrioventricular block, and Q-T prolongation; bronchoconstriction; vomiting; severe diarrhea; and fecal incontinence also occur. The nicotinic effects are manifested by fasciculation and paralysis at the skeletal neuromuscular junction. Central effects[61] give rise to apprehension, dizziness, amnesia, seizures, coma, and respiratory depression. Lower chronic doses of OPs lead to irritability, fatigue, loss of concentration, and memory loss.

Clinical Experience With Organophosphate Intoxication

Much of the information about actions of OPs in humans has been gathered from animal studies and management of pesticide poisoning. It should be noted that animal studies do not necessarily represent human reactions, and pesticide studies may not accurately represent the development of the cholinergic syndrome after nerve agent exposure. Although some evidence exists from accidental exposure to sarin and from some human volunteer studies conducted early in the Cold War, the clinical evidence base is smaller than that for pesticide poisoning. During the early stages of the Cold War a number of experimental studies were done on human volunteers exposed to nerve agent, and these have been reviewed by Sidell.[36] The attacks in Japan in 1994 and 1995 also have provided important information concerning the signs and symptoms after sarin release.[31,55]

Clinical Evidence From Recent Military Experience

The Iran-Iraq War produced first-hand clinical information about the effects and management of nerve agent poisoning.[52] Iranian casualties from nerve agents apparently fell into four broad categories. Individuals who suffered the greatest exposure died in the field; filtration mask protection by Iranian troops was severely compromised by their beards, which they had for religious reasons. Despite the fact that Iraqi attacks were made against troops having compromised or poor protection, the number of deaths appears to have been low. The most severely injured who reached medical care were unconscious and unresponsive and often in respiratory arrest. The next group who were seriously poisoned had symptoms of dizziness, disorientation, anxiety, salivation, and respiratory difficulty. Disorientation was a problem, and often cases with only mild symptoms were difficult to manage because of this (this parallels experience gained with the management of OP pesticides). Finally, most of those exposed required only decontamination. Treatment of nerve agent poisoning relied on giving large doses of atropine, usually 50 to 200 mg intravenously. These cases were usually comatose, and the degree of advanced life support given was limited. Most patients received only atropine 2 mg every 8 hours. Comatose patients with significant cardiovascular deterioration usually did not survive.

Clinical Evidence From Pesticide Poisoning

Considerable clinical evidence exists about the effects of OP pesticides from the many thousands of cases that occur in agricultural areas of the world each year.[62] Although these give an overall picture that corresponds to the signs and symptoms described previously, considerable differences exist with nerve agents. It is also likely

Figure 83B-4. Military automatic intramuscular injection device containing nerve agent antidotes. *(ComboPen, Meridian Medical Technologies, Colombia, Md.)*

that the various nerve agents have relatively different effects on the central and nervous systems.

Cardiovascular Effects of Nerve Agents

Critical care management of OP pesticide poisoning has indicated short-term and medium-term cardiac changes.[63,64] After an initial tachycardia (mediated through the anomalous sympathetic nervous system) and a vagally induced bradycardia, ventricular dysrhythmias, including torsade des pointes and prolongation of the Q-T interval may occur. Dysrhythmias have been reported as a poor prognostic sign.

The Treatment of Nerve Agent Poisoning: Antidotes and Life Support

Atropine. Atropine has long been a mainstay in the management of OP poisoning.[58,62] Its antagonistic action against acetylcholine at the muscarinic synapses allows control of the muscarinic effects, the most severe of which is bradycardia. Atropine also has been used for many years in the management of OP pesticide poisoning. However, the relevance of the experience with pesticides to poisoning with nerve agents is not clear.[36] The traditional military response to confirmed or suspected attack with nerve agents is to use a self-administered autoinjector containing atropine 2 mg, a benzodiazepine, and an oxime. An example is shown in Figure 83B-4. During the Cold War, NATO troops were provided with three such devices to be used sequentially. Useful treatment indications have been gained from the Iran-Iraq War[65] and the Japanese terrorist experience.[55] Atropine 2 mg is given intravenously (pediatric dose 0.02 to 0.05 mg/kg) with repeat doses every 5 to 10 minutes until pupillary dilatation occurs and the heart rate increases above 80 beats/minute.[36,66] Atropine infusions may be used for persistent bradycardia in pesticide poisoning.[67]

Oximes. Oximes are compounds capable of reactivating, in some cases, the complex formed by the OP and AChE. Clinically this means that oximes can reverse the actions of OP at the nicotinic receptor and reduce the degree of paralysis.[68,69] Oximes are widely used in the clinical management of both OP pesticide and nerve agent poisonings. Chemically they are monopyridinium or bispyridinium compounds that can bind to the complex and cause the nerve agent molecule to separate from the enzyme. Oximes are a mainstay of the standard military response to nerve agent attacks and are widely used in the management of pesticide poisoning. However, their effectiveness depends on (1) the exact nature of the nerve agent involved and (2) the length of time after the attack before they are given. This is because aging chemical changes take place in the nerve agent–enzyme complex. Aging occurs very rapidly in humans after soman exposure, but less so after exposure to other nerve agents. One of the major problems related to oxime research is the selection of a suitable animal model. Originally monkeys and guinea pigs were both thought to be good models for human OP intoxication, and human treatment protocols were developed from such studies. However, major differences are known to exist between enzyme complex aging rates for primates and those for rodents.[70] The rate of formation of aged enzyme in different species increases in the following order: mouse < rat < guinea pig < rabbit < dog < cow < monkey = human. From erythrocyte studies in humans, the rate of aging is known to be very rapid (half-life 1.3 minutes), indicating that the guinea pig would not be a good model for the use of oximes in humans.

Several oximes are available, and recent years have seen the development of new compounds.[68,69] The most commonly used is pralidoxime (as either the chloride or methane sulphonate [mesylate]). Obidoxime is used in some countries for OP pesticide poisoning and may be effective against tabun. Recent research has concentrated on the rational use of a range of oximes both in terms of the type of oxime used and dose and timing.[68,69,71] HI-6, a Hagadorn oxime, reactivates the soman-enzyme complex, the most difficult clinical situation to treat. However, HI-6 may be useful because of other pharmacologic properties and may be advantageous in the treatment of cyclosarin poisoning and other cases in which obidoxime was previously used.

For most anesthesia providers treating a patient with the symptoms of nerve agent poisoning, a civilian setting is the most likely. Exposure to sarin is the most probable situation, and treatment schedules logically should be based on this premise. Military anesthesia providers may face other hazards, but they would be provided with specialized detection equipment and treatment modalities based on a threat assessment. All nerve agent casualties should receive pralidoxime mesylate initially, in addition to atropine and ventilatory life support.

Practical Treatment Regimen. Oxime therapy should be given simultaneously with atropine.[66,68] A slow intravenous injection of pralidoxime is recommended to prevent laryngospasm, muscle rigidity, and hypertension. Pralidoxime 15 to 30 mg/kg intravenously or intramuscularly is given over 20 minutes for adults and children. This dose may be repeated after 4 hours (or 1 hour if paralysis is worsening). The target therapeutic blood concentration should be 4 μg/mL. However, studies by Worek and colleagues[71] show that the full therapeutic effects of pralidoxime may be achieved at higher concentrations. The same group demonstrated that reinhibition of AChE is a possibility after pralidoxime treatment in human erythrocytes, but the relevance to the whole body is unclear. Sarin is broken down rapidly in the blood by hydrolysis. Oxime treatment in the hospital should continue for as long as atropine is required.

Benzodiazepines. The central actions of OPs give rise to spike discharges and seizures. Benzodiazepines have long

been used to counter this action. Given the known action of OPs at the GABA receptor and the antagonistic action of benzodiazepines at this site, the action may be noncholinergic.[72,73]

Seizures may be an early sign of severe nerve agent poisoning and must be controlled quickly to avoid long-term cerebral damage.

Pyridostigmine Pretreatment. The problem of aging of the OP AChE complex, particularly with soman and the ineffectiveness of oxime therapy, gave rise to a novel military approach to prophylaxis against nerve agent poisoning.[37] Pyridostigmine is a dimethyl carbamate compound with a quaternary nitrogen atom. As a result, it does not penetrate the blood-brain barrier to any extent. In common with other carbamates such as neostigmine and physostigmine, pyridostigmine is an anticholinesterase and has essentially the same action as OPs. In the case of carbamates, the complex formed with the enzyme is readily reversible. The normal treatment dose of pyridostigmine is 30 mg every 8 hours. No plasma protein binding occurs and no drug interactions involving competition for binding sites. Of the absorbed dose, 79% to 90% is excreted unchanged in the urine. The reversibility of the complex formed with AChE is such that the enzyme returns to 90% of normal within 12 hours after the last dose. In addition, at steady state, only 40% of the available AChE is complexed. Given the considerable safety margin that exists in the level of enzyme at cholinergic synapses, treatment with pyridostigmine does not produce any more than mild parasympathetic signs.[74]

The protective action of pyridostigmine against OPs is based on the fact that the carbamylate-complexed AChE is resistant to attack after subsequent exposure to OPs. If a person taking pyridostigmine is exposed to a subsequent potentially lethal dose of OP, a reserve of enzyme is effectively autotransfused into the patient during the subsequent period. This process does not require the presence of an oxime. OP is rapidly hydrolyzed in the bloodstream after exposure and has no further action on the released AChE. The amount of enzyme released from the carbamylate complex is sufficient to restore neuromuscular transmission because of the safety margin that exists at the synapse. However, in severe cases of OP poisoning, life support measures are necessary to bridge the gap between OP attack on the synapse and restoration of the ACHE level through the autotransfusion.

Anesthetic Implications of Pyridostigmine Pretreatment. The anticholinergic actions of pyridostigmine have considerable relevance to normal anesthetic practice. Butaryl cholinesterase, a determinant of the metabolism of succinylcholine, is also inhibited, and prolonged action of this drug may be expected in patients taking pyridostigmine.[75] The carbamate neostigmine is usually given at the end of an operation to reverse the action of nondepolarizing neuromuscular blocking drugs. Pretreatment with a carbamate in a patient who is not subsequently exposed to OP may be expected to produce some resistance to the action of the neuromuscular blocker. Experimental studies indicate that pyridostigmine does not alter the overall characteristics of neuromuscular block in an isolated human forearm, and the neuromuscular effects may be minimal, particularly because more central muscles of respiration such as the diaphragm have a higher safety margin of neuromuscular transmission and are less affected by the pyridostigmine pretreatment.[76] Estimations of the degree of neuromuscular block using fade relationships such as the train-of-four[77] theoretically may be affected by pyridostigmine pretreatment because the determinant of fade is feedback to the prejunctional cholinergic receptor[78] (see also Chapter 18). The hysteresis loops for the onset and offset of fade and paralysis relationships in the isolated forearm are not affected by pyridostigmine pretreatment.[76] The civilian anesthesia provider is referred to more specialized military texts[36,41] for a more complete discussion of pyridostigmine and its clinical actions.

VESICANT AGENTS

Vesicant agents were first used as chemical weapons during World War 1.[42] The most well known is sulfur mustard (1917, commonly known as mustard gas). It was used as a disabling agent and has a long latency of 2 to 4 hours. Its successor, lewisite (1919), an arsenic-based compound (2-chlorovinyl dichloroarsine), is more volatile, has a short latency, and causes immediate eye pain in addition to its vesicant properties.[46] Sulfur mustard is the most commonly encountered vesicant. Although an early chemical warfare agent, it is still widely distributed around the world and its easy synthesis makes it a possible agent for use by terrorists. It has a number of pathologic properties that make it of concern to anesthesia providers. The overall management of mustard gas injury is the domain equally of the surgeon and specialized pulmonary physician.[36,79,80] Intensive care unit (ICU) management presents longer term problems that are mainly respiratory. Eye and skin injuries fall within the aegis of other specialities.

Properties

Sulfur mustard (*bis*-2-chloroethyl sulfide) is a colorless or pale yellow, oily liquid that smells faintly of mustard. Its odor threshold is 1.3 mg/m^3, which is below the concentrations usually reached in a battlefield, and several minutes of detection are possible before incapacitating doses are reached. The LCt_{50} is approximately 1500 mg/min/m.[3] Although the latency of action in cooler climates is approximately 4 hours, information from the Iran-Iraq War, the scene of its most recent use,[81,82] indicates that at higher ambient temperatures, the agent has a far shorter latency and causes significant respiratory damage apart from its classic action as a skin vesicant.

Signs and Symptoms

After exposure to mustard gas, a latent period of 4 to 12 hours occurs, after which ocular symptoms comprising eye pain, blurred vision, and lachrymation are experienced, accompanied by a diffuse erythema of exposed skin with edema and first-degree burns. The groin and genital areas are particularly susceptible. Exposure to high doses produces severe cutaneous injury with necrosis. The burns bear some resemblance to thermal burns, but are very slow to heal and prone to secondary infection.

Figure 83B-5. Cutaneous vesication caused by mustard gas exposure. *(Courtesy Her Majesty's Stationery Office, London, United Kingdom.)*

Figure 83B-6. Eye injury caused by mustard gas exposure. *(Courtesy Her Majesty's Stationery Office, London, United Kingdom.)*

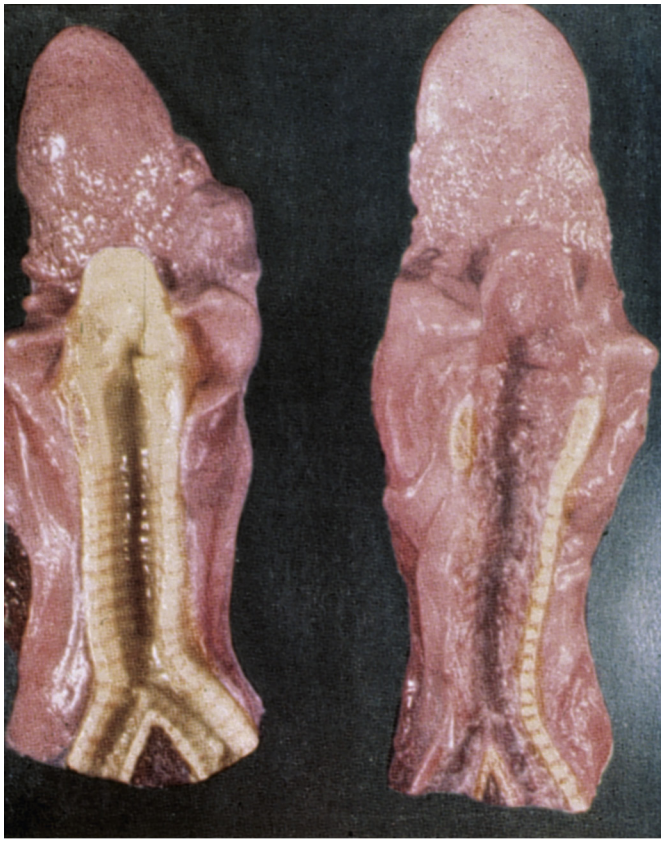

Figure 83B-7. Tracheal injury caused by mustard gas. *(Courtesy Her Majesty's Stationery Office, London, United Kingdom.)*

The bullae characteristic of exposure to mustard agent are filled with a fluid that is not corrosive (Fig. 83B-5). A feature of exposure is that fluid-filled bullae appear for several days afterward in an apparently random way (i.e., not cropped). The eyes are particularly vulnerable to mustard gas, causing a usually temporary blindness (Fig. 83B-6). The fluid in the bullae has itself no vesicant effect.

Respiratory Effects

The respiratory effects of mustard gas exposure are potentially serious, particularly when the ambient temperature is high.[82-84] After exposure, an early tracheobronchitis with dry cough and hoarseness occurs. Heavy exposure will produce severe damage to the tracheal and main bronchial architecture with necrosis, sloughing, and blockage (Fig. 83B-7). A chemical bronchiolitis occurs at lower doses in high ambient temperatures and causes severe bronchospasm, requiring ventilation and intensive care.[82] Lung damage after mustard gas exposure can be severe and permanent, with chronic obstructive pulmonary disease, bronchiectasis, and reactive airways dysfunction syndrome.

Cellular Action of Mustard Agent

Sulfur mustard agent acts at a cellular level forming highly reactive sulfonium ions, which attack DNA by alkylation of sulfhydryl and amino groups.[36] This causes the epithelial manifestations of exposure and also long-term carcinogenesis, particularly of the skin, pharynx, and respiratory tract.

Treatment

Mustard gas exposure has no specific treatment, but experimental studies in animals have shown a combination of sodium thiosulfate, vitamin E, and dexamethasone

can improve survival and reduce organ damage.[36] The key points of treatment are (1) the need for decontamination, (2) the latent period of action, and (3) respiratory support for exposure affecting the respiratory tract. Willems[80] reviewed information concerning the clinical management of mustard gas casualties and found that a proactive approach to airway management and ventilation was evident with endotracheal intubation done early to allow adequate ventilation and assess for debridement of the large airways. Willems reported that the onset of severe respiratory symptoms is a serious development, with a loss of 87% of patients who required ventilation. Another point of concern for longer term management is the leukopenia that follows exposure to mustard gas. This becomes evident 3 to 5 days after exposure and usually reaches its lowest point 7 to 9 days after exposure. Cellular replacement, either peripherally or as marrow, could be considered here because mustard is bound very quickly in the body after exposure and will not cause destruction of new cells.

Recent Clinical Evidence

The Iran-Iraq war during the 1980s saw the extensive use of sulfur mustard and produced a significant amount of clinical information about casualties[81] with both cutaneous and respiratory injuries. The treatment given reflects the experience gained in the treatment of burn injuries since its first use. Decontamination was achieved early to limit the contact time with the agent. Because of the long latency of mustard gas, vesicle formation was often not present at this time. Shaving of the affected areas was done and dilution of the agent by irrigation. The management of the vesicles followed the pattern of aspiration, removal of necrotic tissue, and the use of silver sulfadiazine cream. From the anesthetic standpoint, the respiratory effects found in the casualties were important and unprecedented from the use of mustard in the lower temperature conditions of World War I. Chemical bronchiolitis giving rise to increased airway resistance was reported, together with soiling of the larger airways due to sloughing. Intermittent positive-pressure ventilation with positive end-expiratory pressure was required with ICU support for the more seriously injured cases. Many of these were managed in hospitals around Europe, introducing chemical warfare injury to many anesthesia providers and intensivists for the first time. For the casualties who reached definitive hospital care, the recovery period was often a long one, and patients had cachexia with significant negative nitrogen balance.

LUNG-DAMAGING AGENTS

Lung-damaging agents were formally known as choking agents, a term that does not adequately describe the many levels of the lung at which they act. Lung-damaging agents act at both the upper and lower respiratory tract levels, but their main lethal action is to cause toxic pulmonary edema. Lung-damaging agents were the first to be used as chemical weapons during World War I, with the use initially of chlorine, followed by phosgene. These agents are a universal hazard in military and civilian populations because they are also used widely as industrial feed stocks in many chemical engineering processes. The isocyanates are widely used in this respect, and the accidental release of methyl isocyanate at Bhopal, India in 1984 caused the largest number of casualties ever recorded after toxic release in either war or peace, with over 5000 deaths from toxic pulmonary edema.[85,86] Chemical warfare and HAZMAT sources list many lung-damaging agents.[36,48]

BOX 83B-4 *Properties and Toxic Exposure Levels of Phosgene*

Properties

Chemical name: Carbonyl chloride ($COCl_2$), chloroformyl chloride
Boiling point: 8.2° C (46.76° F)
Vapor pressure: 1215 mm Hg at 20° C (68° F)
Vapor density: 3.5 × air
Breakdown: slow aqueous hydrolysis to HCl and CO_2

Toxic Exposure Levels

1 ppm chronically: Chronic lung disease
>25 ppm/minute: Acute lung effects
50 to 100 ppm/minute: Initial inflammatory response that may be followed by pulmonary edema
>150 ppm/minute: Clinically significant and life-threatening pulmonary edema
Lethal exposure in humans: 800 ppm for 2 minutes

Phosgene

Phosgene[87] has been used as a chemical warfare agent, is an established worldwide industrial hazard, and may be regarded as a potential terrorist threat. It is a model for consideration of other hazards in its class. Phosgene is carbonyl chloride, familiar to earlier anesthesia providers as the product of the reaction of trichloroethylene with soda lime used in circle absorbers. First synthesized in the nineteenth century, phosgene has been in industrial use for over a century but achieved notoriety during World War I, when it was used extensively by both sides from 1915 onward. It caused more than 85% of all deaths from chemical warfare agents.[42] Phosgene is a gas at normal temperatures and is nonpersistent (Box 83B-4). It is less water-soluble than chlorine, its immediate chemical warfare predecessor in 1915, a feature that results in the gas being taken further down the respiratory tree and into the alveoli. Phosgene has been known since World War I to have a dual latency of action, which underlies its essentially dangerous character. The stages after exposure are as follows:

- Stage 1: Immediately after exposure, intense upper respiratory irritation occurs, with coughing, retching, choking, and chest tightness. These symptoms are accompanied by eye irritation and lacrimation. In some cases, death followed exposure to high concentrations of phosgene without development of toxic pulmonary edema. The reason for this is obscure, but it may be related to hypoxia as a result of intense laryngeal or bronchospasm.
- Stage 2: The immediate choking symptoms are followed by a latent period of 2 to 24 hours before the onset of more serious symptoms and signs, including dyspnea,

painful cough, and cyanosis, with increasing signs of pulmonary edema leading to circulatory collapse and cardiac arrest.

Pathophysiology of Toxic Pulmonary Edema. The lung is a delicately balanced system in which the entire cardiac output passes through the pulmonary circulation arranged as a fine capillary mesh in the interstitial space (a loose organization of collagen, elastin, and various cell types). Because of its fragile organizational nature, the lung commonly reacts to toxic challenge by producing pulmonary edema, in which fluid flows from the capillaries to the interstitial space and then to the interalveolar space. Phosgene reacts through covalent attack on many substrate groups, including, NH_2 and SH.[88] Potential cell targets are type I and II pneumocytes and alveolar macrophages. Covalent binding can be seen as the primary attack leading to free radical release. This stage is followed by a secondary attack involving released inflammatory mediators, including prostaglandins (causing vasoconstriction, vasodilatation, and platelet disaggregation), bradykinin (causing increased capillary permeability), 5-hydroxytryptamine (causing constriction of postcapillary vessels), thromboxane A_2 (causing vasoconstriction), and the release of complement activating enzymes (leading to attraction of leukocytes and leukotriene release).

Management of Phosgene Exposure. Patients who have been exposed to phosgene should be removed from the site of exposure as quickly as possible by protected emergency responders. There is usually no requirement for decontamination unless liquid contamination has occurred. Phosgene has no specific antidote, and treatment is based around use of supportive measures and pharmacologic modification of the effects of the inflammatory mediator cascade.[87] One of the firm rules for the management of phosgene exposure dating from World War I was complete bed rest after exposure and observation for 24 hours, and this still applies. No patient who has had a risk for significant exposure should be discharged from the hospital in less than 24 hours unless accompanied by a responsible observer. Provision of specialized respiratory care both at the prehospital and hospital level is necessary. Some cases may require early intubation and ventilation, and more will require O_2 and supported ventilation in the early stages. The method of provision of emergency ventilation is a matter of interest. Recent work in physical trauma has indicated that the "open lung" strategy[89,90] is of value in the prevention of inflammatory cascades by opening the alveoli and keeping them open by use of the correct level of positive end-expiratory pressure. This technique follows the hypothesis that repeated opening and closing of alveoli causes kinin release through the action of shear forces in the alveolar walls. This may be an important lesson for the early management of lungs damaged by phosgene exposure, and the manner of emergency ventilation may be critical. Bag-valve ventilation, which can lead to very high inflation pressures and high flow rates, may be harmful. The use of emergency ventilation strategies that provide controlled flow rates with the early use of positive end-expiratory pressure is more appropriate. These can be provided by the use of small automatic gas-powered ventilators (see Fig. 83A-3). Modern experience of the management of mass casualties with toxic pulmonary edema is limited, but it must be assumed that a considerable proportion who would survive the acute toxic pulmonary edema will go on to develop ARDS unless the appropriate measures are taken. A study by Parkhouse and colleagues[91] demonstrated improved oxygenation, decreased shunt fraction, and decreased mortality in phosgene-exposed pigs who received a protective in contrast to a conventional ventilation strategy.

The Use of Steroids. The use of inhaled and systemic steroids in the treatment of toxic phosgene exposure has been controversial.[92] Recently, however, chlorine has produced some encouraging results in both pig and rat studies. Gunnarsson and associates[93] found that in a study of 18 pigs subjected to 140 ppm chlorine for 10 minutes of inhaled beclomethasone dipropionate produced higher PaO_2 and ventilation-perfusion ratios, with less histologic damage, than the control group. In another study, Wang and colleagues[94] exposed 24 pigs to a higher concentration of 400 ppm for 10 minutes and found that the inhaled steroid budesonide 0.1 mg/kg given within 30 minutes of exposure was associated with more favorable cardiorespiratory symptoms and lower wet lung weights at autopsy. Demnati and co-workers[95] studied the effects of dexamethasone in rats exposed to a high concentration of chlorine (1500 ppm for 5 minutes). They found that the dexamethasone group had significantly reduced pulmonary airway resistance and methacholine-induced bronchoconstriction than the controls. However, species differences in challenges to chemical warfare agents dictate caution when applied to humans. In a clinical area in which few therapeutic options are available, the results provide encouragement for further research and for clinical intervention if the need arises. Borak and Diller[96] reviewed the available evidence for treatment regimens in human phosgene exposure.

Role of Cyclic Adenosine Monophosphate Diesterase Inhibitors. Kennedy and colleagues[97] suggested that aminophylline may protect against phosgene-induced phosgene exposure as a result of its ability to increase cyclic adenosine monophosphate levels. Other compounds, including β-adrenergic agonists, also have this effect and may indicate a new therapeutic direction.

Phosgene and Glutathione Modification. Another promising therapeutic approach is provided by compounds that can increase intracellular reduced glutathione levels as a means of preventing lipid peroxidation–induced phosgene exposure. The rationale behind this approach is that phosgene reacts with cellular SH groups, reduces reduced glutathione redox state, and increases arachidonic acid mediator production and lipid peroxidation. Sciuto and co-workers[98] studied the effects of *N*-acetylcysteine on anesthetized rabbits exposed to 1500 ppm phosgene. The *N*-acetylcysteine–treated group had smaller increases in pulmonary wet weight, lower leukotriene levels, and higher glutathione levels. This work suggests that *N*-acetylcysteine may protect against phosgene exposure by maintaining reduced glutathione levels and inhibiting production of inflammatory leukotrienes.

CELLULAR TOXIC AGENTS (BLOOD AGENTS): HYDROGEN CYANIDE

Hydrogen cyanide (HCN) is one of several agents known originally as *blood agents,* although the term is a misnomer because the agent acts at the cellular mitochondrial level.[99] HCN is a highly volatile liquid used widely in industry and potentially available to terrorists. It has been used since World War I as a chemical warfare agent. Its very short persistence means that decontamination is usually not required after release. It is not absorbed by the activated charcoal of level C respirators (see the section on Involvement of the Anesthesia Provider in the Management of Casualties From Exposure to Chemical and Biologic Warfare Agents), but is removed by impregnating the charcoal with silver salts, with which HCN reacts. HCN in high concentrations is rapidly fatal. The LCt_{50} has been estimated at 200 mg/m^{-3} for 10 minutes. HCN acts by binding to the iron atom in cytochrome oxidase enzymes inhibiting the catalytic function that allows O_2 to act as an electron receptor and produce adenosine triphosphate. Because of this mitochondrial uncoupling, the resulting lactic acidosis theoretically cannot be reversed by restoring oxygenation of the blood by resuscitation measures to improve tissue oxygenation.

Signs and Symptoms

After exposure in humans, the first sign is hyperventilation, which has the effect of increasing the absorbed dose. This is followed by dizziness, rapid loss of consciousness, and seizures, followed by respiratory arrest. At levels that are not fatal, patients report a smell of almonds, a feeling of apprehension, and a metallic taste in the mouth; dyspnea also may occur. Because of the rapid action of HCN, patients with acute intoxication are unlikely to be encountered in hospital. Long-term management of the consequences of HCN poisoning is unlikely, although survivors of near fatal doses can suffer long-term effects, such as intellectual deterioration, mental confusion, and parkinsonism.

Treatment

In the body, HCN is broken down by rhodanese, which detoxifies cyanide to thiocyanate.[100,101] This process can be accelerated by provision of sodium thiosulfate, which provides a store of sulfane sulfur for the enzyme.[102] The usual dose of sodium thiosufate is 50 mL of 25% solution (pediatric dose 1.65 mL/kg of 50% solution). It is usually administered in conjunction with sodium nitrite (300 mg given intravenously over 10 minutes [pediatric dose 0.15 to 0.33 mL/kg of a 3% solution]), which causes the formation of methemoglobin. This acts as a scavenger for HCN and reduces its plasma levels. Sympathomimetic support may be required for hypotension produced by sodium nitrite. HCN also reacts with heavy metals, and this is the basis of the use of dicobalt edetate and hydroxycobalamin as cobalt providers for this reaction. Cobalt ions themselves are toxic, but the toxicity can be countered by giving glucose, which is part of standard therapy. Dicobalt edetate is thought to be more effective in the binding of cyanide ions than methemoglobin despite its secondary effects of hypertension and nausea. It has long been thought that O_2 therapy and ventilation have no role in the treatment of cyanide intoxication because the blood is fully oxygenated in this condition. However, this view has recently been challenged because some studies have shown that O_2 enhances the antidotal effects of the classical cyanide antidotes.[103] Table 83B-3 details current antidote treatment approaches.

TOXINS

Toxins are high molecular weight compounds that are in the middle of the CBW spectrum.[47] They do not reproduce and have characteristics of chemical warfare agents, although they have been considered with biologic agents by international convention. They are produced naturally by bacteria and by organisms ranging from protozoans up to reptiles such as snakes and scorpions.[104] Toxins are hazardous to humans from natural and deliberate exposure, and this has fueled much research into their actions and treatment.[105] Scientifically, they are of considerable interest and are used as research tools to probe natural processes such as nerve conduction and neuromuscular transmission. In the context of toxic warfare, toxins have often been cited as *doomsday weapons,* and considerable public fear exists about their actions. More than 500 toxins have been described, but only a few are suitable for battlefield and terrorist attack because of difficulties in production and their lack of stability in a released aerosol. The characteristics of some common toxins are shown in Table 83B-4.

In the chemical warfare context, the anesthesia provider may encounter toxins as either short latency (neurotoxins, such as botulinum toxin), requiring immediate life support and treatment, or long latency (the DNA toxins, such as ricin), which cause major organ dysfunction and present intensive care problems.

Botulinum Toxin

Botulinum toxin is produced by the anerobe *Clostridium botulinum* and has the reputation of being the most toxic substance by weight, being at least 5000 times more toxic than sarin.[106] Botulism, the natural occurrence of the toxin in food poisoning, is a disease of both humans and animals. Seven different functionally related neurotoxins (A through G) are produced by the parent organism. Botulism is essentially an intoxication, brought on by ingestion of the toxin produced by clostridrial infection of food, usually incorrectly canned meats. Primary botulism, a direct infection, is rare and affects only infants in the human species. The interest of botulinum toxin as a toxic agent is that it can be relatively easily produced by fermentation processes (which have been developed to produce antitoxins) and that it is stable as an aerosol, making mass delivery a theoretic possibility. Calculations that 1 kg of the toxin would be sufficient to destroy every human on the planet have rested on this fact. However, botulinum intoxication can be treated, and this modifies the toxicity considerably. It is estimated that less than 10% of natural cases receiving ventilatory and antitoxin support are fatal. A consensus document examines the risks to civilian populations exposed to botulinum toxin.[107]

Botulinum toxin acts at the nerve terminal of cholinergic synapses and blocks the release of acetylcholine by being taken up into the vesicles and translocated to the

TABLE 83B-3 **ANTIDOTES USED IN THE TREATMENT OF CYANIDE POISONING**

Antidote	Action	Route	Dose	Concurrent Drugs	Duration of Administration	Possible Side Effects
Oxygen	Increases arterial O_2 content, potentiates activity of other antidotes	Inhalation via mask or ETT	High flow via mask or 100% via ETT	O_2 used as primary antidote in all cases	≤24 hr	Unlikely—possible in patients with COPD
Amyl nitrite	Methemoglobin formation	Inhalation	Adult: 0.2 mL Pediatric: 0.2 mL; may need repeating	O_2 (not simultaneously)	30 sec/min	Difficult to achieve effective antidotal levels without cardiovascular collapse
Sodium nitrite	Methemoglobin formation	Intravenous injection	Adult: 300 mg (10 mL of 30 mg/mL 3%) Pediatric: 0.13-0.33 mL/kg of 30 mg/mL (3%) solution (i.e., 4-10 mg/kg body weight)	Adult: Sodium thiosulfate 25 mL of 500 mg/mL, (50%) solution and O_2 Pediatric: Sodium thiosulfate 1.65 mL/kg body weight of 250 mg/mL (25%) solution (~400 mg/kg body weight) and O_2	≥5 min, ≤20 min	Methemoglobinemia, vasodilation, and cardiovascular collapse
Dicobalt edetate	Binding of cyanide ions by dicobalt edetate and by free cyanide ions	Intravenous injection	Adult: 300 mg (20 mL of 15 mg/mL) (15%) Pediatric: 4-7.5 mg/kg (0.3-0.5 mL/kg of 15 mg/mL (15%)	50 mL dextrose (500 g/L) intravenously immediately after each dose and O_2	1 min	Urticaria, edema of face and neck, chest pains, dyspnea, hypotension, seizures
4-DMAP	Methemoglobin formation	Intravenous injection	Adult: 3.25 mg/kg Pediatric: 3.25 mg/kg	O_2 and sodium thiosulfate	1 min	Methemoglobinemia, vasodilation, and cardiovascular collapse; hemolysis; elevated bilirubin and iron (this is unlikely to be relevant to single-dose exposure)
Hydroxycobalamin	Binds cyanide ions	Intravenous injection	Adult: 5-10 g Pediatric: 70 mg/kg	5 g reconstituted in 100 mL 0.9% saline; O_2	20 min	Reddish discoloration to skin and mucous membranes
Sodium thiosulfate	Sulfur donor for endogenous enzymatic conversion of cyanide to thiocyanate	Intravenous injection	Adult: Sodium thiosulfate 25 mL of 500 mg/mL (50%) solution and O_2 Pediatric: Sodium thiosulfate 1.65 mL/kg body weight of 250 mg/mL (25%) solution (~400 mg/kg body weight) and O_2	O_2 and sodium nitrite *or* O_2 and DMAP	10 min	Excess administration may cause hypernatremia

COPD, Chronic obstructive pulmonary disease; *ETT,* endotracheal tube.

TABLE 83B-4 **CHARACTERISTICS OF COMMON TOXINS**

Source	Toxin	Action
Bacteria		
Bacillus anthracis	Anthrax toxin	DNA toxin
Staphylococcus aureus	Staphylococcal enterotoxin B	Enterotoxin
Vibrio cholerae	Cholera toxin	Enterotoxin
Clostridium botulinum	Botulinum toxins	Prejunctional decrease in acetylcholine release
Clostridium perfringens	Perfringens toxin	Necrosis through phospholipase C
Clostridium tetani	Tetanus toxin	Neurotoxin increase in excitability of motor neurons
Protozoa		
Gonyaulax catenella	Saxitoxin	Depolarization block
Fungi		
Fusarium spp.	Tricothecenes	DNA toxin; hemorrhagic syndrome
Plants		
Ricinus communis (castor bean)	Ricin	DNA toxin; hepatorenal Na^+ channel blockade failure
Amphibia		
Colombian frog	Batrachotoxin	Irreversible; Na^+ channel blockade
Reptilia		
Asian cobra *(Naja naja oxiana)*	Cobra toxin	Postsynaptic neurotoxin via phospholipase A_2
Taiwan banded krait *(Bungarus multicinctus)*	α-Bungarotoxin	Acetylcholine receptor blocker
Fish		
Deadly pufferfish	Tetrodotoxin	Na^+ channel blockade

Modified from Baker DJ: Anesthesia in extreme environmental conditions. Part 2. Chemical and biologic warfare. In Grande CG, editor: Textbook of trauma anesthesia and critical care, *St Louis, Mosby–Year Book, 1993, pp 1320-1354.)*

cytoplasm, where it catalyzes the proteolysis of components involved in the calcium-mediated exocytosis of acetylcholine. The inhibition is permanent, and recovery occurs only after the creation of new terminal boutons. The toxin thus blocks neurotransmission, parasympathetic synapses, and peripheral ganglia. The signs and symptoms of botulism can be explained on this basis.

Conventionally, after ingestion of the toxin (the usual route), a latent period of several hours occurs, after which the parasympathetic action produces a dry mouth, followed by signs of a progressive bulbar palsy (dysarthria, dysphasia, and dysphagia) and ocular signs (diplopia and ptosis). These signs are followed by a progressive symmetric descending muscular weakness, leading to respiratory failure requiring prolonged ventilatory support. Neuromuscular testing shows a classic presynaptic decremental pattern to repeated stimuli with posttetanic facilitation. Single-fiber electromyography detects the neuromuscular changes before conventional nerve stimulation; increased jitter and blocking occur, which are reduced by increasing the nerve firing rate.[108] The pattern of signs and symptoms after a deliberate mass inhalation release is not known, but botulinum toxin must be considered along with the nerve agents in any cases manifesting with sudden disturbances of cholinergic transmission.

Conventional level C protection (see section on Personal Protection) and decontamination procedures are effective against the toxin, and several antisera agents are available. A heptavalent antitoxin exists for all the serotypes, but the human efficacy is not known with certainty.[107] Established cases require supportive treatment with antitoxin and positive-pressure ventilation. The latter may be required for some time.

Saxitoxin

Saxitoxin has been suggested as a possible terrorist toxic agent, but no record exists of its production or use in a military context. In nature, it is produced by dinoflagellate sea organisms (causing the "red tide") including *Alexandrium tamarense, Gymnodinium catenatum,* and *Pyridinium bahamense*. The toxin is concentrated in shellfish and is the cause of paralytic shellfish poisoning.[104] The toxin is approximately 20 times more toxic than sarin, having an LD_{50} in mice of 8 μ/kg. Saxitoxin is active by the inhalation route and causes bulbar palsy, respiratory failure, and cardiovascular failure. The toxin acts by blocking voltage-gated sodium channels.[109] Treatment is based on ventilatory and organ support. An antitoxin has been developed in guinea pigs.[110]

Ricin

Ricin is considered a serious terrorist threat because it can be extracted relatively easily from the seeds of the castor bean plant, *Ricinis communus*. Waste from the production of castor oil contains approximately 5% ricin, making it a potential source for terrorists. Ricin has been used in assassinations,[42] and high inhaled concentrations are thought to be fatal. A substantial latent period occurs before generalized signs and symptoms of the inhibition of protein synthesis, which include fever, abdominal pain, diarrhea, weakness, drowsiness, confusion, seizures, coma, cardiovascular collapse, and respiratory failure, all progressing to multiple organ failure and death within 36 to 72 hours. Ricin poses a considerable ICU problem. Treatment is supportive, but an antitoxin has been developed for use in animals.[111,112]

PHARMACOLOGIC AGENTS AND AGENTS OF BIOLOGIC ORIGIN

The events in the Moscow theater siege in 2002[113] highlighted the possible use of substances that were originally developed as anesthetic agents or adjuncts used as "knock down" weapons. In the siege, a substance was released into the air-conditioning system by special forces entering the theater, which led to the deaths from respiratory failure of 127 of 800 of the hostages. The event emphasized the need for immediate life support after toxic attack with short-latency agents. The Russian government, after challenge, declared that the agent used was "fentanyl." Many fentanyl agents have been synthesized

apart from those familiar in clinical practice and some are too toxic for general use. Another possibility is the use of a short-chain neuropeptide. Considerable research effect went into investigating such compounds during the last days of the USSR.[44] Agents such as 3-quinuclidinyl benzylate (BZ or agent-15) (also initially considered as a possible cause of the theater casualties) have been used for many years and are centrally acting anticholinergic agents. Phencyclidine compounds (related to ketamine) and other hallucinogens were tested during the early days of chemical warfare research during the Cold War and should be considered as part of the differential diagnosis of patients presenting with central nervous system symptoms after a possible toxic attack.

CLASSIC BIOLOGIC WARFARE AGENTS

General Considerations

Although many organisms have been suggested as being capable of use as biologic warfare agents, only a few have been studied to the point of being a threat rather than a hazard.[42] Management of deliberate epidemics is the role of specialist physicians, and anesthesia providers are likely to encounter only agents that have serious pulmonary effects and are likely to require ICU care. Many analogies from normal epidemic outbreaks are relevant to deliberate biologic warfare attacks, particularly by terrorists. The severe acute respiratory syndrome (SARS) epidemic in 2004 was a valuable lesson about the spread of a new infectious pathogen in a world linked by fast air travel connections. Although previous slower forms of travel allowed the incubation of symptoms before arrival at the destination, air travel does not, and patients may be asymptomatic at the time of their arrival. All hospital practitioners must now be aware of the possibility of transmission of infection from distant locations. Recent travel history should be an essential part of the initial patient interrogation process.

Anthrax

Bacillus anthracis, an aerobic gram-positive, spore-forming, rod-shaped organism, is one of the few listed "standard" biologic warfare agents that has been proved to be a hazard and a weaponized threat. The natural reservoir of the disease is spores in the soil, and it is these highly resilient spores than form the basis for its use as a biologic agent. During tests in World War II, a whole Scottish island was experimentally contaminated and remained in this condition for over 40 years.[42] Evidence for weaponization of the bacillus by several other countries has been presented. An accidental release from a military installation in the USSR in 1979 claimed more than 100 lives.[43] The Iraq War in 2003 was fought under the shadow of a possible anthrax attack, although no such weapons were found. Although the standard biologic warfare release is by aerosolization of the spores, the agent was distributed in the United States by mail as a powder in 2001 and claimed several lives, demonstrating its terrorist use.

Anthrax exists in cutaneous, gastrointestinal, and pulmonary forms, but the pulmonary form is the major concern of the anesthesia provider and intensivist. In its natural state, pulmonary anthrax is rare, but deliberate release of spores in an aerosol would make the presentation more common.

Physical Findings. The physical findings in pulmonary anthrax are nonspecific, but chest radiography may show signs of effusion or pulmonary edema and mediastinal widening. An immunoassay is available that can detect circulating toxin. The infective dose of anthrax when inhaled is 8000 to 15,000 spores. Spores between 2 and 5 μm reach the alveoli; spores greater than this size are trapped in the upper airways. After trapping, the spores are removed to the mediastinal and hilar lymph nodes by pulmonary macrophagocytes. After a germination period of 1 to 3 days, large amounts of anthrax toxin are released into the circulation, causing the clinical manifestations of the pulmonary form of the disease. An initial insidious phase lasting 1 to 4 days consists of general malaise, fatigue, myalgia, nonproductive cough, and fever. During the next phase of the pulmonary disease, a necrotizing hemorrhagic mediastinitis occurs causing chest discomfort, dyspnea, and stridor. In untreated cases, multiple organ failure follows, which is very refractory to treatment and causes death within 24 to 36 hours. In 50% of cases, hemorrhagic meningitis with coma occurs.

Pathogenesis. Considerable work has been done on the mechanism of the pathogenesis of anthrax infection and the effects of the toxin. This consists of three proteins with a central protective component binding the other two, known as the edema and lethal factors. After transfer to the cytoplasm edema factor, a calmodulin-dependent adenyl cyclase converts adenosine triphosphate to cyclic adenosine monophosphate,[114] which in turn causes tissue edema and suppression of the oxidative burst associated with polymorphonuclear phagocytosis.[115] Lethal factor is thought to be associated with macrophage expression of tumor necrosis factor and interleukin-1, cytokines that are a fundamental part of the systemic inflammatory response.

Treatment. Treatment of anthrax infection has classically been founded on the use of benzylpenicillin, but evidence of resistance has been reported. The current antibiotic recommendation is to use ciprofloxacin 400 mg every 8 hours, and this was widely used as prophylaxis during the 2001 anthrax attacks in the United States. Other approaches may be more appropriate, including doxycycline 200 mg intravenously followed by 100 mg intravenously every 8 hours, gentamycin, erythromycin, or chloramphenicol (Table 83B-5).

The recommended antibiotic prophylaxis is ciprofloxacin 500 mg every 12 hours or doxycycline 100 mg every 12 hours orally. This should be started as soon as possible after exposure.[116] Vaccines have been studied, and the standard Michigan vaccine should be given at 0, 2, and 4 weeks and then at 6, 12, and 18 months, followed by annual boosters. If vaccines are unavailable, antibiotic prophylaxis should be continued for 60 days. For anesthesia providers, intensivists, and other staff working on the longer term care of patients with anthrax, prophylaxis is important, together with careful filter protection of ventilation and disinfection. Wherever possible, disposable circuits should be used.

TABLE 83B-5 TREATMENT FOR PATIENTS EXPOSED TO BIOLOGIC WARFARE AGENTS

Agent	Infective Dose	Incubation Period	Effects (After Inhalation)	Staff Protection	Specific Treatment	Chemoprophylaxis	Vaccine	Mortality if Untreated
Bacillus anthracis	8000-15,000 spores	1-5 days	Mediastinitis, meningitis, MOF	Isolation, vaccination, universal precautions	Ciprofloxacin 400 mg IV tid; doxycycline 200 mg IV once, then 100 mg IV tid; penicillin 2 million units IV 2 hourly plus streptomycin 30 mg/kg IM daily	Ciprofloxacin 500 mg PO bid × 4 wk + vaccinate; doxycycline 100 mg PO bid × 4 wk + vaccinate	Michigan at 0, 2, 4 wk, 6, 12, 18 mo, then annually	Pneumonic, 100%
Yersinia pestis	100-500 organisms	2-3 days	Pneumonia, septicemia, MOF	Isolation, universal precautions	Streptomycin 30 mg/kg IM daily × 10 days; doxycycline 200 mg IV, then 100 mg IV tid × 14 days (chloramphenicol)	Doxycycline 100 mg PO bid × 7 days; tetracycline 500 mg PO daily × 7 days	Greer at 1-3 mo plus 3-6 mo	Pneumonic, 100%
Viral hemorrhagic fevers	1-10 organisms	4-21 days	Coagulopathy, edema, MOF	Isolation, HEPA masks, universal precautions	Ribavirin 30 mg/kg IV once, then 15 mg/kg IV daily × 4 days, then 7.5 mg/kg IV tid × 6 days (immunoglobulin)	NA	None	90% (Ebola-Zaire)
Viral encephalitides	10-100 organisms	2-6 days (VEE) 7-14 days (EEE/WEE)	Encephalitis, seizures, coma, CNS damage	Universal precautions	Supportive, anticonvulsants	NA	Available for VEE, EEE, and WEE	75% (EEE)
Francisella tularensis	10-50 organisms	2-10 days	Pneumonia, pleural effusions	Universal precautions	Streptomycin 30 mg/kg IV daily × 10-14 days; gentamicin 3-5 mg/kg IV od	Doxycycline 100 mg PO bid × 14 days	Live attenuated	35%
Variola organisms	10-100	7-10 days	Rash, secondary pneumonia	Isolation, universal precautions	Cidofovir 5 mg/kg IV once every 2 wk	Vaccinia immunoglobulin	Wyeth	Unvaccinated 30%, vaccinated 3%
Burkholderia mallei	1-10 organisms	10-14 days	Septicemia, pneumonia, lymphadenopathy	Universal precautions	Co-amoxiclav 20 mg/kg IV tid	Tetracycline 500 mg PO daily × 14 days	None	Uncertain: >30% if septicemic
Coxiella burnetii	1-10 organisms	10-14 days	Myalgia, malaise, fever	Barrier nursing	Doxycycline 100 mg PO bid × 5-7 days after exposure × 5 days	Doxycycline 100 mg PO bid for 8-12 days	Q vax	<1%
Brucella spp.	10-100 organisms	5-60 days	Malaise + cough, sacroiliitis, pancytopenia	Barrier nursing	Doxycycline 100 mg PO bid plus rifampicin 900 mg tid PO for 6 wk	Doxycycline and rifampicin for 3 wk	None	<5%
Escherichia	10-100 organisms	1-5 days	Vomiting and diarrhea, renal failure	Barrier nursing	Antibiotics not required	NA	None	<5% *E. coli* O157:H2

Plague

Plague was the scourge of the medieval world, and natural outbreaks continued well into the twentieth century. Plague has long been considered a potential biologic warfare agent and was researched extensively by the USSR.[44] The pulmonary form is very serious and requires ICU support. The causative organism, *Y. pestis,* is an anaerobic, gram-negative coccobacillus transmitted to humans by fleas carried by rodents or by animal-human or human-human droplet infection.[117,118] Bubonic, pneumonic, and septicemic forms of plague exist; the latter two are fatal without treatment. Only approximately 100 to 5000 organisms constitute an infective dose. The incubation period is 2 to 3 days, after which a pneumonia develops with malaise, high fever, myalgia, hemoptysis, and finally septicemia. There is dyspnea, stridor, and cyanosis. With the worsening condition, intermittent positive-pressure ventilation is required with aggressive antibiotic treatment. Confirmation of the diagnosis comes from the causative organism in blood, lymph nodes, or sputum cultures. An enzyme-linked immunosorbent assay is available. Pneumonic plague has long been recognized as being fatal, but antibiotic treatment reduces the mortality to at least 60%. The first line of treatment is streptomycin 30 mg/kg every 12 hours for 10 days. Alternatives are gentamycin or chloramphenicol. An inactivated vaccine (Greer vaccine) is available, but its effectiveness is not thought to be high.

Cholera

Cholera is a widespread natural infection originating from the Far East, which caused several epidemics in Europe throughout the nineteenth century. Although cholera is in the domain of the specialized physician, the profound fluid imbalances caused by the disease make admission of patients to the ICU likely in severe cases. Cholera has been suspected of being weaponized, but it can be spread effectively only by causing mass poisoning through the water supply. Outbreaks occurring in China during World War II were thought to be caused in this way.[42]

Pathogenesis. The infection is localized to the small bowel and causes a major outpouring of fluid and electrolytes. Paradoxically, fluid can still be absorbed, and this is the basis of the use of oral rehydration solutions in mass outbreaks in developing countries.

Treatment. The management of cholera is essentially fluid and electrolyte replacement. Traditionally, the intravenous route was used, but modern practice is to use oral rehydration solutions containing electrolytes and glucose,[119] Early rehydration in this way avoids the need for admission to the ICU. In the case of a deliberate cholera epidemic, early rehydration would be a high priority for treatment of mass casualties. Tetracyclines have traditionally been the antibiotic treatment of choice but resistance has been reported.[119]

Glanders

Glanders is an equine disease caused by the gram-negative bacillus *Burkholderia mallei*. It has long been considered a potential biologic warfare agent in a modified form because the organism is known to be highly infectious in the aerosolized form. Acute and chronic forms occur in humans.[120] The septicemic form appears 10 to 14 days after exposure, making the agent one of long latency. It is characterized by a sudden onset of high fever, rigors, and myalgia, with cervical lymphadenopathy, splenomegaly, leukopenia, or leukocytosis. In this form, septic shock and multiple organ failure occur, and the fatality rate without treatment is high. After inhalation of the organism, the acute pulmonary form is seen, with septicemia, bilateral pneumonia, and pulmonary nodular necrosis. The chest radiograph shows miliary shadowing. The severe acute forms of the disease are most likely to concern intensivists, but an oropharyngeal form also occurs with ulceration of the septum and turbinate and a blood-stained mucopurulent discharge and macropapular or pustular rash similar to smallpox. In the chronic form, glanders can produce chronic lymphadenopathy, multiple musculocutaneous abscess formation, and oropharyngeal nodules. The first-line treatment of glanders is an antibiotic combination (co-amoxiclav and sulfadiazine 30 mg/kg^{-1} every 8 hours for 3 weeks). Doxycycline, rifampicin, and ciprofloxacin are second-line drugs. No vaccine against glanders exists.

Viral Diseases Regarded as Potential Biologic Warfare Hazards

A number of viral illnesses are considered to be potential biologic warfare agents. They are the province of the specialized infectious disease physician, and the anesthesia provider is referred to the specialized texts for a broader discussion.

Smallpox. Of the potential biologic warfare viral disease agents, smallpox is placed high on the potential terrorist hazard list because of the continuing presence of laboratory stocks of virus, which is normally promulgated only through human hosts. The success of the worldwide vaccination campaign led the WHO to declare smallpox an extinct disease, and mass vaccination programs were stopped. However, laboratory studies continued, and there is a fear at present that strains could be stolen and used to create a deliberate widespread epidemic in a largely unprotected population. Intensive care may be required for cases contracting overwhelming secondary infection. Although treatment is based on isolation and supportive therapy, there is current interest in the use of the antivirals cidofovir and ribavirin.[121]

INVOLVEMENT OF THE ANESTHESIA PROVIDER IN THE MANAGEMENT OF CASUALTIES FROM EXPOSURE TO CHEMICAL AND BIOLOGIC WARFARE AGENTS

APPROACHES TO MANAGEMENT OF CHEMICAL AND BIOLOGIC WARFARE INCIDENTS

Anesthesia providers may be confronted with the management of victims from the deliberate or accidental release of CBW hazards inside and outside the hospital.

A system of management of such cases is essential that provides for the safety of the medical responders and the correct treatment for the patient. Management should be considered in terms of (1) management of the incident and (2) management of the patient's condition. In terms of the four properties of agents in the CBW spectrum (see the section on Agents of Chemical and Biologic Warfare: Background and Development), management of the incident is determined by persistency and transmissibility, and management of the patient's condition by toxicity and latency.

Many chemical hazards have very limited persistency, and decontamination is not required. Limited persistency means reduced risk for contact transmission to other persons. However, certain chemical agents have long persistency and thus high transmissibility. Many such agents do not pose a significant threat by inhalation, but may be absorbed through the epithelia (e.g., nerve agent VX). For such agents, careful decontamination is essential.

Most classic biologic warfare agents have low persistency, being rapidly degraded by the environment, and depend on host transmission via an incubation period. In such cases, transmissibility is high. Anthrax is a notable exception; its spores have very long persistency, but no infective transmissibility. At the other extreme, the viral hemorrhagic fevers have very short persistency but high infective transmissibility.

MANAGEMENT OF THE INCIDENT

Disaster planning is a process familiar to many anesthesia providers and provides a good model of how to approach toxic releases. A toxic release is a special case of disaster and may be either accidental or deliberate. Plans put in place for a terrorist release of a CBW agent are equally valuable for the more likely case of accidental release. Moles[122] summarized the essential points of disaster planning as follows:

1. The importance of risk assessment: Not all listed hazards are identifiable risks
2. The essential stage of preplanning: Should bring together all the different emergency agencies, such as fire, civil defense, and police, who would be involved in CBW incident management
3. A phased response: Importance of, based on exercises and assessment

PERSONAL PROTECTION

Protection is a key feature of incident management, and anesthesia providers should be familiar with personal protection levels (Box 83B-5), protective suits and masks, and techniques of decontamination. As Box 83-7 shows, several levels of protection are used in the management of toxic releases, but the appropriate level for medical intervention is level C, which allows reasonable tactile dexterity and contact with the patient to provide essential life support and antidote therapy onsite.[49] Level C protection (Fig. 83B-8) is equivalent to that used by the military to provide protection against the most toxic chemical warfare agents and virulent biologic warfare organisms.

DETECTION AND IDENTIFICATION OF THE HAZARD

Unlike military CBW releases, civil incidents may not provide early information about the nature of the hazard (Box 83B-6). Patterns of signs and symptoms manifesting in victims may be the first indication of the nature of the causative agent. Detection and

BOX 83B-6 ***Management of Chemical and Biologic Warfare Releases: Military and Civil Approaches***

Military: Toxic release is an anticipated event following intelligence. Military have analysis of hazards and threats.

- Tuned detection systems for specified hazards
- Use of generic detection systems
- Ordered responses
- Appreciation of the nature of the event by combat trained personnel

Civilian: Toxic agent release is (usually) an accidental event

- Natural epidemics
- Casualties may be the first indication of the nature of the incident
- No fixed detection systems
- Ability to respond without battlefield constraints
- Widespread HAZMAT system of hazard control
- Uncontrolled and usually ill-disciplined population

Figure 83B-9. Special triage, decontamination, and resuscitation center set up at a Parisian teaching hospital. *(Courtesy Service d'Aide Médicale Urgente [SAMU] de Paris, France.)*

monitoring devices for established military chemical warfare hazards exist but are not widely available in the civil context. Intelligence information may be available for terrorist attacks. In the case of accidental toxic agent release, information would be available from the HAZMAT system and the appropriate classification codes (see Box 83-3).

EARLY PATIENT MANAGEMENT AFTER CHEMICAL AND BIOLOGIC WARFARE RELEASE

If the released hazard is persistent and transmissible, decontamination is essential in the decontamination zone. In some countries, level C–protected medical staff or paramedics can now operate in this area and work alongside fire personnel in providing (1) triage, in terms of whether the patient requires decontamination and the patient's medical status; (2) immediate life support measures (TOXALS); and (3) immediate antidote and other pharmacologic support.

Figure 83B-9 shows a medically operated chemical warfare casualty reception facility in a Parisian hospital. Early life support measures in the decontamination zone are very important[123] (see also Chapter 107). The concept of TOXALS, introduced in 1996,[124] expands the familiar ABCs of life support to relate to toxic releases as follows:

- **A**irway (see also Chapter 55) of the casualty patient must be obviously maintained at all times. In the unconscious casualty, this may involve simple basic airway maneuvers plus suction of the copious secretions associated with chemical poisoning. Occasionally, advanced airway management, such as tracheal intubation, may be required to protect the airway from the excessive secretions and to prevent aspiration of regurgitated stomach contents.
- **B**reathing must be carefully observed until full decontamination and recovery have occurred. Supplemental O_2 will speed the recovery from volatile chemical poisoning. If breathing becomes compromised, artificial ventilation with supplemental O_2 must be administered using a self-inflating resuscitation bag-valve-mask or automatic ventilator. Entrained air must be filtered when ventilating casualties in a contaminated environment.
- **C**irculation must be carefully observed and monitored. Noninvasive blood pressure, pulse oximetry, and electrocardiogram monitoring are all useful indicators of circulatory function. The early establishment of intravenous access aids the administration of fluids and drugs.
- **D**isability (conscious level) should be assessed using the simple *AVPU* scale (**A**lert, responds to **V**oice, responds to **P**ain, **U**nresponsive). This assessment should be repeated at frequent intervals to assess the progress of the casualty.
- **D**rugs, especially the specific antidotes, should be administered when a specific agent has been identified.
- **E**xposure of the casualty is essential not only to assess physical damage, but also to remove all clothes that have been contaminated by the chemical. Approximately 80% of surface contamination is removed by undressing.
- **E**nvironment. The primary management as described may be severely limited by the need for the rescuer to wear protective clothing. Only those skilled in these techniques and trained in protective clothing should enter and treat casualties in a contaminated area. All others should await the casualties' arrival in the cold or clean zone after decontamination.

Identification of the chemical and its specific antidote might take some time. However, this must not delay the basic medical management of the casualty.

Somatic Systems Affected by Toxic Hazards

Early patient management is based on (1) identification information and (2) the manifesting signs and

symptoms. Usually information will be available to help with identification of the agent used. On the basis of manifesting signs and symptoms, it is useful to consider attacks on the various clinical systems as guide to the agent used (Table 83B-6). A wide range of chemical agents affect the respiratory system. These are summarized in Table 83B-7.

TABLE 83B-6 EFFECTS OF CHEMICAL AND BIOLOGIC WARFARE AGENTS ON SOMATIC SYSTEMS

System Affected	Agents
Epithelial	Vesicants (e.g., sulfur mustard), smallpox, ricin
Respiratory	
Upper, lower airway	Vesicants, phosgene
Respiratory control system	Nerve agents, ABO
Gaseous exchange	Pulmonary edemagens
Mechanics of breathing	Nerve agents, neurotoxins
Central nervous system	Nerve agents, cyanide, neuropeptides, agents of anesthetic origin (phencyclidines, BZ)
Peripheral nervous system	Nerve agents, neurotoxins (e.g., botulinum, saxitoxin)
Immune system	Vesicants, ABO (provocation of immune responses, inflammatory responses, organ failure)
Cardiovascular	Nerve agents, ABO
Alimentary, renal	Nerve agents, toxins, infectious agents

ABO, Agents of biologic origin; *BZ,* quinuclidinyl benzilate.

Problems in the Medical Management of Chemical and Biologic Warfare Incidents

Potential problems in managing CBW incidents include:

- Failure to recognize CBW release
- Failure to implement appropriate HAZMAT procedures to limit the number of secondary casualties
- Release of the agent overwhelming available emergency and medical resources
- Insufficient planning and training
- Lack of appropriate protective equipment
- Lack of resuscitation skills for early life support
- Lack of specific knowledge for the management of toxic or infectious hazards
- Panic and hysterical reactions from a frightened general public fueled by irresponsible reporting

These problems may be minimized by careful planning, equipping, and training, with the objective of making a CBW release manageable in the same sense as for other mass disasters.

EFFECTS OF CHEMICAL AND BIOLOGIC WARFARE AGENTS ON ANESTHETIC PRACTICE

MANAGEMENT OF MIXED TOXIC AND PHYSICAL INJURY

Chemical warfare and HAZMAT release may be accompanied by explosion and fire causing associated injuries requiring surgical intervention. The effects of the release

TABLE 83B-7 EFFECTS OF TOXIC AGENTS ON RESPIRATION

Respiratory Component	Effect	Toxic Agent
Central nervous system	Depression of respiratory drive and seizures leading to apnea	Nerve agents, cyanide, neuropeptides
Peripheral nervous system	Neuromuscular paralysis of respiratory muscles	Nerve agents, neurotoxins
Nasopharynx	May become blocked by excess secretions Prodromal rhinitis and rhinorrhea Sneezing	Lung-damaging agents, nerve agents Vesicants Early symptom of mustard agent
Larynx	Irritation, laryngeal spasm	Upper respiratory irritant, lung-damaging agents Riot-control agents, particularly CS and CR (tear gas)
Large airways	Blocked by secretions Blocked by inhaled vomitus Sloughing of walls of trachea and main bronchi, produces "pseudodiphtheritic" membrane, serious cause of large airway obstruction, leading to bronchopneumonia and death	Nerve agents (theoretic) Various agents Vesicant agents
Small airways	Blocked by secretions Cholinergic innervation affected; bronchospasm (relieved by atropine) Chemical bronchiolitis, followed by serious bronchospasm	 Nerve agents Vesicant agents
Alveoli	Toxic pulmonary edema	Various agents, especially lung-damaging agents (latency 6-24 hr) Vesicant agents, particularly if inhaled at high ambient temperature*

agent on the subsequent conduct of general anesthesia are important. Many of the agents described earlier affect the condition of the patient and the action of anesthetic agents.

EFFECTS ON THE CONDITION OF THE PATIENT

Shock and toxic airway injury can produce ventilation-perfusion inequality, which affects preoxygenation for emergency induction of anesthesia (see also Chapter 55). The respiratory uptake of anesthetic vapors and alveolar ventilation itself are affected by degrees of shunt and pulmonary edema. Above all, the action of toxic agents may be expected to alter the balance and flow of general anesthesia and may cause delays in recovery, which would be labor-intensive in management. In terms of postoperative intensive care, patients who have been exposed to pulmonary edemagens and to OPs may pose the greatest problem (Box 83B-7).

Intensive Care Implications

Chemical warfare agent exposure may cause several syndromes that require medium-term or even long-term ICU treatment. These include pulmonary edema and ARDS. In the case of OP exposure, it is possible intermediate syndrome may develop,[125,126] with a reparalysis of the patient requiring several days of ventilation. Experience with OP anticholinesterases in this area is lacking, although considerable evidence has been reported from pesticide poisoning.

Many of the infectious agents considered biologic warfare agents can cause infections and even an overwhelming inflammatory response and organ dysfunction. Intensive care is required for cases of systemic inflammatory response syndrome and multiple organ dysfunction syndrome cases (see also Chapter 100). The continued possibility of an avian flu pandemic highlights the need to provide simple mass ventilation systems in high-dependency units. Many patients infected with biologic warfare agents can receive ventilation using simpler machines than those found in the ICU and that can be operated by non-ICU personnel. Mass procurement of devices and training is necessary. The ability of hospitals to provide intermittent positive-pressure ventilation for large numbers of casualties is a necessary step in managing not only epidemics of respiratory disease but also the consequences of a number of the CBW agents in which respiratory failure is the end stage of the pathologic condition.

Chapter 84

Anesthesia for Eye Surgery

MARC ALLAN FELDMAN

Acknowledgment: The editors and the publisher would like to thank Dr. Anil Patel, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Understanding ocular anatomy and physiology and the systemic effects of ophthalmic medications is essential to preparing an appropriate anesthesia plan.
- Pressure on the globe or any orbital contents can result in a trigeminovagal or oculocardiac reflex with bradycardia, atrioventricular block, or even asystole.
- The blood supply to the retina is governed by the ocular perfusion pressure, which is determined by the arterial blood pressure and the intraocular pressure (IOP).
- Sufficient concentrations of inhaled anesthetics decrease IOP, whereas ketamine and succinylcholine can increase IOP.
- Sudden increases in IOP in the setting of open globe injury can lead to vitreous loss and blindness.
- Complications of retrobulbar block include retrobulbar hemorrhage, increased IOP, intraarterial injection with convulsions, and subarachnoid injection via the optic nerve sheath with respiratory arrest.
- Nitrous oxide should be avoided for 15 minutes before the insertion of intraocular gas. Nitrous oxide must be avoided for 7 to 45 days after use, or until the gas bubble is resorbed.
- True ophthalmic emergencies, such as chemical burns and central retinal artery occlusions, must be treated within minutes to avoid permanent vision loss. Open globe injuries and other urgent procedures can be scheduled after appropriate NPO status.
- Eye compression from a facemask or positioning can lead to central retinal artery occlusion.

OCULAR ANATOMY

The eye is a sphere measuring approximately 24 mm in diameter. It sits in the pyramidal bony orbit. The wall of the globe has three layers: the sclera, the uveal tract, and the retina.

The sclera is the outermost layer. It is the tough, fibrous white of the eye. The transparent cornea is the anteriormost part of the sclera. Most of the focus power of the eye is from the curvature of the cornea.

The middle layer, the uveal tract, has three structures: the choroid, the iris, and the ciliary body. The choroid is a layer of blood vessels located posteriorly. Bleeding in this layer is one cause of intraoperative expulsive hemorrhage. The pigmented iris controls light entry with muscle fibers that change the size of the pupil. Sympathetic stimulation dilates the pupil by causing iris dilator muscles to contract, whereas parasympathetic stimulation causes miosis, or pupillary constriction, by causing the iris sphincter muscles to contract. The ciliary body lies just behind the iris; it produces aqueous humor. Ciliary muscle fibers adjust the focus by releasing tension on the suspensory fibers, or zonules, of the lens. Opacification of the lens causes a cataract. Uveitis is an inflammatory condition of these structures (iris, choroid, and ciliary body).

The innermost eye layer is the retina. Light stimulates retinal photoreceptors to produce neural signals that the optic nerve carries to the brain. There are no capillaries in the retina; the choroid layer provides the retina with oxygen. Retinal detachment from the choroid layer compromises the retinal blood supply and is a major cause of vision loss. The retinal layer ends approximately 4 mm behind the iris. The area between the limbus of the cornea and the retina is called the *pars plana*. Because there is no retinal layer there, it is a safe entrance site for vitrectomy procedures.

The center of the eye is filled with vitreous gel. This thick fluid has attachments to blood vessels and the optic nerve. Traction of the vitreous on the retina is a cause of

retinal detachment. Scarring, bleeding, or opacification of the vitreous is treated by vitrectomy.

The extraocular muscles move the globe within the orbit. They arise from a fibrous ring near the apex of the orbit and insert on the sclera. The six extraocular muscles lie within a cone behind the eye surrounding the optic nerve, ophthalmic artery and vein, and ciliary ganglion.

The eyelids have an outer layer of skin, a muscle layer, a tarsal plate of cartilage, and a layer of conjunctiva. The conjunctiva is a mucous membrane that lines the inner eyelids and covers the globe up to the corneal-scleral junction.

The lacrimal gland sits in the superior temporal orbit. It releases tears across the surface of the globe. Tears drain via the puncta near the medial canthus of the eyelids. Tears flow through the canaliculi to the lacrimal sac and duct, to drain into the nasopharynx.

The ophthalmic artery provides most of the blood supply to the orbital structures. It is a branch of the internal carotid artery, close to the circle of Willis. The superior and inferior ophthalmic veins drain directly into the cavernous sinus.

Cranial nerves (CN) innervate the ocular structures. The optic nerve (CN II) carries the neural signals from the retina. The oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) control the extraocular muscles. Touch and pain sensation is carried via the trigeminal nerve (CN V). Sensation to the lower lid is via the maxillary nerve. Sensation to the upper lid is via the frontal branch of the ophthalmic nerve. The nasociliary branch of the ophthalmic nerve sends sensory fibers to the medial canthus, lacrimal sac, and ciliary ganglion.

The ciliary ganglion provides sensory innervation to the cornea, iris, and ciliary body. Parasympathetic fibers originate from the oculomotor nerve (CN III) and synapse in the ciliary ganglion before supplying the iris sphincter muscle. Sympathetic fibers originate from the carotid plexus and travel through the ciliary ganglion to innervate the dilator muscle of the iris. Local anesthetic blockade of the ciliary ganglion produces a fixed, mid-dilated pupil.

The facial nerve (CN VII) exits the base of the skull from the stylomastoid foramen. It supplies motor innervation to the orbicularis muscle via the zygomatic branch. Local anesthetic block of the facial nerve can prevent lid squeezing.

OCULOCARDIAC REFLEX

The oculocardiac reflex was first described by Aschner and Dagnini in 1908.[1,2] Traction on the extraocular muscles or pressure on the globe causes bradycardia, atrioventricular block, ventricular ectopy, or asystole. In particular, it is seen with traction on the medial rectus muscle, but it can occur with stimulation of any of the orbital contents, including the periosteum.

The reflex is trigeminovagal. The afferent limb is from orbital contents to ciliary ganglion to ophthalmic division of the trigeminal nerve to the sensory nucleus of the trigeminal near the fourth ventricle. The efferent limb is via the vagus nerve to the heart.[3]

The reflex may be seen more often with procedures under topical anesthesia. Retrobulbar block is not uniformly effective, however, at preventing the reflex. Orbital injections can trigger the response. The response is exacerbated by hypercapnia or hypoxemia.

In the event of arrhythmia, the anesthesiologist first should ask the surgeon to stop manipulations. The ventilatory status is assessed. If significant bradycardia persists or recurs, intravenous atropine is administered in 7-μg/kg increments. Rarely, severe bradycardia or asystole occurs. Although chest compressions might be required to allow the atropine to circulate, usually the heart rhythm returns to normal with cessation of manipulation alone. The response fatigues with repeated stimulation.

Pretreatment with intravenous atropine or glycopyrrolate can be effective. Pretreatment may be indicated in patients with a history of conduction block, vasovagal responses, or β-blocker therapy.

INTRAOCULAR PRESSURE

The blood supply to the retina and optic nerve depends on the intraocular perfusion pressure.[4] This perfusion pressure is defined as the difference between the mean arterial pressure and the intraocular pressure (IOP). High IOP impairs the blood supply, leading to a loss of optic nerve function. After an incision in the globe is made, factors that would increase IOP can cause prolapse and loss of intraocular contents; this can cause permanent vision loss.

The globe is a relatively noncompliant compartment. The volume of the internal structures is fixed except for aqueous fluid and choroidal blood volume. The quantity of these two factors regulates IOP.

Two thirds of the aqueous fluid is actively secreted by the ciliary body by a sodium-pump mechanism. One third comes from passive filtration through vessels on the iris. Aqueous fluid is produced at a rate of 2 μL/min. Aqueous fluid flows over the lens and through the pupil to bathe the inner corneal endothelium. It then enters the angle of the anterior chamber to flow through the trabecular meshwork to the canal of Schlemm. The canal of Schlemm is continuous with channels to the episcleral veins. IOP is primarily regulated by the resistance at the trabecular meshwork. Normal pressure is 10 to 20 mm Hg.

Impairment of aqueous drainage at any point can elevate the IOP. Sclerosis of the trabecular meshwork is believed to cause the chronic pressure elevation in open-angle glaucoma. Closed-angle glaucoma occurs when there is an obstruction to aqueous drainage from closure of the anterior chamber angle. This happens from peripheral iris swelling or anterior displacement. Patients with a preexisting narrow angle may be predisposed to this condition. The acute increase in pressure causes severe pain and is an ophthalmologic emergency.

Changes in choroidal blood volume can increase IOP rapidly. Hypercapnia causes choroidal congestion.[5] Coughing, straining, or vomiting can increase IOP to 30 to 40 mm Hg. Endotracheal intubation can cause similar increases. These increases are transient and are relatively innocuous in a closed eye. In an open eye, such

as after traumatic injury or during cataract surgery, these increases can lead to loss of intraocular contents, hemorrhage, and permanent vision loss.[6]

Extrinsic compression of the eye also increases the IOP. A normal blink increases the IOP by 10 mm Hg. A forceful lid squeeze can increase IOP to more than 50 mm Hg.[7] A poorly placed anesthesia mask can put enough pressure on the eye to reduce blood flow to zero.

Deep inhaled or intravenous (e.g., propofol) anesthesia causes a dose-related reduction in IOP by 30% to 40%.[8] Opioids have little effect. Usual doses of atropine do not cause a significant increase in IOP, even in patients with open-angle glaucoma. Ketamine can cause a modest increase in IOP.

Intravenous succinylcholine causes IOP to increase by 6 to 12 mm Hg[9]; this lasts for 5 to 10 minutes. The use of succinylcholine for induction of anesthesia in cases of open-globe injury with full stomach has been controversial. Loss of vitreous in patients from succinylcholine has not actually been reported.

OPHTHALMOLOGIC DRUGS

Ophthalmologic drugs are systemic medications. Eye drops can have systemic effects and important drug interactions with anesthetics. Acetazolamide is a carbonic anhydrase inhibitor and is used for the treatment of glaucoma to decrease chronically increased IOP. It also induces an alkaline diuresis that can result in potassium depletion. Patients taking acetazolamide should have electrolytes checked preoperatively. Atropine eye drops can cause tachycardia, dry skin, fever, and agitation.[10] Overdose can be treated with incremental doses of physostigmine.

Echothiophate is a topical anticholinesterase drug used to maintain miosis in the treatment of glaucoma. Systemic absorption leads to total body inhibition of plasma cholinesterase. Subsequent administration of succinylcholine can cause prolonged muscle paralysis (see Chapter 34).[11] Inhibition of the metabolism of ester-type local anesthetics may predispose a patient to local anesthetic toxicity. Echothiophate is a long-acting. A return toward normal enzyme activity can take 4 to 6 weeks after discontinuation of the drug.

Mannitol is an osmotic diuretic that causes a decrease in IOP lasting 5 to 6 hours. Patients who receive mannitol during surgery may need a urinary catheter to avoid overdistention of the bladder. Mannitol causes an increase in the circulating blood volume, which can lead to congestive heart failure in patients with poor ventricular function.

Phenylephrine is an α-adrenergic agonist applied topically to dilate the pupil. Systemic absorption of the 10% solution is associated with severe hypertensive reactions.[12] The 2.5% concentration is safer, but can exacerbate hypertension in some patients.

Pilocarpine and acetylcholine are cholinergic drugs used to constrict the pupil and can cause bradycardia and acute bronchospasm.

Timolol maleate is a topical β-blocker used for the treatment of glaucoma. Systemic absorption causes β-blockade, with possible bradycardia, bronchospasm, or exacerbation of congestive heart failure.[13] These concerns are especially important in patients with severe chronic obstructive pulmonary disease.

Tamsulosin hydrochloride (Flomax) has selective α-adrenoreceptor antagonistic properties and binds for a long period to nerves to the iris dilator muscle, affecting iris dilation and leading to complications in cataract surgery. The iris remains floppy even after a 7- to 28-day interruption of the tamsulosin regimen.[14]

PREOPERATIVE EVALUATION (see Chapter 38)

Eye surgery is the most common surgery in the elderly (see Chapter 80). In 2005, the Medicare program paid for nearly 3 million claims for cataract surgery. These outpatient procedures are quick and do not involve blood loss or significant postoperative pain. They are not minor procedures, however; ophthalmic surgery can be a major life event. Establishing a professional relationship reduces anxiety and helps the patient prepare for surgery. Giving information to the patient is just as important as getting information from the patient. An informed patient is more calm, comfortable, and cooperative. The patient needs to know what to expect.

Patients undergoing eye surgery can be a high-risk group. Adults tend to be older. Most patients have other risk factors, such as diabetes, hypertension, and atherosclerosis.[15] Cataracts are a marker for increased mortality in the Nurses' Health Study.[16] Yet, ophthalmic surgery is still low risk. Mortality after eye procedures is more infrequent than for the general surgical population. Backer and colleagues[17] found that eye surgery did not pose the risk of myocardial reinfarction seen with general surgical procedures. Patients' chronic diseases have less effect on outcome with these procedures. In a study of unanticipated hospital admissions after outpatient ophthalmic surgery, age and American Society of Anesthesiologists (ASA) physical status were not significant factors.[18]

There is controversy regarding the best preoperative management. Some clinicians say that because cataract extraction is a low-stress procedure with no blood loss, no preoperative evaluation is needed. Publication of a large, multicenter trial showed no effect of preoperative blood tests and electrocardiogram on postoperative outcome.[19] Another opinion is that every patient must receive a full evaluation to include every possible test, to detect every possible finding, to institute every possible therapy, and to delay as long as possible, so that the patient can be in the best possible condition and have the lowest possible risk. The appropriate approach is likely in between these two approaches. Appropriate preoperative medical consultation is important. A study of malpractice litigation in cataract surgery found that medical consultation accounted for 16% of the liability; this compared with 17% attributed to either local or general anesthesia.[20]

Risk cannot be ignored. Neither should we reduce every risk to the lowest conceivable minimum. The anesthesiologist's goal is to prepare the patient to present an acceptable risk at surgery. Acceptable risk is determined by the medical care team with the informed consent of

the patient. If a patient's condition would indicate inpatient admission for medical treatment, or if a reversible condition would likely lead to a perioperative complication, the risk is unacceptable.

The goal is to develop guidelines that would encourage consistency of care and minimize disruption to patients and the operating room. The following guidelines are presented after review of literature and published guidelines (see Chapters 38 and 80).

PATIENT HISTORY

Previous hospitalizations and surgical procedures are reviewed. Allergies and drug sensitivities are noted. Latex allergy should be addressed specifically. A current list of medications is obtained. Patient factors that could influence anesthetic management include dementia, deafness, language difficulty, restless legs syndrome, obstructive sleep apnea, tremors, dizziness, and claustrophobia. A preoperative patient questionnaire can be very helpful. A thorough review of the patient history helps with perioperative planning and establishing a physician-patient relationship.

PHYSICAL EXAMINATION

Check for signs of major cardiac or pulmonary conditions and problems. Particular attention should be paid to positioning issues, such as severe scoliosis or orthopnea (see Chapter 41).

LABORATORY STUDIES

No routine screening tests have been shown to improve outcome. Yet, laboratory studies should be determined based on the results of the history and physical examination. Generally, the tests that a patient needs before ophthalmic procedures are the same tests a patient would require at a routine examination if surgery were not planned. Tests are chosen when the results are likely to change management. Urgent medical management is obtained for results reaching critical limits. Indications for laboratory studies and critical results are as follows:

- *Electrocardiogram:* New chest pain, decreased exercise tolerance, palpitations, near-syncope, fatigue, or dyspnea; tachycardia, bradycardia, or irregular pulse on examination
  - *Critical results*: Signs of acute ischemia or injury, malignant arrhythmia, complete heart block, atrial fibrillation that is new, or heart rate more rapid than 100 beats/minute
- *Serum electrolytes*: History of severe vomiting or diarrhea, poor oral intake, changes in diuretic management, or arrhythmia
  - *Critical results*: Sodium less than 120 mEq/L or greater than 158 mEq/L; potassium less than 2.8 mEq/L or greater than 6.2 mEq/L
- *Urea nitrogen*: Signs or symptoms of renal decompensation
  - *Critical result*: Greater than 104 mg/dL
- *Serum glucose*: Polydipsia, polyuria, or weight loss
  - *Critical results*: Less than 46 mg/dL or greater than 480 mg/dL
- *Hematocrit/hemoglobin*: History of bleeding, poor oral intake, fatigue, decreased exercise tolerance, or tachycardia
  - *Critical results*: Hematocrit less than 18% or greater than 61%; hemoglobin less than 6.6 mg/dL or greater than 19.9 mg/dL

OPHTHALMIC EVALUATION

Visual acuity of both eyes should be noted. Patients with poor vision in the nonoperative eye face much greater potential functional loss. These patients have a higher anxiety level. If the patient is to be patched overnight, the physician should anticipate the increased need for postoperative assistance for a temporarily blind patient.

The axial length of the globe should be assessed. When ultrasound measurements are available, the axial length should be noted. If no ultrasound is available, a myopic patient likely has an increased axial length. If a posterior staphyloma is present, the risks of injection anesthesia may be dramatically increased. Preoperative glaucoma history, increased IOP, and increased axial length are important risk factors for suprachoroidal hemorrhage. The risk can be reduced with intense control of intraoperative heart rate and arterial blood pressure. Preoperative softening of the globe with a compression device also may decrease risk.

CARDIOVASCULAR EVALUATION

The American Heart Association and American College of Cardiology published guidelines for perioperative cardiovascular evaluation for noncardiac surgery.[21] Ophthalmic procedures, such as cataract extraction, are specifically identified as low-risk procedures. For these procedures, evaluation is focused on patients with major clinical predictors of risk. These major predictors and the evaluation of the patient are reviewed in Chapters 38 and 39.

HYPERTENSION

Hypertension is a common problem in ophthalmic patients. Severe hypertension can lead to perioperative complications (see Chapter 39). Degrees of hypertension have been defined. Stage 3 of severe hypertension is defined as a systolic blood pressure of 180 mm Hg or more or a diastolic blood pressure of 110 mm Hg or more. Elective procedures in patients with sustained stage 3 hypertension should be delayed until after 2 weeks of antihypertensive therapy.

PULMONARY CONSIDERATIONS

Ophthalmic procedures generally require that the patient lie flat comfortably and quietly. If the patient cannot lie flat, or if there is intractable cough, a perioperative complication is more likely. Preoperative risk reduction strategies include cessation of cigarette smoking, treatment of airflow obstruction with bronchodilators or steroids, and administration of antibiotics for respiratory infections.

Patients should be assessed for sleep apnea. Intravenous sedation is often contraindicated in these patients. For some patients, treatment with a mild stimulant such as caffeine can be helpful in keeping them awake and cooperative during a procedure.

ENDOCRINE CONSIDERATIONS (Also see Chapter 39)

Diabetes mellitus is common in patients undergoing ophthalmic surgery. An early morning start for surgery is desirable to lessen the disturbance to the patient's usual daily routine. Severe hyperglycemia and hypoglycemia should be avoided. A fasting blood glucose measurement should be checked preoperatively. Insulin therapy should be used, if needed, to maintain blood glucose at 150 to 250 mg/dL. The potential for autonomic neuropathy needs to be considered, especially when elevating the patient from the supine position.

Patients undergoing long-term steroid therapy generally do not require "stress-dose" steroid treatment for ophthalmic surgery. The patient should be given his or her normal steroid dose on the day of surgery. The physician should be alert to the occasional patient who might require additional glucocorticoid perioperatively. Unexpected hypotension, fatigue, and nausea may be signs of a patient who needs additional steroid.

ANTICOAGULATION

Many patients undergoing ophthalmic surgery take anticoagulants. Perioperative management of anticoagulants involves weighing the relative risks of thrombotic against possible hemorrhagic complications. Either of these results can be devastating to the patient. In a study of more than 19,000 cataract procedures, the incidence of hemorrhagic and thrombotic complications was infrequent.[22]

The risk of thrombotic complications depends on the following:

1. The indication for anticoagulation. Serious complications from arterial thromboembolic disease, such as atrial fibrillation or valvular heart disease, are much more common than complications from venous disease, such as deep vein thrombosis.
2. The risk factors for thromboembolism, especially if and when the patient had a previous episode of thromboembolism.

The risk of hemorrhagic complications depends on the following:

1. The degree of anticoagulation.
2. The hemorrhagic potential of the surgical procedure. Serious hemorrhagic complications are most probable in orbital and oculoplastic surgery; of intermediate probability in vitreoretinal, glaucoma, and corneal transplant surgery; and least likely in cataract surgery.

A consensus is developing that cataract surgery can be performed safely while maintaining patients receiving warfarin. For intermediate-risk procedures, such as some glaucoma surgeries, stopping warfarin intake for 4 days preoperatively is indicated. For high-risk cases for hemorrhage or thrombosis, conversion from warfarin to heparin may be required.

ANESTHETIC TECHNIQUES

REGIONAL TECHNIQUES

Eye surgery usually requires immobility (or akinesia) of the eye and profound anesthesia of the surgical site. Any discomfort during the procedure can be magnified by the patient's anxiety and fear of possible vision loss.[23] Various regional anesthetic techniques have been developed that satisfy the requirements of ophthalmologic surgery and are generally reliable and safe. Discomfort and anxiety are associated with many of these blocks, and so are rare but severe complications. Supplementation with intravenous sedation and continuous patient monitoring are frequently preferred.[24,25] Intravenous sedation also may be associated with an increased incidence of medical events.[26]

Regional anesthesia has several advantages over general anesthesia (see Chapters 57 and 89). The local block gives significant postoperative analgesia. Nausea and vomiting are infrequent. The patient can return to ambulation faster. Most patients meet recovery discharge criteria at the end of surgery, and can bypass a stay in the postanesthesia care unit.

An intravenous infusion is started. Arterial blood pressure, electrocardiogram, and oxygen saturation monitors are placed. Supplemental oxygen is administered with nasal prongs. A foam wedge is placed to keep the knees flexed to prevent lower back pain. An air blower is often placed with the outlet on the chest to eliminate carbon dioxide and oxygen buildup under the drapes and to prevent claustrophobia.

An intravenous administration of midazolam (0.5 to 1 mg), fentanyl (12.5 to 50 μg), and propofol (30 to 50 mg) provides excellent amnesia and sedation for the placement of the blocks. This author omits midazolam and fentanyl in patients with limited cognitive reserve resulting from stroke or mild dementia. For local anesthesia, we use a 1:1 ratio of bupivacaine 0.75% and lidocaine 2% without epinephrine.[27] Hyaluronidase is added to speed tissue penetration. Hyaluronidase can also be important in preventing anesthetic-related damage to the extraocular muscles.[28] A human recombinant brand (Hylenex) is commercially available.

FACIAL NERVE BLOCKS

A facial nerve block is performed when complete akinesis of the eyelids is desired.[29] Three methods for the eyelid block are as follows:

1. *Modified van Lint block:* The needle is placed 1 cm lateral to the orbital rim, and 2 to 4 mL of anesthetic is injected deep on the periosteum just lateral to the superolateral and inferolateral orbital rim. The disadvantages of this block include discomfort, proximity to the eye, and common postoperative ecchymoses.
2. *O'Brien block:* The mandibular condyle is palpated inferior to the posterior zygomatic process and anterior to

the tragus of the ear as the patient opens and closes the jaw. The needle is inserted perpendicular to the skin approximately 1 cm to the periosteum. As the needle is withdrawn, 3 mL of anesthetic is injected.

3. *Nadbath-Rehman block*: A 12-mm, 25-gauge needle is inserted perpendicular to the skin between the mastoid process and the posterior border of the mandible. The needle is advanced its full length, and after careful aspiration, 3 mL of anesthetic is injected as the needle is withdrawn. This blocks the entire trunk of the facial nerve. The patient should be told to expect a lower facial droop for several hours postoperatively. The major disadvantage to this block is the proximity of the injection to important structures, such as the carotid artery and the glossopharyngeal nerve.

RETROBULBAR BLOCK

The retrobulbar block provides excellent akinesia and anesthesia of the eye.[30] A 3-cm, 23- to 25-gauge blunt Atkinson needle is recommended to protect against ocular perforation. The needle is placed at the junction of the inferior and lateral walls of the orbit just above the inferior orbital rim.[31] The needle is advanced approximately 15 mm along the wall of the orbit until it is past the equator of the eye. The needle is turned superiorly to aim toward the superior orbit. The needle is advanced until it enters between the extraocular muscles; 2 to 3 mL of anesthetic solution is injected. Some intorsion on downgaze is expected because the superior oblique muscle is outside the muscle cone and may not be blocked.

Retrobulbar hemorrhage is the most common complication of this block; proptosis and subconjunctival ecchymosis also are seen. Monitoring of the IOP is mandatory. If the pressure becomes elevated, a lateral canthotomy is performed to decompress the orbit. Bleeding outside the muscle cone is seen as subconjunctival ecchymosis without proptosis. After some monitoring, if IOP does not increase, then the surgical procedure can be performed safely.

Intravascular injection can occur despite a negative aspiration test. The total dose of local anesthetic used is small, and even if the total dose is given intravenously, no systemic effects would be likely. Accidental intraarterial injection can give high brain levels via retrograde flow in the internal carotid artery. Central nervous system excitation and seizures can be seen, but are usually highly transient, as the local anesthetic redistributes out of the brain. Obtundation and respiratory arrest have been reported. These prolonged effects are thought to be due to injection into the optic nerve sheath, which is continuous with the subarachnoid space.

Optic nerve damage and ocular perforation with retinal detachment and vitreous hemorrhage also have been reported. Special care must be taken when injecting patients with high myopia. If the axial length of the globe is longer than 25 mm, the eye is larger, and the sclera is thinner, increasing the risk of ocular penetration. A different anesthesia technique may be advisable in such cases.

POSTERIOR PERIBULBAR BLOCK

To prevent retrobulbar hemorrhage, posterior peribulbar anesthesia has become more popular.[32] A blunt, 23-gauge, 7/8-inch Atkinson needle is placed at the junction of the middle and lateral thirds of the lower lid just above the inferior orbital rim; 1 mL of local anesthetic is put just below the orbital septum, 3 mL at the equator, and 2 mL posterior outside the muscle cone. If no bulging is noted at the superior nasal lid area, a second injection of 2 to 3 mL is administered inferonasally. Disadvantages of the technique include a longer onset time (9 to 12 minutes) and lower incidence of complete akinesia. Globe perforation from peribulbar injection has been reported.[33]

SUB-TENON BLOCK

To avoid the complications of sharp needles, a technique was developed using a blunt cannula under the fascia of Tenon.[34] Various lengths of cannulas have been used. Using topical anesthesia with sedation, a speculum is placed to retract the lids. A 2- to 3-mm spot of cautery can be made 5 mm from the limbus in the inferonasal or inferolateral quadrant. A 2-mm snip is made in the conjunctiva with blunt dissection through the fascia of Tenon. A blunt cannula is directed under fascia of Tenon posteriorly, but not beyond the equator of the globe, with injection of 1 to 3 mL of local anesthetic. A small degree of conjunctival edema is often seen. Analgesia is usually excellent.[35]

TOPICAL ANESTHESIA

Cataract surgery can be performed using topical anesthesia alone.[36] This technique arose with the increase in popularity of small incision surgery and phacoemulsification. Topical anesthesia avoids the potential complications associated with retrobulbar and peribulbar injections. In addition, patients have the most rapid visual rehabilitation, with improved vision almost immediately after the procedure. Disadvantages of the technique include the potential for eye movement during surgery, increased patient anxiety, and discomfort from the microscope light.[37] Tetracaine 0.5% and lidocaine 4% have been used successfully. Two drops of tetracaine are given initially. Approximately three more doses of tetracaine or lidocaine are applied every 5 minutes just before surgery.

Appropriate patient selection is crucial. A confident, calm, and cooperative patient usually does well. A nervous, hypersensitive patient may be a better candidate for another technique. Photophobic patients, those with small pupils, or the requirement of a large incision are other problems that may occur.

GENERAL ANESTHESIA

The choice of general versus regional anesthesia is made based on the duration of surgery, the relative risks and benefits of each technique for the patient, and patient preference. Neither technique has been shown to be safer.

In the past, regional anesthesia had an advantage of greatly reduced postoperative nausea and vomiting. With

the advent of shorter-acting general anesthetics and nonopioid analgesia, the incidence of nausea and vomiting has decreased dramatically. Droperidol has been used frequently as an antiemetic, although late postoperative anxiety can occur in some individuals. Ondansetron may be as effective with fewer side effects. A comparison of memory function in patients after general anesthesia or local anesthesia with sedation showed no advantage to either technique.[38]

The goals of general anesthesia include a smooth endotracheal intubation, stable IOP, avoidance of severe oculocardiac reflexes, a motionless field, and smooth emergence. These goals can be accomplished with inhaled volatile anesthesia, balanced opioid anesthesia, or intravenously administered anesthetics, with or without muscle relaxants. The laryngeal mask airway (LMA) can be used for ophthalmologic surgery and may be associated with less coughing on emergence. Because of the inaccessibility of the airway during the surgery, and the risk of laryngospasm or aspiration of gastric contents, LMA should be used only by anesthesia providers who are highly skilled with the technique. In some cases, the LMA may be more appropriate for extraocular surgery.

Nitrous oxide presents a special problem in some vitreoretinal procedures.[39] In the technique called *fluid-gas exchange,* the surgeon injects an intravitreal air bubble to tamponade the retina against the wall of the globe. Sulfur hexafluoride is a poorly soluble gas used to prolong the resorption of intravitreal air bubbles. Nitrous oxide diffuses and causes bubble expansion, with the potential for dangerous increases in IOP. Nitrous oxide should be shut off for 15 minutes before placing the sulfur hexafluoride bubble and should be avoided for 7 to 10 days thereafter.

This problem is potentially worse with a relatively newer drug, perfluoropropane (C3F8), because this drug can persist for weeks. In this case, nitrous oxide should be avoided for at least 1 month, or until the bubble is resorbed. If a patient presenting for nonophthalmic surgery has a history of a recent retinal procedure, it is critical to establish whether the patient has an intravitreal gas bubble before using nitrous oxide. Otherwise, blindness can result.

ANESTHESIA FOR PEDIATRIC OPHTHALMOLOGIC PROCEDURES

Anesthesia for pediatric eye surgery can be considered a subspecialty of its own (see also Chapter 93).[40] Small children may require examination under anesthesia. Intramuscular ketamine sometimes can be a good choice; it can be used when intravenous access may be problematic. Some ophthalmologists prefer ketamine because it does not reduce IOP as barbiturates, and deep levels of inhaled anesthetics do.

The most common eye surgery in children is for strabismus, or misalignment of the eyes. There is generally no severe postoperative pain, but nausea and vomiting are significant 50% to 80% of the time without treatment. Droperidol 5 to 75 μg/kg seems to decrease nausea and vomiting significantly without undue delay of discharge. Ondansetron has similar effects without sedation. If forced ductal testing is used to assess the muscle tightness, the surgeon should be notified if succinylcholine is used. Succinylcholine causes a tonic increase in eye muscle tone, which resolves in approximately 20 minutes.

Strabismus is a common condition, and most children are otherwise healthy. There is a more frequent incidence of strabismus in trisomy 21 or Down syndrome, cerebral palsy, and hydrocephalus. Malignant hyperthermia and myotonic dystrophy are associated with strabismus. Myotonic dystrophy also occurs in patients with ptosis and cataracts.

Cataracts can be seen in children with Pierre-Robin syndrome and phenylketonuria. Patients with Marfan syndrome have a frequent incidence of subluxation or dislocation of the lens. Aniridia, the congenital absence of the iris, is associated with Wilms tumor and hypertension. Congenital glaucoma also occurs with Sturge-Weber syndrome and with seizures and angiomas of the mouth and larynx. Pediatric ophthalmic conditions associated with congenital syndromes are summarized in Table 84-1.

OPHTHALMOLOGIC PROCEDURES

GENERAL PROCEDURES

Most general ophthalmologic procedures are performed with topical or local anesthetic injection techniques. Enucleation can be performed during regional anesthesia, but is usually performed during general anesthesia.

INCISION AND DRAINAGE OF CHALAZION

A chalazion is an eyelid mass that results from chronic inflammation of the meibomian gland. Surgical treatment is indicated when there is inadequate response to conservative methods.

TARSORRHAPHY

The partial or total suturing together of the eyelids is performed to protect the eye and to allow healing of ulcers or exposure problems.

TEMPORAL ARTERY BIOPSY

A biopsy of the temporal artery is performed to diagnose temporal arteritis.

ANTERIOR CHAMBER PARACENTESIS

A tap of the anterior chamber fluid is done for diagnostic testing or to reduce IOP quickly.

ENUCLEATION

Enucleation refers to the removal of the entire eyeball after the muscles and optic nerve have been cut. Indications for surgery are a blind painful eye and intraocular tumors.

CATARACT EXTRACTION

Cataracts are opacities of the crystalline lens of the eye. Cataract extraction is performed under topical or regional block. General anesthesia is rarely used.

TABLE 84-1 **OCULAR MANIFESTATIONS AND PEDIATRIC SYNDROMES**

Ocular Manifestation	Pediatric Syndrome	Ocular Manifestation	Pediatric Syndrome
Strabismus	Trisomy 21		Aniridia
	Cerebral palsy		Sturge-Weber syndrome
	Meningomyelocele		Neurofibromatosis
	Prematurity		Ehlers-Danlos syndrome
	Retinoblastoma		Homocystinuria
	Craniopharyngioma	Retinal hemorrhage	Acquired immunodeficiency syndrome (AIDS)
	Malignant hyperthermia		
	Myotonic dystrophy		Multiple myeloma
	Ehlers-Danlos syndrome	Vitreal hemorrhage	Sickle cell syndromes
Ptosis	Malignant hyperthermia	Orbital tumor	Multiple myeloma
	Myotonic dystrophy	Glioma of the optic nerve	Neurofibromatosis
Cataract	Trisomy 21		
	Myotonic dystrophy	Retinopathy	Diabetes mellitus
	Pierre-Robin syndrome		Hypertension
	Phenylketonuria	Ophthalmopathy	Juvenile diabetes
	Homocystinuria		Graves disease
	Lowe syndrome	Ocular muscle weakness	Myasthenia gravis
	Rubella	Ocular erosions	Stevens-Johnson syndrome (erythema multiforme)
	Sarcoidosis		
	Galactosemia	Conjunctivitis or iritis	Reiter syndrome
	Hypoparathyroidism		Infectious mononucleosis
	Diabetes mellitus		Rheumatoid arthritis
	Glucose-6-phosphate dehydrogenase deficiency	Keratoconjunctivitis sicca	Sjögren syndrome
			Sarcoidosis
Lens subluxation	Marfan syndrome		Systemic lupus erythematosus
	Homocystinuria	Uveitis	Ankylosing spondylitis
	Ehlers-Danlos syndrome		Juvenile arthritis
Glaucoma	Homocystinuria		Sarcoidosis
	Lowe syndrome	Optic neuritis	Multiple sclerosis
	Rubella		

Intracapsular Cataract Extraction

Intracapsular cataract extraction is the total removal of the opaque lens with the lens capsule. It can be done with a cryoprobe. Intracapsular cataract extraction is performed in selected cases of lens subluxation, dislocation, or a lens containing a foreign body.

Extracapsular Cataract Extraction

Extracapsular cataract extraction refers to the removal of the lens, while leaving the posterior lens capsule and zonules intact. A rim of the anterior capsule also is preserved; this provides an excellent location for an intraocular lens implant.

PHACOEMULSIFICATION

Phacoemulsification refers to the use of ultrasonic vibration of fragments of the lens with simultaneous irrigation and aspiration. This technique allows for very small incisions. New techniques are bringing the use of the femtosecond laser for the initial steps of creating corneal incisions, capsulotomy, and fragmenting the lens.[41] Because use of the laser requires patient cooperation and because supplemental oxygen is contraindicated, these parts of the procedure are generally done under local anesthesia.

GLAUCOMA PROCEDURES

Glaucoma is a general term for diseases of the eye characterized by an increase in IOP.

FILTRATION PROCEDURES

Trabeculectomy is a surgical excision of the trabecula to increase the drainage of aqueous humor. Baerveldt and Ahmed devices are glaucoma drainage implants that shunt aqueous fluid out of the eye to drain under the conjunctiva of the orbit.

PROCEDURES FOR THE CORNEA

Penetrating Keratoplasty

A corneal transplant is done to replace an optically poor, infected, or traumatized cornea. Control of IOP and avoidance of patient movement are especially important in these open-globe procedures.

Lamellar Keratoplasty

Instead of a full thickness corneal graft, a layer of the corneal donor is used.[42] A gas bubble can be used to hold the graft in place to adhere to the patient's cornea. In Figure 84-1, intraoperative ocular coherence tomography[43]

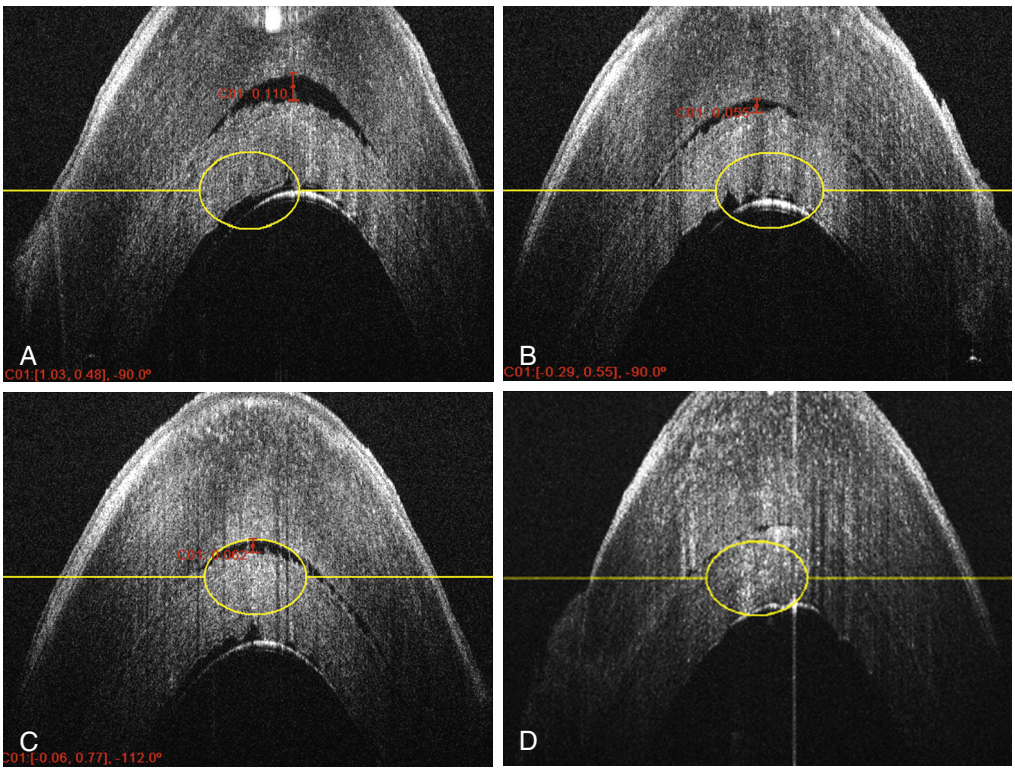

Figure 84-1. Intraoperative optical coherence tomography cross sections in a patient undergoing Descement stripping automated endothelial keratoplasty (DSAEK) immediately after delivery and unfolding of the donor graft (**A**). After elevation of the intraocular pressure, the size of the gap is decreased (**B, C**). After sweeping maneuver, there is no interface gap (**D**). *(Courtesy William J. Dupps.)*

shows how after placement of the corneal graft, the eye is pressurized to cause the graft to adhere.

Radial Keratotomy

A series of incisions is made in the cornea in a spikelike manner to change the shape of the cornea to correct myopia.

Pterygium Excision

A pterygium is an abnormal fold of membrane in the interpalpebral fissure. An excision is generally performed when the abnormal tissue impinges on the cornea, affecting vision, or for cosmetic improvement.

VITREORETINAL SURGERY

Retinal Cryotherapy

A cryoprobe is used for prophylaxis of certain retinal breaks and tears. This technique is used in some patients with retinal tumors and vascular malformations.

Repair of Retinal Detachment

Retinal reattachment involves localizing all tears and holes, creating chorioretinal adhesions, and scleral buckling with silicone belts around the globe to pull the sclera in to support the retina.

Vitrectomy

Vitrectomy is the surgical extraction of the contents of the vitreous chamber and their replacement with a physiologic solution. A posterior vitrectomy is indicated for the removal of foreign bodies, to repair retinal detachments, to remove membranes and media opacities, and to alleviate vitreous traction on the retina. These procedures may be prolonged. Many patients have diabetes or severe chronic hypertension, which can influence the conduct of anesthesia (see Chapter 39).

OCULOPLASTIC SURGERY

Most oculoplastic surgery is performed with local infiltration anesthesia. Some longer, more invasive procedures require general anesthesia.

Ectropion Repair

Ectropion usually results from the effects of aging on the eyelid. Other causes include mechanical or congenital lid pathology. The eyelid is turned outward.

Entropion Repair

Involutional entropion usually results from aging. The eyelid is inverted or turned inward.

Ptosis Repair

Ptosis, or drooping of the upper eyelid, can be congenital (dystrophy of the levator muscle) or acquired from aging or trauma.

Blepharoplasty

Blepharoplasty is plastic surgery of the eyelids to remove redundant tissue that is obstructing vision, or for improved appearance.

DACRYOCYSTORHINOSTOMY

Dacryocystorhinostomy refers to the formation of a communication channel between the lacrimal sac and the nasal cavity. This is performed for congenital or acquired nasolacrimal duct obstruction. It usually requires general anesthesia.

ORBITAL SURGERY

Most orbital surgery is performed using general anesthesia. If the surgery is anterior, local anesthesia can be used. Examples of orbital surgery include the following:

- Repair of blowout fracture
- Drainage of orbital abscess
- Decompression of the optic nerve
- Exenteration of the orbit for malignancy

OPHTHALMOLOGIC EMERGENCIES

Most urgent ophthalmologic procedures do not need to be performed on an emergency basis. This is important because the anesthetic plan must consider the NPO (nil per os, nothing by mouth) status and general medical condition of the patient. This does not apply to true eye emergencies. In these rare conditions, therapy should be started within minutes. Other urgent ophthalmologic conditions can start within 1 to several hours, without a change in outcome.

True Emergencies

Therapy should be started within minutes for chemical burns of the cornea and central retinal artery occlusion.

Urgent Situations

Therapy should be started in 1 to several hours. Urgent situations include open-globe injuries, endophthalmitis, acute narrow-angle glaucoma, acute retinal detachment, corneal foreign body, and lid laceration.

Semiurgent Situations

Therapy should be started within days, but sometimes can be rescheduled for several weeks. Semiurgent situations include ocular tumors, blowout fractures of the orbit, congenital cataract, and chronic retinal detachment.

Open Globe and Full Stomach

A patient with eye trauma presents a challenge to the anesthesia provider. The dilemma is to protect the patient from pulmonary aspiration of stomach contents and to protect the eye from acute changes in IOP, which could cause vitreous loss, retinal detachment, and blindness. A rapid-sequence induction of anesthesia provides rapid control of the airway, but succinylcholine causes a modest increase in IOP. Of course, intubating the trachea during light anesthesia or inadequate neuromuscular blockade can cause large increases in IOP, which needs to be avoided. Attentiveness to neuromuscular monitoring can confirm the adequacy of neuromuscular blockade (see Chapters 34 and 53). Regional anesthetic techniques can also be performed.[44] Factors to consider include the following:

- *Size of the perforation:* Small punctures have higher resistance to vitreous loss with changes in IOP.
- *Pulmonary status:* Patients with decreased functional residual capacity become rapidly hypoxic making a more rapid technique preferable.
- *NPO status:* What is the magnitude of the pulmonary aspiration of gastric contents risk?
- *Length of procedure:* If the surgery is short, and a large dose of nondepolarizing neuromuscular blocker is used, can the block be reversed (see Chapter 35) or will postoperative mechanical ventilation occur?

ANESTHESIA-RELATED EYE INJURIES

Anesthesia providers must be aware of possible ocular damage during anesthesia and surgery (see Chapter 41). If a patient emerges from a general anesthetic complaining of vision impairment, an emergency may exist because of the possibility of central retinal artery occlusion. When using a facemask, care must be taken to avoid applying undue pressure to the eye. Systemic hypotension and anemia also can be contributing factors in vision loss.

A second potential complication is corneal abrasion. General anesthesia decreases basal tear production. Proper eye care with taping of lids with or without an ocular lubricant provides protection. If a patient emerges from general anesthesia with eye pain or a foreign body sensation, the patient must be observed continually to ensure improvement. If left untreated, corneal abrasions can progress to form corneal ulcers.

Chapter 85

Anesthesia for Ear, Nose, and Throat Surgery

D. JOHN DOYLE

Acknowledgment: The editors and the publisher would like to thank Drs. Marc Allan Feldman and Anil Patel who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Difficult airways are more frequently encountered in patients undergoing ear, nose, and throat (ENT) surgery, especially for cancer. Reviewing the results of a preoperative computed tomography (CT) scan or an endoscopic airway examination may help identify pathologic features likely to produce airflow obstruction or complicate tracheal intubation.
- Although the tracheas of ENT patients are often intubated using ordinary polyvinyl chloride endotracheal tubes (ETTs), microlaryngeal, laser-safe and wire-reinforced tubes are frequently employed (see also Chapter 55).
- Endotracheal intubation in an awake patient with a flexible bronchoscope is commonly used when intubation following the induction of general anesthesia would be imprudent. (Also recall that the induction of anesthesia sometimes results in a deteriorated laryngoscopic view) (see also Chapter 55).
- Fiberoptic endotracheal intubation is usually well tolerated, is gentle on the airway, and does not require force to obtain glottic exposure.
- When the airway disorder is so extensive that awake endotracheal intubation is impractical, tracheostomy performed using local anesthesia (with or without judicious intravenous sedation) is usually the best option. In extreme loss-of-airway emergencies, a cricothyrotomy may be preferable to a tracheostomy because cricothyrotomy takes much less time to complete.
- In some head and neck cases, such as in patients undergoing parotid surgery, the need for electrical testing of the facial nerve precludes the extended use of neuromuscular blocking drugs.
- In many patients with head and neck disorders, gentle emergence from anesthesia, free of coughing and straining, is vitally important to prevent emergence rebleeding as a result of venous engorgement.
- Bleeding following tonsillectomy usually occurs within the first 6 postoperative hours, but it can also occur several days later.
- Facial trauma can produce unremitting bleeding and the aspiration of teeth, blood, bone, and tissue fragments, as well as cervical spine injury. Airway trauma can result from blunt or penetrating injuries, burns, inhalational injury, and iatrogenic causes. In both situations, initial management is dictated by the degree of respiratory distress or potential airway compromise, the available equipment, and clinical preferences.
- Intubating the trachea of a patient with laryngeal trauma may result in further injury to the airway or even complete airway loss. If intubation is attempted, it is advised to use a fiberoptic bronchoscope with a small ETT. Positive-pressure ventilation may worsen any subcutaneous emphysema. In some cases, a tracheostomy may be the most prudent course.
- Causes of stridor include inhaled foreign bodies, bilateral vocal cord palsy, airway edema, angioedema, epiglottitis, traumatic injury, subglottic stenosis, and other pathologic entities. Regardless, the first issue in the setting of stridor is whether or not endotracheal intubation or a surgical approach to the airway is immediately

KEY POINTS—cont'd

necessary to rescue the patient from death or injury. Heliox administered with a nonrebreathing facemask can be helpful as a temporizing measure.

- The chosen anesthetic technique for endoscopic procedures varies with patient and lesion particulars, clinical preferences, and the selected surgical tools (laser, rigid bronchoscope). Total intravenous anesthesia is a popular choice for many of these cases.
- Lasers can be used to vaporize otolaryngologic lesions; however, special precautions are needed to prevent accidental thermal injury or an airway fire (see also Chapter 88), a potentially deadly complication that may also occur during tracheotomy surgery. Oxygen must be kept to a minimum when a significant potential for an airway fire exists. Moreover, nitrous oxide should not be used during airway surgery because it supports combustion just as does oxygen (see also Chapter 88).

On October 16, 1846, Dr. William Morton famously used ether delivered by inhalation to provide general anesthesia to Gilbert Abbott and allow surgeon Dr. John Warren to remove a tumor from Abbott's neck.[1,2] From this first public demonstration of ether anesthesia onward, the relationship between anesthesiology and ear, nose, and throat (ENT) surgery has been vital. Indeed, no other branch of surgery has as great a need for a mutual understanding between the surgeon and the anesthesiologist, with joint procedural planning and close cooperation being crucial. For example, many ENT surgical procedures require that the anesthesia provider share the airway with the surgeon; consequently, a good anesthesia provider must be unusually knowledgeable about ENT procedures and possible effects on the patient.

Anesthesia for ENT surgery encompasses a vast range of procedures varying enormously in complexity, duration, and potential for complications.[3] On any given day, ENT anesthesiologists may be assigned to simple high-volume cases, such as myringotomies and tonsillectomies, to all-day procedures in patients with cancer. They may also encounter patients with severely distorted airway anatomy, sometimes even causing airway obstruction, as well as procedures involving tracheal, glottic, or subglottic surgery that require sharing of the airway in conjunction with the use of special equipment such as surgical lasers. Nasal procedures usually require airway protection from blood and secretions, as well as gentle emergence from anesthesia. Intraoral ENT procedures, such as tonsillectomies, may employ instruments intended to keep the mouth open but that may also unintentionally obstruct the airway. Extreme lateral rotation of the head may be required for some ear procedures. These are just some of the special perils of providing anesthesia for ENT procedures.

SYNOPSIS OF EAR, NOSE, AND THROAT ANATOMY

Figures 85-1 to 85-4 illustrate various aspects of ENT anatomy. The oropharynx extends from the uvula to the hyoid bone. The hypopharynx extends from the hyoid to the cricoid cartilage. The glottis includes both vocal cords, the anterior commissure, and the posterior intra-arytenoid area. The subglottis extends 5 mm (anteriorly) to 10 mm (posteriorly) below the apex of the vocal cords (also known as vocal folds). The larynx, essential to respiration and speech, has a clinically important glottic closure reflex mediated through bilateral superior laryngeal nerves. This reflex serves to protect the airway against aspiration. For example, swallowing activates this protective reflex. On occasion this protective reflex can be

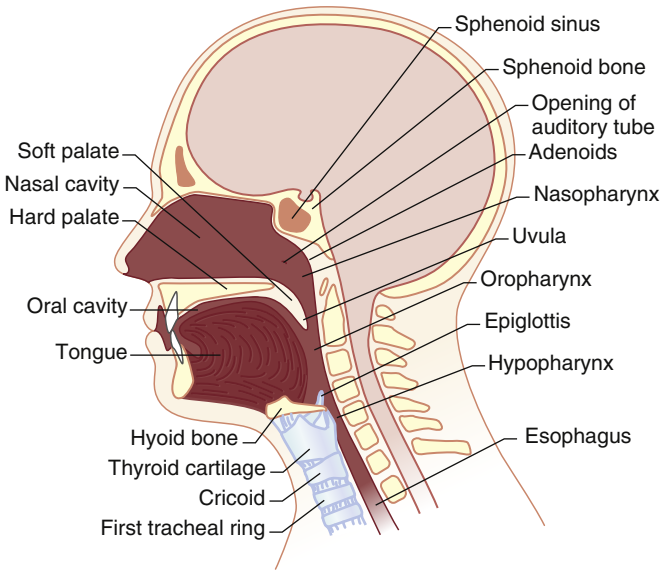

Figure 85-1. Highlights of otolaryngologic anatomy. Note (1) the anterior position of the trachea relative to the esophagus; (2) the oropharynx, extending from the uvula to the hyoid bone; (3) the hypopharynx extending from the hyoid bone to the cricoid cartilage; (4) the cricoid ring, a structure that is pushed posteriorly during the Sellick maneuver component of rapid-sequence induction, done with the intention of occluding the esophagus to help prevent regurgitation of gastric contents; and (5) the location of the first tracheal ring, important as a surgical landmark because most tracheostomies are performed between the second and third tracheal rings. *(From Feldman MA, Patel A: Anesthesia for eye, ear, nose, and throat surgery. In Miller RD, editor:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 2357-2388.)*

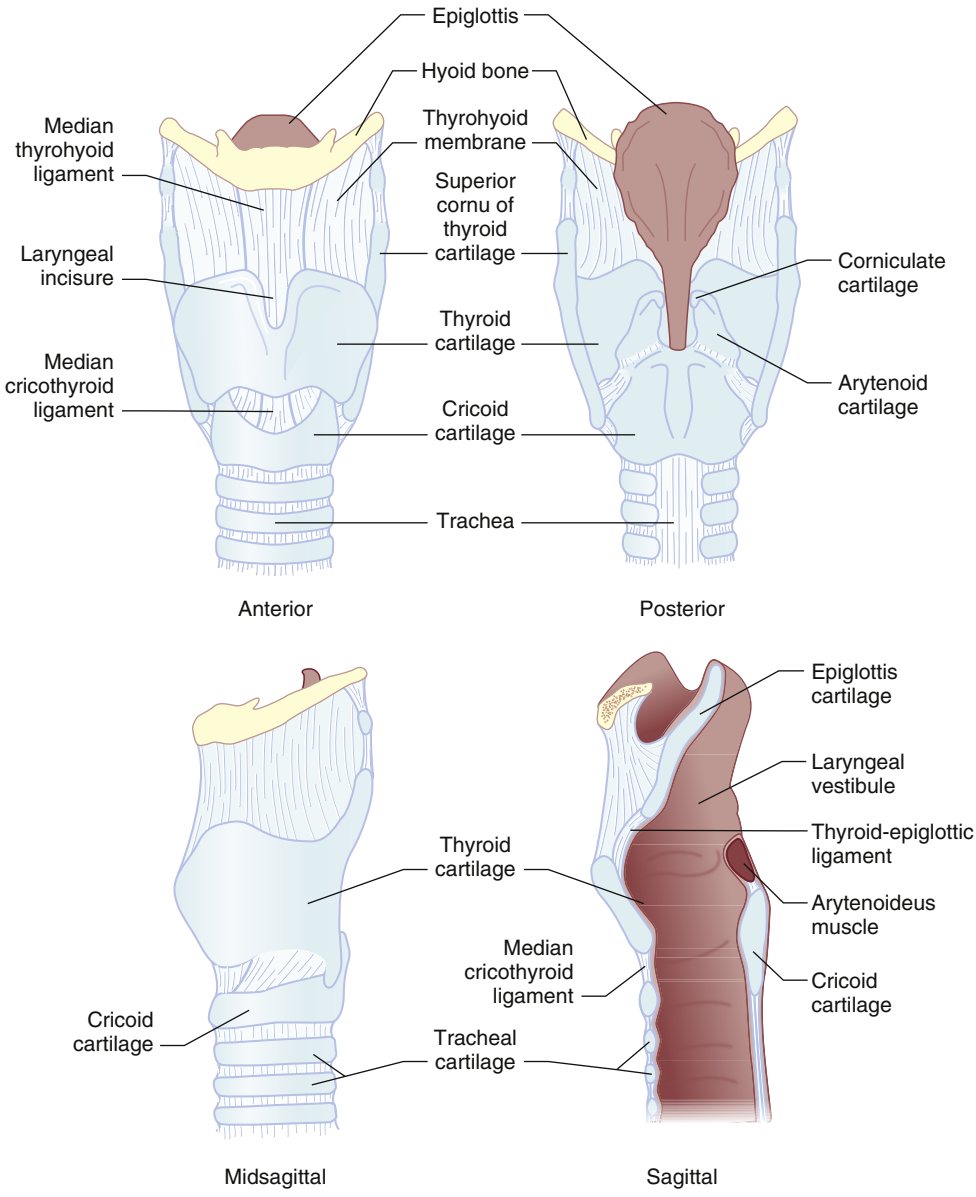

Figure 85-2. Anterior, posterior, midsagittal, and sagittal views of laryngeal anatomy. Note (1) how the cartilaginous tracheal rings are incomplete posteriorly to allow the trachea to collapse slightly to facilitate the passage of food down the esophagus (and to provide orientation during bronchoscopic procedures!); (2) the superior cornu of the thyroid cartilage, an important landmark in the superior laryngeal nerve block because this is close to where the internal branch of the superior laryngeal nerve penetrates the thyrohyoid membrane; and (3) the median cricothyroid ligament and (not labeled) the twin lateral cricothyroid ligaments, known collectively as the cricothyroid ligament and entered in both emergency cricothyrotomy procedures and with emergency transtracheal jet ventilation. *(From Feldman MA, Patel A: Anesthesia for eye, ear, nose, and throat surgery. In Miller RD, editor:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 2357-2388.)*

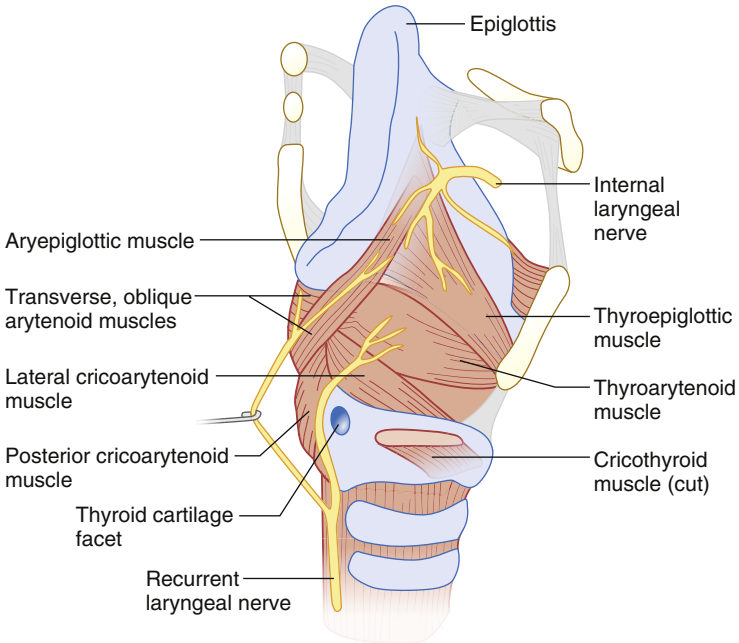

Figure 85-3. Laryngeal anatomy focusing primarily on the internal laryngeal nerve and the recurrent laryngeal nerve. The two recurrent laryngeal nerves provide motor innervation to all the intrinsic muscles of the larynx, except the cricothyroid and inferior pharyngeal constrictor muscles, which are innervated by the external branches of the two superior laryngeal nerves (external laryngeal nerve). Sensory innervation of the larynx down to the vocal cords is supplied by the internal laryngeal nerve branches of the superior laryngeal nerves (internal laryngeal nerve), these in turn being branches of the vagus. Sensory innervation below the vocal cords and to the upper trachea is supplied by the recurrent laryngeal nerves. *(From Schuller DE, Schleuning AJ:* Otolaryngology: head and neck surgery, *ed 8. St. Louis, 1994, Mosby, p 252.)*

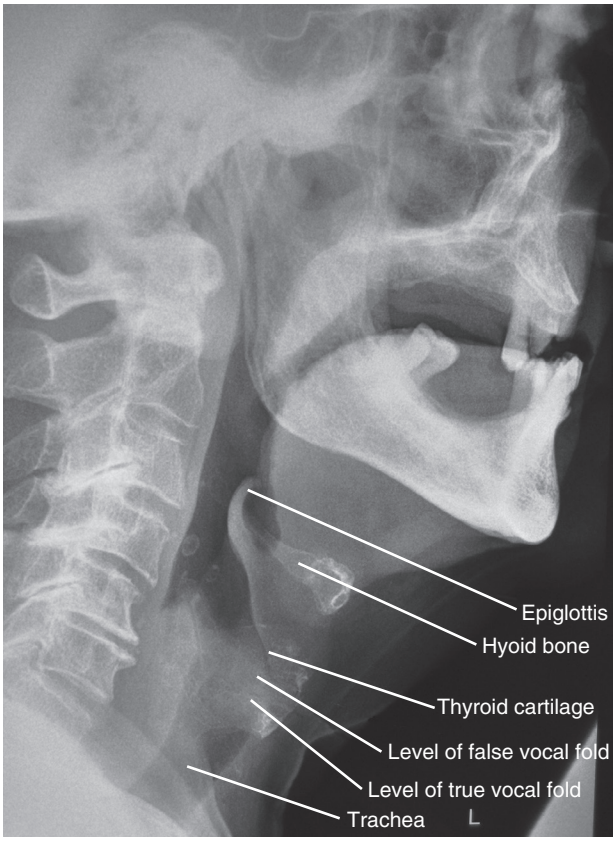

Figure 85-4. Lateral radiograph demonstrating laryngeal anatomy. Notice (1) the normally wafer-thin epiglottis, which serves as a protective cover to the laryngeal inlet during swallowing and may become much larger and "thumb shaped" when edematous (e.g., as a result of pediatric epiglottitis); (2) the limited amount of prevertebral soft tissue in the oropharyngeal and hypopharyngeal regions; when edematous (e.g., as a result of a retropharyngeal abscess), this tissue may expand anteriorly to obstruct the airway; and (3) the hyoid bone, which aids in tongue movement and swallowing and which, if found fractured on autopsy, is suggestive of foul play by throttling or strangulation. (Did you notice the missing teeth?) *(From Feldman MA, Patel A: Anesthesia for eye, ear, nose, and throat surgery. In Miller RD, editor:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 2357-2388.)*

problematic because when sustained spasm of the glottic muscles (a condition known as laryngospasm) occurs,[4-6] gas exchange cannot take place. Laryngospasm is associated with light anesthesia and is frequently triggered by blood or secretions irritating the vocal cords, as often occurs after septoplasty and rhinoplasty surgery. Because it can make ventilation impossible, laryngospasm may constitute a true anesthetic emergency (see later).

Branches of the right and left vagus nerves innervate the larynx. The right vagus nerve gives rise to the right recurrent laryngeal nerve, whereas the left vagus nerve gives rise to the left recurrent laryngeal nerve. The two recurrent laryngeal nerves provide motor innervation to all the intrinsic muscles of the larynx, except the cricothyroid and inferior pharyngeal constrictor muscles, which are innervated by the branches of the superior laryngeal nerves. The internal laryngeal nerve is the internal branch of the superior laryngeal nerve (see Fig. 85-3). It descends to the thyrohyoid membrane, pierces it along with the superior laryngeal artery, and provides sensory innervation to the larynx down to the vocal cords. Sensory innervation below the vocal cords and to the upper trachea is supplied by the recurrent laryngeal nerves (see Fig. 85-3).

Injury to the recurrent laryngeal nerves, which supply most of the laryngeal intrinsic muscles, is a feared but often preventable complication in thyroid surgery and a host of other procedures, including tracheal intubation.[7-12] If the damage is unilateral, the patient may present with hoarseness from unilateral loss of vocal cord abduction occurring in conjunction with intact cricothyroid mediated adduction. This situation causes the affected vocal cord to assume a paramedian position. Bilateral nerve damage can result in dyspnea, stridor, and even full airway obstruction from bilateral vocal cord paramedian positioning. Such patients may require a tracheostomy. Intraoperative neuromonitoring (see also Chapter 49) is often used to reduce the chance of injury to the recurrent laryngeal nerves, especially in thyroid surgery.[13-15]

PREOPERATIVE EVALUATION FOR EAR, NOSE, AND THROAT SURGERY

Although the preoperative evaluation of the surgical patient is discussed in detail in Chapter 38, a few issues are especially pertinent to ENT cases. Many ENT patients, especially those with malignant head and neck diseases, have histories of prolonged tobacco and alcohol use, whereas many others suffer from obesity or obstructive sleep apnea (OSA). Patients with chronic airway obstruction may develop pulmonary hypertension, sometimes leading to right-sided heart failure (cor pulmonale). A history of hoarseness may signal recurrent laryngeal nerve injury or worse, whereas the presence of stridor is *always* a cause for immediate concern. In cases involving the airway, the anesthesiologist and surgeon frequently review available radiographic and video studies to establish an airway plan collaboratively. A history of head and neck radiation for malignancy treatment frequently makes intubation difficult because the structures may become tough and fibrotic ("like wood"), yet they are predisposed to bleeding with instrumentation. A history of snoring may signal that the patient has undiagnosed sleep apnea and is prone to airway obstruction.

ENT cases frequently involve geriatric patients, many of whom are at a high risk for postoperative delirium and cognitive dysfunction (see also Chapter 80).[16-18] Although many ENT procedures involve infrequent risk, some of the large head and neck operations are considered to have "intermediate" surgical risk. A preoperative resting 12-lead electrocardiogram (ECG) is recommended for patients with known coronary heart disease, peripheral arterial disease, or cerebrovascular disease who are undergoing such procedures (see also Chapter 38). Additionally, patients with a history of heart failure, diabetes mellitus, or renal failure who are undergoing intermediate-risk operative procedures benefit from an ECG (see also Chapter 39). Preoperative ECG testing is not indicated in asymptomatic persons undergoing infrequent-risk procedures.

A *preoperative endoscopic airway examination can be performed* in selected patients. This technique uses an

ordinary flexible fiberscope usually used for awake endotracheal intubation to conduct a quick transnasal laryngoscopic examination using topical anesthesia. This examination allows the clinician to determine whether a problematic laryngeal disorder exists, such as supraglottic lesions that would not be apparent by ordinary means. The procedure requires minimal time and patient preparation, and it is well tolerated by patients. A review by Rosenblatt provides ample details.[19]

AIRWAY MANAGEMENT IN OTOLARYNGOLOGY

Both easy and difficult airways are frequently encountered in ENT anesthesia. The American Society of Anesthesiologists (ASA) Difficult Airway Algorithm (or similar algorithm),[20-28] should ordinarily be a starting point for nearly all aspects of ENT airway management. To a large extent, the specific airway management techniques chosen depend on clinical circumstances, the airway management skills and preferences of the anesthesiologist and surgeon, and the available equipment.

The following general management options exist: (1) general endotracheal anesthesia; (2) general anesthesia using a supraglottic airway (SGA) device (e.g., laryngeal mask airway [LMA]); (3) general anesthesia using an ENT laryngoscope (to expose the airway) in conjunction with jet ventilation; (4) use of intermittent apnea; (5) general anesthesia using the patient's natural airway, with or without adjuncts such as jaw positioning devices or nasopharyngeal airways; and (6) local anesthesia in conjunction with intravenous sedation, with the patient breathing spontaneously. The first option is doubtless the most popular. However, the technique chosen and implemented depends on factors such as the perceived difficulty of intubating the trachea with ordinary methods. Evaluation of the airway in this particular respect is also discussed in Chapter 55.

The airway can become obstructed for many reasons. Examples include the following: aspirated foreign bodies; infections such as epiglottitis, diphtheria, or Ludwig angina; laryngospasm; tumors and hematomas impinging on the airway; trauma to the airway; OSA; tonsillar hypertrophy; and airway edema (e.g., from anaphylaxis, prolonged laryngoscopy, or smoke inhalation or burn injury). In most cases, airway management is determined after a discussion between the anesthesia and surgical teams.

Most patients undergoing ENT surgery have their airway managed by tracheal intubation. Although under ordinary circumstances tracheal intubation is straightforward, patients whose tracheas are expected to be difficult to intubate can be identified and usually managed with techniques such as videolaryngoscopy or fiberoptic intubation. A key decision in such cases is whether the tracheal intubation should be performed with the patient awake or following the induction of general anesthesia. Another important decision is what tools or interventions to employ in the event that difficulty with ventilation or intubation is encountered. In exceptional cases, a tracheostomy using local anesthesia must be performed.

Patients for ENT surgery are often managed using an ordinary polyvinyl chloride (PVC) endotracheal tube (ETT), but microlaryngeal tubes (MLTs), laser tubes, and wire-reinforced tubes are also frequently used. Reinforced tubes have the advantages that they are unlikely to kink and they fit especially well into tracheostomy stomas because of their excellent flexibility. Laser tubes are discussed in Chapter 88.

Practical considerations in this setting start with the fact that the tube must be adequately secured using tape or other means; some maxillofacial surgeons suture the tube to the side of the mouth or even tie the tube to the teeth with wire. In addition, the ETT cuff pressures ordinarily must be kept less than 25 mm Hg to avoid ischemic damage to the tracheal mucosa. When nitrous oxide is used, cuff pressures gradually increase as nitrous oxide enters the cuff by diffusion. This is of particular concern in surgical procedures of long duration, such as free-flap surgery.

Before attempting tracheal intubation, its difficulty using direct laryngoscopy can often be predicted. The 11-point airway assessment tool included with the 2003 ASA Difficult Airway Algorithm is an excellent source of information and advice.[20] In addition, following the completion of tracheal intubation, the difficulty (if any) encountered should be summarized. The Intubation Difficulty Scale (IDS) introduced by Adnet and associates can be useful.[29-33] IDS is a numeric score indicating overall intubation difficulty based on seven descriptors associated with intubation difficulty: number of supplementary intubation attempts, number of supplementary operators, alternative techniques used, laryngoscopic grade, subjective lifting force, the use of external laryngeal manipulation, and the characteristics of the vocal cords.

Most endotracheal intubations are achieved using traditional Macintosh and Miller laryngoscopes, although several alternative laryngoscopes have been advocated. When the view at laryngoscopy is suboptimal, the use of introducers such as the Eschmann stylet (gum elastic bougie) can sometimes be very helpful.[34-39] It is used as follows: When a poor laryngoscopic view of the glottic structures is obtained, the introducer should be inserted into the patient's mouth and gently advanced through the glottic opening (in the case of a grade II view) or anteriorly under the epiglottis (in the case of a grade III view). Subtle clicks resulting from the introducer passing over the tracheal rings help confirm proper placement of the introducer. With the introducer held steady, one then "railroads" a tracheal tube over the introducer into the glottis.

Video laryngoscopes such as the GlideScope (Verathon, Bothell, WA), the McGrath (Covidien, Mansfield, MA) video laryngoscope, the Storz video laryngoscope (Karl Storz, Tuttlingen, Germany), and the Pentax AWS (Hoya Corporation, Tokyo) have become particularly valuable, especially in patients with an "anterior" larynx or in patients with cervical spine immobilization.[40-50]

As discussed in Chapter 55, awake endotracheal intubation involves ETT insertion in a conscious or lightly sedated patient. It is usually performed because endotracheal intubation during general anesthesia is judged to be too risky. Some concerns may reflect possible difficulties

with ventilation or endotracheal intubation or possible aspiration of gastric contents. Although fiberoptic intubation using topical anesthesia is the most common approach to awake endotracheal intubation, other methods include awake blind nasal intubation using an Endotrol (or similar) ETT or the use of a Macintosh, Miller, GlideScope, or other laryngoscope with topical anesthesia. Certain airway blocks can be used in addition to topical anesthesia. These are discussed in Chapter 55.

The use of fiberoptic intubation for the airway management of patients undergoing otolaryngologic surgery is popular because this technique works well in the presence of many kinds of airway disease. Although fiberoptic intubation can often be safely performed during complete general anesthesia,[51] many clinicians opt to perform this technique using topical anesthesia with the patient only lightly sedated (awake fiberoptic intubation), depending on the skill level of the anesthesiologist, the cooperation of the patient, and the severity of the pathologic process. A central consideration behind the choice of "awake" versus "asleep" fiberoptic intubation is the safety margin an awake technique allows: If intubation is not successfully accomplished, the patient's ability to maintain his or her own airway remains intact. In addition, during awake intubation, airway reflexes are generally maintained sufficiently to guard against pulmonary aspiration, an important point in patients with a high risk of aspiration of gastric contents. Patients who have recently eaten and have undergone trauma are at especially high risk.

Awake endotracheal intubation is not synonymous with fiberoptic intubation. Awake intubation can be accomplished safely using many other airway devices. Other possible options for awake intubation include, but are not limited to, direct laryngoscopy with Macintosh and Miller laryngoscopes, blind nasal intubation, use of a GlideScope or other video laryngoscope, use of a lighted stylet, and so on.

Typically, in intubation of the trachea in an awake patient, the airway is initially anesthetized with gargled and atomized 4% lidocaine. Superior laryngeal and transtracheal blocks are occasionally also employed. In addition, judicious sedation is usually administered. Midazolam, fentanyl, remifentanil, ketamine, propofol, and clonidine have all been used in this setting. More recently, the use of dexmedetomidine, a selective α_2-agonist with sedative, analgesic, amnestic, and antisialagogue properties, has been reported. A key advantage of dexmedetomidine is that it maintains spontaneous respiration with minimal respiratory depression.[52-55] Patients being sedated with dexmedetomidine are generally easy to arouse. However, this advantage, along with that of maintaining spontaneous respiration, may not occur when very large doses are given.

Doyle described the successful use of the GlideScope in four cases of awake endotracheal intubation.[56] The following potential advantages are as follows: First, the view is generally excellent. Second, the method is less affected by the presence of secretions or blood as compared with the use of fiberoptic intubation. Third, no special restrictions exist on the type of ETT that can be placed when using the GlideScope, but this is not the case for fiberoptic methods. Fourth, the GlideScope is much more rugged than a fiberoptic bronchoscope and is far less likely to be damaged with use. Advancing the ETT into the trachea over the fiberoptic bronchoscope often fails as a result of ETT impingement on the arytenoid cartilages; this is generally not a problem with the GlideScope.

In the end, however, the use of awake fiberoptic intubation in the setting of the patient with airway disease remains steadfastly popular because it is gentle to the airway, is generally well tolerated, and does not require the application of force to obtain glottic exposure.

Special mention needs to be made of the necessity of being fully prepared for dire ENT airway emergencies because these patients may require immediate surgical intervention. In addition to a conventional difficult airway cart, practitioners may wish to maintain a special ENT airway cart with equipment such as that listed in Box 85-1.[57] In addition to these items and unlisted items favored by individual practitioners, ENT surgeons want ready access to an emergency tracheotomy tray, as well as to some form of suspension laryngoscope or rigid bronchoscope. Special attention to the maintenance and cleaning of fiberoptic bronchoscopes is also important, given that they must always be easily accessible and reliable when needed. In the case of electronic fiberscopes incorporating a video display, it is particularly important to establish that illumination settings and white balancing have been correctly set before use.

AIRWAY DISORDERS IN OTOLARYNGOLOGY

Otolaryngologic airway disorders can sometimes present the clinician with tremendous anesthetic and airway challenges. In many such cases, awake endotracheal intubation (e.g., by fiberoptic methods) is the method of choice. When awake intubation is impractical (e.g., overwhelming tumor invasion of the airway, inadequate equipment, limited experience), tracheostomy using local anesthesia

BOX 85-1 *Possible Items for an Ear, Nose, and Throat Airway Emergencies Cart*

- Bag-valve-mask resuscitator (Ambu bag)
- Oropharyngeal and nasopharyngeal airways
- Supraglottic airway collection
- Endotracheal tubes, including microlaryngeal tubes and laser tubes
- Malleable stylets
- Topical anesthesia, with syringes, and atomizers
- Laryngoscope collection with extra bulbs and batteries
- McGill forceps (useful for nasal intubation)
- Boedeker forceps (for use with video laryngoscopes)*
- Airway introducer (gum elastic bougie)
- Tube exchange catheters
- Carbon dioxide detection system
- Video laryngoscope (e.g., GlideScope, McGrath, Pentax-AWS)
- Surgical airway kit (e.g., Melker cricothyrotomy kit)
- Emergency tracheotomy tray
- Fiberoptic bronchoscope

*The Boedeker (curved) intubation forceps is useful for removal of foreign bodies when a video laryngoscope is used.[57]

(with minimal sedation, or no sedation in extreme cases) is sometimes preferred. In such cases, complete airway obstruction is the outcome most feared; this can occur when anesthetic drugs or neuromuscular blocking drugs decrease the tone of the airway musculature, thereby unfavorably changing the airway architecture.

Many ENT pathologic conditions can make airway management difficult. *Airway infections* can include upper airway abscesses, retropharyngeal abscesses, quinsy, Ludwig angina, and epiglottitis (supraglottitis). *Airway tumors* may be present as oral or tongue malignancies, as glottic, supraglottic, and infraglottic tumors, or as anterior mediastinal masses. *Other pathologic conditions* may also complicate airway management, such as congenital malformations (Pierre-Robin sequence, Goldenhar syndrome), periglottic edema (e.g., following rigid bronchoscopy), recurrent laryngeal nerve injury (e.g., following thyroid surgery), maxillofacial trauma, or OSA. Some of the more important of these conditions are discussed in the following paragraphs.

ANGIOEDEMA

Angioedema (former term: angioneurotic edema) is a rapid form of tissue swelling mediated by anomalous activation of the complement system with release of histamine and other inflammatory mediators.[58] It is usually the result of an allergic reaction. Hereditary angioedema is a variant family that arises from an autosomal dominant genetic mutation. Complete loss of the airway can occur in severe cases of either form. Just as with anaphylaxis, epinephrine may be lifesaving when the cause of angioedema is allergic, but treatment with epinephrine is not helpful in cases of hereditary angioedema.[59] Intubation of the trachea is often required in affected patients usually during topical anesthesia with the patient awake or lightly sedated.

ACUTE EPIGLOTTITIS

Epiglottitis, an inflammatory disease of the epiglottis, arytenoids, and aryepiglottic folds, is among the most dreaded of airway-related infections, especially in the pediatric population (see also Chapter 93).[60-64] In the past, victims were usually children 2 to 6 years of age, who were often infected with *Haemophilus influenzae*. Today, a vaccine against *H. influenzae* has reduced the frequency of this tragic affliction. The clinical presentation often includes a sore throat, dysphagia, muffled voice, and fever. Difficulty with swallowing leading to drooling from the mouth may occur. Victims may appear to be systemically ill ("toxic") and assume an open-mouth "tripod" position to ease breathing. Stridor, respiratory distress, and complete airway obstruction may occur. The chief differential diagnosis in children is laryngotracheobronchitis (croup).[65,66]

Examining the child's airway at the bedside may exacerbate the condition, and anything that could bring the child to cry (e.g., needles) should be avoided when possible. A common management approach involves careful inhaled induction of anesthesia using sevoflurane with the child sitting in the anesthesiologist's lap. Then oral intubation of the trachea can be performed using a smaller than usual tracheal tube. The child should receive "deep" anesthesia but should still be breathing spontaneously. Intravenous access and full monitoring should be established as anesthesia is deepened. If at laryngoscopy the airway cannot be identified, one trick is to have someone compress the child's chest, thus generating a small air bubble in the glottis that the person performing the anesthetic can aim for in the trachea. Failure to secure the airway in this manner may necessitate rescue through rigid bronchoscopy, by establishing a surgical airway, or by other means. In the past these children were often then managed by tracheostomy; however, contemporary management usually includes intensive care unit (ICU) admission, throat and blood cultures, conversion to nasotracheal intubation, and intravenous antibiotic therapy.

Epiglottitis can also occur in adults.[67] The first president of the United States, George Washington, is said to have died of it, although being repeatedly phlebotomized (as was the custom of the day) undoubtedly contributed to his demise. Here the situation is less ominous because the adult airway is larger. In cooperative adults, cautious oropharyngeal examination and fiberoptic nasopharyngoscopy help assess the degree of disease. The current consensus is that many adults can be adequately treated in an ICU with inhaled mist, antibiotics, and corticosteroids and that tracheal intubation is necessary only if symptoms of respiratory distress develop (see Chapter 101). Should intubation be needed, awake fiberoptic laryngoscopy is probably the best way to secure the airway in cooperative adults, whereas the use of inhaled induction of anesthesia in adults with a compromised airway is now considered to be more perilous than was once thought.

RETROPHARYNGEAL ABSCESS

Retropharyngeal abscess formation may occur from bacterial infection of the retropharyngeal space following dental or tonsillar infections.[68-74] If the condition is untreated, the posterior pharyngeal wall may advance anteriorly into the oropharynx, with resulting dyspnea and airway obstruction. Other clinical findings may include difficulty in swallowing, trismus, and a fluctuant posterior pharyngeal mass. An abscess cavity may be evident on lateral neck radiographs, and anterior displacement of the esophagus and upper pharynx may be present. Airway management may be complicated by trismus or partial airway obstruction. Because abscess rupture can lead to tracheal soiling, contact with the posterior pharyngeal wall during laryngoscopy and intubation should be minimized. Incision and drainage are the mainstays of treatment. Tracheostomy is often, but not always, required.

LUDWIG ANGINA

Ludwig angina is a multispace infection of the floor of the mouth.[75-79] The infection usually starts with infected mandibular molars and spreads to submandibular, sublingual, submental, and buccal spaces. The tongue becomes elevated and displaced posteriorly, which may lead to loss of the airway, especially when the patient is in the supine

position. As with retropharyngeal abscess, an additional concern is the potential for abscess rupture into the hypopharynx (with possible lung soiling) either spontaneously or with attempts at laryngoscopy and intubation. Airway management options depend on clinical severity, imaging findings (e.g., computed tomography [CT] or magnetic resonance imaging [MRI] findings), and surgical preferences, but elective tracheostomy before incision and drainage remains a classic, if dated, treatment modality.[79] Most experts advocate fiberoptic intubation when possible. In addition, because Ludwig angina is often associated with trismus, nasal fiberoptic intubation is frequently needed.

AIRWAY TUMORS, POLYPS, AND GRANULOMAS

Airway tumors can be benign or malignant (Figs. 85-5 to 85-7), but regardless of their pathologic characteristics, airway obstruction is always a potential concern.[80-83] Discussion with the surgical team concerning the size and location of the tumor, along with a review of any video-recorded nasopharyngeal video examinations, will help determine whether awake endotracheal intubation is needed. Polyps may also be found throughout the airway and can lead to partial or complete airway obstruction. Vocal cord polyps, cysts, and granulomas may result from traumatic intubation, vocal cord irritation from ETT movement, or other causes, especially in women.[84-90] Vocal cord cancer can also occur.[91] The potential also exists for exacerbation of asthma in patients with nasal polyps who receive aspirin, ketorolac (Toradol), and other nonsteroidal antiinflammatory drugs (NSAIDs) (the Samter triad).[92,93]

LARYNGEAL PAPILLOMATOSIS

Patients with laryngeal papillomatosis caused by human papillomavirus (HPV) infection may require frequent application of laser treatment for attempted papilloma eradication.[94-99] In some cases the airway may be close to obstruction because of an overgrowth of lesions. During laser treatment, inspired oxygen concentration should be kept to a minimum, with the avoidance of nitrous oxide, to reduce the chance of an airway fire (see Chapter 88). After treatment, the airway is raw and edematous. Laryngotracheomalacia may occasionally be present, sometimes leading to complete upper airway collapse following extubation of the trachea.

ANESTHESIA FOR PANENDOSCOPY

Panendoscopy, sometimes known as triple endoscopy, involves three diagnostic components: laryngoscopy, bronchoscopy, and esophagoscopy. Such procedures and others involving the larynx, pharynx, or trachea often require specialized ENT laryngoscopes, frequently in conjunction with a small-diameter ETT or a tube specifically designed for laser surgery. Panendoscopy is used in patients with head and neck cancer to search for vocal cord lesions, obtain tissue biopsies, monitor for tumor recurrence, and so on. In such cases, one should consider the following specific issues in discussion with the surgical team: What is the anticipated pathologic process, and how is it expected to affect intubation or ventilation? (In some cases the patient's disease may not allow the use of an ETT, so that jet ventilation or a rigid bronchoscope is needed.) What is the plan for airway management, and how does it affect the delivery of anesthesia? How does the presence of coexisting disease (e.g., coronary artery disease, chronic obstructive pulmonary disease, gastroesophageal reflux disease) affect management? What specialized equipment may be needed? (For example, when airway obstruction is present, the surgeon may employ dilatational balloons, lasers, or a microdébrider to open up the airway).

Five airway options for panendoscopy exist: (1) use of an ETT, typically a narrow-bore MLT that provides the surgeon with a superior glottic view; (2) jet ventilation in conjunction with a rigid ENT laryngoscope, without the use of an ETT; (3) hybrid methods, such as the intermittent use of an SGA or an MLT tube in conjunction with a rigid laryngoscope, jet ventilation, or intermittent apnea; (4) tracheostomy using local anesthesia before inducing general anesthesia; (5) and elective placement of a specially designed transtracheal jet ventilation cannula (e.g., Ravussin jet ventilation catheter before induction[100]). The last two options are only occasionally used for patients with a suspected difficult airway; awake tracheal intubation is the most common approach in patients with a difficult airway. Moreover, when jet ventilation is used, total intravenous anesthesia (TIVA), for example with infusions of propofol and remifentanil, is needed. Finally, when panendoscopy is combined with laser surgery, a laser-safe ETT is often used.[101,102]

Panendoscopy is generally done while the patient is under general anesthesia with the patient's neck flexed and the head extended, usually employing a shoulder roll and a head ring (Jackson position). Typically, an anterior commissure laryngoscope is used and fixed into position by suspension (Fig. 85-8). This technique allows the surgeon's hands to be free and the operating microscope to be used. Other specialized ENT surgical laryngoscopes that are commonly used, often in conjunction with a microscope for laryngeal microsurgery, include the Dedo laryngoscope (Elmed, Addison, IL) and the Universal Modular Glottiscope (Endocraft, Providence, RI). Here, once the laryngoscope is correctly configured ("suspended"), the surgeon brings the operating microscope into the field and uses a variety of microlaryngeal instruments to treat the patient.

A variety of anesthetic techniques can be used for panendoscopy procedures. The most common approach is to perform the procedure while the patient is under general anesthesia with muscle relaxation in conjunction with an MLT-type tracheal tube (Fig. 85-9). This technique is familiar to anesthesiologists, provides both airway protection and control of ventilation, allows for reliable capnographic carbon dioxide (CO_2) measurements, and allows for the use of volatile anesthetics without operating room pollution. Disadvantages of the technique include higher than usual ventilation pressures as a consequence of the tube's narrow diameter, somewhat hindered surgical access, and concerns for tube ignition when a laser is in use.

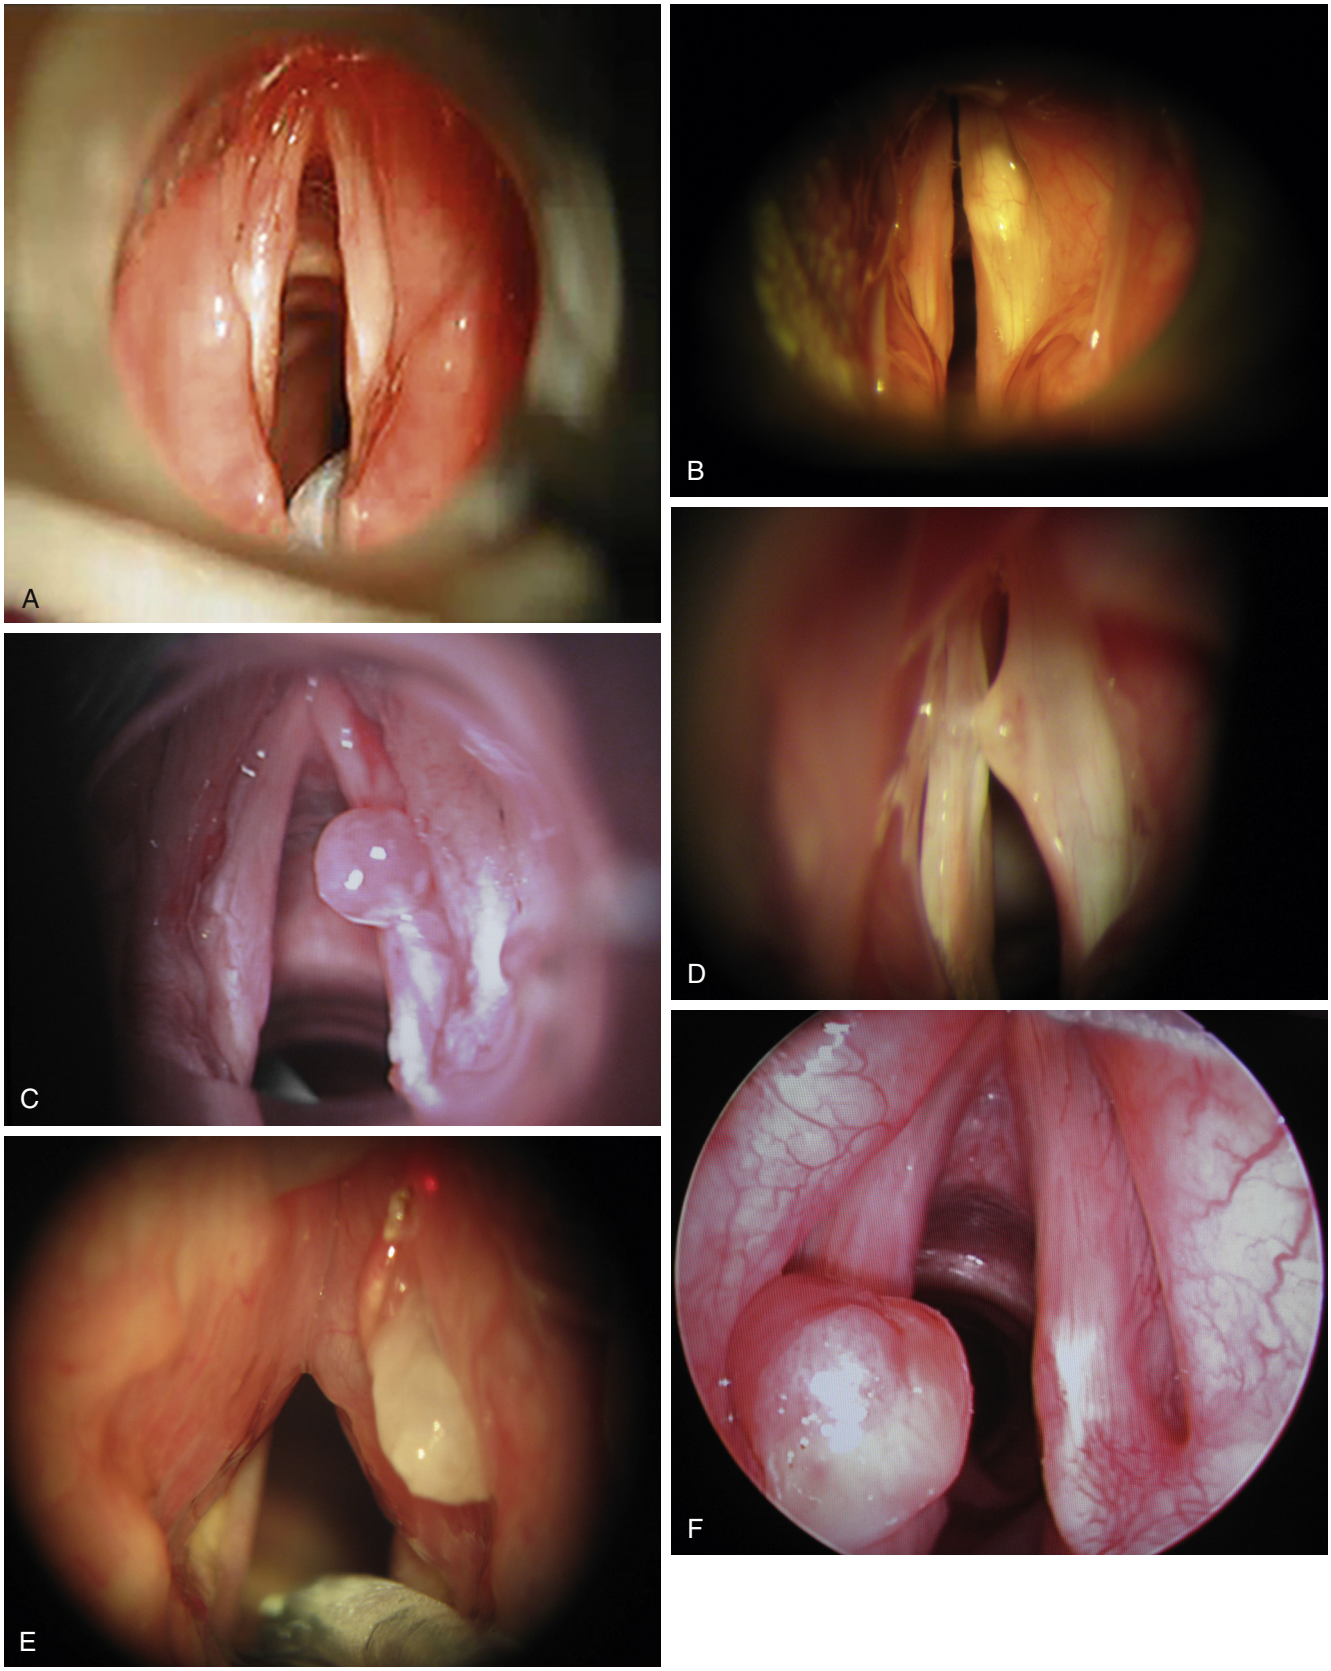

Figure 85-5. Vocal cord lesions with little or no airway compromise. **A,** Normal vocal cord. **B,** Minor right vocal cord lesion. **C,** Granuloma on the middle right vocal cord. **D,** Kissing nodule on the right vocal cord. **E,** Anterior webbing of the vocal cord. **F,** Intubation granuloma. *(From Feldman MA, Patel A: Anesthesia for eye, ear, nose, and throat surgery. Figure 85-7. Vocal cord lesions with severe airway compromise. **A,** Papilloma of vocal cord. **B,** Severe subglottic stenosis (2-mm airway). **C,** Bilateral papilloma. **D,**Extensive supraglottic carcinoma.

Because a tracheal tube may impair access to some glottic structures, however, some cases are performed using intermittent apnea during general anesthesia and administration of neuromuscular blocking drugs. Disadvantages of this technique include the need for a TIVA technique, the need for repeated intubation-extubation cycles (potentially producing glottic trauma), fragmentation of the surgical work into brief apneic segments, and the repeated interruption of ventilation and oxygenation.

Next, panendoscopy is often performed using supraglottic jet ventilation.[103,104] This technique requires TIVA and entails some special issues because it involves the delivery of high-pressure oxygen pulses (typically 20 to 50 psi in adults, frequently delivered 1 second on/3 seconds off), usually through an adapter that attaches to the surgical laryngoscope. Additionally, subglottic methods (e.g., using a Hunsaker catheter[105,106]) and transtracheal methods of jet ventilation[107-110] have been described. Each pulse of oxygen entrains room air, thus increasing the gas volume delivered and diluting the oxygen concentration (Venturi effect). Disadvantages of jet ventilation include the need for TIVA, the potential for barotrauma (remember that a pressure of 50 psi is equivalent to 3515 cm H_2O), an inability to measure either end-tidal CO_2 ($ETCO_2$) or tidal volume easily, and the fact that the technique is often suboptimal in obese individuals. Finally, a variant of jet ventilation known as high-frequency jet ventilation is sometimes used in these cases,[111,112] often in conjunction with a special ventilator, an intratracheal catheter, and transcutaneous CO_2 monitoring.

OTOLARYNGOLOGIC TRAUMA

Although the topic of anesthesia care for the trauma patient is the subject of Chapter 81,[113] a few special points pertaining to patients who have undergone head and neck trauma should be emphasized. First, patients with head and neck trauma may have a concurrent brain injury or injury to the cervical spine. Until cleared of a possible cervical spine injury, patients should be placed in a rigid cervical collar. In addition, although placing the patient's head in the customary "sniffing" position can facilitate laryngoscopy, this technique is contraindicated in patients with a suspected cervical spine injury for fear of exacerbating any injury. Additionally, jaw thrust and chin lift maneuvers can be more difficult when a cervical collar is used or when comminuted mandibular fractures are present.

Second, facial injuries can produce extensive bleeding, as well as the aspiration of blood, bone, cartilage, teeth, and tissue fragments. Third, the airway may be compromised, especially when bilateral mandibular fractures are present. Airway trauma from blunt or penetrating

injuries, burns, inhalational injury, or even iatrogenic causes may be present. Immediate airway management options include orotracheal intubation (awake versus rapid-sequence induction), a surgical airway carried out using local anesthesia, or even intubation through an open airway in cases of tracheal transection. Oropharyngeal airways may not be tolerated in patients with an intact gag reflex, and inserting a nasopharyngeal airway may exacerbate bleeding.

Although fiberoptic intubation would seem to offer many advantages in trauma cases, clinical experience suggests otherwise, at least in some cases, because navigating through a distorted airway filled with blood and foamy secretions challenges even the most experienced bronchoscopists. Special concerns exist when the trachea is intubated in a patient with laryngeal trauma because this may result in further injury or even complete airway loss (e.g., in the event of inadvertent ETT placement through a laryngeal fracture into the mediastinum). Clinical findings suggestive of laryngeal trauma include abrasions, discoloration, indentation, bleeding, or pain in the region of the larynx, as well as dyspnea, dysphagia, dysphonia, stridor, hemoptysis, subcutaneous emphysema, and hoarseness. Signs of pneumothorax may also be present, whereas fiberoptic endoscopic examination may reveal edema, the presence of bleeding or hematoma, or abnormal vocal cord function. If endotracheal intubation is attempted in this setting, a fiberoptic bronchoscope with a small-diameter ETT can be used carefully, bearing in mind the foregoing concerns about fiberoptic intubation in the trauma setting. Additionally, positive-pressure ventilation by mask or SGA in this setting may worsen any subcutaneous emphysema. A tracheostomy may be the most prudent course in some cases. Finally, the application of cricoid pressure in blunt laryngeal trauma may result in cricotracheal separation and so is contraindicated. In any event, in both facial trauma and airway trauma, initial management is dictated by the degree of respiratory distress or potential airway compromise, the available equipment, and clinical preferences.

Midfacial fractures deserve special mention. These fractures are defined by the Le Fort classification. A Le Fort I fracture is a horizontal fracture that involves the inferior nasal aperture, separating the maxillary alveolus from the rest of the midfacial skeleton. Le Fort II fractures are pyramidal nasomaxillary fractures that break from the upper craniofacial skeleton. Le Fort III fractures, less commonly encountered than the others, involve the separation of the facial skeleton from the skull base. These fractures are illustrated in Figure 85-10.

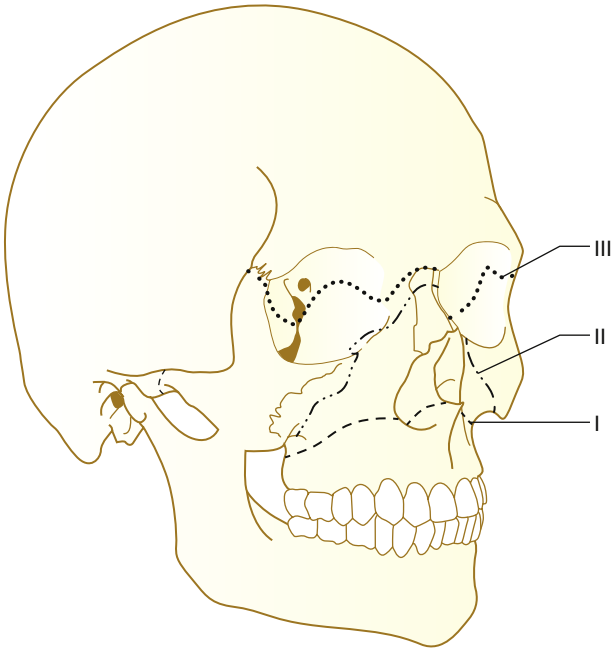

Figure 85-10. Classification of midfacial fractures. Le Fort I: alveolar fracture. Le Fort II: zygomatic-maxillary complex fracture. Le Fort III: cranial facial dysostosis with separation of the midface from the skull. *(From Schuller DE, Schleuning AJ:* Otolaryngology: head and neck surgery, *ed 8. St. Louis, 1994, Mosby, p 157.)*

NASAL SURGERY

Nasal surgery can involve external procedures, procedures within the nasal cavity, surgery involving the nasal bones, and nasal sinus surgery. Besides the usual concerns, preoperative assessment should focus on the suitability of topical nasal vasoconstrictor use, the possibility of undiagnosed OSA, and the potential presence of the Samter triad (nasal polyps, asthma, and a sensitivity to aspirin and NSAIDs that may produce deadly bronchospasm). Because postoperative bleeding is a common complication after nasal surgery, patients should not be taking NSAIDs and aspirin for 1 to 2 weeks preoperatively.

Preoperative planning begins by deciding whether the procedure is best performed with local (usually accompanied by intravenous sedation) or general anesthesia. Although local anesthesia may be suitable for simple procedures such as cauterization or straightforward polypectomy or turbinectomy surgery in adults, often general anesthesia is required. When general anesthesia is chosen, a choice must then be made among a simple facemask (as may be appropriate for pediatric myringotomy surgery), an SGA device (e.g., flexible LMA), and a tracheal tube (e.g., an unkinkable wire-reinforced design). This decision should be made jointly with the surgeon. Although the use of an SGA during ENT surgery has its enthusiasts, negative experiences, such as airway obstruction related to device malpositioning, have led many clinicians to prefer a tracheal tube in such cases.

Patients undergoing rhinoplasty are typically young, healthy individuals requiring reconstruction of the external nose for deformity treatment.[114,115] Septoplasty (correction of a deviated septum)[116-118] and surgery to remove nasal polyps[119-120] are often performed to improve nasal airflow and ventilation of the sinuses. Some malignant lesions require excision of the entire nose with follow-up staged reconstruction using a forehead flap. Open nasal fracture reduction procedures are usually performed after the initial swelling has resolved; if the injury is corrected too late, the bones can be difficult to align and can lead to significant surgical bleeding. General endotracheal anesthesia is usually carried out in such cases, often using a midline reinforced ETT taped to the chin. In closed nasal fracture reduction, the surgeon applies forceful pressure

to realign the nasal bones, a procedure that usually takes only a few seconds but nevertheless is so intensely painful that the procedure is usually preceded by a single induction dose of propofol, followed by airway support as needed as a nasal cast is applied. However, when the reduction is expected to be bloody or otherwise complicated, the airway is usually protected with an ETT or an SGA device. In many of these procedures, nasal packs, stents, and/or casts are placed; nasal stents offer an advantage over packs in that one can breathe through them.

In many ENT cases, a "throat pack" made of a long piece of saline-soaked gauze is stuffed around the ETT to prevent blood and surgical debris from entering the pharynx and larynx. Typically, a few inches of gauze are kept outside the mouth as a reminder of its presence, because an inadvertently retained pack can lead to catastrophic airway obstruction after extubation.[121] In addition to suctioning, many clinicians follow throat pack removal with pre-extubation laryngoscopy and a neck flexion-extension maneuver to encourage any residual clot (the so-called "coroner's clot") to fall past the soft palate into a position where it can be removed under direct vision.

Gentle awakening in nasal surgery is important because coughing and bucking on emergence frequently produce undesirable bleeding. Techniques that are often helpful include the use of a remifentanil infusion and the application of lidocaine down the ETT with the cuff temporarily deflated while the patient is still under deep anesthesia. Oral and gastric suction before emergence will decrease the incidence of postoperative nausea and vomiting (PONV) (see Chapter 97). When nasal packing is used, patients should be advised before induction of anesthesia that, on emergence, they should breathe through the mouth. On awakening, applying pressure on the nose with a facemask should not be done for fear of ruining the surgeon's handiwork. In addition, all postoperative patients with nasal packs will have obstructed nasal passages unless nasopharyngeal airways are incorporated into the nasal pack, and patients with OSA are in particular need of careful postoperative respiratory monitoring. Finally, postoperative pain in these procedures usually does not require opiates, and the use of oral acetaminophen and an NSAID usually suffices (see also Chapter 98).

In many of these procedures, a topical vasoconstrictor such as phenylephrine, oxymetazoline, or cocaine is used. Although these topical agents are important drugs that reduce bleeding and improve visualization during nasal and endoscopic procedures, they sometimes produce cardiovascular toxicity.[122] The cardiovascular effects of cocaine, usually administered as a 4% (40 mg/mL) topical solution, result from the drug's blocking the reuptake of norepinephrine at sympathetic nerve terminals. Consequently, cocaine would not be a first-choice vasoconstrictor in patients with coronary artery disease or hypertension or in patients taking monoamine oxidase inhibitors.[123] When cocaine use is appropriate, the dose should not ordinarily exceed 1.5 mg/kg.

Phenylephrine is an α-adrenergic agonist topical vasoconstrictor either used alone or in combination with lidocaine. The initial dose should not exceed 500 μg (<20 μg/kg in children ≤25 kg). Because severe hypertension sometimes results following phenylephrine use, blood pressure monitoring is particularly important. Instances of unacceptable hypertension should be treated with direct vasodilators or α-receptor antagonists; the use of β-adrenergic and calcium channel blockers should be avoided because they may worsen cardiac output and produce pulmonary edema.[124]

Oxymetazoline, a selective α_1-agonist and partial α_2-agonist imidazoline-derivative, is perhaps the most popular topical vasoconstrictor in ENT surgery, primarily because of its excellent safety profile and availability as an over-the-counter product.[125-127] Three sprays of 0.05% solution are administered in each nostril. This drug should be avoided in patients taking monoamine oxidase inhibitors. However, despite its relative safety, complications have been reported.[128,129]

TONSILLECTOMY AND ADENOIDECTOMY

The adenoids are a mass of lymphoid tissue located posterior to the nasal cavity, in the roof of the nasopharynx. If this tissue become hyperplasic, nasopharyngeal obstruction and a number of related problems can occur such that the adenoids merit surgical removal (adenoidectomy). When removed, the tonsils are usually taken as well. Other indications for tonsillectomy include tonsillar hyperplasia, recurrent tonsillitis, and malignant disease.[130] An especially important consideration here is that chronic oropharyngeal airway obstruction as a consequence of tonsillar hypertrophy can lead to OSA and its attendant complications (daytime sombulence, cor pulmonale, pulmonary hypertension, right ventricular hypertrophy, cardiomegaly). In addition to the usual, preoperative assessment focuses on findings suggestive of OSA, possible cardiac comorbidities, and a history of recurrent upper respiratory tract infections. The presence of a fever or a productive cough may be grounds for postponement of the surgery or for postoperative care in setting of increased vigilance (e.g., ICU or step-down facility), especially in infants (see also Chapter 93).

Induction of anesthesia in adults usually entails administering intravenous drugs, whereas inhaled inductions are popular with children, followed by placement of an intravenous catheter and administration of glycopyrrolate. Oral RAE (named after the inventors Ring, Adair, and Elwyn) tracheal tubes or wire-reinforced tubes, taped in the midline to the mandible, are often preferred by surgeons and are less likely to kink following retractor placement. When a tonsillar or parapharyngeal abscess is present, the patient may have a compromised airway complicated by trismus and pharyngeal edema. Although awake abscess decompression by needle aspiration before the induction of anesthesia is sometimes done, awake fiberoptic intubation is the usual approach in this setting.

At the end of the surgical procedure, the throat pack, if previously placed, should be removed, the oropharynx should then be suctioned, and an orogastric tube should be used to empty the stomach. Extubation is sometimes performed using deep anesthesia but more commonly is carried out when the patient has intact airway reflexes. Coughing on the tracheal tube on emergence may be attenuated by the administration of lidocaine, either

given intravenously or placed down the tracheal tube with the cuff temporarily deflated. Emergence on a light remifentanil infusion can also be beneficial.

Posttonsillectomy hemorrhage is a dreaded surgical emergency, especially in children[131-133] (see also Chapter 93). It usually occurs within the first 6 postoperative hours, but it can also occur several days later. When possible, the patient should receive appropriate intravenous fluids preoperatively (including blood products when necessary). The presence of hypovolemia may dictate a reduction in induction drug dosage or the use of etomidate. Because the stomach may contain a considerable amount of blood, a *rapid-sequence induction* with cricoid pressure is usually performed with a view to protect the airway from aspiration of gastric contents. Vigorous suctioning is also needed to remove the copious oropharyngeal blood likely to be found during laryngoscopy.

ENDOSCOPIC SINUS SURGERY

Endoscopic sinus surgery has become a common ENT procedure. Indications are varied and include conditions such as nasal polyposis, recurrent or chronic sinusitis, epistaxis control, tumor excision, orbital decompression (e.g., for Graves ophthalmopathy), foreign body removal, treatment of sinus mucoceles, and more.[134-136]

Proper anesthetic management helps ensure a good outcome. Considerations in such cases include local versus general anesthesia, SGA device versus ETT, and inhaled anesthesia versus TIVA, and they take into account patient comorbidities, as well as preferences of the surgeon and anesthesiologist. The most important goals are a blood-free surgical field, patient immobility, stable cardiorespiratory conditions, and gentle emergence from anesthesia. Controlled hypotension is sometimes used to improve surgical conditions; when this approach is used, intraoperative β-adrenergic blockade is associated with better operating conditions than when vasodilation drugs are administered.

Despite minimal arterial blood pressure differences, propofol-remifentanil intravenous anesthesia may provide better surgical conditions as compared with a traditional balanced technique (e.g., using an isoflurane-opiate technique), possibly because of lower heart rates and cardiac output.[137] Use of an SGA device is preferred to an ETT because of better surgical conditions and smoother emergence. However, SGA devices are prone to malpositioning and provide less protection from gastric regurgitation as compared with an ETT.[138]

The procedure typically begins with decongestion of the nose and infiltration of 1% lidocaine with 1:100,000 epinephrine, often followed by the bilateral nasal placement of pledgets soaked in 4% cocaine. In most cases, an image-guided surgical system is used; this allows the surgeon to know exactly where he or she is operating by using a preoperative CT scan. This technology allows the surgeon to visualize four different views simultaneously: the coronal, sagittal, and axial CT scan images at the same time as the real time endoscopic view. This system requires a special headset that may preclude the use of electroencephalographic (bispectral index) monitoring (see also Chapter 44).

Given the close proximity of major blood vessels and nerves, the orbit, and the brain, complications are possible, especially when the surgical landmarks are obscured by blood. Some major complications include orbital hematoma formation, blindness from orbital trauma or damage to the optic nerve, formation of cerebrospinal fluid leak, carotid or ethmoid artery invasion, entry into the cranial cavity, severe hemorrhage, and death.

Finally, not all sinus surgery is endoscopic. For example, although now largely replaced by endoscopic methods, the once common Caldwell-Luc procedure involves fenestration of the anterior wall of the maxillary sinus with surgical drainage of this sinus into the nose through an antrostomy.

THYROID AND PARATHYROID SURGERY

The usual indications for thyroid surgery include thyroid cancer, symptomatic thyroid goiter, and failed medical management of hyperthyroidism; the surgical procedure is almost always elective.[139] The most common indication for parathyroid surgery is hypercalcemia from hyperparathyroidism secondary to a benign parathyroid adenoma. When the hypercalcemia is severe, preoperative treatment (e.g., fluids, furosemide, bisphosphonates) may be needed.

Hyperthyroid patients should be treated preoperatively to reduce the risk of thyroid storm (thyrotoxicosis). Thyrotoxic patients may experience sinus tachycardia, atrial fibrillation, myocardial ischemia, congestive heart failure, nervousness, tremulousness, insomnia, heat intolerance, weight loss, and other findings.[140,141]

Large goiters may result in deviation of the larynx, tracheal compression leading to considerable airway narrowing, Horner syndrome, or superior vena cava obstruction, especially with retrosternal extension.[142,143] Preoperative airway evaluation by endoscopic examination and by CT is often useful to determine the extent of the disease and the possibility that sternotomy will be needed.

General anesthesia with tracheal intubation and muscle relaxation is usually employed, although many surgeons routinely use a nerve integrity monitor (NIM) ETT for neuromonitoring,[144-146] in which case neuromuscular blocking drugs must be avoided in the postintubation period. Gentle emergence from anesthesia is necessary to avoid coughing on the ETT and the possibility of hematoma formation from venous engorgement. The use of a small-dose remifentanil infusion (0.01 to 0.05 μg/kg/minute) in the extubation period is a popular means to diminish coughing on the ETT. Although deep extubation also reduces the incidence of bucking and straining, many clinicians avoid this technique wherever possible because of airway obstruction.

Possible complications of thyroid and parathyroid surgery include hematoma formation (possibly resulting in airway impairment), vocal cord dysfunction from recurrent laryngeal nerve injury, pneumothorax, and other conditions. In patients with compressive goiters, postthyroidectomy tracheomalacia may occur following goiter excision. In postoperative patients who have undergone parathyroid and total thyroidectomy, serial calcium levels are taken to detect inadvertent hypocalcemia.

AIRWAY FIRES

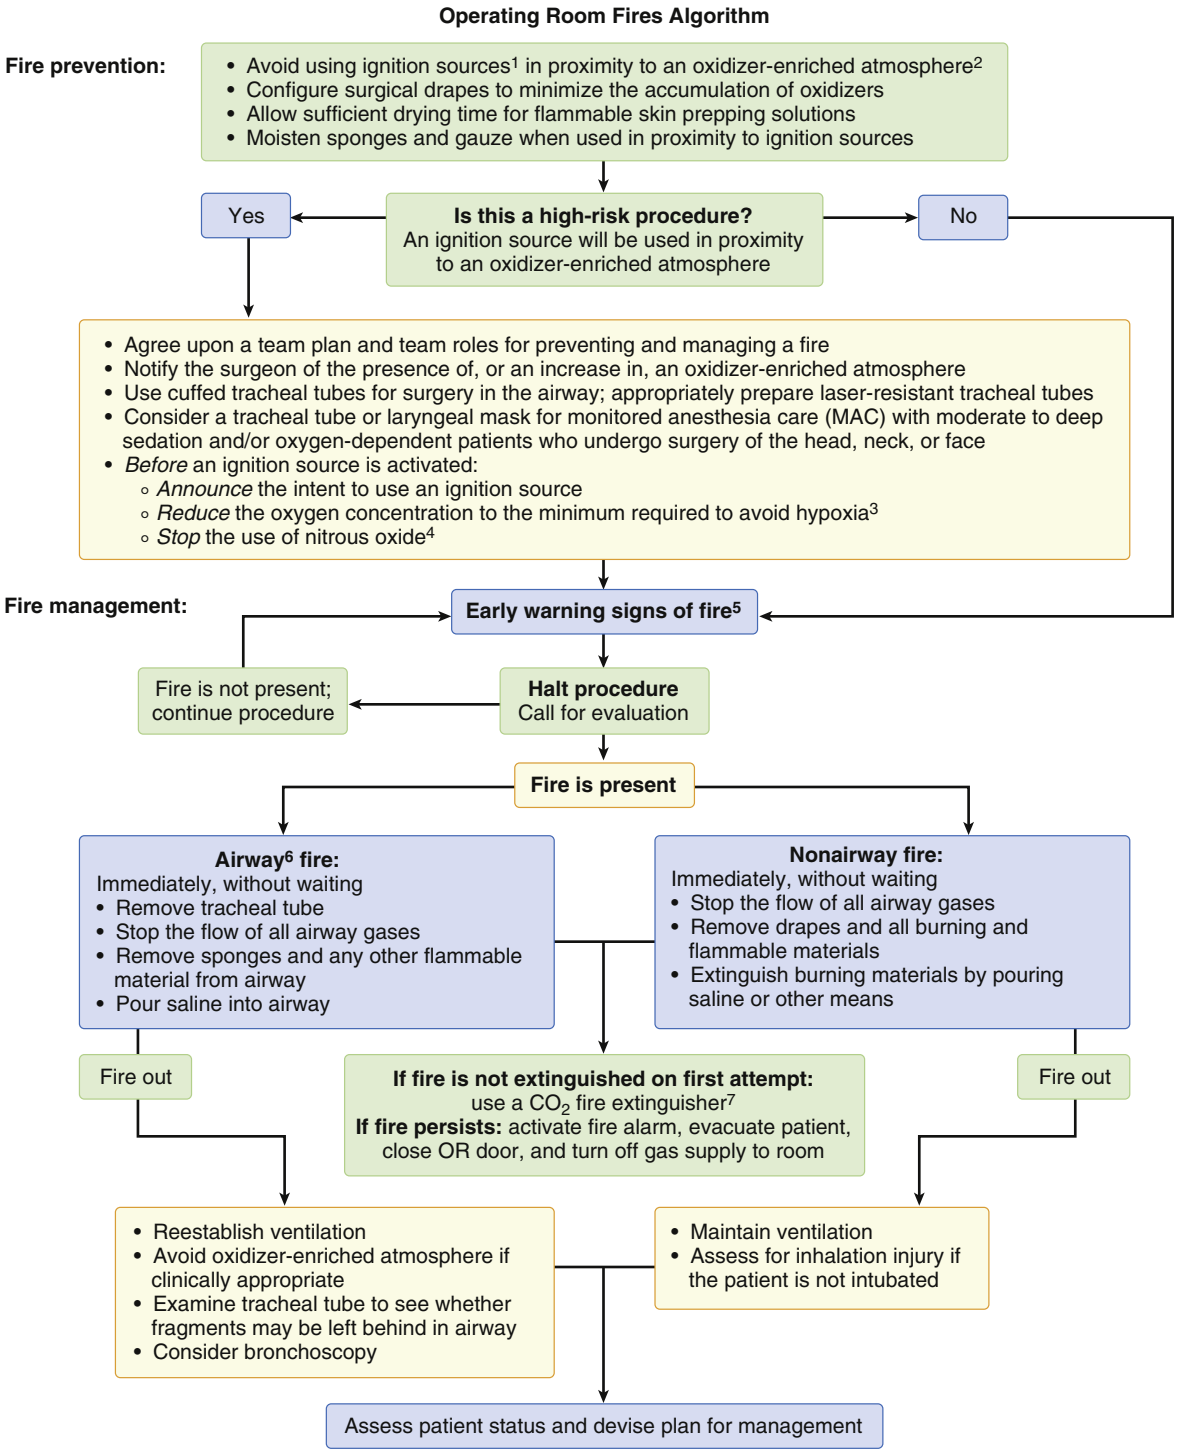
An airway fire is a potentially deadly complication that may occur during tracheotomy surgery, during laser surgery to the airway, and elsewhere (see also Chapters 55, 88, and 109). For a fire to occur, the triad of fuel (e.g., ETT, drapes, sponges), oxygen, and an ignition source (e.g., laser or electrocautery) is needed. The ASA published an Operating Room Fires Algorithm (Fig. 85-11),[147] to which the reader is referred. An additional helpful resource is a checklist developed by Dr. B. Abdelmalak (Box 85-2). Prevailing conventional wisdom, at least until recently, holds that cases of airway fire call for immediate removal of the ETT. Although this is a reasonable rule of thumb, it should also be noted that in some patients, removal of the ETT would result in irreversible loss of the airway. Clinicians in such a setting face a particularly difficult choice: leave the ETT in place and risk fire-related injury to the patient, or remove the ETT and risk deadly loss of the airway.

EAR SURGERY

Ear operations range from simple, brief procedures such as myringotomy and tube placement to much more involved procedures such as skull-based surgery. These procedures are best divided into external ear procedures (e.g., removal of exostoses or foreign bodies), middle ear procedures (e.g., myringotomy, tympanoplasty, stapedectomy), mastoid operations (e.g., mastoidectomy), and inner ear procedures (e.g., cochlear implant placement). In such procedures, and especially with inner ear procedures, patients are particularly prone to PONV (see also Chapter 97).

Although many simple procedures can be performed in well-selected individuals by using local anesthesia and intravenous sedation, more complex procedures, especially those requiring an operating microscope (for which immobility is essential), are usually best accomplished using general anesthesia with the presence of a secure airway. Regardless, in all such cases the anesthesiologist must consider issues such as the appropriate form of airway management, whether nitrous oxide is contraindicated, the possibility that postintubation muscle relaxants should be avoided to permit facial nerve monitoring, and the possible need for antiemetic prophylaxis. Most patients require a tracheal tube; the unkinkable, wire-reinforced variety is commonly used to avoid airway trouble following head rotation. Alternatively, preformed tracheal tubes (e.g., RAE tubes) are commonly used.

Nitrous oxide is avoided in middle ear procedures because it diffuses from blood to the middle ear, thereby increasing middle ear pressure and potentially distending any carefully placed tympanic membrane grafts. However, many ENT surgeons now use "underlay" grafts, in which increased middle ear pressures can actually help hold the graft in place, as opposed to older "overlay" grafts, in which a high middle ear pressure would dislocate the graft.



Many middle ear operations are performed to ameliorate hearing loss from infection or inflammation. The most frequent of these procedures, myringotomy with tube placement, is most commonly performed in children by using simple sevoflurane mask anesthesia, in conjunction with acetaminophen or (less commonly) fentanyl to treat postoperative pain. The procedure can usually be safely accomplished without establishing intravenous access.[148]

Stapedectomy, typically performed to treat otosclerosis, is usually performed using general anesthesia and may involve the use of surgical lasers (hence a potential need for laser precautions), as well as facial nerve monitoring (hence a potential need for periods with minimal neuromuscular blockade). The use of a volatile anesthetic in combination with a remifentanil infusion helps provide mild hypotension (which reduces blood loss), as well as surgical immobility. Nitrous oxide can theoretically be used early in the procedure, but it must be avoided later on to avoid damaging possible "overlay" grafts to the tympanic membrane. However, most clinicians simply avoid nitrous oxide entirely, to reduce the incidence of PONV (see also Chapter 97). Gentle emergence, often involving a remifentanil infusion, helps avoid coughing or "bucking" with the tracheal tube present, with possible displacement of the bone prosthesis. Not surprisingly, extubation of the trachea during deep anesthesia is sometimes performed. Ossiculoplasty procedures involve similar considerations.

Common inner ear procedures include surgery to the cochlea, endolymphatic sac, and labyrinth. Patients with pathologic processes in the labyrinth and endolymphatic sac, such as patients with Meniere's disease, often suffer from vertigo and hearing loss and are especially prone to PONV. In cochlear implant surgery, mastoidectomy is performed to implant the signal coupler while the electrode array is implanted into the cochlea, a procedure often taking over 4 hours. Considerations similar to those for stapedectomy apply, including the potential need for nerve monitoring, the avoidance of PONV, and gentle emergence from anesthesia. Some surgeons also request a degree of hypotension as a means to reduce blood loss.

Untreated chronic otitis media often leads to mastoiditis, tympanic membrane perforation, and damage the ossicular chain. Additionally, the formation of a cholesteatoma (an invasive growth of keratinizing squamous epithelium) may spread into the mastoid cavity, inner ear, and even to brain to cause additional damage. When antibiotic treatment fails, mastoidectomy (removing infected material, draining subperiosteal abscesses, and reestablishing middle ear ventilation) may be indicated. Because blood loss can be substantial, controlled hypotension is sometimes requested. The nerve identification and gentle emergence issues discussed earlier often apply as well. Nitrous oxide is often avoided, at least in the later stages, because of the tympanoplasty component of the procedure.

Surgical procedures of the outer ear may be used to correct congenital and acquired malformations. Although these patients often present no special challenges, beware of patients whose malformation is part of Goldenhar syndrome or Treacher Collins syndrome because these patients frequently offer airway challenges. General anesthesia is typically employed, and postoperative pain can be substantial when a rib graft is used.

[1] Ignition sources include but are not limited to electrosurgery or electrocautery units and lasers.
[2] An oxidizer-enriched atmosphere occurs when there is any increase in oxygen concentration above room air level and/or the presence of any concentration of nitrous oxide.
[3] After minimizing delivered oxygen, wait a period of time (e.g., 1 to 3 minutes) before using an ignition source. For oxygen-dependent patients, reduce supplemental oxygen delivery to the minimum required to avoid hypoxia. Monitor oxygenation with pulse oximetry and, if feasible, inspired, exhaled, and/or delivered oxygen concentration.
[4] After stopping the delivery of nitrous oxide, wait a period of time (e.g., 1 to 3 minutes) before using an ignition source.
[5] Unexpected flash, flame, smoke or heat, unusual sounds (e.g., a "pop," snap or "foomp") or odors, unexpected movement of drapes, discoloration of drapes or breathing circuit, unexpected patient movement or complaint.
[6] In this algorithm, airway fire refers to a fire in the airway or breathing cicuit.
[7] A CO_2 fire extinguisher may be used on the patient if necessary.

PAROTID AND OTHER SALIVARY GLAND SURGERY

The salivary glands comprise a pair of parotid glands, two submandibular glands, two principal sublingual glands, and a number of minor salivary glands. As exocrine glands, their function is variously to produce saliva, digestive enzymes (amylase), and lubrication, as well as to provide a bacteriostatic function. Indications for submandibular gland surgery include tumors, chronic sialadenitis refractory to medical treatment, and removal of impacted stones. The most frequent parotid disease warranting surgery is a benign neoplasm, frequently a pleomorphic adenoma. Superficial parotidectomy (complete or limited) with facial nerve dissection is the most commonly performed procedure for these lesions, although a simpler enucleation procedure is sometimes also performed.[149-151] Identification of the facial nerve and its branches, often employing nerve stimulation methods, is central to the procedure. For this reason the surgical team usually requests that muscle relaxants be avoided after endotracheal intubation has been achieved.

Besides the usual considerations applying to all surgical patients, preoperative evaluation (see also Chapter 38) of patients for salivary gland surgery should consider any previous head and neck surgery and any history of radiation therapy (which can make mask ventilation difficult). The physical examination should look for tumor displacement of the airway, as well as impaired temporomandibular joint (TMJ) mobility and other predictors of airway difficulties. Available head and neck CT scans or MRI studies should be reviewed with the surgical team, with a focus on airway issues.

During these procedures, complete immobility of the patient is important. Consequently, general anesthesia with endotracheal intubation is usually required, although cases of parotid surgery performed using local anesthesia have been reported.[152] Management of the airway with an LMA for parotid surgery has been described; however, the typical 2- to 4-hour duration of the operation and the need for an operative side-up head position lead most anesthesiologists to use a tracheal tube. Sufficient anesthetic depth and patient immobility are usually achieved using relatively large doses of opioid and inhaled anesthetics, with muscle relaxants avoided to allow facial nerve monitoring for both parotid and (less commonly) submandibular surgery. I frequently employ a single, small dose of rocuronium to facilitate endotracheal intubation, followed by sevoflurane anesthesia in conjunction with a remifentanil infusion (e.g., 0.1 μg/kg/minute) to provide immobility. Finally, preservation of the facial nerve is of prime importance in these operations; consequently, the surgeon often must identify the facial nerve by using a nerve stimulator. This crucial step is not possible if neuromuscular blockade is present.

BOX 85-2 *Management of Airway Fires*

Prevention and Preparedness

1. Keep the O_2 concentration at approximately 30%, or less if possible. Use an O_2/air mixture. Avoid N_2O.
2. Use a "laser-safe" endotracheal tube.
3. Inflate the endotracheal tube cuff with dyed normal saline to provide an early indicator of cuff rupture.
4. Use a pre-prepared 50-mL syringe of saline to extinguish any fire, and flood the surgical field if a fire occurs.
5. Have an extra endotracheal tube available for reintubation in case a fire occurs.
6. Inform the surgical team working on the airway of any situation in which high concentrations of O_2 are being used.

In the Case of an Airway Fire

1. Stop lasering. Stop ventilation. Turn O_2 off (as well as N_2O if it was mistakenly in use).
2. Inform the surgical team, and assign someone to call the control desk for help.
3. Remove the burning endotracheal tube* and drop it in the bucket of water, if available.
4. Put out the fire with your improvised fire extinguisher.
5. The area should be flushed with saline.

When the Fire Is Extinguished

1. Ventilate the patient with 100% O_2 by facemask (or supraglottic airway if appropriate).
2. When the patient is stable, assess the extent of airway damage. Consider using a ventilating rigid bronchoscope; debris and foreign bodies should be removed.
3. Reintubate the patient if significant airway damage is found.
4. When appropriate, arrange for admission to an ICU.
5. Provide supportive therapy, including ventilation and antibiotics, and extubate when appropriate.
6. Tracheotomy may be needed.

Courtesy Dr. B. Abdelmalak, Cleveland Clinic, Cleveland, Ohio.

*Removing the endotracheal tube may be inappropriate in some cases (see text).

SLEEP APNEA SURGERY

OSA involves repetitive partial or complete upper airway obstruction from collapse of the pharyngeal airway during sleep.[153-158] This condition typically occurs despite continued movement of the diaphragm and can lead to apneas (with complete obstruction), hypopneas (with partial obstruction), and respiratory effort–related arousals. The last of these can occur without desaturation, whereas hypoxia itself leads to arousal from sleep, with reopening of the airway and the intake of a breath. Severity is related to the number of these respiratory events per hour as determined by polysomnography. Patients in whom conservative treatment (e.g., weight loss, continuous positive airway pressure, bilevel positive airway pressure, oral appliances) fails may benefit from either surgical modification of the upper airway or, rarely, tracheostomy. Commonly performed procedures include uvulopalatopharyngoplasty, uvulopalatal flap surgery, tonsillectomy and adenoidectomy, genioglossus advancement, maxillomandibular advancement, and other procedures. Sometimes these procedures are performed in combination. Possible comorbidities such as obesity (see also Chapter 71), metabolic syndrome, type 2 diabetes, coronary artery disease, or cor pulmonale should be identified. Patients with OSA can be difficult to intubate tracheally or ventilate by mask, and they are especially prone to postoperative hypoxia. In addition, they frequently have

conditions such as macroglossia, redundant pharyngeal tissue, lingual tonsil hypertrophy, or an anterior larynx, all of which can make direct laryngoscopy difficult.

Clinical features that increase the likelihood that OSA is present include a body mass index greater than 30 kg/m^2, large neck circumference (>17 inches in men; >16 inches in women), a high Mallampati score (3 or 4), and the presence of features such as a large uvula, macroglossia, retrognathia, tonsillar hypertrophy, or a high arched palate. The airway features predisposing to OSA may also lead to a difficult airway. For example, difficult intubation is encountered five to eight times more often in patients with OSA compared with other patients. Additionally, snoring and OSA are independent risk factors for difficult ventilation by mask.

General endotracheal anesthesia is preferable for OSA surgery because of the risk of aspiration of blood from the surgical site and the risk of laryngospasm should blood or secretions make contact with the vocal cords.

Postoperative vigilance is paramount. One reason is that patients with OSA have an increase in postoperative obstructive episodes, peaking on postoperative day 3 and returning to preoperative levels after a week. Consequently, patients with OSA who are undergoing airway surgery are not outpatient candidates. Postoperative airway edema is another concern and constitutes another reason that it is wise to minimize respiratory depressants such as opioids and sedatives postoperatively. Dexamethasone is often given to reduce airway edema.

ZENKER DIVERTICULUM

Zenker diverticulum, first described in 1874, is a herniation or outpouching of pharyngeal mucosa through the posterior wall of the hypopharynx (often between the oblique and horizontal components of cricopharyngeus).[159,160] Typically seen in the sixth to ninth decades of life and occurring in approximately 1 in 800 upper gastrointestinal barium studies, patients may describe regurgitation of undigested food when supine and food caught in the throat (i.e., in the mucosal pouch), as well as coughing, dysphagia, and halitosis. Confirmation of the clinical diagnosis is usually by barium swallow and/or endoscopy.

Surgery can be either open or endoscopic. In the open (transcervical) approach, the diverticulum is exposed through a lateral neck incision and is then resected (diverticulectomy) or tacked superiorly to the prevertebral fascia (diverticulopexy). Cricopharyngeal myotomy may be added to help prevent recurrence. In the endoscopic approach, no skin incision is required; here the surgical procedure usually involves ablating the common wall between the pouch and the cervical esophagus by using an endoscopic stapler, surgical laser, or other means.

Several anesthetic considerations apply. First, patients are frequently older, with applicable comorbidities, such as coronary artery disease. Second, the possibility that food caught in the pouch could end up in the airway is a concern. Additionally, oral medications such as antihypertensives administered the day of surgery may lodge in the pouch and be aspirated. Perhaps preoperative evacuation of the pouch can be performed by applying external pressure before anesthesia, but this is not commonly done because of concerns of causing iatrogenic pulmonary aspiration. More commonly, the patient is positioned with a 30-degree head-up tilt before the induction of anesthesia.

Although awake endotracheal intubation should provide excellent protection against the risk of aspiration of pouch contents, a theoretic concern exists that any coughing during the procedure, either from the use of transtracheal local anesthesia or from the instrumentation, could lead to regurgitation of pouch contents with possible aspiration. A more common technique is the use of rapid-sequence induction of anesthesia, usually with the modification that cricoid pressure is not used, for fear of discharging the pouch contents with the applied pressure. (Application of cricoid pressure is recommended only if the neck of the pouch is below the cricoid cartilage; see Fig. 85-12). Some experts have expressed the concern that using succinylcholine, especially if it is not preceded by a nondepolarizing muscle relaxant, could produce muscle fasciculations that could cause pouch compression (see also Chapter 34). Even after endotracheal intubation, seepage of material around the ETT cuff can occur with surgical manipulation; some clinicians place a moist gauze throat pack to prevent aspiration of this material. Finally, the procedure is occasionally performed using regional anesthesia with deep and superficial cervical plexus blocks (see also Chapter 57).

Care should be taken to avoid perforation of the diverticulum, such as with blind placement of a nasogastric tube or during difficult tracheal intubation. During the surgical procedure, retraction of the carotid sheath may stimulate baroreceptors and initiate arrhythmias, especially bradycardia, whereas significant blood loss and air embolism may occur if major vessels are accidently cut. A smooth awakening from anesthesia that is free from coughing and straining is important to avoid the risks of neck hematoma and the attendant possibility of a compromised airway.

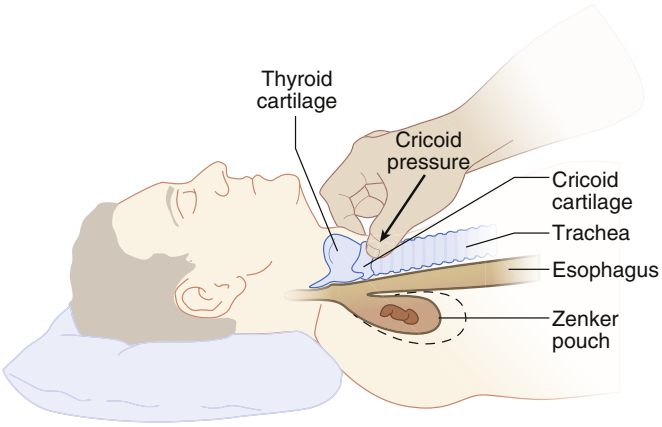

Figure 85-12. Anatomic relationship of the diverticulum to the cricoid cartilage during application of cricoid pressure. *(From Thiagarajah S, Lear E, Keh M: Anesthetic implications of Zenker diverticulum,* Anesth Analg *70:109-111, 1990.)*

ANESTHESIA FOR SURGICAL AIRWAYS: CRICOTHYROTOMY AND TRACHEOSTOMY

Two general approaches exist to create a surgical airway. In dire emergencies one may perform a cricothyrotomy,[161,162] by entering the airway through the cricothyroid membrane. This is done either by inserting a narrow-bore transtracheal ventilation catheter percutaneously through the cricothyroid membrane and employing emergency high-pressure jet ventilation or by inserting a wider-bore tube of sufficient diameter to allow low-pressure ventilation through a conventional resuscitator bag (e.g., "Ambu" bag). This second approach through the cricothyroid membrane can be achieved by using a vertical scalpel incision, identifying the cricothyroid membrane, cutting through the membrane with a horizontal stab incision, and placing (for example) a 6-mm inner-diameter tracheal tube. Alternately, one can use a commercial kit employing (for example) the Seldinger technique (e.g., Melker cricothyrotomy kit, Cook Medical, Bloomington, Ind.). An educational cricothyrotomy video is available at http://www.cookmedical.com/cc/educationMedia.do?mediaId=1522

The second approach to achieving a surgical airway is a tracheostomy.[163,164] (Although the terms "tracheotomy" and "tracheostomy" are used interchangeably by clinicians, based on their Greek roots, the former term refers to cutting into the trachea, whereas the latter refers to the opening that has been created.) This approach is best suited for situations that are not high-level emergencies, takes rather longer to complete, and usually involves entering the airway between the second and third tracheal rings following a careful dissection of the neck tissues. Although it is very often performed using general anesthesia in an intubated ICU patient in whom ventilator weaning has failed, it is sometimes performed using local anesthesia, either employing no sedation (this is the usual case in stridulous patients, especially those requiring Heliox) or using a drug such as dexmedetomidine because of its lack of respiratory depression. In any event, the decision to perform a tracheostomy using local anesthesia is made jointly with the surgeon and depends on the extent of airway disease, the experience of the surgical team, and the degree to which the patient is able to tolerate lying supine with his or her head in extension. In some cases the procedure must be performed with the patient in a semiupright sitting position (see also Chapter 41).

In the case of patients whose tracheas are intubated, at one point in the procedure the anesthesia provider will be asked to withdraw the tracheal tube slowly to permit the airway to be entered without obstruction. Additionally, at this time the airway should be entered using a scalpel and not using cautery, to prevent an airway fire in an oxygen-rich environment.

A number of problems may arise in the postoperative period following a tracheotomy.[165-167] Bleeding, pneumothorax, subcutaneous or mediastinal emphysema, and hypoventilation or airway obstruction may occur immediately after the procedure, whereas possible late complications include tracheal stenosis, tracheoesophageal fistula formation, tracheomalacia, and even tracheal necrosis. Although posttracheotomy bleeding is usually inconsequential, bleeding into the airway may cause the patient to cough and buck forcefully. In addition, major bleeding from a large artery or vein (often the communicating branch of the superior thyroid artery) may necessitate immediate exploration of the surgical field, whereas bleeding from the innominate artery may occur from erosion by the distal end of the cannula. (One hint that the tracheostomy could be applying pressure to the innominate artery is the finding of pulsations in the tracheotomy cannula after initial insertion. Treatment includes inflating the tube cuff and pulling the tube assembly anteriorly to tamponade the bleeding. An oral tracheal tube should then be inserted for management in the operating room.)

Not infrequently, tracheotomy tubes must be changed, for instance because of a cuff leak or because of obstruction from the buildup of secretions. A central concern in this instance is that the replaced tube could enter a false passage rather than the trachea. (This in itself is unfavorable, but should the false passage be inadvertently ventilated, the resulting subcutaneous emphysema could eliminate the possibility of easily reestablishing the airway.) This potential problem eventually disappears as the tracheal stoma matures to form a well-defined and self-supporting orifice. However, this rigidity and tissue support are lacking in a fresh tracheostomy, so that following removal of the tracheostomy tube, the tissue may "collapse in" on itself to block the passage. Consequently, certain precautions when dealing with a fresh tracheostomy tube must be borne in mind. First, for the first week or so, tube changes should be performed in the operating room with a full set of tracheotomy instruments (e.g., cricoid hooks) and a means to intubate "from above" as a last resort if the airway is lost. Second, once the tracheotomy site has begun to mature, it is no longer necessary to carry out tube changes in the operating room, but a full set of instruments (especially cricoid hooks) should still be available. Additionally, changing the tube over a tube changer may also be useful, but some clinicians find that it may unnecessarily complicate matters. Third, before any tube change, the patient should breathe 100% oxygen. Finally, a fiberoptic bronchoscope may be potentially useful in confirming tracheal placement of a tracheostomy tube before attempting any positive-pressure ventilation that could lead to subcutaneous emphysema should the tube, in fact, be malpositioned.

NECK DISSECTION AND LARYNGECTOMY

Neck dissection is commonly performed in isolation or during laryngectomy to prevent or treat any local spread of head and neck malignancy.[168,169] The extent of a neck dissection operation is based on the extent to which the neck's six lymph node levels are involved, as well as on the extent to which additional structures (spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle) are removed. Depending on the degree to which the tumor can be removed and recurrence or spread can be prevented, as well as the extent that phonation and swallowing can be preserved, various surgical options are exercised. Limited disease is sometimes managed by

radiation, by laser and microsurgery, or by partial laryngectomy, thus preserving organ function. In total laryngectomy, the larynx is removed in its entirety, with the airway ending in a stoma formed by bringing the cut end of the trachea to the neck surface (with the result that the trachea now becomes independent of the esophagus.) Often a perforation between the trachea and the esophagus (tracheoesophageal puncture) is made to allow eventual placement of a voice prosthesis.[170] In some cases the procedure is supplemented with microvascular free tissue transfer (free flap).

Anesthesia can be induced through a standard intravenous line, followed by large-bore intravenous and arterial lines placed after induction. A central line can usually be avoided, with systolic pressure variation of the arterial line tracing and other clinical findings to guide fluid replacement. Although nerve function monitoring is usually required during the neck dissection phase, neuromuscular blockade is acceptable at the beginning. When neuromuscular blockade is no longer desirable, opioid infusions (e.g., remifentanil) are often used to maintain adequate analgesia in conjunction with an inhaled anesthetic agent. Many clinicians prefer using a balanced technique in preference to deep inhalational anesthesia or TIVA (propofol with or without remifentanil) to avoid the troublesome hypotension. Excessive intravenous crystalloid administration should be avoided to prevent operative site edema.

In total laryngectomy cases, a tracheostomy is customarily performed near the beginning of the procedure, by using a wire-reinforced ETT placed into the stoma. (Warning: Accidental endobronchial intubation commonly occurs in this setting.) In some cases the patient is turned 180 degrees from the anesthesia machine; care must be taken to ensure that nothing is disconnected in the process. Extubation in such cases is extraordinarily simple; the ETT should be removed from the stoma when extubation criteria are met. Should reintubation ever become necessary, one merely reintroduces the tracheal tube into the stoma. The patient is then simply brought to the postanesthesia care unit with an oxygen mask placed over the stoma, although when a free flap has been performed, the patient is often brought to the ICU intubated, ventilated, and sedated (depending on the surgeon's preferences and local protocols.)

MAXILLARY, MANDIBULAR, AND TEMPOROMANDIBULAR JOINT SURGERY

Maxillectomy surgery may be limited (e.g., removal of one antral wall, such as in a medial maxillectomy), subtotal (e.g., removal of two walls of the antrum), or total (removal of the total maxilla).[171-173] Orbital exenteration sometimes accompanies the procedure should the intraorbital contents be violated by tumor. Indications for maxillectomy include the following: tumors of the maxillary sinus, palate, and other structures; some intractable fungal infections; and other conditions. The procedure is performed using general anesthesia with tracheal intubation and invasive monitoring appropriate to the patient's condition and the extent of the surgery. Although massive blood loss is unusual, precautions should be taken because hemorrhage may occur (e.g., with transection of the internal maxillary artery). Hypotensive anesthesia, when appropriate, can help reduce blood loss. Medial maxillectomy procedures conducted endoscopically do not require anything different from ordinary sinus surgery for anesthesia. When electromyography-based cranial nerve monitoring is employed, long-acting paralytic agents should be avoided.

Surgery of the mandible and TMJ may be carried out by maxillofacial surgeons, as well as by otolaryngologists and plastic surgeons.[174-176] Mandibular surgery can range from simple biopsies to all-day radical procedures involving microvascular osteocutaneous flaps. Awake nasal intubation may be required in some cases. Hypotensive anesthesia is often used for orthognathic procedures to minimize blood loss. In some cases the jaw is wired shut, and reintubation, should it be required postoperatively, can be a challenge.

TMJ dysfunction often manifests with pain and decreased mouth opening. Conditions such as osteoarthritis, synovitis, or fibrosis may be responsible. Most TMJ procedures are performed using general nasotracheal anesthesia. As with mandibular surgery, the presence of very limited mouth opening may dictate that the procedure be done with awake nasal intubation.

EAR, NOSE, AND THROAT LASER SURGERY

Lasers are commonly used in ENT surgery[177-180] (Box 85-3 and Table 85-1). The most widely used laser in ENT surgery is the CO_2 laser, which allows precise cutting with a particularly fine zone of coagulation that reduces bleeding. Tissue vaporization is particularly efficient with this laser because of the excellent absorption of the produced far-infrared photons (10,600-nm wavelength) by water present in tissue. This laser is used in the removal of laryngeal tumors and lingual tonsillar tissue, in the ablation of hemangiomas, and for the resection of some oropharyngeal malignant tumors.

Another popular laser in ENT surgery is the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, which emits photons with a wavelength of 1064 nm. These photons are poorly absorbed by water and thus tend to penetrate tissue more deeply than do those from a CO_2 laser. In addition, light from an Nd:YAG laser can be transmitted through flexible quartz fibers that can be used in conjunction with a flexible fiberoptic bronchoscope for use in treating tracheobronchial lesions.

Because surgical lasers involve high amounts of energy, they have the potential for unintended tissue damage, as well as for causing fires. Stray laser beams can ignite surgical drapes. To mitigate these risks, one should place warning signs outside the operating room, provide opaque coverings on any operating room windows, and issue protective goggles. The presence of high oxygen concentrations near the patient's face can facilitate ignition in this region, so delivering supplementary oxygen by facemask or nasal cannula requires special care. American National Standards Institute standard Z136.3 (Safe Use of Lasers in

Health Care Facilities) provides additional information on this and related matters.

One special concern is that regular ETTs can ignite from a laser beam. In the past, metallic tapes applied in a spiral manner were sometimes used. Today, however, several special-purpose ETTs are available for this purpose (Table 85-2).

The choice of anesthetic technique depends on the clinical circumstances. TIVA techniques for laser ENT surgery are particularly popular and are essential when patients are unintubated and jet ventilation is used. When patients are intubated, a potent inhalational agent such as sevoflurane is often used, although not infrequently an infusion of remifentanil is used as an anesthetic adjunct in such cases (typical rate: 0.05 to 0.1 μg/kg/minute). (Remifentanil, with its vagomimetic effect, is especially useful to limit the heart rate in the face of intense sympathetic stimulation from the effects of the suspension laryngoscope.) Finally, to reduce the chance of a fire, while lasers are in use nitrous oxide should not be used, and the oxygen concentration should be limited to the lowest concentration necessary to maintain acceptable arterial oxygen saturation levels. For additional details, see Chapter 88.

Airway management is often a challenge in laser surgery cases, and the surgeon and anesthesiologist must work together to devise a plan. One issue is whether general anesthesia should be preceded by awake intubation because the presence of airway disease may complicate both ventilation and intubation. Another issue is whether the procedure should be performed using general anesthesia with the patient breathing spontaneously, albeit with assistance, as is sometimes desirable when an anterior mediastinal mass is present. Muscle relaxation is often employed to help ensure an immobile surgical field. In the United States, where sugammadex is still not available (at the time of writing), succinylcholine is often used as an initial relaxant in patients with a potentially difficult airway because its short duration of action adds a measure of safety should the patient become impossible to intubate or ventilate following administration of the drug. Many Europeans would instead be more comfortable using rocuronium as a relaxant, followed by a "sugammadex rescue" should the airway become unmanageable following relaxant administration. Many clinicians, however, simply intubate the patient awake whenever issues of this kind arise.

In some cases the entire surgical procedure is done without intubation. The advantages of this approach are a decreased risk of fire (no ETT to ignite) and improved access to airway structures. Disadvantages include the risk of aspiration with an unprotected airway and potential difficulties in ventilating the patient. Typically in such cases, an anterior commissure laryngoscope or similar device is used in conjunction with TIVA and jet ventilation. In other cases, the laryngoscope is used in conjunction with a small-diameter ETT (e.g., MLT size 5.0), and the procedure is performed while the patient has brief periods of apnea in conjunction with intermittent removal of the ETT to allow unimpaired access to the glottic structures.

Laser vaporization of tissue, especially from CO_2 lasers, often results in a plume of smoke that can be hazardous.

BOX 85-3 ***Some Otolaryngologic Clinical Situations in Which Laser Techniques Can Be Useful***

NOSE
Turbinate reduction
Septoplasty
Removal of nasal obstructions, polyps, synechiae
Treatment of rhinophyma
Treatment of keloids and hypertrophic scars

OROPHARYNX AND PHARYNX
Vaporization of papillomas, leukoplakias, and hemangiomas
Tumor surgery (e.g., partial glossectomy)
Laser-assisted uvulopalatoplasty
Tonsillectomy

LARYNX
Removal of vocal cord polyps and granulomas
Epiglottectomy
Cordectomy
Arytenoidectomy

TRACHEOBRONCHIAL TREE
Treatment of tracheal stenosis
Removal of nodules, polyps, tumors, and fibromas

EAR
Surgery of the stapes
Laser-assisted myringotomy
Cholesteatoma

KTP, potassium titanyl phosphate; *Nd:YAG,* neodymium:yttrium-aluminum-garnet.
*Wavelengths are given in nanometers (nm). There are 10^9 nm to a meter.
†The argon laser produces blue-green coherent light at a number of wavelengths but most of the energy is at wavelengths 488 nm and 514 nm.

The use of a smoke evacuator at the surgical site along with protective masks that filter out particulate material is often advised, especially when virus particles are present in the vaporized tissue.

Extubation of the trachea in these cases can be challenging. Some patients benefit from the administration of intravenous dexamethasone to reduce edema. Stridor is sometimes encountered after extubation; although this condition may require reintubation, one can sometimes avoid this by the use of inhaled racemic epinephrine or the use of Heliox, a mixture of helium (typically 70%) and oxygen. Extubation over a tube exchanger can be helpful when the need for reintubation is a concern and is expected to be challenging.

Even when the tracheas of patients are extubated conservatively following laser surgery, however, airway problems can arise later. In cases of immediate respiratory distress following laser procedures, consider the following possibilities: tissue edema (e.g., after Nd:YAG laser use), residual muscle relaxant or anesthetic effects, airway secretions, pneumothorax, bleeding, and pneumomediastinum.

PHONOSURGERY

Phonosurgery is surgery conducted to improve a patient's voice.[181-185] In many cases the patient's voice has been damaged as a result of unilateral vocal cord paralysis. One common operation used in this setting is medialization of the paralyzed vocal cord (laryngoplasty) so that the normal vocal cord can make contact with the paralyzed side. This procedure is done using local anesthesia with minimal sedation (e.g., 20 mg propofol administered just before the injection of the local anesthetic) because the patient needs to phonate on request. Continuous intraoperative imaging of the vocal cords, especially during phonation, is carried out to achieve the repair. An infusion of dexmedetomidine is sometimes used.

HEAD AND NECK FLAP RECONSTRUCTIVE SURGERY

Tissue transfer in the form of pedicle flap or a microvascular free flap is commonly employed to reconstruct defects created following tumor surgery.[186-188] Potential advantages of such flaps include the avoidance of staged procedures, improved wound healing, superior cosmetic results, and improved tolerance for postoperative radiation therapy. For optimal anesthetic care, anesthesiologists must have a clear understanding of these procedures and their implications for anesthetic management.

A *pedicle flap* is one in which the flap vessels are transferred intact with the rotated flap. If the flap is moved from a distant "donor" site and the flap vessels are reanastomosed to the recipient site vessels, then the tissue is termed a *microvascular free flap*. Examples of myocutaneous pedicled flaps are the pectoralis major flap and the latissimus flap used (for instance) to cover the carotid artery after the point where it is sacrificed and reconstructed using a vein graft. In contrast to pedicle flaps, free flaps provide the surgeon with more options for donor sites. Frequently, separate surgical teams for the donor and recipient sites are employed. Surgery in relation to free flaps can be elective, or it may be performed on an emergency basis to rescue an ischemic flap. Elective procedures tend to be long-duration operations conducted using general anesthesia. An arterial cannula is generally used, although special care must be taken to ensure that the arterial cannula and any additional intravenous catheters are not inadvertently placed at a site where tissue harvesting is planned (e.g., radial forearm flap). Central lines are not usually placed, in part because information about volume status can usually be better achieved using less invasive means such as systolic blood pressure variability. Many of these procedures begin with a tracheostomy and end with the patient being cared for in an ICU while intubated and ventilated. Intraoperative and postoperative flap monitoring is achieved clinically (examination for color, turgor, edema, and capillary refill), as well as by using technical means of blood flow assessment, such as Doppler ultrasound.

Intravenous crystalloids and colloids are administered liberally but cautiously to prevent hypovolemia and hypotension that could lead to ischemic flap failure.

Conversely, excessive fluid leads to detrimental edema formation within the flap. The use of vasopressors such as phenylephrine or norepinephrine is generally discouraged during free flap procedures because these drugs may contribute to graft ischemia as a result of vasoconstriction.

STRIDOR AND HELIOX

Stridor is noisy inspiration resulting from turbulent gas flow in the upper airway. Stridor should always command clinical attention because it is almost always the result of airway obstruction.[189-194] The first issue of clinical concern in the setting of stridor is whether intubation is immediately necessary. If intubation can be delayed for a period of time, a number of potential options can be considered, depending on the severity of the situation and other clinical details. These options include the following: expectant management with full monitoring, 100% oxygen by facemask, and positioning the head of the bed for optimum conditions (e.g., 45 to 90 degrees); use of nebulized racemic epinephrine (e.g., 0.5 to 0.75 mL 2.25% solution in 2.5 mL normal saline) and dexamethasone ([Decadron] 4 to 8 mg intravenously every 8 to 12 hours) when airway edema may be the cause of the stridor; and use of Heliox (70% helium, 30% oxygen). Dexamethasone can take several hours to take full effect, and nebulized cocaine in a dose not exceeding 3 mg/kg can be used instead of racemic epinephrine. Finally, whenever possible, immediate attempts should be made to establish the cause of the stridor (e.g., foreign body, vocal cord edema, arytenoid cartilage dislocation, tracheal compression by tumor).

Not infrequently, stridor occurring after extubation is the result of laryngeal edema, and it may be more problematic in children because of their small airway size. Be aware that as laryngeal edema progresses, diminished stridor may reflect impending total airway obstruction. The specific cause of laryngeal edema can often be established with fiberoptic nasopharyngeal examination, and causes are often classified as supraglottic, or subglottic. Supraglottic edema most commonly follows surgical instrumentation, impaired venous drainage, eclampsia or preeclampsia, hematoma formation, or excessive fluid administration. Finally, subglottic edema may result from traumatic intubation attempts, bucking on the ETT, prolonged intubation, tight-fitting tubes, or excessive cuff pressures.

The manner in which Heliox helps relieve airway obstruction is worthy of note. Some airway-obstructing conditions may be thought of as breathing through an orifice, involving flow through a tube whose length is smaller than its radius. Gas flow through an orifice is always somewhat turbulent. Under such conditions, the approximate flow across the orifice varies inversely with the square root of the gas *density*. This is in contrast to laminar flow conditions, in which gas flow varies inversely with gas *viscosity*. Although the viscosity values for helium and oxygen are similar, their densities are very different. For example, the density for air and oxygen at 20° C is 1.293 and 1.429 g/L, respectively. However, the density of helium at that temperature is only 0.178 g/L.

Figure 85-13. An E-size tank of Heliox, with an attached nonrebreathing facemask in a plastic bag. In this case, the mixture is 70% helium and 30% oxygen, although other mixtures are available. This gas mixture is usually given using a nonrebreathing facemask with a gas flow of 10 L/minute as a temporizing measure in stridulous individuals.

Clinically, Heliox is usually administered from an E-size cylinder through a nonrebreathing facemask starting at a flow of 10 L/minute (Fig. 85-13). When the usual 30% oxygen concentration is too low, one trick is to titrate in additional oxygen by nasal cannula. In summary, a setup to administer Heliox should be readily available in every ENT operating room suite to assist in the treatment of stridor.

ANESTHESIA FOR FACE TRANSPLANTATION

Face transplantation remains a very rare procedure (Fig. 85-14).[195,196] The procedure can be total or partial. The recipient must be able to undergo a very prolonged anesthetic and be free of serious comorbidities. Each procedure is unique with respect to indications, as well as with respect to the nature and the extent of the graft. In the case of the donor, although anesthetic principles similar to conventional organ procurement apply, because of the surgical complexity and time involved, harvesting of the facial graft should ordinarily be performed before harvesting other organs. Although the donor usually has an ETT in place at the time of tissue procurement, a tracheostomy

Figure 85-14. Ms. Connie Culp before (**A**) and after (**B**) the two stages of her face transplant at Cleveland Clinic. Stage 1 was carried out in December 2008 (lead surgeon: Dr. Maria Siemionow). *(Images courtesy the Cleveland Clinic, Cleveland, Ohio.)*

may be performed first to avoid interference with the surgical field. Recipient patients who do not have a tracheostomy may first require awake fiberoptic oral intubation, followed by a tracheostomy. A wire-reinforced ETT is often used. Large-bore catheters are placed to facilitate fluid resuscitation, whereas a central line may be useful to monitor central venous pressure. If a central line is used, however, it must not impinge on the surgical field. Blood and fluid management is no different from that during other long surgical procedures involving microvascular free flaps. As with microvascular surgery, pressors such as phenylephrine or norepinephrine, commonly used to treat hypotension, are discouraged because of the risk of compromising graft perfusion. Finally, there may be periods when muscle relaxation must be avoided to allow nerve identification using electrical stimulation.

Chapter 86

Administration of Anesthesia by Robots

THOMAS M. HEMMERLING

Key Points

- Robots are able to measure many variables, make decisions, and take actions. Robots in anesthesia can be divided into pharmacologic robots, which deliver drugs to establish or maintain components of anesthesia, and manual robots, which are able to assist or replace human gestures in anesthesia. Decision support systems can be defined in this context as predecessors of robots in anesthesia, because they measure parameters and make decisions, but leave action taking to the human user.
- Decision support systems in the operating room will continue to evolve. Currently, they are often integrated into anesthesia information management systems and limited to reminders of timely and appropriate antibiotic administration and prophylaxis of postoperative nausea and vomiting. Recent research focuses more on the establishment of decision support systems to assist anesthesiologists in complex working environments characterized by multitasking and considerable lack of vigilance or fatigue.
- Decision-support systems can improve outcome; the adherence to them is linked to a constant reminder function in real time.
- Closed-loop systems in anesthesia are pharmacologic robots; they allow the autonomous control of anesthesia; most systems have been developed as research tools for the administration of propofol. All studies confirm an equal or mostly superior performance and maintenance of a given target, in comparison to manual control.
- The control mechanisms range from simple on/off control to model-driven control by proportional-integral-derivative control, with additional possibility of self-adaptation. Sometimes, fuzzy-logic control principles are applied, as well as neural networks. No control mechanism has been shown to be superior.
- Similar to surgical robots, manual robots have been developed that assist anesthesiologists to perform manual gestures, such as endotracheal intubation or regional nerve blocks.
- Tele-anesthesia is the application of telemedicine in anesthesia, mostly reduced to real-time monitoring and audio-video consultation or remote preoperative assessment. Recently, remote-controlled anesthesia delivery has been pioneered.

A robotic surgical system (or any other such system) is an extension of the surgeon's own arms and hands. The surgical robot never makes any movement without the surgeon "moving it," and there is no haptic feedback. Anesthesia's conceptual systems emphasize closed-loop, self-adaptive, control systems: these systems seem closer to the definition of a robot than any current commercially available surgical robot.

WHAT IS A ROBOT?

No clear definition of a robot exists. The word *robota* has been termed by the Czech playwright Karel Capek in his 1920s play, *Rossum's Universal Robots* (RUR). His description is colorful: slaves do human labor joyfully, so that humans can enjoy life without concerns.

Most modern definitions agree that a robot is a device that is self-controlled, consisting of anything from mechanical, electrical, to electronic units. Another common feature is the fact that these devices replace certain human gestures, either intellectual or mechanical. Important features of modern robots are exemplary in industrial robots: the reproducibility of the quality of the work without fatigue; a very high precision, especially in mechanical robots; independence from work conditions; and the absence of any emotional influence.

Robots can consist of the following elements: "effectors," which can be the equivalent of human arms or legs; "sensors," acting as infusion pumps, which perceive the environment and transfer it into information that can be fed to computers; a central processing unit, which works as the brain; and several other electronic, electric, or mechanical pieces of equipment, such as a screen with an interface, that mimic fundamental human functions. What makes robots different from other devices is their ability to function autonomously and their ability to react to their environment, adjust different environments, and analyze their own actions, including correcting previous actions.

The Director of the Centre for Intelligent Machines at McGill University in Montreal, Canada, Gregory Dudek, gives the following definition (http://www.cbc.ca/news/background/tech/robotics/definition.html):

They have to have a way of making measurements of the world, they have to have a way of making decisions — in other words, something like a computer, you could call that thinking informally — and they have to have a way [of] taking actions. And so if a thing has all three parts, we might call it a robot.

In this chapter, we consider decision support systems (DSSs) as predecessors of robotic anesthesia and closed-loop systems as pharmacologic robots in anesthesia, separate from manual robots, which are also described.

DECISION SUPPORT SYSTEMS FOR INTRAOPERATIVE USE IN ANESTHESIA

DSSs are the first bridge between manual, subjective, human anesthesia monitoring and delivery of perioperative care and fully automated systems. Currently, DSSs are mostly used in critical care and intensive care medicine but slowly are being developed in the field of anesthesia. Anesthesiologists face increasingly complex environments with older patients and patients who suffer from complicated diseases that require increasingly more intricate surgeries (see also Chapter 80). Continuing economic pressures require anesthesiologists to multitask to cover remote anesthesia sites, other anesthesia tasks, management tasks, teaching, or simply to cover more than one operating room. Add to this challenging environment a shortage of specialized personnel, and the need for the development of DSSs for anesthesia providers is acutely evident (Table 86-1). DSSs are developed based on six principles[1]:

1. Developing a protocol based on a consensus of users
2. Initial pilot study testing
3. Integration of these protocols into computerized protocols with additional testing
4. Validation using historical data
5. Clinical validation and correction of faults before implementation into daily practice
6. Preparation and use of routine clinical protocols with DSSs

DSSs use algorithms of predefined scenarios to create specific advice: diagnostic suggestions, treatment options, or triage evaluations. These algorithms are based on many inputs, such as patient demographic data, vital signs, blood loss, intravenous (IV) fluid administration, and many other types of advanced information.

The earliest DSSs were mostly a follow-up of the more widespread investigation and use of anesthesia information management systems (AIMS) (see also Chapters 4 to 6). AIMS have been used to design and integrate DSSs, mostly to help anesthesia personnel adhere to clinical protocols.

The most popular DSS used in anesthesia practice is a pop-up menu reminding anesthesiologists to administer antibiotics after induction of anesthesia. An example is a system called smart anesthesia manager (SAM), which is integrated into an AIMS.[2] AIMS are generally used to document and investigate the quality of care in retrospect—that is, after a certain period. Despite the fact that these investigations can lead to quality improvement by changing existing policies, AIMS do not control adherence to given protocols in real time, and avoid important tasks, such as administration of antibiotics. As a result, SAM was developed over a period of 3 months by a collaborative effort of a biomedical engineer, two anesthesiologists, and a database programmer who subsequently tested and refined it over a period of 2 years at the University of Washington in Seattle.

The AIMS has SAM communicate with both the AIMS server and workstation. The SAM server module interacts with the AIMS database to identify issues and create, if necessary, messages that are then displayed using a client module.

The DSS can deliver these messages using pop-up menus on the AIMS screens in the operating room and deliver them directly to a specific anesthesiologist by text (e.g., via a pager or smartphone). The dual-split design

TABLE 86-1 DECISION SUPPORT SYSTEM (DSS): OUTCOMES

	With DSS (N = 75)	Without DSS (N = 75)	P
Events not detected (%)	0.8 ± 3.4	26.5 ± 19.7	<.0001*
Detection delay (sec)	9.1 ± 3.6	27.5 ±18.9	<0.0001*
Critical events/hr	8.4 ± 6.8	9.1 ± 6.7	NS
Low SpO_2/hr	0.7 ± 1.0	1.4 ± 2.2	0.036*
Low RR/hr	3.0 ± 3.0	3.0 ± 3.6	NS
Low MAP/hr	4.7 ± 6.4	3.5 ± 3.6	NS
Low HR/hr	0.3 ± 0.7	0.4 ± 0.4	NS

Data are presented as mean ± SD.
*P <.05 (two-tailed), t-test for continuous data.
DDS, Decision support system; *HR,* heart rate; *MAP,* mean arterial pressure; *RR,* respiratory rate; *SpO_2,* peripheral oxygen saturation.

(i.e., display and text delivery) of the messaging ensures better compliance because the anesthesia provider might not be in the operating room at the site of the AIMS screen at the time of the message delivery, but can receive the text messages provided that the pager or smartphone is active. The SAM message on the AIMS screen is a standard pop-up menu that asks the provider to administer the antibiotic and has to be closed once the action is confirmed.[3]

The implementation of SAM increased compliance to deliver the initial antibiotic dose by 11%,[4] from 88.5% ± 1.4% to 99.3 ± 0.7%. When the compliance to readminister the antibiotic during the course of surgery was examined,[3] the integration of SAM improved compliance by 21%, from 62.5% ± 1.6% to 83.9 ± 3.4%. In an earlier study, a similar system was integrated into an AIMS by O'Reilly and associates[5] that documented adherence to a timely (within 60 minutes of incision) administration of antibiotics over a period of 1 year after implementation of such a DSS. Gradually, the adherence increased from 69.9% to 92.3%.

Another main area in which DSSs have been developed is adherence to guidelines for prophylaxis of postoperative nausea and vomiting (PONV) (see also Chapter 97). Adherence to PONV guidelines is usually quite poor, with one study of over 5000 patients determining that only 38% of patients at frequent risk for PONV were actually prescribed adequate prophylaxis, even with a paper version of the guideline present.[6] A study by Kooij and associates[6] investigated a large number of patients in an anesthesia preadmission clinic in which anesthesiologists evaluated patients before surgery using an AIMS (see also Chapter 38). They then implemented a very simple DSS that calculated the risk factors for PONV. When general anesthesia was selected as the mode of anesthesia, this prompted the message: "This patient has at least three positive risk factors for PONV and is eligible for PONV prophylaxis, but is not prescribed prophylaxis yet. Do you want to prescribe PONV prophylaxis?" To which the anesthesia provider would respond either affirmatively or negatively. Three study periods were created: an initial 8-week control period to examine the initial status of guideline adherence using only a paper version guideline, followed by a 16-week decision support enhanced period and finally, an 8-week postdecision support period in which only a paper version guideline for PONV prophylaxis was available. A significant improvement from 38% to 73% adherence to current guidelines of PONV prophylaxis prescriptions occurred (Fig. 86-1).

However, once the decision support system was no longer in place, the "old" routine of nonadherence to the guidelines resumed and the percentage of guideline adherence declined to the prestudy level. The study results are similar to those of many other studies in which adherence to guidelines of PONV prophylaxis were integrated into an AIMS: that is, when design and implementation of such a DSS is simple, its implementation significantly increases adherence to guidelines.[7] Integrating such a DSS is important because the study clearly showed a lack of learning from example in the respective anesthesiologists. Once the DSS was removed, the old habit of nonadherence returned. DSSs can therefore help decrease human error only when they are constantly present; as learning tools they are no more effective than any other learning tool, and providers will adhere to specific guidelines more frequently when they are constantly reminded. In a subsequent study, Kooij and associates[8] showed that automated reminders in the operating room during surgery do improve adherence to guidelines of PONV prophylaxis and thus improve patient outcome by reducing PONV, especially in high-risk patients. With automated reminders, the percentage of overall PONV

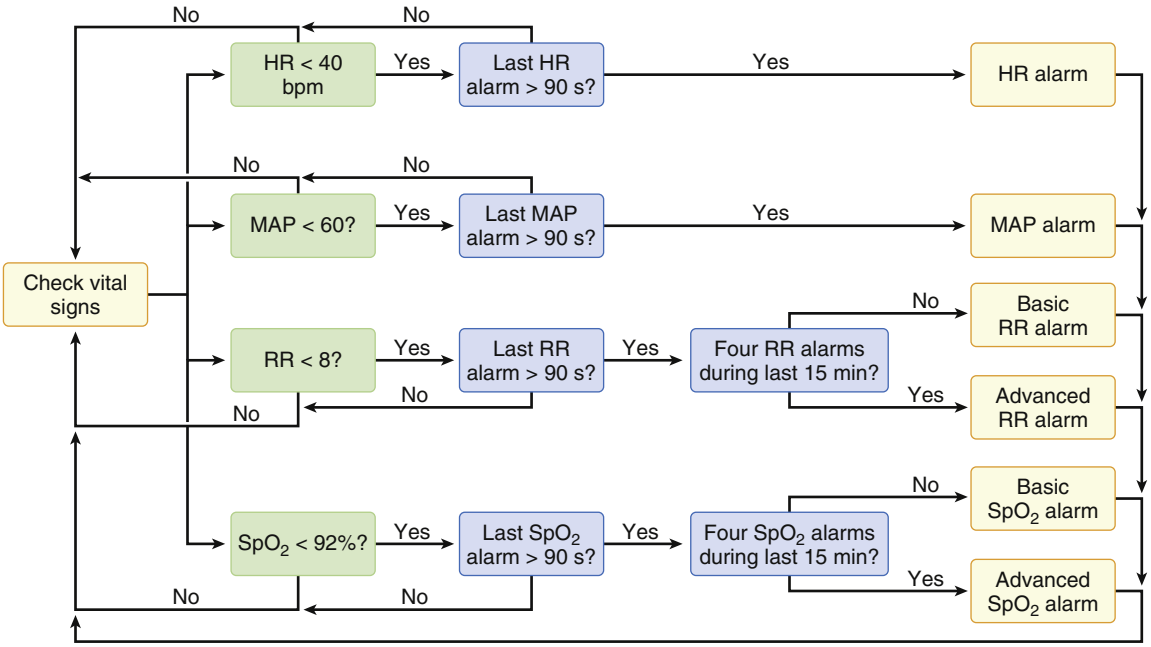

Figure 86-1. Algorithms for decision support system for detecting respiratory and hemodynamic critical events during sedation. *HR,* Heart rate; *MAP,* mean arterial pressure; *RR,* respiratory rate; *SpO_2,* peripheral oxygen saturation.

in high-risk patients was only 31% versus 47% without reminders ($P < .001$).

Most of the DSSs integrated in AIMS have been limited to simple reminders of drug dosing or redosing, reminders for specific monitoring settings, such as turning on standard alarms after separating from cardiopulmonary bypass,[9] and correcting billing reminders.[7,10]

Very few studies have tried to implement DSSs in the anesthesia operating room environment for more complex situations, such as inadequate anesthesia or critical events.

One of the initial descriptions of a DSS, called RESAC for real-time system for advice and control, as a guidance for controlling general anesthesia was published in 1993[11] and used an Atari ST computer for programming. RESAC used 39 parameters, which were retrieved either automatically in real time or by asking the anesthesiologist. The anesthesiologist was also asked to input certain surgery-related data, such as time of surgical stimulation or application of dressings, as well as subjectively chosen limits for patient data, such as heart rate or systemic arterial pressure.

At 1-minute intervals, RESAC then produced text messages concerning the adequacy of anesthesia, with the anesthetist choosing either to follow the decision support information or ignore it. The system had a high error rate; two of the seven patients tested had technical errors and thus the system could not be used. This study's importance lies in the fact that just over 20 years ago, the theoretical structure of an appropriate DSS as an aid to delivery of general anesthesia was presented with many features necessary for the design of such a system: the capability of entering a large set of data, including patient-relevant data in real time and definite time points of surgery, and the ability of the user to set certain personal, subjective target values for parameters such as heart rate or arterial blood pressure. These values could even be altered throughout the course of surgery. Certain design structures can be revisited 20 years later in the design principles of the McSleepy pharmacologic anesthesia delivery robot. A more recent publication evaluated rule-based computer algorithms to detect light (possibly inadequate) anesthesia or unstable arterial blood pressure values using hemodynamic real-time patient data during surgery.[12] Using an AIMS, Krol and Reich[12] constructed a consensus of data that indicated light anesthesia or unstable anesthesia based on data of 162 patients from experienced anesthesiologists. Eighty-one events of light (possibly inadequate) anesthesia were observed. The data of 239 patients undergoing cardiac surgery with cardiopulmonary bypass were investigated for periods of unstable arterial blood pressure values. The authors then developed computer algorithms based on hemodynamic parameters, heart rate, and mean and systolic arterial pressure. To avoid the influence of artifacts, the mean of eight block measurements were taken at 2-minute intervals. However, as of December 2012, the DSS based on these algorithms had not been tested. DSSs are being developed to aid clinicians to detect inadequate anesthesia: groups are working on algorithms based on displaying age-adjusted minimum alveolar concentrations (MAC) alerts[13]; a fuzzy-logic based DSS analyzing systolic arterial blood pressure and heart rate variables as a guidance for anesthetic depth was also proposed[14] but not tested in patients as a real-time guidance device for anesthesia care providers.

The only DSS designed and clinically tested for anesthesia delivery during surgery is part of the hybrid sedation system (HSS).[15] It was specifically developed to recognize critical hemodynamic and respiratory events during sedation with propofol in patients who had received a spinal analgesia. HSS uses the following variables: heart and respiratory rate, mean arterial blood pressure, and peripheral oxygen saturation. Based on individual thresholds, the system creates acoustic alarms that trigger audiovisual pop-up menus offering the various reasons for the alarm, and the treatment options displayed on a touch screen with touch buttons; the anesthesiologist then needs to confirm the actions to be taken, which are recorded for medicolegal reasons. A flow chart describes the algorithms used (see Fig. 86-1).

The acoustic alarms and pop-up menus can be transmitted either via wifi on any smartphone or as text message. The pop-up menus also take into account the possible absence of the anesthesiologist from the operating room and have a specific button that, when pressed, can alert the anesthesiologist to immediately return to the operating room in case of life-threatening emergency (Fig. 86-2).

HSS was tested in patients undergoing surgery with spinal analgesia and propofol sedation; the percentage of critical predefined events detected in a group of 75 patients in whom the DSS was installed was compared to those in another group of 75 patients in whom the critical events were predefined—their definition displayed in the operating room in the visual field of the anesthesiologist, who was advised to react accordingly—but no DSS was made available. Results showed that 25% of critical events go undetected without the DSS and that the response time is usually approximately 30 seconds in comparison to an almost immediate response when pop-up menus of a DSS are used (see Table 86-1).

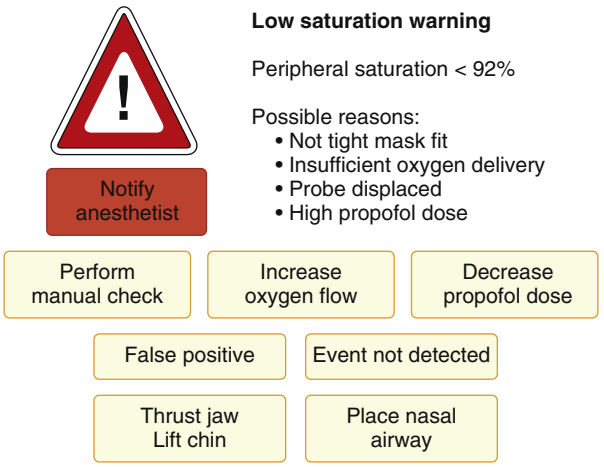

Figure 86-2. The pop-up menu appears with an audible alarm, in this case when the peripheral oxygen saturation drops to levels below 92%. It indicates possible predefined reasons; the user has to click the touch button on the screen to confirm what he or she has done.

As of December 2012, development of DSSs for anesthesia can be described as follows. So far, DSSs have been designed mostly as very simple alert reminders to execute drug dosing at given time intervals, such as for antibiotic administration or prescription, administration of drugs for PONV prophylaxis, or for billing purposes. Some systems have been designed to detect states of inadequate anesthesia, based on analysis of data retrieved from AIMS. First attempts are underway to develop DSSs to help anesthesiologists perform anesthesia, but have not been tested in significant numbers of patients. The only DSS currently tested in a significant number of patients is a system that allows detection of respiratory and critical events, automatically alerts visually and acoustically the anesthesiologist in real time, and offers diagnostic and treatment advice whose execution needs to be confirmed to the system for the pop-up menus to go away. It is clear that the development of DSSs for intraoperative use in anesthesia that assist anesthesiologists in the difficult decision-making process is still in its very infancy.

CLOSED-LOOP SYSTEMS

WHAT IS A CLOSED-LOOP SYSTEM?

An anesthetic closed-loop control system uses feedback from the patient to automatically adjust the dose of a given drug. The response of the patient, such as the degree of sleep at a given time point, is compared with a targeted, desired response at predefined time intervals with the objective of having a difference = 0 between the measured and desired drug effect. The difference is processed by a controller, which is a central processing unit (CPU) with integrated algorithms.

The most commonly designed and tested closed-loop feedback control systems in anesthesia are the closed-loop control of propofol systems using feedback from BIS monitoring. Figure 86-6 explains different control mechanisms.

The controller uses different algorithms and algorithm constructs to act on the difference between target effect and measured effect.

The most commonly used control mechanisms are as follows.

On/Off Control

On/off control means that at given intervals, the difference between target effect and measured effect is

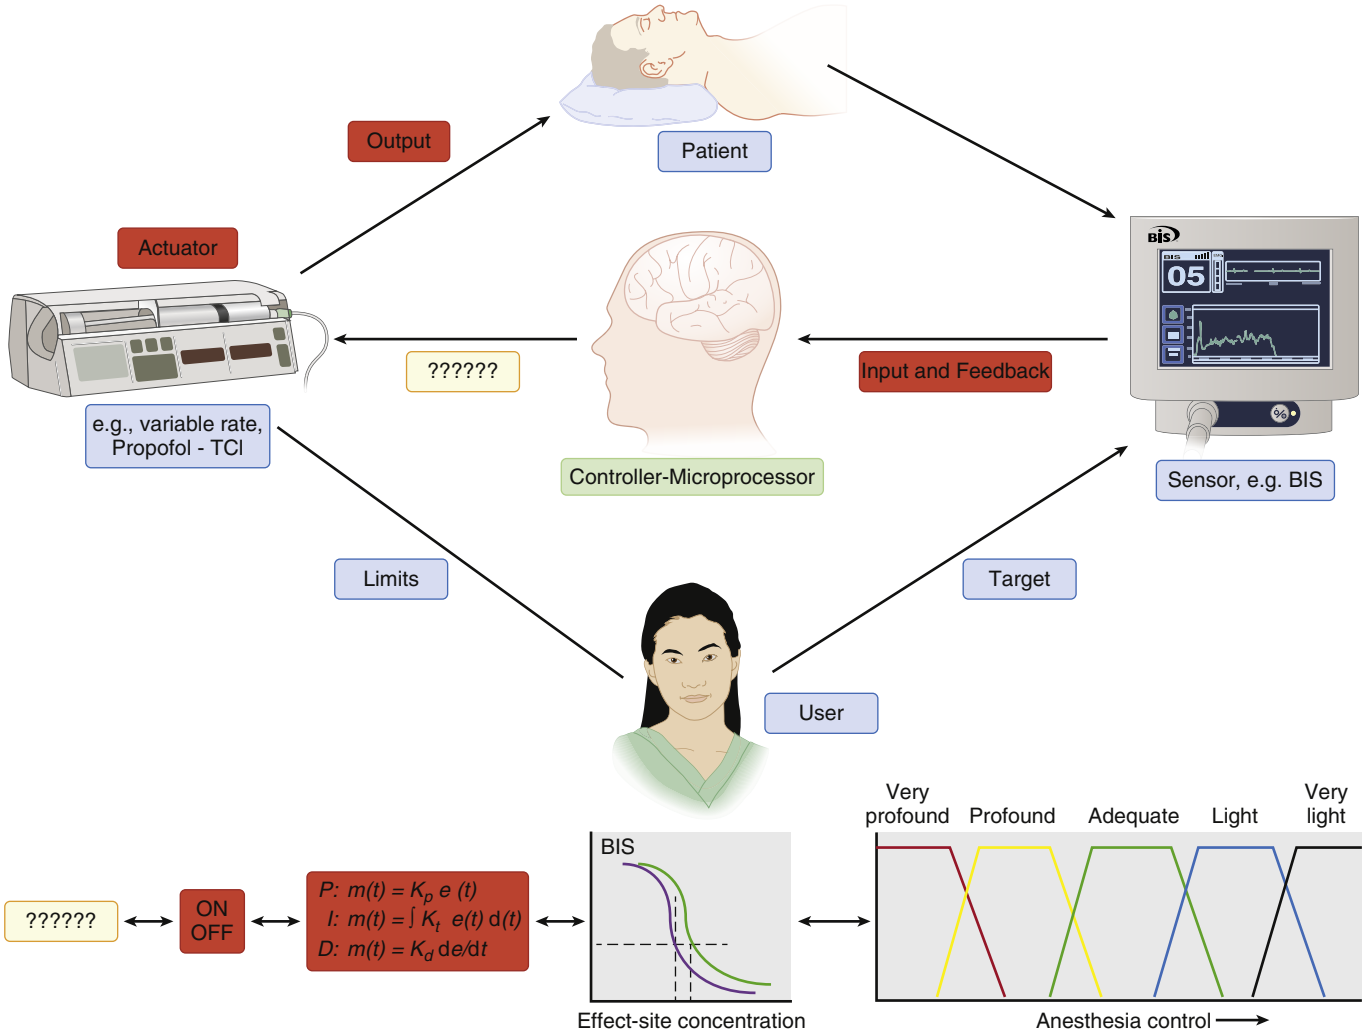

Figure 86-6. Illustration of several control mechanisms; *bottom from left to right:* On/off; proportional integral derivative; model-based; fuzzy logic. *TCI,* Target-controlled infusion.

calculated for the times when this difference is not zero; a fixed dose of a drug, such as a fixed infusion rate, or a bolus is administered. These systems have been used especially for the administration of neuromuscular blocking drugs. They are obviously very simple but can result in astonishing controller performance.

For example, with a neuromuscular blocking drug the infusion pump of a closed-loop control system with an on/off controller delivers 1 mg/kg/hr atracurium in the controller "on" position; when "off," the infusion is interrupted.

Proportional-Integral-Derivative Controller

A PID controller stands for proportional-integral-derivative control mechanisms. The PID controller calculation (algorithm) involves three separate constant parameters: *P* depends on the present error, difference between measured and target effect at present time interval; *I* depends on the accumulation of past errors, past differences between measured and target effect, such as the trend toward overshoot of effect; and *D* is a prediction of future errors, future differences between measured and target effect. These are very popular for closed-loop systems of propofol administration.

Model-Based Control

Model-based control mechanisms were developed hand in hand with the development of pharmacokinetic models for target-controlled infusion of anesthetic drugs. The algorithms are based on the interaction between pharmacodynamic results, such as the effect of a certain drug on the body, and pharmacokinetic phenomena, what the body does to the drug, the compartment of drug distribution, and the elimination process. Some research groups have used these control mechanisms for closed-loop administration of anesthetics. At times these models are individually created by using data from a patient's reaction to a fixed dose at induction. Sometimes, these models are altered in the course of the closed-loop administration and these are called adaptive or self-adaptive.

Rule-Based Control

Rule-based control uses a set of rules that are applied to alter the drug dose to achieve the target effect.

Rule-based mechanisms are used when uncertainty exists about actions, often combined with fuzzy-logic control. The idea behind rule-based system control is the simulation of human behavior, where rules are used to guide treatment strategies. Often, they oversimplify human thinking.

Fuzzy Logic

First termed by Zadeh in 1965, fuzzy logic deals with approximate reasoning rather than precise or exact reasoning. Some of these control systems have been used when neuromuscular blocking drugs have been given via closed-loop controls. Whereas most system controls use either 0 or 1 to act, fuzzy-logic systems use a continuous 0-to-1 thinking strategy, with overlapping categories.

Neural Network

Neural networks try to simulate the human brain. A neural network tries to learn from wrong and right decisions; information streams connect different levels of layers, connected with different neural knots, based on mathematical calculations and algorithms. The knots function like the human brain and decide, "all" or "nothing," to transfer the information from one layer to the next.

Adaptive, or self-adaptive models are those with or without some form of system "learning," in which previous actions of the controller are taken into account and subsequent changes are executed automatically.

VARVEL PARAMETERS IN CONTROLLER PERFORMANCE EVALUATION

The Varvel parameters are performance error (PE), bias or median performance error (MDPE), inaccuracy or median absolute performance error (MDAPE), divergence, and wobble.[25]

The median performance error (MDPE) or bias describes whether the measured values are above or below the target; it describes the direction of the measured values, general overprediction or underprediction, but not the size of the performance error. It is a signed value indicating the "direction" of the performance error.

The median absolute performance error (MDAPE) describes the amplitude of an error—the difference between measured value and target value; such as a MDAPE value of 10% means that 50% of the measured value is within 10% of the target.

Divergence is a time-related parameter that indicates how the inaccuracy of the infusion device changes as time increases. A nonzero value indicates a widening gap between actual serum and target concentrations, whereas a zero value means that performance accuracy does not change over time. A positive value means that the gap between target and measured values widens over time; a negative value means that the measured values converge over time to the target value.

Wobble is a time-related index of changes in performance accuracy and measures the intrasubject variability in performance errors. An increased value of wobble indicates an oscillating behavior of the controller.

No accepted limits exist that represent good controller performance; however, these parameters allow comparison of controller performances of different models and different studies.

CLINICAL PERFORMANCE ASSESSMENT

Clinical performance is defined by the percent of time with a certain offset from the target value. This is more relevant for the clinician; excellent, good, poor, or inadequate control for BIS could mean the measured value within 10%, 11% to 20%, 21% to 25%, and more than 25% off target values, respectively. These classifications are usually chosen by the research groups and can alter from one group to the next and from one target parameter to the next.

The clinical performance values can be valuable for the reader. As an example, when the BIS target is chosen to be at 50 for the controller 80% of the time, the controller manages to keep the BIS values within 10% of the target, which means that during 20% of the time the BIS values are either above 55 or below 45. Let us assume further that during 10% of the time the BIS is at values higher than 55, which are usually values at which strong surgical stimuli might cause a wakeup reaction in some patients. Therefore, during 10% of the time, the BIS controller is in an area at which this risk is elevated. The same applies for the amount of time the controller keeps BIS values at 60 or higher. Therefore, for most clinicians, the clinical performance results are more important than the Varvel controller performance values.

EARLY WORK: THE WORK BY SCHWILDEN AND HIS RESEARCH GROUP

One of the first works on closed-loop feedback control was done in the late 1980s by Schwilden and associates,[26,27] before the introduction of commercially available depth of consciousness monitors.

In 1987, Schwilden and associates used the median electroencephalography (EEG) frequency of the power spectrum and a model-based, adaptive controller to administer methohexital in 13 volunteers. The controller set point was 2 to 3 Hz, and the closed-loop system maintained EEG within this target area 75% of the time. In 1989, they used the same setup for closed-loop application of propofol to a target of 2 to 3 Hz of median EEG frequency of the power spectrum. The average measured EEG frequency was 2.5 ± 0.3.

EARLY CLOSED-LOOP ANESTHESIA WORK: THE RESEARCH GROUPS OF KENNY; CLOSED-LOOP CONTROL OF ANESTHESIA: THE WORK OF KENNY'S GROUP IN GLASGOW, SCOTLAND

In 1999, Kenny and Mantzaridis[28] presented a closed-loop control system of propofol using auditory evoked potentials (AEPs) as measurement for depth of anesthesia; it was similar to the description of the closed-loop system already published as an abstract in 1992.[29]

A 3-second running average of AEP index was used in a personal computer (PC)–based proportional integral control algorithm; the actuator was a target-controlled infusion pump of propofol. Analgesia in 100 patients (mean age 50 years, American Society of Anesthesiologists [ASA] physical status I and II only, undergoing body surface surgery) was provided using target-controlled infusion of alfentanil at a plasma concentration target of 15 ng/mL. Induction of anesthesia was performed without feedback, but instead using preset increments of target concentrations of propofol. The target depth of consciousness, in this case the AEP target, was manually chosen by the user and was in the range of 30 to 40, with a mean of 38. Usually, no neuromuscular blocking drug was given, which probably renders the depth of consciousness monitoring value more susceptible for artifacts. The aim of ventilation was mostly spontaneous breathing during surgery, which was successfully achieved in the majority of the patients, a result that seems independent from closed-loop control but related to this type of anesthesia. The closed-loop control period (duration of anesthesia after induction to end of surgery) was short at 38 minutes, because of the specifics of the surgery. However, the controller performance was generally very good, although the wide range of quality of control indicated that some patients had a rather significant offset from target with results, as shown in Box 86-1. Varvel parameter results were not presented.

A follow-up closed-loop study was conducted with 10 patients (ASA physical status I and II) undergoing major orthopedic surgery for a longer duration (72 minutes) than in the previous study.[29] The researchers used the same type of general anesthesia–that is, a spontaneously breathing patient with a laryngeal mask airway inserted for airway protection and BIS as the monitoring control parameter.[30] Analgesia this time was achieved using epidural analgesia.

This study presents the Varvel performance parameter results and clinical performance values, offset from the target BIS. Whereas the Varvel performance values at an overall MDPE of 2.2%, MDAPE of 8%, and wobble of 7.3% are satisfactory, when compared to their previous study, the clinical performance was not as good.[28] With feedback from AEP, the measured values were within 5% and 15% of the target in 65% and 99% of the time, with BIS feedback, it was only in 34% and 75% of the time, respectively.

The authors explain this with a slightly different patient population, different analgesic technique, different induction of anesthesia method, and different monitoring method of depth of consciousness. In addition, the smaller sample size of 10 patients in the latter study might have contributed to the worse clinical performance. Insufficient control of anesthesia and maintenance of the measured BIS value around a given target in closed-loop systems is usually marked by a phenomenon termed oscillation. Of the 10 patients, 3 showed marked oscillations, the worst in one patient (Fig. 86-7).

In this patient, the initial BIS target was 57, which probably was too high, too close to an arousal barrier, at which point the patient was possibly at risk for waking up as a result of surgical stimuli, insufficiently masked by analgesia. After decreasing the target to 45 at 45 minutes of surgery, the oscillations were reduced. However, the example of oscillations demonstrates a common problem in designing closed-loop systems. In their initial system, Absalom and Kenny did not include adaptive control mechanisms that allow adaptation of control algorithms for an individualized patient over time, something that more recent study groups have done.[31] The higher the BIS value, the closer to the threshold of 60, the more the patient is susceptible to have arousal reactions as a result of surgical stimuli. This also means that good analgesic control

BOX 86-1 ***Control of AEP Index as Percent of Total Closed-Loop Anesthesia Time (Mean [SD], [Range])***

Within target value ± 5%	65.2 (14.1) [10.3 – 89.0]
Within target value ± 10%	89.6 (9.5) [46.7 – 100.0]
Within target value ± 15%	98.7 (4.6) [74.9 – 100.0]

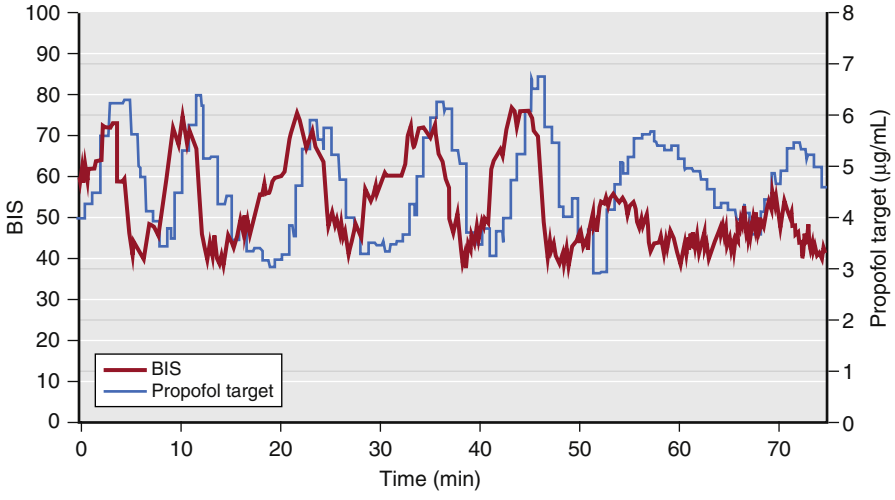

Figure 86-7. Illustration of marked oscillations, worst case in one patient. Oscillations usually indicate poor control performance, a problem all control systems encounter in specific patients. The frequency and magnitude of oscillations with a specific controller is an indication of its performance, the less oscillations occur, the better the controller. *BIS,* Bispectral index. *(From Absalom AR, Sutcliffe N, Kenny GN: Closed-loop control of anesthesia using Bispectral index: performance assessment in patients undergoing major orthopedic surgery under combined general and regional anesthesia,* Anesthesiology *96:67-73, 2002.)*

is important for any closed-loop system of propofol to function properly; waking up reactions during surgery while having insufficient analgesia can occur with total IV anesthesia, independent of whether the anesthesia is automated (see also Chapters 33 and 50).

Kenny's research group tried to improve their control algorithms and presented their results in a follow-up study with 20 patients (mean age 43 years, ASA physical status I and II) undergoing body surface surgery of 27 minutes on average. This study used a very different population and type of surgery compared to their earlier study with unsatisfactory closed-loop control[30] in which patients were older (mean age 67 years) and undergoing major surgery of approximately 70 minutes with epidural analgesia. In comparison to their previous study,[30] the changes in the control algorithms were the use of a newer BIS software, adjustments in the gain constants used in the control algorithms in the second part of the patients (11 to 20), and alteration of the control algorithm to allow effect-site steering, rather than blood site steering in the attempt to avoid oscillations by faster increase in effect-site concentrations with too light anesthesia. Although the Varvel performance parameter values slightly improved from the earlier study, the clinical performance did not change.

The Kenny group also used the closed-loop system for research into the interaction of drugs, such as remifentanil and propofol.[32] This is an important aspect of the development and use of closed-loop systems, which allow the automated administration of propofol without human intervention. Furthermore, anesthesia can be given around a specific target, allowing research into the interactions of propofol and other drugs.

Kenny's group designed a closed-loop system for propofol sedation for colonoscopies using the BIS value as a control parameter, which they tested in 16 patients.[33] Patients were sedated to a clinical sedation target of OAA/S rating of 3, and the achieved BIS target at that clinical value was used as a set point, with the possibility of modifying it in case of clinically insufficient sedation. Interestingly, the performance of their sedation system is better than that of their general anesthesia control, with BIS values within 10% of set point during 81% of the time versus 57% [30] and 71%.[34] Yet, the BIS target was 80 in the sedation study, and even a fully awake patient cannot have a BIS value higher than 99; therefore, a maximum positive offset of 19 cannot be passed in the sedation study.

Important messages from that small-scale study are the propofol doses required to achieve the same clinical sedation end point vary widely, with one patient necessitating a maximum propofol target of 5.6 μg/mL or 160 mg of propofol for induction of an OAA/S state of 3—another argument for automated systems, because empirical drug dosing has significant limitations. A feedback control approach avoids some of these limitations including the feasibility of using BIS monitoring to titrate sedation for nonsurgical procedures. This monitor can also be used as a control parameter for closed-loop sedation (also see Chapter 50).

Summary of Kenny's Work

The efforts of the Kenny research group can be summed up as follows:

1. Kenny and Absalom's group designed one of the first closed-loop propofol sedation systems using BIS feedback and successfully tested it in humans.
2. They used their PID controller–based propofol closed-loop system with feedback from AEPs and BIS; the controller performance was significantly better with AEP feedback than with BIS feedback.
3. The closed-loop system used target-controlled infusion as actuator; the closed-loop feedback control was used for maintenance of anesthesia, but not for induction of anesthesia.
4. They clearly described the problem of oscillations of controlling parameter values and proposed improvements in control design, specifically the use of effect-site concentrations rather than blood or plasma site concentrations. Whether these changes significantly improved controller performance cannot be answered because of the small sample size of their study.
5. They identified the potential of using closed-loop systems as a research tool to investigate drug interactions, as they did between remifentanil and propofol.
6. Although they incorporated control algorithms for application in ASA physical status III and IV patients, they actually never tested them in this patient population; they also only used it in anesthesia without controlled ventilation and neuromuscular blockade.
7. Closed-loop control was mostly for short-term procedures.

CLOSED-LOOP SYSTEMS FROM STRUYS AND DE SMET'S GROUP: FROM CLOSED-LOOP TO ADAPTIVE MODEL-BASED COMPUTER CONTROL

After the earlier work by Schwilden and associates[27] Struys and De Smet's research group chose to design a closed-loop propofol system around model-based controllers, which also are adaptive, meaning the dosing is not only corrected according to the offset between measured and set point target of BIS but also adjusted to individual patient reactions to propofol over time. The exact algorithm is not described in the first study. They first presented their system in 10 patients (ASA physical status I and II) undergoing orthopedic surgery with spinal analgesia of short duration (approximately 30 minutes).[35] Similar to Kenny's group, the actuator was a target-controlled propofol infusion pump, induction was automatic by a stepwise approach, but without feedback from BIS control. Similar to later work by Kenny's group,[33] the sedation target was set clinically, but was more intense at an OAA/S value less than 1 and the BIS target at that point set as the closed-loop target. Because the OAA/S target was lower, the resulting BIS target was also lower than in Leslie's study[33] at an average of 64. The publication is scarce in presenting actual performance parameters, either clinical or others. The graph depicting the difference between the target and measured BIS values over time shows a wide range of offsets.

In a subsequent study,[36] detail is given about the "adaptive" feature of their model-driven closed-loop control system of propofol. A control factor is integrated into the algorithms that analyze the difference between two consecutive measured BIS values, multiplied by a differential factor: Adaptive control corrective factor = (BIS_{T1} – BIS_{T0}) × Differential factor (based on simulation studies, the differential factor was established as 0.05).

The system uses an open-loop, plasma target-controlled infusion, with RUGLOOP (tracking of concentration infusion and data management program) calculating the effect-site plasma target concentrations. Once the target BIS level of 50 was reached during induction, the model was calculated based on paired measurements of BIS levels and calculated plasma target concentrations, thus calculating an individual model for each patient, based on results from an open-loop induction, similar to the Bayes principle.

The study design has some characteristics: first, the sample size is small at 10 patients each group (closed-loop versus open-loop); second, whereas BIS monitoring at a target of 50 was used in the closed-loop group, clinical signs of "adequate anesthesia" were used in the control group. Although this might be reflecting some standard practice, it limits the possibility of comparing the performance of anesthesia control. Therefore, a more rapid extubation of the trachea in the closed-loop group might not only be related to closed-loop control, but also to the fact that BIS was not used in the control group to titrate anesthesia. The comparison of controller performance values, based on Varvel parameters, is also less valid, because BIS was not used as a controlling variable in the control group.

Therefore, the Varvel parameters in Struys' study should be compared with the work from Kenny's group, which used different and simpler control mechanisms without adaptive modeling (Table 86-3).

Whether the integration of model adaption (Struys' group) has improved controller performance in comparison to the simple PID (Absalom and Kenny) is not clear and supports a theory of many control system engineers. Control algorithms seem less important than the time interval of feedback control.

The idea that control algorithms are somewhat less important seems in contrast to a simulation study (simulated 10 patients) by Struys and associates[37] in which the control performance of the aforementioned two closed-loop control systems was compared, favoring the patient-individualized, model-based adaptive closed-loop system with effect-site control over the standard PID controller (Table 86-4). However, the clinical performance (i.e., maintenance of BIS value within 10% of target value), slightly favors the model-based adaptive controller. The PID controller performs better when higher BIS targets (BIS = 70) are maintained, thus avoiding BIS values that are too low; the reverse is true for BIS values that are too high.

The Varvel performance values are better for the model-based adaptive control system than the PID system, except for the MDPE values. These values are less important, because they indicate the direction of the bias of measured value from target value but not its size.

Obviously, this study has its limitation, which is related to the patient simulator; the "historic" data fed into the simulator might have favored the model-driven control system because both the simulator and the model-driven control system used the same type of model. Clinically, both controllers would have probably satisfied adequate anesthesia conditions.

Simulation studies can be used to fine-tune controlling algorithms, as De Smet and colleagues[38] have extensively demonstrated by creating highly complex control models. Whether this relates to improved controller performance in the clinical setting needs to be shown.

Struys and De Smet's work can be summed up as follows:

1. They were one of the first groups introducing the Bayes theorem into closed-loop design, using the information about the individual pharmacokinetic behavior of an individual patient to create an individualized pharmacokinetic model, which they used for their closed-loop feedback system.

**P < 0.05* between both controllers.

BIS, Bispectral index; *PID,* proportional interactive derivative.

2. They realized the usefulness of adaptive modeling, meaning that the control algorithms could be corrected throughout surgery, depending on how the model performed.
3. Clinically, however, their control system did not perform better than other control systems described in this chapter.
4. They used their closed-loop propofol system mostly for small-scale studies in which they focused on the theoretical development of their models.
5. As with Kenny and Absalom, the Struys and De Smet's group used their closed-loop controlling system in patients with ASA physical status I and II.
6. Closed-loop control was used mostly for short-term procedures of 30 to 45 minutes.

THE CLOSED-LOOP ANESTHESIA DELIVERY SYSTEM: PURI'S RESEARCH GROUP

Puri's research group presented a novel closed-loop anesthesia delivery system in 2007[39] and called it closed-loop anesthesia delivery system (CLADS). The system can be used for both induction and maintenance of anesthesia. As in most other systems, the BIS was used as the control parameter within a standard feedback system, consisting of a commercially available syringe infusion pump, propofol, a microprocessor running a self-made program based on algorithms and communicating with each other using RS 232 ports. An interface allows the user to operate the system manually from a PC. The system allows the user to choose a target BIS value; the maximum infusion rate is related to the ASA physical status classification, with ASA I through III considered low risk and any ASA classification above this as high risk. Whereas BIS values are recorded into the system every 5 seconds, the propofol infusion rate can be changed only every 30 seconds or more. The system uses a proportional integral differential, based on the current infusion rate and the change in BIS values. Before accepting the BIS numbers, the signal quality index also must be checked. Effect delay is based on the time delay for the propofol to produce effect on BIS.[37]

In the first study, they compared 20 patients in whom hypnosis was delivered using CLADS versus 20 patients in whom propofol hypnosis was performed manually to maintain a BIS of 50.[39] Analgesia was maintained using fentanyl 1 μg/kg/hr and muscle relaxation using a bolus administration of vecuronium in both groups. The controller CLADS outperformed the manual group in terms of maintaining the BIS close to the target (target ± 10), on average 87% of the time versus 77% of the time in the manual group.

Even more importantly, CLADS provided a more precise induction of anesthesia, using a significantly smaller dose of propofol, thus creating less overshoot of the BIS target.

In this first study, patients were young, approximately 40 years of age, with normal body weights undergoing elective noncardiac surgery. Puri and associates[40,41] then applied their system to a sicker patient population undergoing cardiac surgery and compared it with manually controlled anesthesia. In the follow-up study using the same design, they included 37 patients, randomized in two groups of 19 and 18 patients (CLADS versus manual propofol control, respectively) undergoing elective cardiac surgery.[41] In this sicker and older population undergoing major surgery, they confirmed their earlier results: the CLADS achieved an induction of anesthesia with less BIS overshoot, this time even resulting in better hemodynamic control. All performance indexes were significantly better in the CLADS group than in the manual group.

They also used CLADS to control postoperative sedation.[41] After cardiac surgery, CLADS was used to maintain a BIS target of 70 for postoperative sedation in the intensive care unit (see also Chapter 101). The performance of CLADS was better than manual performance to maintain the BIS at approximately 70; the mean duration (in percent) of time at which the BIS was between 60 and 80 in the CLADS group was 69% versus 45% in the manual group. Although not specifically described in the results section, an average performance error of −3 in the manual group suggests a trend toward lower BIS values during the average duration of postoperative mechanical ventilation of 6 to 9 hours on average. Whether the longer time from cessation of sedation to tracheal extubation in the manual group is related to a generally deeper sedation or a longer ventilation time is not clear.

Their system performs as well in patients undergoing abdominal or orthopedic procedures in general anesthesia at an altitude of 3505 m.[43] The most interesting result of the study was the confirmation of a previous finding that patients need a larger dose of propofol for induction of anesthesia at higher altitudes than lower altitudes, thereby avoiding subjective influences by using the closed-loop system.[44] Perhaps these patients needed larger doses of propofol to achieve a target BIS. Is this due to a specific patient population or the altitude?

To confirm the robustness of their system even with sicker patients undergoing complex surgery, the same group presented a case series of 13 patients undergoing adrenalectomy for pheochromocytoma.[45] The results were similar to the findings in other patients, with 87% of the time the BIS being within 10% of the target value of 50, similar performance indexes, and good hemodynamic stability. The BIS values in this study population trended toward light anesthesia, with average BIS values of approximately 60; perhaps this indicated an increased risk for awareness, which could be countered by decreasing the target value of BIS.

The same group recently adapted their system for use with volatile anesthetics, calling it "improved anesthetic agent delivery system" (IAADS).[46] They used their system in 40 patients undergoing cardiac surgery, in which 20 patients were assigned to the closed-loop group and 20 patients to the control group. Isoflurane was injected into a low-flow breathing system with a 20 mL syringe and syringe pump.

They used algorithms similar to those in their previous propofol closed-loop system, CLADS; however, the minimal lockout period for any isoflurane changes was not

clear: their CLADS system does not change any infusion rate of propofol in intervals shorter than 30 seconds. The pharmacokinetics of isoflurane are very different with a much longer elimination period, thus changes of isoflurane concentrations should be smaller during a given time.

The uniqueness of the study lies in the fact that two different anesthetics were delivered using a closed-loop system at different times. (1) Induction of anesthesia was performed using CLADS with propofol, or manually administered propofol; (2) the initial anesthesia maintenance before cardiopulmonary bypass (CPB) surgery was performed using IAADS with isoflurane, or manual isoflurane during CPB; and (3) anesthesia was maintained using either closed-loop or manually administered propofol and isoflurane after CPB.

The study might be regarded as more of an exercise of feasibility than of widespread clinical importance; the necessity of using propofol as a continuous infusion during CPB is limited because isoflurane can be injected into the circuit. The overlapping of propofol and isoflurane effect was addressed in the algorithms; the algorithms appeared to work independently. This means that once the propofol infusion was stopped, the isoflurane controller took over, and vice versa. The possible additional effect of either drug on the other was not considered. However, such pharmacokinetic interactive modeling (propofol effect on isoflurane and vice versa) might not be necessary because a constant feedback system is in place—that is, if BIS is still low because propofol is not eliminated, the isoflurane controller delivers less isoflurane and then increasingly more until the propofol effect has disappeared. It is not clear how often the infusion rate of propofol or the isoflurane-dial setting was changed (actually, none of the articles of this research group reveals the number of propofol modifications per hour for the CLADS, only for the manual control). In fact, the isoflurane-dial setting in the manual group was only changed two times before CPB and two times after CPB; no information is given on how often the isoflurane infusion was changed in the IAADS group. More changes might have probably resulted in a better maintenance of the BIS target in the manual group.

Summary of Puri's Work

The efforts of the research group around Puri can be summarized as follows:

1. The CLADS is a PID-controlled closed-loop system of propofol delivery for hypnosis and sedation. Its performance is similar to that of other research groups. The studies were conducted on small numbers of patients (usually 20 patients per group). However, closed-loop applications in major or higher risk surgery, such as cardiac surgery or adrenalectomies for pheochromocytoma, are valuable and interesting.
2. The studies confirm that closed-loop systems are not just reserved for healthy young patients undergoing minor surgery but can equally be used in major surgery and in older and less healthy patients.
3. Puri's group presents one of the few studies of a closed-loop system using volatile anesthetics as the controlled drug; technologically, they use isoflurane as a liquid injected into a breathing circuit via a conventional syringe pump. This kind of closed-loop administration of inhaled anesthetics is fundamentally different from commercially available systems such as the ZEUS (Draeger, Lübeck, Germany) system, which is a target-controlled system, meaning that the end-tidal concentration of any given inhaled anesthetic is maintained regardless of fresh-gas flow, but is not controlled to maintain a given target of unconsciousness.
4. Their system can be used for closed-loop control of propofol sedation. In the multitask environment of an intensive care unit, closed-loop control of propofol sedation might be very helpful (see also Chapter 101).
5. In addition to the need for studies in larger patient populations, more information needs to be provided within each study, especially about the controller function (e.g., the number of propofol infusion rate modifications per hour or changes of isoflurane concentrations with either CLADS or IAADS).

LIU'S RESEARCH GROUP: FROM SINGLE-LOOP CONTROL OF PROPOFOL TO DUAL-LOOP CONTROL OF PROPOFOL AND REMIFENTANIL

In 2006, Liu and colleagues published their novel closed-loop system for propofol-based induction[47] and maintenance of anesthesia.[48] They used a closed-loop system in which feedback control was obtained using BIS monitoring but output was not by a propofol infusion rate, but target-controlled infusion rate of propofol (Fig. 86-8).

Another novelty was the feed-forward loop, which allowed fast correction of a measured BIS value of higher than 60 to avoid awakening of the patient. The target BIS was 50, with minimal and maximal propofol target concentrations set at 1 and 5 μg/mL; however, these could be modified by the user. It also integrated a safety measure when BIS values were recorded as corrupted by artifacts; the last target of propofol was not altered in that situation. Whereas Puri's group had used continuous infusions of fentanyl to provide intraoperative analgesia, Liu's group used a target-controlled infusion of remifentanil, manually controlled, and preemptive standard analgesia. They used their closed-loop system in a preliminary study only for induction of anesthesia, defined as the time between the beginning of anesthesia and achieving a target BIS of 50, therefore, before laryngoscopy or intubation. The randomized trial had 40 patients in two equal groups of 20 for closed-loop induction or manual induction of anesthesia using target-controlled propofol.[47]

In this study, they showed smaller propofol consumption and shorter induction times to reach the target value with closed-loop induction of anesthesia (381 seconds versus 490 seconds in the manual group). No hemodynamic differences were found between the groups with significant but clinically insignificant overshooting of the target in the manual group.

Interestingly, in their larger scale follow-up study of 164 patients, randomized in two groups of 81 (manual target-controlled propofol administration) and 83 (closed-loop group),[48] the duration of the induction of anesthesia was significantly faster in the manual group

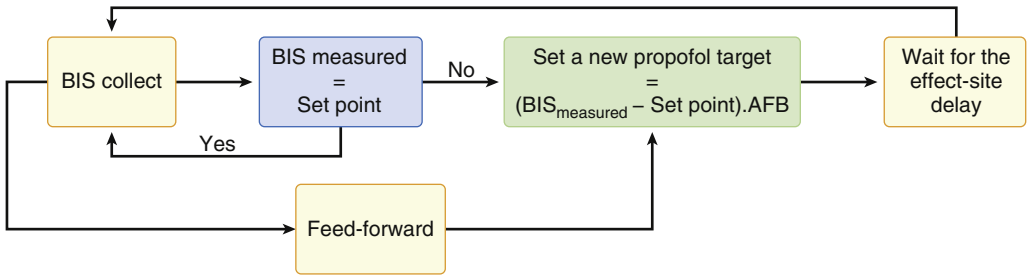

Figure 86-8. The main control algorithm. Effect-site delay was calculated using the pharmacokinetic model of Schneider. The feed-forward term amplified the correction of the propofol target when a measured bispectral index (*BIS*) value greater than 60 was detected. *AFB,* Amplification of the feedback. *(From Liu N, Chazot T, Genty A, et al, Titration of propofol for anesthetic induction and maintenance guided by the bispectral index: closed-loop versus manual control: a prospective, randomized, multicenter study,* Anesthesiology *104:686-952, 2006.)*

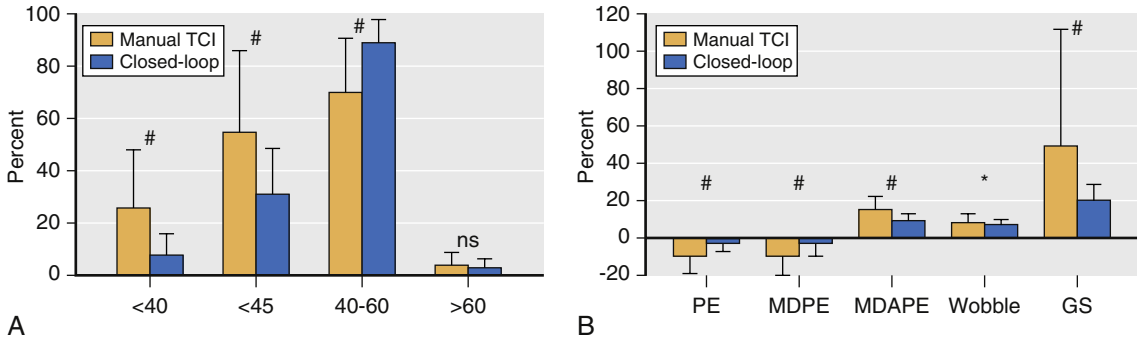

Figure 86-9. A, Efficiency of the system during maintenance of anesthesia. *P < .0001. Bispectral index* (BIS) < 40 = percentage of time when the bispectral index (*BIS*) value was under 40; BIS < 45 = percentage of time when the BIS value was under 45; 40 < BIS < 60 = percentage of time when the BIS value was between 40 and 60; BIS > 60 = percentage of time when the BIS value was greater than 60; closed-loop = closed-loop group. *manual TCI,* Manual target-controlled infusion group guided by the BIS; *ns,* not significant. **B,** Control performance during maintenance of anesthesia. *$P < .05$; †$P < .0001$. *Closed-loop,* Closed-loop group; *manual TCI,* manual target-controlled infusion group guided by the BIS; *GS,* global score; *MDAPE,* median absolute performance error; *MDPE,* median performance error; *PE,* performance error. *(From Liu N, Chazot T, Genty A, et al, Titration of propofol for anesthetic induction and maintenance guided by the bispectral index: closed-loop versus manual control: a prospective, randomized, multicenter study,* Anesthesiology *104:686-952, 2006.)*

than in the closed-loop group (271 seconds versus 320 seconds), using a significantly larger propofol dose. This showed how some "significant" results in small-scale studies can sometimes become insignificant or even the obvious in larger scale studies. Nevertheless in patients approximately 60 years of age, half of whom underwent major surgery, the results of the closed-loop control are impressive: all clinical performance variables as well as the Varvel parameters of systems control efficiency are significantly better with closed-loop control (Fig. 86-9).

The Varvel parameters also depend on the level of BIS value; thus, Liu and co-workers[49] used a composite parameter, called global score (GS) to better describe and distinguish performance differences between control systems and global score, which is calculated as follows: GS = (MDAPE + Wobble)/% of time BIS value between 40 and 60.

Liu's group[51] also showed that closed-loop propofol anesthesia in even the most difficult surgeries in sick patient populations is an appropriate approach. Their study had 20 patients who were undergoing single-lung or double-lung transplantation with clinical control values similar to those in less sick patient populations. The results showed that anesthesia was within acceptable BIS values of 40 to 60 for 84% of the time, with very limited overshoot (<40) in 13% and even less undershoot (>60) in 3%.

Liu and his research group followed their earlier work to create a dual-loop system administering both propofol and remifentanil in closed-loop control using one controlling parameter, the BIS. Their assumptions were that small errors in BIS (the difference between the set point and the measured BIS value) are indications of changes in nociception; therefore, only target concentrations of remifentanil are changed; larger errors are indications of changes in hypnosis (and nociception), and both drug concentrations are changed. They also present an interaction rule, which means that if the controller increases the remifentanil concentration more than three successive times, the propofol concentration is increased as well, regardless of the BIS error. In addition, propofol and remifentanil concentrations cannot be changed in a contrary sense–that is, the controller cannot increase propofol and decrease remifentanil, and vice versa (Fig. 86-10).

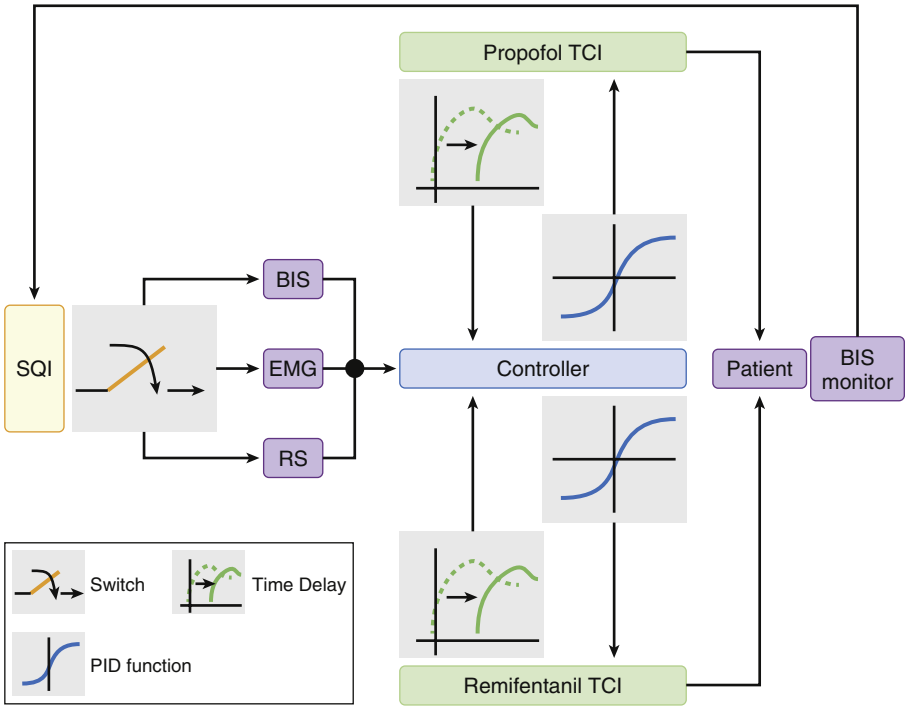

Figure 86-10. Control algorithms for Liu's dual-loop system. *BIS,* Bispectral index; *EMG* electromyogram; *PID,* proportional-integral-derivative; *SR,* suppression ratio; *SQI,* signal quality index. *TCI,* target-controlled infusion.

This dual controller of two PID controllers has the following main elements:

1. Calculation of the BIS error (difference between BIS target and measured value)
2. Feedback amplification (continuous target concentration modification to achieve BIS error = 0)
3. Variable time delay between each drug concentration modification based on pharmacokinetic principles for both drugs and age of the patient
4. Feed-forward rapid response when BIS increases over 60
5. Interaction rule: Remifentanil increases of more than three times trigger propofol concentration increase
6. Maintenance of last target concentration when BIS dysfunction or poor signal quality occur

The assumption that small changes of BIS indicate changes in nociception and larger changes indicate changes in nociception and/or depth of consciousness is a somewhat arbitrary assumption by Liu's research group. Clinically, however, the technique seems to work well.

In 2011, Liu and colleagues published a study of 196 patients undergoing surgery (30% major, 15% ASA physical status III) using either the dual-loop propofol remifentanil control system (N = 83) or manual control (N = 84). As in other closed-loop studies, the dual-loop system achieved better maintenance of BIS values to the target of 50, probably influenced by the generally larger number of concentration changes in comparison to manual control. For propofol there were 26 versus 9 changes per hour manually and for remifentanil 32 changes versus 8 changes per hour manually and by the smaller increments of concentration changes. Obviously, a direct way of judging the performance of remifentanil control separately exists, because they defined nociception through changes in BIS. More conventionally, it is accepted that nociception during general anesthesia is reflected by hemodynamic changes; the study did not find any changes in heart rate or arterial blood pressure control between manual and dual-loop control. There was a 1 minute more rapid extubation time in the dual-loop group, which is of no clinical significance. As in their earlier work, clinical performance (maintenance of BIS within 40 to 60) and avoidance of overshooting (BIS < 40) and undershooting (BIS > 60), as well as systems control, were better in the dual-loop group, with a global score of 26 versus 43 in the manual group.

Liu and colleagues[50] followed their philosophy of extracting two components (one for pain or nociception, one for nociception and or hypnosis) from a depth of consciousness monitoring parameter by using the spectral M-entropy monitor as guidance for their dual-loop control system. The concept is similar to that in their previous work, when they used the BIS.[51] Interestingly, because of the smaller group size (31 patients in the manual group, 30 patients in the dual-loop group) or the use of the entropy monitor, no differences were found between the two groups during either the induction or duration of anesthesia regarding the propofol or remifentanil dose or that the relation between state entropy and response entropy might be a surrogate measure of antinociception,[52] they found no differences in terms of antinociception between the two groups, no significant differences of any response entropy–related performance index, but a significantly better control of hypnosis with state entropy values between 40 and 60 in 80% of the anesthesia time in the dual-loop group versus only 60% in the manual group.

The same research group recently tested their dual-loop system for deep sedation in critically ill patients.[53]

In contrast to Puri's group,[42] which can adjust their controller to different degrees of sedation (for postoperative sedation, they used a target BIS of 70), Liu's controller does not adjust the target BIS value according to the varying demands of sedation. They used the same BIS target of 50 for sedation purposes, which is probably unnecessarily deep for intensive care sedation in most patients (see also Chapter 101). In this small study, 14 patients received manual sedation (manual analogue-sedation because both propofol and remifentanil were used) and 15 patients received automated analogue-sedation using the dual-loop control system for 8 to 24 hours. The BIS was maintained more often within 40 to 60 in the dual-loop control group versus manual control group. This is not surprising when the mean target modifications of propofol and remifentanil per hour were 1 to 2 in the manual group versus 30 to 40 in the dual-loop group. In situations in which deep sedation in critically ill patients is necessary, an automated closed-loop sedation system has the advantage of maintaining a steady sedation state for a longer period. This is especially important in an intensive care unit, where the increased magnitude of care and multitasking responsibilities limit the frequent adjustments of propofol or remifentanil dosing, as indicated with the limited number of dose modifications of 1 to 2 per hour in comparison to most comparative intraoperative studies, in which anesthesia providers manually perform many more frequent infusion rates.

Summary of Liu's Work

The efforts of the research group around Liu can be summed up as follows:

1. Liu and his group have established a wide-ranging multicenter platform, which allows evaluation of the dual-loop system in a large scale of patients, from healthy to very sick patients, undergoing minor to difficult surgeries such as lung transplantation. They studied the system in over 3000 patients (personal communication with Dr. Liu, 2012) without any system-inherent failure or adverse effect. This makes the dual-loop system the closed-loop system with the biggest patient population.
2. The advantage of closed-loop systems over manually administered anesthesia is the larger number of modifications of concentrations of propofol and/or remifentanil that can be given over time. The responsibilities of anesthesiologists and critical care specialists are extensive, and such automatic systems are needed.
3. Undoubtedly, using the theorem that small changes in BIS values are a surrogate for (anti-) nociception is sometimes questioned; no study is available that supports this way of thinking. However, in clinical practice, remifentanil is mostly given because of hemodynamic variable changes, which is also just an indirect, albeit widely accepted, surrogate for nociception. Giving remifentanil by a closed-loop system makes sense. It would be interesting to see how the system would work with other opioids, such as fentanyl or sufentanil.
4. The fact that dual-loop systems maintain anesthesia around a target of 50 might limit its use for sedative purposes; here, Puri's system has the advantage that any BIS value can be chosen by the user.
5. The dual-loop system can be used for induction and maintenance of anesthesia; for induction it has the advantage over manual induction in avoidance of target overshooting. In hemodynamically frail patients, this might lead to better hemodynamic stability during induction of anesthesia.
6. The advantages of slightly shorter extubation times are probably not clinically relevant.
7. Similar to Puri's system, the dual-loop system, or the single-loop propofol control system for that matter, continues with the last concentration of propofol and/or remifentanil in situations of poor signal quality of the depth of consciousness monitor. In high noise areas such as the intensive care unit, where the signal could be absent for a longer period, this could lead to problems. A better adjustment of the concentrations, such as last average over a longer period, might be more suitable. It is not clear how the user overrides the system in these situations—that is, changes from manual to automated control again.

THE ROSTOCK EXPERIENCE: CLOSED-LOOP CONTROL OF TWO GENERAL ANESTHESIA COMPONENTS

In 2009,[54] a research group from Rostock, Germany, presented a multiple-input-multiple-output controller (MIMO) for closed-loop control of target controlled infusion of propofol using BIS feedback and infusion of mivacurium using electromyography (EMG) feedback, based on an abstract presented in 2006.[55]

The two control systems work independently and are based on different control strategies.

The Rostock group used a conventional adaptive generalized predictive controller (aGPC) for control of neuromuscular blockade. An initial bolus is given and the individual reaction to it is used to drive an upstream on-off controller (see also Chapter 53).

For hypnotic closed-loop control, they used an unusual fuzzy proportional, differential plus integral controller. Proportional means the actual difference between the measured BIS value and the target value; differential means the speed of the change between measured BIS and target BIS; and integral is related to the duration of the difference between measured and target BIS. PID controlling is the basis of most closed-loop systems. The Rostock group linked the PID controller with an attempt to categorize the degree of the difference between measured and target BIS, from high negative to high positive—meaning a big negative difference from measured to target BIS (too profound hypnosis, e.g., −40) to a big positive difference (too light anesthesia, e.g., +40) with fuzzy gradual changes possible. The detailed description of the fuzzy PID controller was published in 2003.[56]

In an initial clinical feasibility study in 20 patients (ASA physical status I and II) undergoing orthopedic or general surgeries, hypnosis was induced manually, after

which propofol was administered in closed-loop fashion via BIS (target = 40) feedback for an average of 95 minutes. Analgesia was manually provided using 0.2 to 0.4 μg/kg/minute of remifentanil, a rather significant dose. The clinical controller performance is not published, but the Varvel parameter values are within the range of other closed-loop studies. The study unfortunately lacks a control group and is of small size.

In 2011, the same group published a feasibility study in 20 patients (17 ASA physical status I and II, 3 physical ASA III) undergoing a variety of minor to major surgeries of a mean 2 hours. After a manual induction of anesthesia, a closed-loop control of propofol (feedback: BIS = 40) and mivacurium (feedback: EMG, T1/T0 = 10%, first dorsal interosseus muscle) was initiated. The controller performance of the propofol system was similar to others observed by other research groups, with BIS within 10% of target during 65% of the time; the controller performance of the mivacurium closed-loop system was equally good with 87% of the time within 10% of the target value. Unfortunately, the complete profile of clinical performance is not presented, especially the percentage of time of BIS greater than 60 or BIS less than 35 is not described. In addition, there is no control group. Whether a complete neuromuscular blockade is advantageous for surgery, especially surgery of the extremity, is doubtful. It would be interesting to see the controller performance of the neuromuscular blockade control in areas of what was formerly referred to as a "surgical relaxation," in which possibly a simple upstream on/off controller will control limits. Historically, intense or deep neuromuscular blockade has been discouraged because of fear of prolonged or residual neuromuscular block. In the last 3 years, extending deep neuromuscular blockade to the end of surgery may have had surgical benefits. Furthermore, such a block can be reversed with sugammadex (see also Chapters 34 and 35). Inherent risks exist for postoperative residual paralysis as well as masking of intraoperative awareness, a somehow limited risk with continuous BIS monitoring (see also Chapter 50).

Summary of the Rostock Experience

The efforts of the research group in Rostock are summarized here:

1. This system seems to be stable, promising control system for propofol and mivacurium, BIS, and EMG feedback control system with both arms acting independently but with as good a performance as other closed-loop systems in the literature.
2. So far, they have published only small series of patients (two studies of 20 patients each), the vast majority ASA physical status I and II patients. The system needs to be tested in sicker patients and larger patient populations.
3. So far, their development is in the feasibility stage, with no study published yet with control groups of manual control.
4. Judging from the early results, adding fuzzy logic to a more conventional PID controller does not seem to improve the controller performance significantly.
5. Their system for induction of anesthesia has not been described.

THE WORK OF THE ITAG RESEARCH GROUP

The Intelligent Techniques in Anesthesia (ITAG) research group's focus is on the importance of robot communication with the user.

The first study was published in 2009 and compared four different interfaces, from simple numerical and graphical, to mixed numerical-graphical, and a two-dimensional interface, using the variables of reaction times, response accuracy, and workload in anesthesia care providers.[57] The choice of interface can reduce the workload significantly; in that study setup, the mixed numerical-graphical interface showed the least workload (Fig. 86-11).

The same research group used the results of that study in subsequent designs of closed-loop studies. They incorporated user interfaces that allowed better communications between potential users, either for purely monitoring purposes or manual intervention, and the closed-loop system.[31]

The presented closed-loop propofol system was a self-adaptive system that showed similar performance values (both clinical and as controller performance), as work presented by other research groups. In a randomized controlled trial, 40 patients undergoing surgery of an average 2 hours were randomly located to either closed-loop propofol administration or manual propofol administration to maintain a BIS of 45.

As mentioned before, the system uses a unique user interface to display the closed-loop control, trying to give as much information as possible to the user, including a color-coded BIS display, with yellow to red indicating areas of particular concern of awareness or risk for arousal.

The system has a variety of user interaction opportunities that allow the user to define a distinctive individual profile of propofol control. These include the setting of minimal and maximal propofol infusion rates, the time intervals to calculate the new infusion rate (e.g., 30 seconds), the time interval to calculate an offset trend to be used for self-adaption, and the speed of application and dose of a rescue bolus, which is the equivalent of the fast-forward mechanism Liu and his research group used to counterattack areas in which the BIS value reached 60 when there is a risk for arousal.

The system measures clinical performance (i.e., maintenance of BIS within 10% of target and avoidance of larger offset from the BIS target), median performance error, median absolute performance error, wobble and the global performance index, a composite parameter, similar to Liu's global score in that the higher it is, the better is the performance. In contrast to Liu's global score, it looks specifically at the percentage of excellent and poor control. A high value of global performance index (GPI) is characterized by a high percentage of BIS within ± 10% of the target and low MDAPE, wobble, and percentage of inadequate control. In this study, the GPI for closed-loop control versus manual control was 155 versus 40, respectively.

The same research group designed a closed-loop system for remifentanil administration and then used

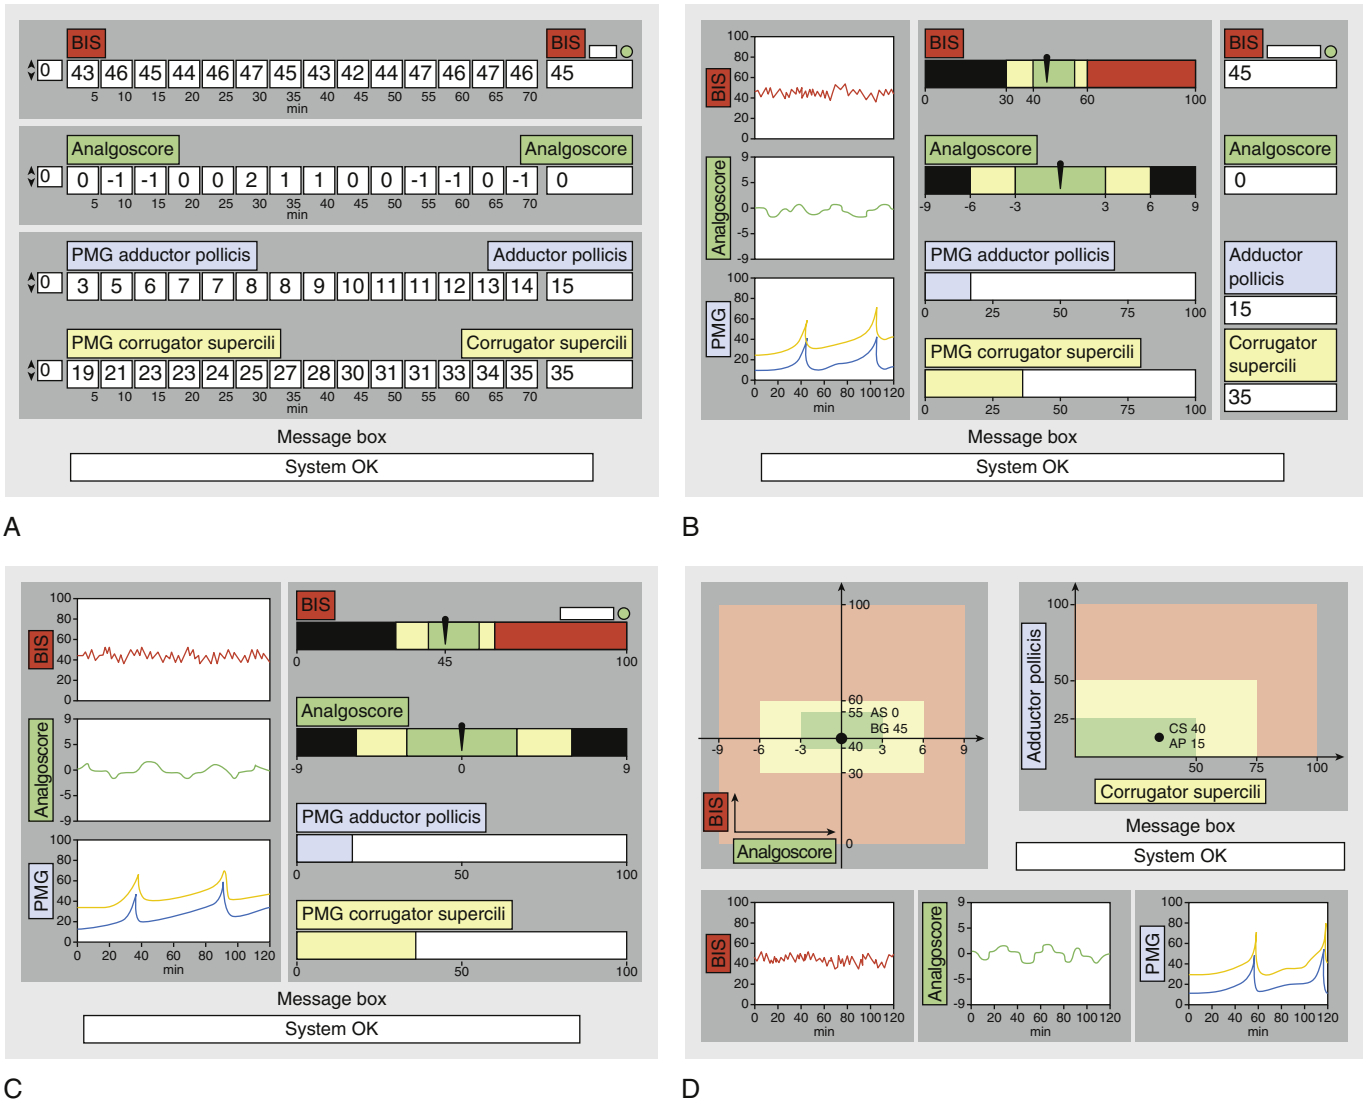

Figure 86-11. A, The numerical display shows trends value every 5 minutes and real-time value for the bispectral index *(BIS),* Analgoscore and phonomyographic *(PMG)* scores at the muscles of the thumb and the eyebrow. **B,** The mixed numerical-graphical display presents graphical trends on the *left,* separated graphical elements at the center, and numerical values on the right. **C,** The graphical display gives rudimentary numerical indications on the graphical elements. **D,** The advanced-graphical display shows two bidimensional scales; one for the BIS (y-axis) and Analgoscore (x-axis), the other for both phonomyographic muscle sites. The *black dot* indicates the real-time value.

the design and control elements to design a pharmacologic robot nicknamed McSleepy. McSleepy has several unique features: it delivers induction and maintenance of anesthesia, hypnosis, analgesia, and muscle relaxation; autonomously it has the capability of live video feeding and telemedical capabilities; it communicates via voice commands with the user, telling him or her to perform certain manual gestures, and it guides during the emergence process; it also has a variety of manual user input possibilities and an intuitive touch screen interface.

It transforms a standard closed-loop system into more of a complete pharmacologic robot.

The features of McSleepy can be summarized as follows:

- Fully automatic or semiautomatic mode (e.g., closed-loop hypnosis control, combined with manual analgesia control)
- Three closed loop controllers for induction and maintenance
  - Self-adaptive PID for hypnosis using BIS or any other depth of consciousness monitoring parameter as feedback
  - Self-adaptive PID for analgesia using the Analgoscore as feedback parameter
  - On/off controller for neuromuscular block using any available neuromuscular blocking device
- Large touch screen interface as communication platform with user
- Four different screens: Setup screen, induction screen, maintenance screen, and emergence screens with automatic change in-between
- Communication with user: Output by voice commands; input at different stages of surgery
- Telemedical capability: Connection via Bluetooth or internet with any wireless device

- Live video feeds
- Recording and monitoring of data
- The concept of McSleepy is based on the experience that anesthesia providers do not like to lose control of what is happening to their patient. Therefore, the anesthesia provider puts in patient data, such as weight, height, ASA physical status classification, and information as to which surgery will be performed, which drugs will be used or whether additional analgesic control is performed. In addition, the user chooses between fully automatic mode, in which all three components of general anesthesia are provided autonomously by the device, or semiautomatic mode, in which only one or more components are controlled autonomously. Therefore, the user or anesthesia provider via the touch screen can use McSleepy to administer anesthesia completely manually, semiautonomously, or fully automatic.

In fully automatic mode, the device allows focus on the patient, including manual ventilation. McSleepy directs and guides the user or anesthesia provider with voice commands. It uses BIS values to advise the user when to commence ventilation via a facemask and uses parameters from the induction screen that provides information on the depth of consciousness, remifentanil dose, and neuromuscular blockade to advise on the right time to intubate the trachea, thus decreasing the workload of the anesthesiologist during induction of anesthesia and allowing focus on other clinical tasks. The targets of BIS, Analgoscore and neuromuscular blockade are automatically chosen in fully automatic mode, but can be manually modified at any time. The user needs to indicate to the device definite steps of surgery, such as intubation, positioning, disinfection, incision, and 20 minutes to the end, which are also used as variables to modify control of drug dosing.

McSleepy uses a moving average infusion rate of a definite time interval before the arrival of the artifact and not just the last infusion rate. The device will not administer a neuromuscular blocking drug if the BIS value is more than 60—that is, to avoid patient awareness while being partially or fully paralyzed. Another built-in safety measure is an automatic delay of 60 seconds between reaching the BIS target for induction and beginning administration of the neuromuscular blocking drug: this gives the anesthesiologist time to push the "cannot ventilate" button on the induction screen to stop the administration of the neuromuscular blocking drug. Once the button "20 minutes to the end" is pushed during surgery, no neuromuscular blocking drug is administered. Manual override is questioned by the device with a reminder that it is 20 minutes to the end of surgery and whether the user wants to proceed. Once the surgery is finished, communicated to the device by the user with a push button, the emergence screen appears and guides the user through the emergence process. This process displays cumulative data of all drugs administered, trends of all parameters, and the present BIS values in reverse color coding, indicating BIS values greater than 60 in a green area. When a definite BIS value of approximately 65 is reached, a voice command indicates to the user that it is time to wake up the patient. The basis for this design is to allow the user to focus visually on the patient or on hemodynamic, respiratory values while voice commands keep the user informed about aspects of anesthesia.[58]

McSleepy was tested in a randomized control trial of 186 patients undergoing elective surgery, mostly major surgery, of an average duration of 3 hours.[59] As other research groups have shown, clinical performance was significantly better in the closed-loop group for control of hypnosis, including avoidance of undershooting and overshooting, whereas the control of remifentanil was equally accurate in the manual and closed-loop groups, as demonstrated by the comparison of the Analgoscore in the two equally sized groups.

A 5-minute significantly quicker emergence occurred in the McSleepy group; however, the clinical relevance after 3 hours of surgery might be limited. The fact that the closed-loop administration avoids significant periods of BIS undershoot (BIS > 60), with the inherent risk for awareness, is clinically more important.

Figure 86-12 is an illustration of the control mechanisms in McSleepy.

The same group also developed a closed-loop system, which integrates a decision support system into a closed-loop propofol sedation system called a hybrid sedation system. The decision support side of the system has been previously described (see section on decision support systems).

The closed-loop system for propofol sedation integrates BIS monitoring, peripheral O_2 saturation, and respiratory rate as sensors into a closed-loop system, using PID controllers. The controller uses an individualized dosing scheme, which is established after an initial bolus is given to the patient and the reaction of the patient is analyzed, thus creating an individualized PID controller (Fig. 86-13).

Summary of the ITAG RESEARCH GROUP WORK

The efforts of the ITAG research group are summarized as follows:

1. The focus of the ITAG group is on the development of an integral pharmacologic robot that can interact with the user. The control mechanisms are of interest, not because they use very different basic controllers—in fact, they use PID and on-off controllers—but because they use surgical time points as control mechanisms, such as positioning, incision, or type of surgery, which can be integrated in the control mechanism.
2. McSleepy offers both fully autonomous and semiautomatic control, thus allowing use in fully manual mode, semiautomatic mode (some anesthesia components are controlled automatically), or fully automatic mode.
3. McSleepy communicates with the user with voice commands, allowing the anesthesiologist to focus on the patient.
4. It incorporates closed-loop safety features such as artifact control, and, in addition, safety features resembling

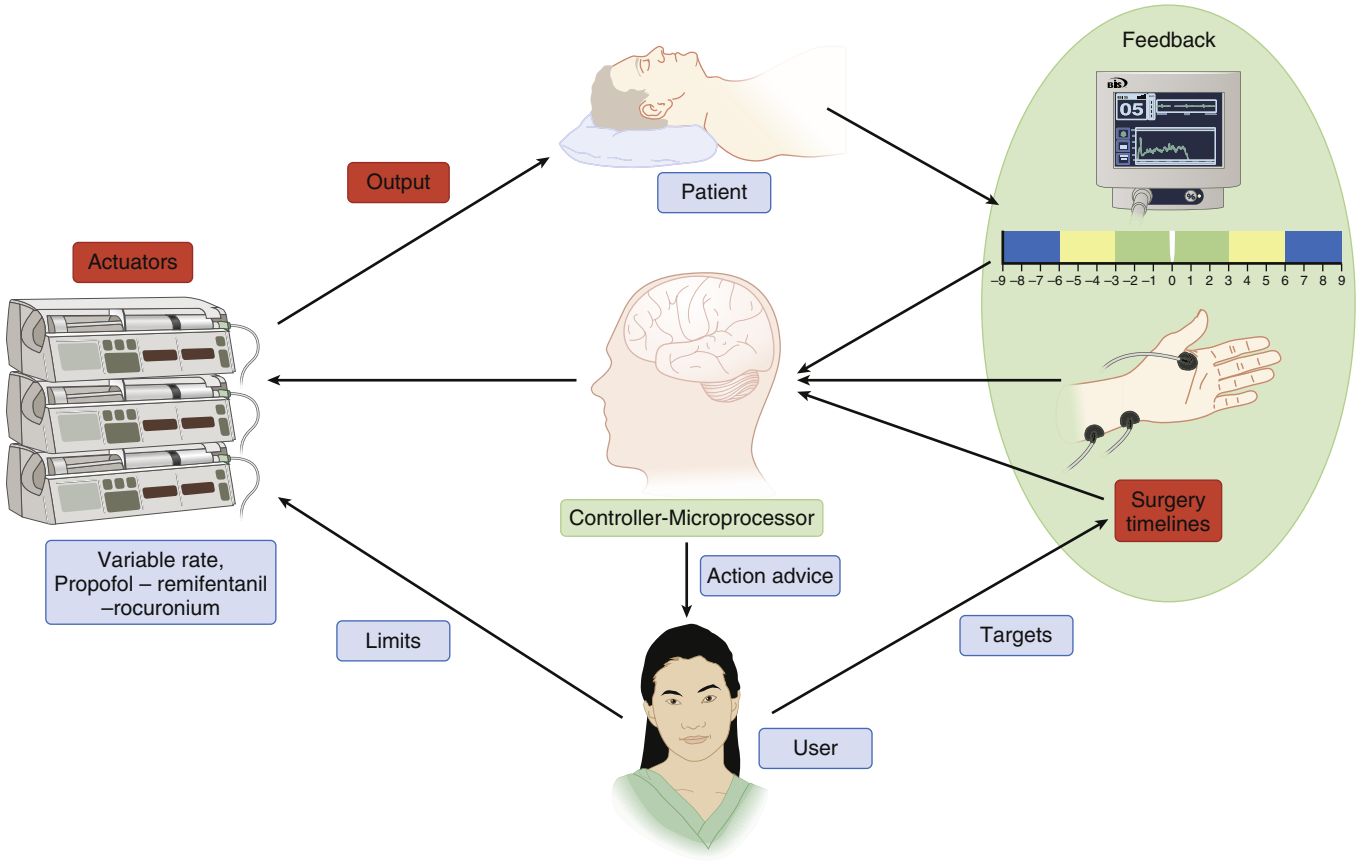

Figure 86-12. Control mechanisms of McSleepy.

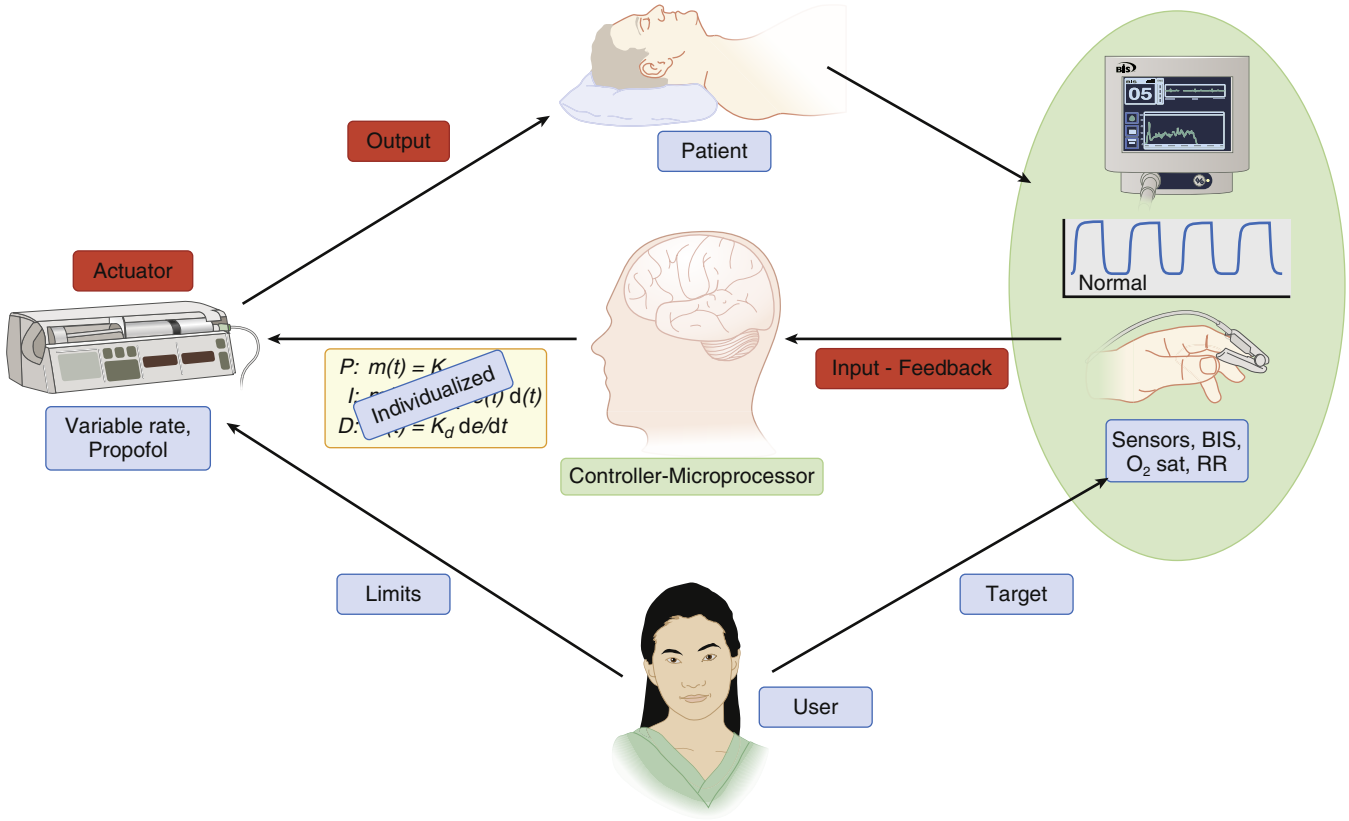

Figure 86-13. Control mechanism of hybrid sedation system. *BIS,* Bispectral index; *O_2 sat,* oxygen saturation; RR, respiratory rate.

common everyday practices, such as the confirmation that facemask ventilation is possible *before* administration of a neuromuscular blocking drug.

5. McSleepy also incorporates telemedical capabilities and video feeds.

CLOSED-LOOP CONTROL SYSTEMS FOR NEUROMUSCULAR BLOCKADE

Closed-loop control systems were designed in the 1980s and primarily used neuromuscular blockade results from electromyography as the feedback method because the device was easy to connect to any closed-loop circuit via an RS232 interface (see also Chapter 53). Interest in these early systems was not so much based on their clinical application, but as a research tool to evaluate the interaction between drugs, specifically the potentiation of neuromuscular blocking drugs by volatile anesthetics. The controllers[97-107] ranged from simple on/off controllers, over classical PID controllers to adaptive model-based controllers; one study group even used a highly complex neural network controller, called a dynamic matrix controller[60] and one a fuzzy-logic controller.[61]

All closed-loop systems started with a manually administered large single bolus of neuromuscular blocking drug to achieve or surpass the desired and mostly profound level of neuromuscular blockade, after which the neuromuscular blockade response was allowed to recover spontaneously, while the closed-loop system started the maintenance of a continuous infusion of a given neuromuscular blocking drug, mostly using the individually calculated reaction of a patient to the bolus dose, thus creating an individualized control mechanism, irrespective of the controller used.

Despite a summary table showing no specific superiority for any type of controlling theorem, the adaptive model-based controller[62] and the dynamic matrix controller are reviewed in this chapter.

The adaptive model-based controller first assumes that a certain model reflects accurately the pharmacokinetic-dynamic relationship of a given drug; Olkkola and associates[62] used a two-compartment model (biophase-effect compartment and central-blood compartment). After a bolus application of the neuromuscular blocking drug, a certain concentration in the biophase is achieved that can be described using a mathematic formula:

$$C_e(t) = \int_0^t dt' \, G(t - t')I(t')$$

This formula describes the relationship between drug input function I (t) and drug concentration in effect compartment $c_e(t)$

And

A second formula describes the relation between concentration $c_e(t)$ and effect E(t):

$$E(t) = \frac{E_{max}[C_e(t)]^{\gamma}}{C_0^{\gamma} + [C_e(t)]^{\gamma}}$$

Certain parameters of these formulas are updated throughout the process of continuous neuromuscular blocking drug administration, thus creating a model-based, adaptive controller. Obviously, the specific parameters of these formulas need to be adjusted for each neuromuscular blocking drug or any other drug, because their uptake and elimination from central compartment to effect-site compartment differs.

Geldner and associates[60] chose a different path; they first performed many cases of general anesthesia with manually guided neuromuscular blockade to establish a neural framework, which was subsequently tested in a validation period. A neural network tries to "act" like a human brain, thereby adapting its action to previous experiences, learning from wrong-right decision making. Using a "dynamic controller," the system is assumed to be able to learn from its right or wrong decisions.[63]

As a basis, the system takes into account, at any given time, the last 20 twitch tension values, calculates a predicted twitch tension response, based on four different infusion rates, and adjusts the actual infusion rate according to the closest match between predicted twitch tension response and target twitch tension response (Fig. 86-14).

The theoretical basis for both model-driven, adaptive as well as neural network–based controllers, is interesting, but no apparent advantage has been found in terms of controller performance of any controller theorem, from very simple on/off controllers to highly complex neural networks, as Table 86-5 shows.

The most important clinical relevance of closed-loop systems for neuromuscular blockade is not so much in their clinical application—that is, the necessity for continuous, steady, or profound neuromuscular blockade is controversial at best, but in their utility for (objective) evaluation of drug interactions, especially the interaction with volatile anesthetics.[64-69]

CLOSED-LOOP CONTROL OF VOLATILE ANESTHETICS

Target-Controlled Infusion of Volatile Anesthetics: The ZEUS Device

It is important to understand that what is called "closed-loop control of volatile anesthetics" is mostly related to the maintenance of a steady end-tidal concentration of volatile anesthetics or oxygen, as is commercially available in the ZEUS Draeger anesthesia machine. Although there is a closed-loop system that continuously measures the end-tidal concentration and regulates the end-tidal concentration to a steady level, irrespective of flow rate, it lacks integrated patient feedback monitoring. Therefore, it is not an automated patient anesthesia delivery system in the sense that the patient's biofeedback is used to guide hypnosis.

The functioning of the system is described as such: "The inspired and expired concentrations are measured by sidestream infrared technology and paramagnetic O_2 sensors. The sample gas flow is fed back to the system, so that the system is completely "closed." In addition, the fresh gas mixture is servocontrolled to keep the inspired O_2 concentration at the targeted level and to maintain a constant ambient pressure at the end of expiration in the

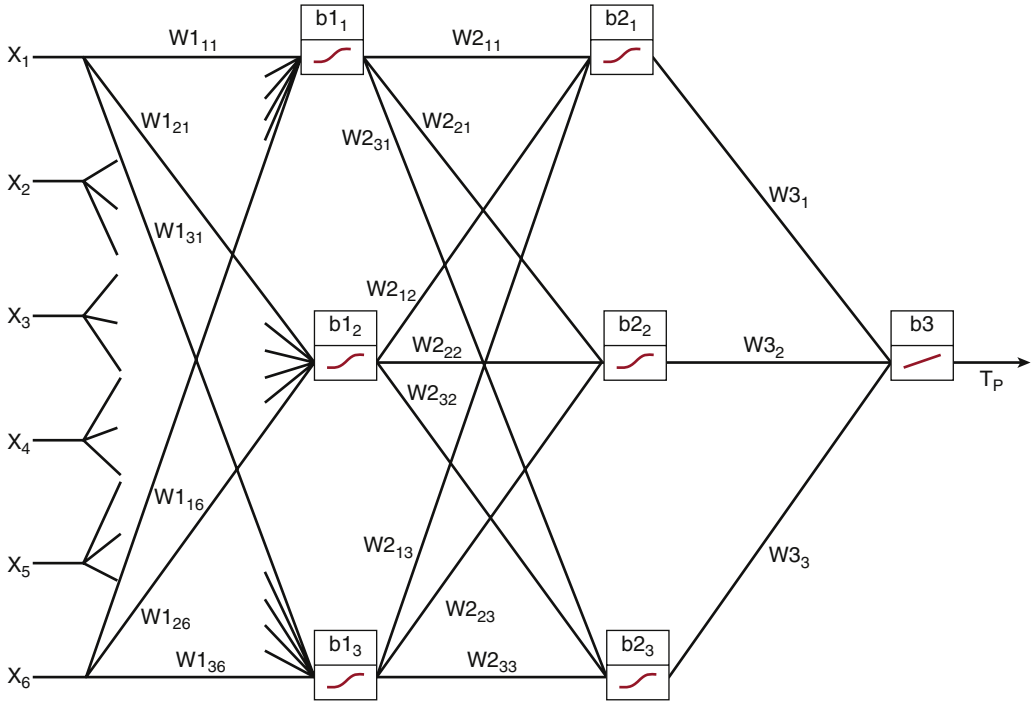

Figure 86-14. Four-level perceptron with activation/regulation knots ("neurones" *b1-b3*), regulation paths (paths *W1-W3*), and last 20 twitch values (x_1-x_{20}), as well as the predicted twitch response T1-Wert (T_p).

manual breathing bag. If this pressure declines, fresh gas flow is automatically increased in response; conversely if the pressure rises, fresh gas flow is reduced."[70]

Undeniably, these systems can have some clinical advantages, such less overshoot and undershoot when end-tidal concentrations need to be changed,[71] lower costs,[72] and a reduction in the workload for the anesthesiologist.[70]

However, they do not adjust the concentration of the end-tidal concentrations of volatile anesthetics according to the measured depth of consciousness or any other patient parameter.

CLOSED-LOOP SYSTEMS FOR VOLATILE ANESTHETICS

Few published studies describe the design and clinical testing of truly closed-loop volatile anesthesia delivery systems that use depth of consciousness monitoring as a

feedback parameter. One such system by the Puri research group[46] has already been described.

Another system was presented by the Bern research group of Zbinden and A. Gentilini.[71-73] The system is similar to Puri's and uses isoflurane, now a rarely used volatile anesthetic. The controlling system integrates an outer cascade, feeding back the end-tidal concentration to the system via a simple proportional-integral controller, and an inner controller that incorporates feedback from the BIS into model-based algorithms to maintain a given level of hypnosis.

The safety switch is an electrical push button to switch the gas supply back to the standard dosing system.[74]

The controller samples the BIS every 5 seconds and adjusts the doses accordingly. The Bern group used a model-derived external controller similar to the control models used for intravenous anesthetic drugs.

The system has safety algorithms built in that are plausibility measures. For example, the inner controller recognizes only "true" isoflurane concentration values between 0 and 5 vol%, and all other measured values are disregarded as artifacts, as well as artifact safety measures when the BIS values are prone to electric or other disturbances. In this event, the system switches to a purely model-based administration of isoflurane, set by the anesthesiologist before the procedure. It also incorporates some adaptive-control mechanisms with the hemodynamic and BIS reaction to the skin incision used to adjust the control algorithms individually. In a randomized control trial (patients undergoing major surgery, ASA physical class I through III, N = 10 each group), closed-loop, BIS feedback administration of isoflurane was compared with manual, BIS-guided isoflurane administration with a target BIS of 50 for a mean duration of approximately 2 hours. Analgesia was maintained manually in all patients to sustain blood pressure and heart rate within 20% of the preoperative values. Unfortunately, the clinical performance of the two groups, meaning the percent of time in which the measured BIS value was within 10% of the target value, is not presented; however, the Varvel values favor closed-loop control. An assessment of how clinically important this difference is cannot be made without the presentation of the clinical performance. In addition, the amount of isoflurane concentration changes over time is not presented, which limits the evaluation of the performance of the manual group. If almost no changes in concentration levels were performed in the manual group, this could affect the reproducibility of the results. Significantly fewer episodes were found of BIS values greater than 65 for more than 3 minutes in the closed-loop group than in the manual group, which could mean better outcome by lowering the risk for awareness during surgery.

One issue is the significantly higher alfentanil concentration in the manual group; however, it is possible that this might not have affected the performance results of the study.

CLOSED-LOOP CONTROL OF ANALGESIA

Although adequate monitoring parameters for hypnosis and neuromuscular blockade are available, no such monitoring parameter is available for assessing pain during unconsciousness. However, there is clinical consensus that hemodynamic changes can be used as an indirect parameter to assess pain or nociception. Most anesthesiologists use vital signs as parameters, such as arterial blood pressure and heart rate, in a variable.

The first attempt to use hemodynamic variables clinically was published in 2000.[75] Arterial blood pressure was rated as having a 5/6 importance for pain control, with heart rate as 1/6. A fuzzy-logic controller was used to direct a continuous infusion of alfentanil. Using this controller in eight patients, the mean arterial pressure stayed within 15% of the target in almost 90% of the time; no results for heart rate stability were given. A research group around Gentilini[76-79] in Bern tested a model-based predictive controller for target-controlled alfentanil in 13 healthy patients undergoing minor surgery. The controller only used mean arterial blood pressure.

The model predictive controller with mean arterial pressure as the primary and predicted plasma alfentanil concentration (Pred Cp) as a secondary input variable is depicted (PK = pharmacokinetic).

This feasibility study did not have a control group. The mean absolute deviations from the target mean arterial blood pressure of 70 to 90 mm Hg (individually chosen by the attending anesthesiologist) was 11 mm Hg during surgery, which is equal to a mean offset of approximately 15%. The study does not present how often the alfentanil concentration was changed during surgery.

None of these closed-loop studies compared the controller performance with a control group, which limits the assessment of performance.

One study presented some novelties: the presentation of a new composite pain score, a closed-loop control algorithm, the closed-loop control of remifentanil, and a focus on the user interface; probably one of the first closed-loop studies that took into account the importance of the user interface.[80]

Because all previous closed-loop studies had used hemodynamic parameters as surrogate targets for intraoperative pain perception and nociception, the latter study composed a novel score, called Analgoscore. Analgoscore uses mean arterial blood pressure and heart rate as the basis for a score that ranges from −9 (too profound analgesia) to +9 (insufficient analgesia), with a target of 0 as a perfect balance between analgesic treatment and pain. The score also takes into account other physiologic changes that can influence the antinociception validity of these hemodynamic parameters, such as hypovolemia and vagal reactions. The control mechanism is an adaptive PID controller, which analyzes past offset in integral time intervals and adjusts the infusion rate accordingly.

In a comparative trial, the Analgoscore was used to titrate remifentanil infusion in 27 patients undergoing surgery of almost 2 hours duration. In one group of 16 patients, remifentanil was administered using the closed-loop system. In the control group of 11 patients, anesthesiologists were advised to use the Analgoscore as guidance for remifentanil infusion rate settings with the goal to maintain a value of 0 as much as possible.

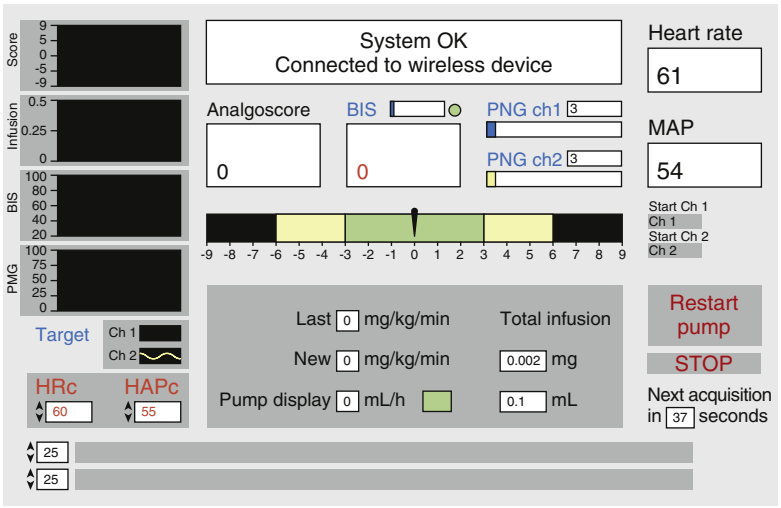

Figure 86-15. User interface. Different areas define different zones of pain control. The range of the Analgoscore is defined from –9 (too profound analgesia) to 9 (insufficient analgesia) in increments of 1. Three control areas were defined, with –3 to +3 representing excellent pain control, –3 to –6 and 3 to 6 good pain control, and –6 to –9 and 6 to 9 inadequate pain control. These areas are color-coded. In addition, a numeric display shows the exact Analgoscore value. Other parameters are displayed: last, new infusion rate of remifentanil in μg/kg/minute and in mL/hr (pump display). The target values for mean arterial pressure (*MAPc*) and heart rate (*HRc*) are displayed, as are the actual heart rate and mean arterial blood pressure every minute. On the *left* side of the interface, trends for Analgoscore, infusion rate, bispectral index (*BIS*), and phonomyography (*PMG*) as an example of parameters reflecting either depth of anesthesia or neuromuscular blockade.

There was a tendency toward more excellent analgesia control (Analgoscore between +3 and –3) in the closed-loop group at 84% of the time versus 70% in the control group. Because the control group used the Analgoscore for pain guidance, specific attention was paid to design a user interface that made this task as easy as possible. The user interface is color-coded, with green indicating the target Analgoscore area, and shows the target and measured values for heart rate and mean arterial pressure, trends, and the last and new infusion rates (Fig. 86-15).

REGULATORY ISSUES: WHY ARE CLOSED-LOOP SYSTEMS NOT YET COMMERCIALLY AVAILABLE?

Based on the presented research, the following assessments of closed-loop systems in comparison to manual anesthesia can be made:

- Better maintenance of a given target
- Less overshooting and undershooting of target
- Quicker reaction to potentially adverse effects, such as BIS values above 60
- Better hemodynamic control
- Tendency toward faster recovery and lower consumption of drugs

In 2008, Manberg and associates[81] described the key product development issues that needed to be addressed with closed-loop systems. It was recently modified according to the recently published literature and to take into account uses of the system for other than for hypnosis.

Selection of all major subcomponents is as follows:

- Drug used (propofol, volatile anesthetic, opioid, neuromuscular blocking drug)
- Infusion pump (peristaltic, piston, syringe, variable rate, target-controlled–based)
- Physiologic control variable (composite score for pain during unconsciousness, electrocardiogram-derivative parameter, neuromuscular blockade monitoring method)
- Monitoring device (stand-alone or integrated)
- Target levels (specific target, range of target, variable, or fixed)
- Controller algorithms (classic on/off PID; model-based; or fuzzy-logic, neural networks; self-adaptive, Bayes principle)
- Single, dual, or triple systems (related to components of general anesthesia, closed-loop controlled)

Assessment and mitigation of all hazards associated with each component, separately and after integration into the system, is a follows:

- Are all risks and performance characteristics known?
  - Were all software and hardware components developed using an effective design control process?
  - Were appropriate software performance models used for testing the potential impact of extreme conditions?
  - Have all international regulatory standards been followed?
  - Have the patient populations and intentions been identified?
    - General anesthesia or sedation?
    - Operating room, intensive care unit, or procedural setting?
    - Elective surgery, ambulatory surgery, intensive care unit analgosedation, procedure suites?

Design and execution of successful clinical trials with meaningful outcome benefit is as follows:

- Selection of primary end point
- A priori identification of clinically relevant degree of improvement of outcome
- Comparison to:
  - Open-loop?
  - Defined treatment algorithm?
  - Standard clinical practice?

It is also evident that decision support systems, which are understudied in anesthesia research, can be a bridge between purely manual anesthesia delivery and robotic anesthesia. The transition from textbook knowledge to decision support systems resembles the step from a typewriter to a computer. Extensive research should be focused in this area in the near future.

TELE-ANESTHESIA

Since late 2000, telemedicine has been a major initiative of the European Union and the World Health Organization (WHO). It is defined as the remote application of medicine and is intended to improve access to high-quality health care in areas where there is a scarcity of such health care facilities. Despite these important initiatives, telemedical applications in anesthesia, called "tele-anesthesia," has been very limited. In theory, tele-anesthesia can be applied to preoperative remote assessment as well as remotely controlled anesthesia delivery.

REMOTE PREOPERATIVE ASSESSMENT

In a pilot study, Wong and associates[82] provided remote clinical consultations in rural areas of central and Northern Ontario, Canada. An anesthesiologist (consultant site) and a nurse (remote site) worked together via an Internet-based portable videocommunication device. With these technologic tools, the anesthesiologist could retrieve the patient's history; do a physical examination, albeit limited to the use of an electronic, digitalized auscultation and visual examination; and assess the airway with a specific airway camera. Unfortunately, this pilot study focused only on the feasibility and degree of satisfaction with the procedure from the patients' and anesthesiologists' perspective, but not on a scientific comparison between remote and local patient preoperative assessment. The validity of the airway assessments obtained using the analogue airway camera is not clear. Several such portable videocommunication units, called remote presence devices, are commercially available and extensively used in surgical rounds across the United States. Remote presence devices can be helpful for consultations in anesthesia, but the validity of these remote consultations in difficult patients needs to be scientifically examined before their widespread use in anesthesia. The early results of use in other fields of medicine is encouraging. The remote presence device is used with a nonexpert local user to perform expert actions, such as remote point-of-care neuromodulation in neurosurgery[83] or assist surgical rounds in surgical intensive care units.[84]

The use of such devices also could be envisioned for preoperative or postoperative rounds in anesthesia patients.

A personal computer–based system with standard audio-video connections via Skype was used to assess patient history and perform an airway assessment autonomously by using the built-in cameras of a modern computer.[85] This system enabled communicating with a patient at home before surgery, establishing the history and airway assessment, without the necessity for the patient to go to a hospital or without necessity of any additional manpower, such as a nurse. Because history taking and airway assessment are the most important features of a preoperative anesthesia assessment, such a system could avoid unnecessary traveling for a majority of patients.

REMOTE LIVE AUDIO-VIDEO MONITORING AND CONSULTATION IN ANESTHESIA

The Internet has made it possible to have Internet-based audio-video communication for live monitoring and consultation. Several case reports have been published in which remote audio-video monitoring, including live patient vital-sign monitoring, were provided over a distance of continents. Remote live audio-video communications has been used to communicate and monitor difficult anesthetic management cases, such as pediatric liver transplantation[86]; more routine cases, such as the live recording of endotracheal intubation[87]; and for the management of difficult intubation.[88]

REMOTE-CONTROLLED ANESTHESIA DELIVERY

A pilot study used a dedicated fiberoptic Internet connection to investigate the feasibility of doing target-controlled propofol infusion via a closed-loop system with EEG feedback. The 11 patients in the study were undergoing general anesthesia in Munich from Erlangen in Germany, a distance of 200 kilometers.[89] The study was successful; however, at one point the Internet connection broke down and one patient was continued with a local propofol infusion. Closed-loop control was performed during 65% of the time and induction was performed manually, with only propofol controlled remotely and by closed-loop. However, the performance of the closed-loop system was unaffected by remote control; the performance was based on the control algorithms and biofeedback system used.

In 2010, the first transcontinental robotic anesthesia was performed between Montreal (remote site) and Pisa (local) site, with all three components of general anesthesia, hypnosis, analgesia, and muscle relaxation controlled remotely via three closed-loop systems, as well as anesthesia from induction to emergence. The endotracheal intubation was monitored live from the remote center and guidance given if necessary; preoperative assessment of the patients was equally performed remotely and locally and

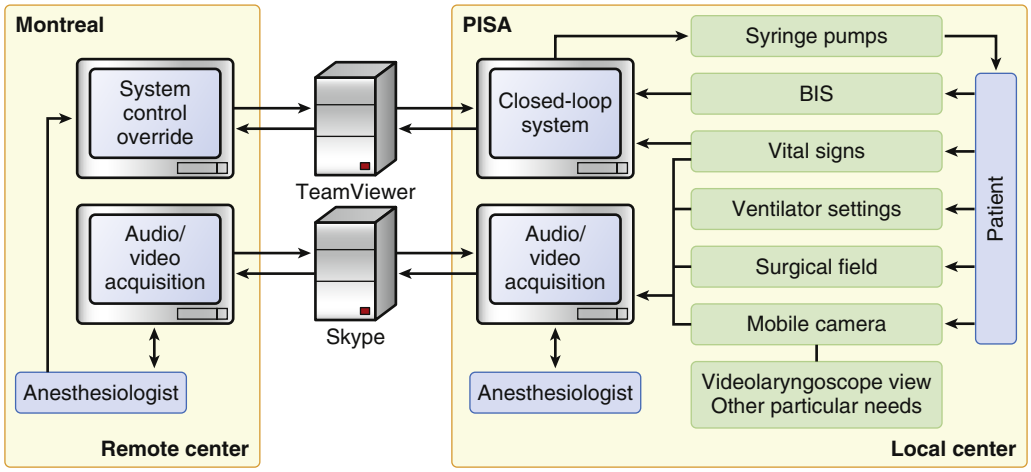

Figure 86-16. Illustration of transcontinental anesthesia setup. *BIS,* Bispectral index.

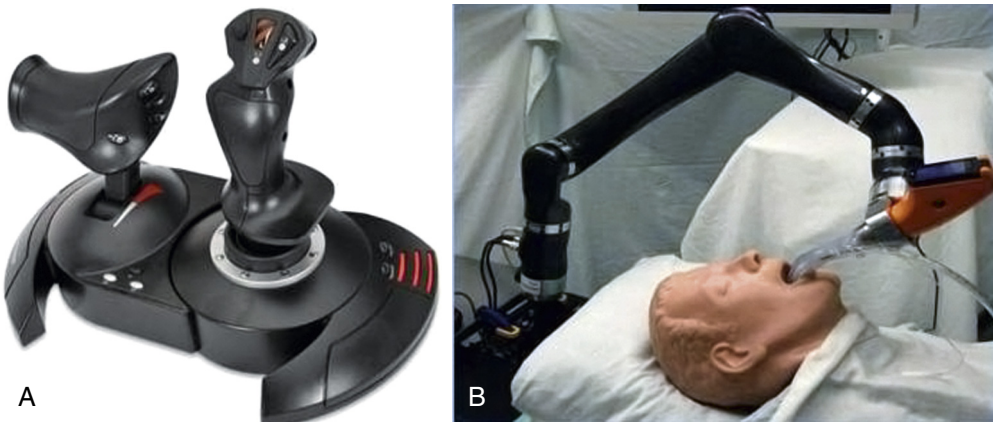

Figure 86-17. The Kepler Intubation system. **A,** Standard game joystick with two handles. **B,** Kepler system consisting of robotic arm, videolaryngoscope in use in airway mannequin.

compared; and four additional cameras allowed remote monitoring: one camera was installed on the head of the local anesthesiologist, a second camera gave a live feed from the ventilator setting and monitoring variables, a third camera gave a live feed from the vital signs monitor, and the fourth camera gave a live feed from the surgical site.[90] Twenty patients were enrolled in this pilot study. Robotic remotely controlled anesthesia was successful in all patients, with no manual or local override necessary. The preoperative assessment of the patient history showed very good agreement between local and remote sites; only the assessment of the Mallampati classification was limited by the quality of the video camera angle (Fig. 86-16).

The latter study shows what is feasible in operating rooms worldwide using current technology, and the high quality of standard, nondedicated Internet connections that allow remote assistance with such anesthetic procedures as:

- Remotely guided videolaryngoscopic intubation
- Remote control of induction, maintenance, and emergence from anesthesia by pharmacologic robots
- Live feeds from key interest areas during surgery: vital sign monitor, ventilator, surgical site, and general overview
- Remote preoperative assessment

MANUAL ROBOTS

ROBOT-ASSISTED INTUBATION OF THE TRACHEA

The work of the anesthesiologist consists of administration of anesthetic drugs, as well as manual gestures from insertion of intravenous cannulas to endotracheal intubation. In the anesthetic sense, a manual robot is the equivalent of a surgical robot, which is an extension of a surgeon's arms and hands but with improved precision and less tremor. Tighe and associates[91] used a DaVinci surgical robot to assist endotracheal intubation in an airway mannequin. One of the DaVinci's robotic arms was equipped with a camera and placed over the head of the mannequin; another arm used a small grasper; and a third arm had a large grasper that allowed hand and arm movements. The fourth arm manipulated the fiberoptic bronchoscope that was inserted nasally and orally. The DaVinci robotic system was not made for this kind of gesture, so the two simulated intubations proved rather difficult; using a $1.5 million robotic system to assist with intubations might be limited to scientific curiosity. The ITAG group from Montreal developed a novel robotic system specifically for endotracheal intubations, called Kepler Intubation system (Fig. 86-17).[92]

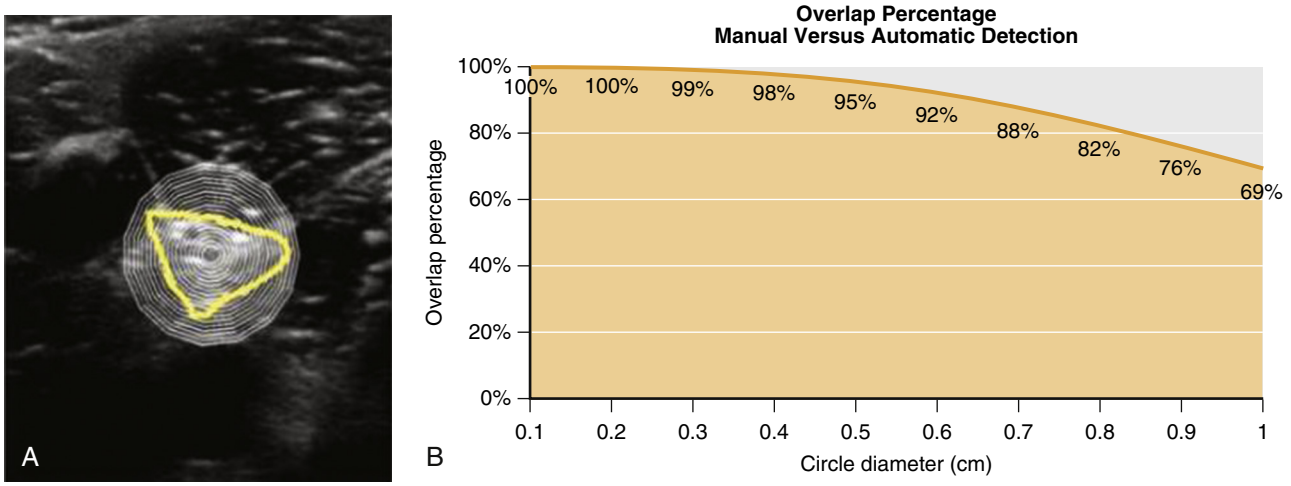

Figure 86-18. A, Automatic nerve detection area (*circle*), manual nerve detection of sciatic nerve in *yellow;* circle is drawn from manually (= automatically) detected nerve center. **B,** Percentage of overlap between automatic and manual detections (manual = *yellow*).

In the first simulation study, endotracheal intubations were successfully performed with direct and indirect views in 30 successful attempts, each showing a considerable learning curve. The system is manipulated using a standard two-part joystick, which is connected with a carbonfiber robotic arm that allows for 6 degrees of freedom and has a standard videolaryngoscope attached. Several live video feeds from inside and outside the throat aided in the alignment of the Kepler for intubation. The advantage of using the Kepler is that its operation is not affected by the user's physical attributes—tall or small, strong or weak users will be able to handle the system equally well. Furthermore, in a third series of 30 intubations, the scope was simply aligned at the top of the mouth and intubation performed automatically using prerecorded movements. The high reproducibility of the intubations was impressive, and these were always performed in exactly 40 seconds, proving the key characteristics of a robot—no fatigue and better reproducibility of the results than humans. The same group followed the simulation study with a trial in 12 patients that had a success rate of 91%; one intubation was not possible because of fogging of the videolaryngoscope and all intubations were performed within 2 to 3 minutes.[93]

It is too early to say where technology in terms of robotic intubations might lead. The question is whether the goal is to simply assist anesthesiologists in this task or replace them and have the whole procedure performed by the robot, autonomously.

MANUAL ROBOTS FOR REGIONAL ANESTHESIA

Regional anesthesia can be a complex procedure; modern regional anesthesia is based on the combined use of an ultrasound device with probe manipulation, synchronous visualization of the nerve on the screen, and a nerve block needle and catheter. In combination with attentiveness to sterile techniques, the medical provider's bimanual coordination might suffer during these manual gestures, as many residents or regional ultrasound novices have experienced. Often, while manipulating the ultrasound probe, the coordination of the needle movements can be difficult and cumbersome. In addition, the mere nerve recognition on the ultrasound screen necessitates thorough training, sometimes a fellowship. Commercially, help is limited but available as either echogenic needles or systems that try to improve the visualization of the needle on the ultrasound screen, such as the advanced needle visualization system (Sonosite, Bothell, WA), which enhances the visibility of the needle by using specific algorithms, and the more cumbersome SonixGPS technology, which shows the relative positions between the needle and the ultrasound image so the needle can be easily positioned in the region of interest. However, these systems simply help to visualize the needle within the ultrasound image. The ITAG group recently published a study in which a specific image recognition software actually identified the nerve autonomously. This software can be used by the anesthesiologist to recognize the nerve and guide a needle to it and can be used as a target area for a completely robotic nerve block.[94] Using proprietary image recognition software on 100 ultrasound images of the sciatic nerve in the popliteal fossa, they were able to detect the nerve center within the automatically defined nerve areal in 99% of the images and showed an overlap between manually defined nerve area and automatically detected nerve area between 100% (1 mm diameter around the nerve center) to 69% (1 cm diameter around the nerve center) (Fig. 86-18).

Developing software that detects nerves can be an important step leading to complete automatic nerve blocks.

Using robotic devices to assist manual gestures involved in regional anesthesia is another means of advancing robotic anesthesia. Tighe and associates[95] performed an ultrasound-guided nerve block and nerve catheter insertion in a regional nerve block mannequin; although the ultrasound probe was placed manually, the block was performed using the DaVinci system similar to their work in robotic intubation. Again, a considerable degree of difficulty was encountered (Fig. 86-19).

The ITAG group designed and developed the Magellan robotic nerve block system and tested it in 13 patients.[96]

Figure 86-19. Manipulation of nerve block needle using the DaVinci system on a regional block mannequin.

Figure 86-20. The Magellan regional block robot in action (*top*) and view from "cockpit" (*bottom*).

Sixteen sciatic nerve blocks were performed, with 100% success rate. The system uses a joystick and a robotic arm with 6 degrees of freedom, which has a standard syringe and needle attached to the end of it. The whole system is managed through a so-called cockpit, which integrates the ultrasound image and live feeds from external video cameras and allows the control of different arm speeds (low to high speed, which can be modified according to the user's preferences) (Fig. 86-20).

At the present stage, the whole system resembles the concept of surgical robots that allow fine-tuned precise handling of the instruments as extension of the user's arms and hands. Future development is envisioned to further automatize the whole process.

Chapter 87

Anesthesia for Robotically Conducted Surgery

SUMEET GOSWAMI • PRIYA A. KUMAR • BEREND METS

Acknowledgment: The editors and the publisher would like to thank Dr. Ervant Nishanian, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Robotic surgery has witnessed explosive growth in recent years. In 2011, 360,000 procedures were performed with the Da Vinci system.
- Robotic surgery is accomplished with an autonomous, reprogrammable manipulator designed to move and articulate specialized instruments through programmed motions that achieve a specific task. A robot can be given three-dimensional coordinates from any imaging device (e.g., computed tomography) that allows it to recognize surfaces on which it will perform a specific, programmed task.
- Robotically assisted surgery involves mechanical devices that move by a motorized system under partially programmed control and that can be instantly controlled or modified by a surgeon's intervention.
- Computer-assisted surgery involves systems that are manually controlled by the surgeon and that include a tracking system, sensors, and end-effector instruments. This system provides direct and continuous control of movements.
- *Telesurgery* refers to the ability to perform surgery using computer-assisted instruments from a remote location.
- *Telemanipulation* refers to the ability to produce electronically precise instrument movements from a remote location.
- *Telepresence* refers to the virtual projection of images from remote sites. Virtual projection allows the surgeon to visualize intended robotic movements at distant locations. It also enables telementoring, which is supervision and instruction from a remote location.
- Robotically assisted surgical thoracic procedures have increased the duration of required general anesthesia. Concomitantly, the duration of one-lung ventilation has been taken to new time extremes, which has given us insight into the respiratory physiology of prolonged one-lung ventilation. As surgeons gain expertise with robotically assisted surgery, operative times are expected to shorten dramatically to approach those for traditional open surgery.
- Because of the proximity of the side cart to the patient, the patient must be guarded against inadvertent contact from the motions of the robotic arms. Even more important, after the instruments are engaged to the arms of the robot and are inside the patient, the patient's body position cannot be modified unless the instruments are disengaged entirely and removed from the body cavity.

Robotic surgery is the resulting transformation of the minimally invasive surgical evolution. Robotic devices are being introduced to surgery because they allow unprecedented control and precision of surgical instruments in minimally invasive procedures. The anticipated benefits of robotic or robot-assisted surgery to the patient include less pain and trauma, shorter hospital stays, quicker recovery, and a better cosmetic result. With these technologic innovations, new anesthetic implications for patient care are being discovered. As surgery evolves into the robotic era, anesthesiologists should keep abreast of these changes and their effect on patient care and safety.

Surgical robots are being used in numerous operating rooms around the world. These are not true autonomous robots that perform surgical tasks; rather, they are mechanical "helping hands" that offer assistance in various fields of surgery. These machines still require human intervention to operate or to provide input instructions. Robotic devices are used to help surgeons, not to replace them.

HISTORY

The word *robot* was first used by Capek in his play *Rossum's Universal Robots* in 1921. It is derived from the Czech word *robota,* meaning "forced labor."[1] Robots were first developed by the National Aeronautics and Space Administration (NASA) for use in space exploration.[2] These devices, or telemanipulators, were capable of performing manual tasks aboard a spacecraft or out in space. The slave devices were controlled electronically from a remote master control on Earth or aboard a spacecraft. Telemanipulators were used extensively aboard NASA's space shuttle missions between 1983 and 1997. Research in trajectory and missile guidance systems eventually led to highly precise targeting mechanisms. Precision pointing at targets, such as the Earth and stars, was crucial for Spacelab telescope experiments. Telemanipulators such as the Instrument Pointing System were specifically designed for extreme accuracy (±1.2 arcsec). Scientists at NASA Ames Research Center were responsible for developing virtual reality. The idea took root with contributions from a visual programming language and Dataglove, an interactive device that facilitates tactile sensing and fine-motion control. Their integration made it possible to interact with three-dimensional virtual scenes. It took the integration of robotic engineering and virtual reality, however, to develop a dexterous telemanipulator for the anastomoses of nerves and vessels in hand surgery.

From these applications, it became apparent to the U.S. Department of Defense (DOD) that virtual reality and telepresence might serve a useful function in treating wartime casualties on the battlefield. Through virtual reality, the surgeon could be brought to the patient's side, an idea described by the term *telepresence*. Data from wounded casualties of the Vietnam War estimated that, of all wounded soldiers, one third died of head and massive injuries, and an additional one third died of exsanguinating hemorrhage, but had the potential to survive if they were treated in time.[2] The DOD sought to improve medical presence on the battlefield given that one third of casualties could be saved. Telepresence allowed a surgeon located aboard an aircraft carrier to perform surgery (with the aid of telemanipulation) on wounded soldiers located in a remote location on the battlefield. With this idea in mind, the DOD funded much of the research in telemanipulation for remote mobile surgical units that would allow for telepresence.

Another impetus for the development of robotic surgery came from the inherent limitations of laparoscopic surgery. Mouret performed the first video laparoscopic cholecystectomy in Lyons, France, in 1987.[3] In 1988, Perissat and coworkers[4] presented this innovation to the Society of American Gastrointestinal Endoscopic Surgeons, and an exponential spread of laparoscopic surgical procedures began. Although laparoscopic surgery provided great benefit for patients, it brought tremendous surgical limitations, such as loss of three-dimensional vision, impaired touch sensation, and poor dexterity provided by the long instruments and the fulcrum effect. The fulcrum effect is a nonintuitive motion of the instrument tips in the opposite direction around a fixed point, usually at the skin entrance site. New skills had to be learned. Initial attempts to surmount the burdens of endoscopic surgery provided the impetus for robotic support systems that can enhance surgical skills and control of instruments.

The first surgical robotic devices appeared in the 1980s for use in stereotactic brain surgery. In 1992, ROBODOC (Integrated Surgical Systems, Sacramento, CA) was introduced for grinding bone to make space for prostheses in hip replacement surgery. Positioning robots were introduced by the mid 1990s. The Automated Endoscopic System for Optimal Positioning (AESOP; Computer Motion, Goleta, Calif.) was introduced for voice-controlled optimal camera positioning, and Laparoscopic Assisted Robotic Systems (LARS; John Hopkins University, Baltimore, Md.), an automated robot, was introduced for organ retraction.[5] The first master-slave manipulator for medical use was developed at Stanford Research Institute in 1991. The goal was to have computer algorithms that translate a surgeon's master manual movements to end-effector slave instruments at a remote site. Early designs had only four degrees of freedom, but by 1992, a German prototype was developed with six degrees of freedom (Fig. 87-1).[6] In 1994, Intuitive Surgical (Sunnyvale, Calif.) obtained technologic rights from the Stanford Research Institute, and a prototype DaVinci system was released in 1997.

Engineers realized that the distance between patient and surgeon had an upper limit, beyond which accuracy and dexterity of instrument control would become degraded. Latency is the time it takes to send an electric signal from a hand motion to actual visualization of the hand motion on a remote screen. The lag time to send an electric signal to a geosynchronous satellite at 22,300 miles above the Earth and return is 1.2 seconds. This transmission delay would prohibit practical surgery. Humans can compensate for delays of less than 200 msec. Longer delays compromise surgical accuracy. Tissue moves when force is applied to it, and with a visual delay greater than 200 msec, the movement would not be noticed fast enough to avoid cutting in an unintended place.

The most optimistic attempt to provide telesurgical presence over long distances was undertaken using high-bandwidth fiberoptic ground cable. The latency time of 155 msec allowed Marescaux and colleagues[7,8] to perform a robot-assisted laparoscopic cholecystectomy between New York City and Strausbourg, France, in 2001. In 2003, a telerobotic surgical service was established between a teaching hospital in Canada and a community hospital 250 miles away. This service was designed to provide telerobotic assistance by an expert surgeon to a community-based surgeon. Some of the procedures performed included laparoscopic Nissen fundoplication, laparoscopic right hemicolectomy, laparoscopic sigmoid–anterior resection, and laparoscopic hernia repair.[9]

Recent years have witnessed an explosive growth in robotic surgery. In 2000, 1500 robotic procedures were performed. In 2004, more than 20,000 robotic procedures were performed. In 2011, 360,000 surgical procedures were performed worldwide with the da Vinci Surgical System. Of the estimated 360,000 surgical procedures, approximately 146,000 were hysterectomies and approximately 113,000 were prostatectomies. [10]

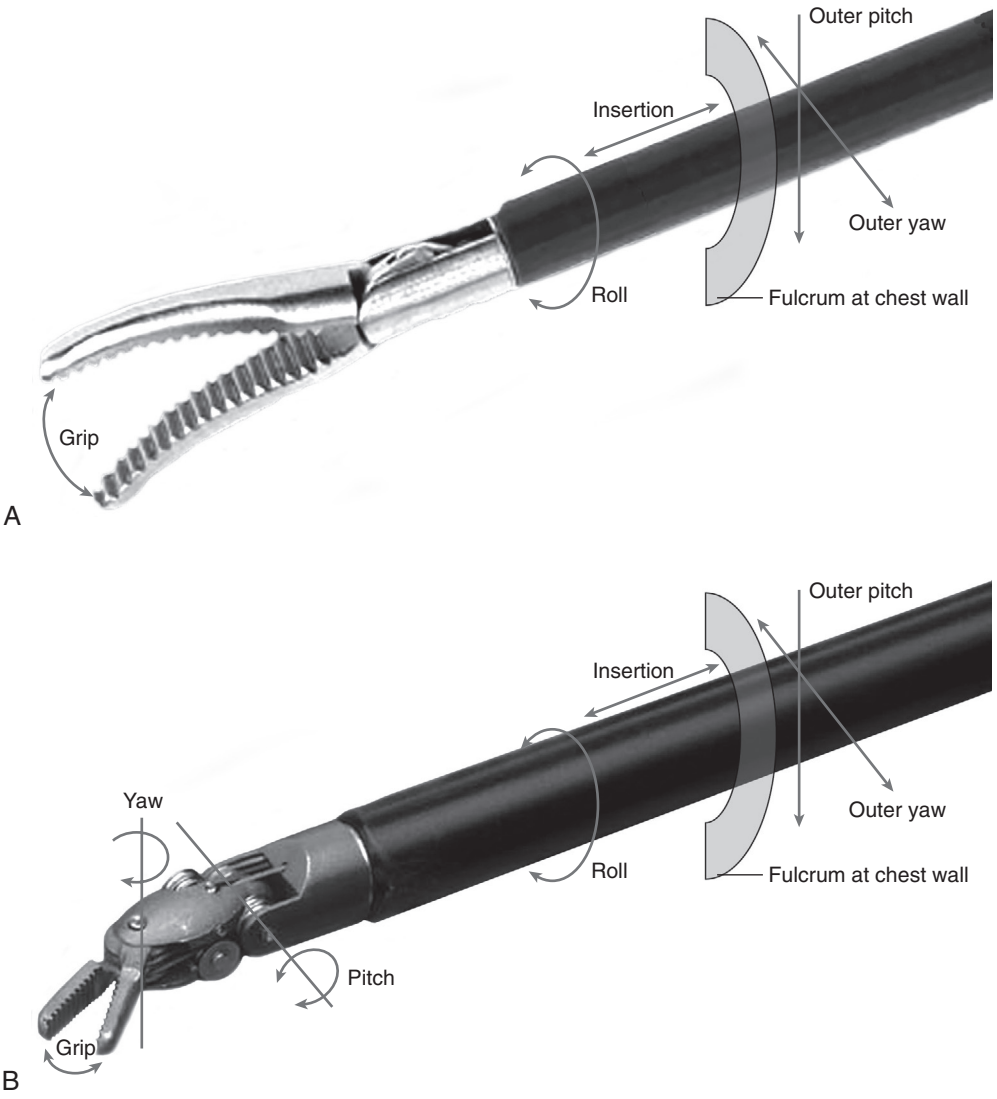

Figure 87-1. Degrees of freedom (DOF) in motion. **A,** Conventional laparoscopic instruments have only four DOF and grip. Insertion (i.e., movement in the *z*-axis), roll, and movement along the *x*- and *y*-axes outside the body relative to a fulcrum point constitute the four DOF. **B,** Depiction of the EndoWrist instrument with two added intracorporeal joints, producing seven DOF. ROBOTIC SYSTEMS

The word *robot* is a ubiquitous term that describes an autonomous device capable of various tasks (see the previous section on history). Industrial robots used in assembly lines perform highly precise, repetitive tasks. The robots are preprogrammed offline, and tasks are invoked on command. Robots used in orthopedic surgery and neurosurgery are examples.[11] Precise tasks, such as drilling and probe insertion, are based on registration. Registration is a mathematical process that allows location and anatomic orientation in three dimensions based on data derived from preoperative computed tomography (CT) or magnetic resonance imaging (MRI).

A second type of robot is defined as an assist device, such as AESOP. These robots are used to control instrument location and guidance. Assist-device robots are not autonomous; they need input cues from an operator.

A third type of robot is a telemanipulator. These robots are under constant control of an operator. These devices mimic the operator's hand motions in an exact or scaled motion. Several telemanipulator robotic devices are available throughout the world. The da Vinci Robotic Surgical System (Fig. 87-2) and the ZEUS Surgical System (Fig. 87-3) were developed in parallel; these two systems are similar with only minor differences. The ZEUS system was subsequently shelved after its competitor, Intuitive Surgical, acquired the company. The da Vinci Robotic Surgical System is described in this chapter as a representation of most modern surgical robots. It has been approved by the U.S. Food and Drug Administration (FDA) for use in urologic procedures, general laparoscopic surgical procedures, gynecologic procedures, transoral otolaryngology procedures, general thoracoscopic procedures, and thoracoscopically assisted cardiotomy procedures.[12]

The components of the da Vinci system include: a Surgeon Console, a patient-side cart, EndoWrist instruments, and an optical vision tower (see Fig. 87-2). The surgeon sits comfortably at the console (Fig. 87-4) and is able to view a high definition, three-dimensional image inside the patient body. The viewing space provided is similar to a double-eyepiece microscope (Fig. 87-5). At the console, the surgeon is actually looking at two separate monitors; each monitor displays one channel of the stereo endoscope to an eye, creating a virtual three-dimensional stereoscopic image of the surgical field (Fig. 87-6, *A*). The

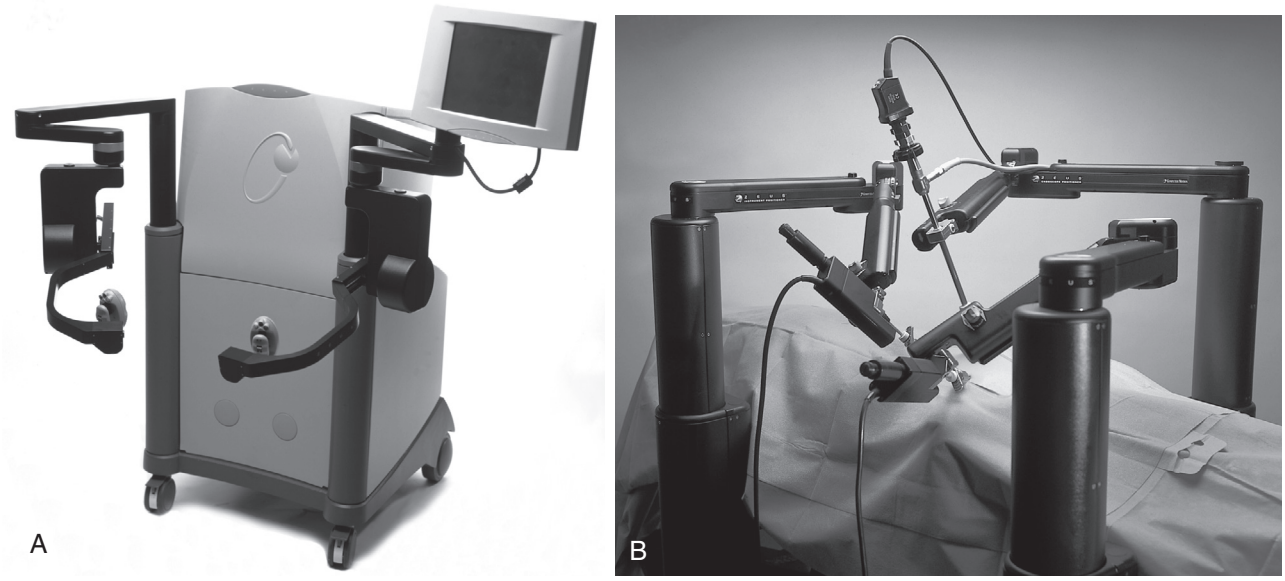

Figure 87-3. A, The console of the ZEUS robotic telemanipulation system consists of a video monitor and two instrument handles that translate the surgeon's hand motions into an electric signal that moves the robotic instruments. **B,** Two table-mounted AESOP arms hold instruments, and a third arm controls the camera. (Courtesy Computer Motion, Sunnyvale, Calif.)

surgeon's fingers grasp the master controls underneath the display (see Fig. 87-6, *B*). The master controls are made of levers that attach to index fingers and thumbs of each hand. Wrist movements replicate the movements of the instruments at the end of the robotic arms. The console has a foot pedal that disengages the robotic motions (i.e., clutching), another that allows adjustment of the endoscopic camera, and a third pedal for controlling the energy of electric cauterization. The surgeon sits at the console and controls the telescope arm and three robotic manipulator arms. The da Vinci Si system, introduced in 2009, has dual console capability to support training and collaboration during robotic surgery.

The patient-side cart (Fig. 87-7) has four arms that can be manipulated by the surgeon through real-time computer-assisted control. The first two arms represent the surgeon's right and left arms, to hold the instruments, and the third arm positions the endoscope. The endoscope consists of dual, independent optical channels capable of transmitting digital images to the console's visual monitor. The optional fourth arm enables the surgeon to hold another instrument or perform additional tasks, such as holding counter traction and following running sutures. The system allows the surgeon to be physically remote from the patient (Fig. 87-8). The cart is bulky and heavy, and it has to be wheeled to the vicinity of the patient's surgical area and locked into place. Because of the proximity of the side cart to the patient, the patient must be guarded against inadvertent contact from the motions of the robotic

arms. Even more important, after the instruments are engaged to the arms of the robot and inside the patient, the patient's body position cannot be modified unless the instruments are disengaged entirely and removed from the body cavity. Any patient movement can be disastrous. The clutching buttons allow the robotic arms to be grossly positioned without moving the instruments within the trocars or access ports. A clutching function allows surgical assistants to exchange various instruments.

The EndoWrist instruments (Fig. 87-9) are designed to have seven degrees of motion—a range of motion even greater than the human wrist. Seven degrees of motion include three arm movements (in-out, up-down, side-to-side), and three wrist movements—yaw (side-to-side, left and right), pitch (up and down), and roll or rotational. The seventh degree of freedom is grasping or cutting. The system design incorporates a frequency filter that eliminates hand tremor greater than 6 Hz. Motion scaling also can be invoked up to a ratio of 5:1 (i.e., the surgeon moves 5 cm, and the robot moves 1 cm). Scaling allows for work on a miniature scale. The instruments in the body cavity must remain sterile, but interface with nonsterile robotic arms. Detachable disposable instruments facilitate this interface. Each type of instrument requires different forces and motion scaling intrinsic to the task, and each type requires specific computer software processing. Additional operating room staff members are required for detaching and exchanging task-specific instruments throughout the case. Monitors are positioned on top of the tower so that all individuals in the operating room have a view of the surgical field.

The optical tower contains the computer equipment needed to integrate the left and right optical channels to provide stereoscopic vision and to run the software needed to control the kinematics of the robotic arms. The computer interfaces the translated motion of the surgeon's hands to a digital code that moves mechanical levers, motors, and cables that allow the robot to articulate the exact motions of the surgeon's hand.

The ZEUS Surgical System (see Fig. 87-3) is another example of a master-slave telemanipulator. It uses the assistance of the AESOP Robotic System for visualization. The system is basically one mechanical arm used by the physician to position the endoscope, which is a surgical camera inserted into the patient. Foot pedals or voice-activated software allow the physician to position the camera, leaving his or her hands free to continue operating on the patient. The manipulators of the ZEUS system are freely mounted on the operating table, similar to the AESOP. It provides tremor filtering and motion scaling from 2:1 to 10:1.

An obstacle that still needs research is tactile sensing. The feedback that the robot offers for the surgeon's applied force is inferior. The robot offers some sensation, but the applied force does not correlate well with the force applied to the tissues. This correlation varies with the type of instrument and depends on the torque applied; the operator must rely on visual cues from tissue distortion to gauge how much pressure is being generated.

CARDIAC SURGERY (ALSO SEE CHAPTER 67)

Application of conventional endoscopic instruments has paved the way for several cardiac procedures to be performed with robotic assistance. Internal mammary artery harvesting was successfully performed thoracoscopically in 1997 by Nataf.[13] In 1998, Loulmet and colleagues[14] reported the first totally endoscopic coronary artery bypass surgery. Cardiothoracic applications of robotically assisted surgery have expanded and include atrial septal defect closures,[15-17] mitral valve repairs,[18] patent ductus arteriosus ligations,[19] totally endoscopic coronary artery bypass grafting,[20,21] minimally invasive atrial fibrillation surgery,[22,23] and left ventricular pacemaker lead placement.[24] Although technical advances in minimally invasive surgery have introduced techniques that are performed through very small ports and may eventually make surgical sternotomy obsolete, surgeons still must be trained and prepared to convert to an open sternotomy if the need arises.

BOX 87-1 *One-Lung Ventilation Strategy*

1. Use $FiO_2 = 1.0$.
2. Begin one-lung ventilation with pressure control ventilation, maintaining a plateau pressure of <30 cm H_2O.
3. Adjust respiratory rate so that $Paco_2$ approaches 40 mm Hg.
4. Perform analysis of arterial blood gases periodically.
5. Apply continuous positive airway pressure to nonventilated lung.
6. Apply positive end-expiratory pressure to ventilated lung.

Anesthesiologists need to acquire familiarity with and expertise in cardiac and thoracic anesthesia, as both organ systems need to be managed safely. The ability to perform and maintain one-lung ventilation is mandatory, as is the management of associated physiologic changes (Box 87-1). Preoperative assessment of lung function is indicated if a patient has significant lung disease. Poor pulmonary function test results or pulmonary hypertension may be contraindications to robotically assisted cardiac surgery because one-lung ventilation may be poorly tolerated. Robotic surgery may require unprecedented, prolonged, one-lung ventilation, which may challenge the extent of our understanding of respiratory physiology. Continuous monitoring of cardiac function with transesophageal echocardiography (TEE) is the standard of care and is used for several procedures required for safer robotically assisted surgery.

ADMINISTRATION OF CARDIOPULMONARY BYPASS

Robotic cardiac surgery may require placement of several additional cannulae before administration of cardiopulmonary bypass (CPB) (also see Chapter 67). Typically, the femoral vessels are accessed as cannulation sites for CPB. Because of the potential for iatrogenic dissection or related injury during cannulation of these vessels, some centers advocate prior radiologic imaging to rule out severe atherosclerotic disease. Venous cannulation is usually accomplished with the percutaneous insertion of a 21-to 28-French (Fr) multiorifice cannula via the femoral vein under real-time TEE guidance. This cannula can be either one or two stage. The tip of the single-stage cannula is placed at the right atrial (RA)–inferior vena cava (IVC) junction. The tip of the two-stage cannula is placed in the superior vena cava (SVC). The choice of venous cannula can vary according to surgeon preference. Some surgeons place a two-stage venous cannula, whereas others prefer a single-stage IVC cannula and an additional percutaneous cannula in the SVC via the right internal jugular vein to empty the heart completely. Cannulation of SVC is accomplished with a percutaneous 15-to 18-Fr Biomedicus cannula (Medtronics, Minneapolis, Minn.) using the Seldinger technique. The tip of the SVC cannula is placed just before the RA-SVC junction. Some surgeons prefer an armored SVC neck cannula because of its resistance to occlusion or kinking by the long transthoracic aortic cross-clamp. At the time of insertion, the cannula is typically flushed with 5000 units of heparin to ensure its patency, or a dilute heparin solution can be infused into the cannula through a microdrip set. A midesophageal, bicaval view on the TEE may be helpful for guidance in positioning of both SVC and IVC cannulae (Fig. 87-10). An alternative to the SVC cannula may be to float a 9-Fr balloon-tipped catheter into the main pulmonary artery via a right internal jugular introducer. This pulmonary artery venting cannula has a much smaller diameter compared with the SVC cannula and allows passive venting of the pulmonary artery at approximately 50 mL/min.[25] Venous drainage is facilitated with either vacuum or kinetic assistance.[25,26] Typically a 17-to 21-Fr catheter is placed in the femoral artery for arterial cannulation. To prevent retrograde aortic dissection, the guide wire should be visualized on TEE imaging in the descending aorta before placement of the arterial cannula.

For myocardial protection, cardioplegia can be administered by antegrade and retrograde delivery routes. After ensuring a competent aortic valve on TEE, a Heartport Straight-shot (Heartport, Redwood City, Calif.) antegrade cardioplegia catheter can be placed into the proximal ascending aorta directly through a right chest wall stab incision. A long-shafted aortic cross-clamp can then be placed distal to the cardioplegia catheter via another stab incision. Alternatively, a 100-cm, 10.5-Fr catheter (EndoClamp; Edwards Lifesciences, Irvine, Calif.) with a distal balloon can be advanced into the ascending aorta via a femoral introducer sheath. The balloon, when inflated, functions as an endovascular cross-clamp, whereas the lumen opening at the tip is used to deliver antegrade cardioplegia. It is of utmost importance to maintain accurate positioning of the balloon of this catheter in the ascending aorta to avoid inadvertent migration and occlusion of coronary circulation or innominate artery obstruction. This can be ensured by simultaneously monitoring arterial pressures in bilateral radial artery catheters, and by visualizing the position of the endoballoon in real time on TEE. [25] In patients with significant aortic insufficiency or severe coronary artery disease, a retrograde cardioplegia catheter may be placed. A percutaneously placed retrograde cardioplegia catheter can be positioned in the coronary sinus via the right internal jugular vein under TEE guidance. It is positioned by rotating (torquing) the catheter under TEE guidance. The proximal coronary sinus can be imaged in midesophageal four-chamber view by advancing and retroflexing the TEE probe. The catheter and the coronary sinus can also be visualized in midesophageal two-chamber view. On correct placement of the catheter, inflation of the coronary sinus balloon changes the RA trace to right ventricular trace. Because these catheters are not heparin coated, 5000 units of heparin should be given intravenously to the patient before placement of this catheter.

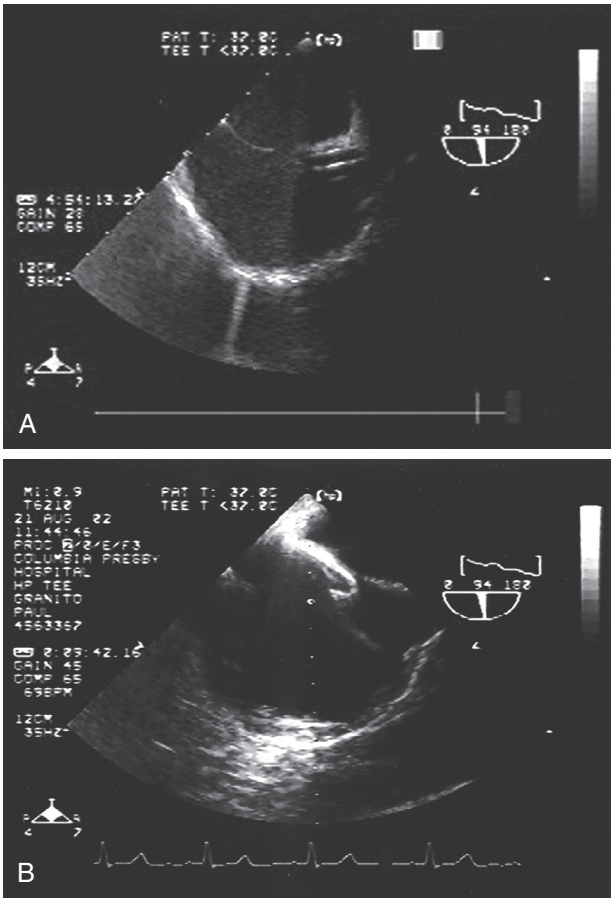

Figure 87-10. A, Ultrasound image of the superior vena cava cannula. **B,** Ultrasound image, bicaval view, depicting the inferior vena cava containing a J guide wire. Both views are helpful in correctly placing cardiopulmonary bypass venous cannulas.

MITRAL VALVE SURGERY

In 1997, two independent groups reported the first robotically assisted mitral valve repair.[27,28] In November 2002, the FDA approved the use of robot-assisted surgery for performing mitral valve repair. Minimally invasive mitral valve repair, initially done through minithoracotomy incisions, could now be performed with a closed chest; however, mitral valve replacements required a small thoracotomy to introduce the new prosthetic valve.

The monitoring requirements and the plan for induction of anesthesia for robotic mitral valve surgery are similar to the open procedure. In addition, bilateral radial artery catheters can be placed to monitor inadvertent innominate artery obstruction by the endoclamp catheter. The plan for induction of anesthesia is similar to that of the open procedure.[29] After the induction of anesthesia, one-lung ventilation is achieved with the use of a double-lumen endotracheal tube, or a single-lumen endotracheal tube with a bronchial blocker. Proper tube position is confirmed with fiberoptic bronchoscopy. A TEE probe is inserted to assess heart and valve function and to guide the placement of a pulmonary artery catheter and other cannulae for CPB. Transcutaneous defibrillation and pacing pads are also applied. Specialized cannulae are placed for the conduction of CPB and cardioplegia as described in the previous section.

The patients are positioned in a modified left lateral position with the right shoulder tilted approximately 30 degrees to the left, with the arm being positioned along the right side. The pelvis is kept relatively flat to facilitate femoral cannulation. Attention should be directed to ensuring that undue tension is not placed on the brachial plexus. The right femoral vessels are exposed, and left-sided single-lung ventilation is established. The surgeon then determines the proper location for port access, which can vary according to a patient's body habitus. After docking the surgical cart, it is imperative to prevent the patient from moving, to prevent any organ injury from the rigid trocars and the instruments. Robot-assisted mitral valve repair is usually accomplished with a 2- to 3-cm right inframammary incision in either the fourth or fifth intercostal space, which provides an excellent view of the leaflets and the annulus.[30] Trocars are inserted around this incision for the placement of robotic arms. After administering heparin according to an activated clotting time-guided protocol, the femoral vein and artery are cannulated as described in the previous section. After initiating cardiopulmonary bypass, the ascending aorta is cross-clamped with either the endoclamp or a transthoracic aortic cross-clamp that is passed percutaneously through the right axilla. The robotic arms are engaged through their respective trocars lateral to the minithoracotomy incision, while the camera arm passes directly through the thoracotomy incision.

Before terminating cardiopulmonary bypass, TEE is used to evaluate the function of the mitral valve, to assess residual valvular regurgitation, and to confirm the disappearance of intracardiac air (see Chapter 46). The anterior leaflet of the mitral valve is inspected further for systolic anterior motion. At the end of the procedure, the double-lumen endotracheal tube is changed to a single-lumen endotracheal tube over a tube changer. Patient selection is important for optimal results (see Chapter 66). Box 87-2 lists the risk factors that make patients unsuitable candidates for robotic mitral valve surgery.[31]

BOX 87-2 *Exclusion Criteria for Robotically Assisted Mitral Valve Repairs*

- Severely calcified mitral annulus
- Severe pulmonary hypertension
- Ischemic heart disease
- Surgery requiring multiple valve repairs
- Previous surgery to right hemithorax
- Severe aortic and peripheral atherosclerosis

No data are present on the difference in outcomes in patients with higher body mass index (BMI) undergoing this procedure. The increases in equipment and intraoperative costs are offset by postoperative quality of life and early return to work. [32]

ATRIAL SEPTAL DEFECT REPAIR

Operations for atrial septal defects are similar to those for mitral valve repairs except that a minithoracotomy is not required.[15] A closed-chest procedure is possible. Similar to all robotic procedures that demand entrance into the thoracic cavity, single-lung ventilation must be instituted during surgery. Atrial septal defect repairs also require opening the heart and preventing any blood from entering the heart; this is facilitated by jugular and femoral vein cannulation and snaring the inferior vena cava and SVC (see also Chapter 67). Cardiopulmonary bypass with cardioplegia administration into the aortic root is used to arrest the heart. Methods of cardiopulmonary bypass using endovascular clamping are described in the previous section.

No data are present on the difference in outcomes in patients with higher BMI who are undergoing this procedure. Cost effectiveness data on patients undergoing atrial septal defect repair are also not available.

INTERNAL MAMMARY ARTERY HARVEST

After induction of anesthesia, single-lung ventilation with a double-lumen tube, a Univent tube, or a bronchial blocker is instituted. The position of the tube is confirmed by bronchoscopy. The patient is positioned in a 30-degree right lateral position. External defibrillation and pacing pads are applied to the left posterior chest and anterolateral right chest. Raising the left arm provides more exposure and stretches the skin overlying the left anterolateral chest. The opposite can be done to the right chest when harvesting only the right internal mammary artery.

CO_2 insufflation, between 5 and 10 mm Hg, is needed to provide exposure by pushing the mediastinal fat pad medially and enlarging the space between the sternum and heart to provide a better view. For harvesting both internal mammary arteries, insufflation of the left hemithorax is sufficient to expose the right internal mammary artery because of the leftward position of the heart[33] and to improve the angle of sight. Insufflation is begun in increments of 2 to 4 mm Hg. The insufflation flow rate is

adjusted automatically to achieve a preset intrathoracic pressure limit. Caution should be exercised when insufflating the thorax in patients who have poor left ventricular function or are hypovolemic (central venous pressure < 5 mm Hg).

Patients should have their intravascular volume status increased before proceeding to full insufflation. CO_2 insufflation and one-lung ventilation increase central venous pressure and pulmonary artery pressure by a small amount.[34] Bilateral pneumothoraces are deliberately produced when doing bilateral internal mammary artery harvest. Most patients studied tolerate small bilateral pneumothoraces for short duration.[35]

CORONARY ARTERY BYPASS GRAFTING (also see Chapter 67)

Robotically-assisted total endoscopic coronary artery bypass graft surgery (also see Chapter 67) has been found to be safe and effective with angiographic patency data comparable to the open procedure.[21] The major exclusion criteria for robotic coronary artery bypass grafting are listed in Box 87-3.[21]

Patients are prepared and monitored for anesthesia in a manner similar to that for mitral valve surgery (discussed under Mitral Valve Surgery). TEE is used routinely as the standard of care for determining cardiac function and for confirming catheter placement. Pulmonary artery catheters are used judiciously in the appropriate patient population. The patient is positioned the same as for internal mammary artery takedown, and trocar positions are placed as depicted in Figure 87-11.

When cardiopulmonary bypass is anticipated, the left femoral artery is cannulated with a 17- or 21-Fr remote access perfusion catheter (Fig. 87-12) with an aortic occlusion balloon. Box 87-4 lists exclusion criteria for endovascular cardiopulmonary bypass. The remote access perfusion catheter allows anterograde flow of 4 or 5 L/min. The cannula has a separate lumen for delivering cardioplegia to the aortic root beyond the occlusion of the balloon. The aortic cannula is positioned in the ascending aorta, 2 cm above the aortic valve, with TEE guidance (Fig. 87-13). The endovascular balloon is inflated with a volume equal to the diameter (in milliliters) of the sinotubular junction of the aorta. A balloon pressure greater than 300 mm Hg usually provides complete occlusion of the aorta.[36] Residual flow around the balloon can be seen and monitored with color flow on TEE. The use of bilateral radial arterial lines is useful in detecting the migration of the occlusion balloon toward the innominate artery. Proximal migration of the balloon can be seen most easily with TEE, preventing balloon herniation through the aortic valve.

After full cannulation and being poised for cardiopulmonary bypass, the right lung is allowed to collapse, and left lung ventilation is begun. The ventilator is adjusted to provide an end-tidal CO_2 partial pressure of 35 to 40 mm Hg. Ports can be placed safely after the right-sided pneumothorax has formed. CO_2 is insufflated into the right hemithorax and continued at a pressure of 5 to 10 mm Hg; this allows the affected lung to collapse further and provides a larger visual field. It also may prevent mediastinal shifts during one-lung ventilation when large tidal volumes are used, such as in a patient with emphysematous lungs. Insufflation to produce a deliberate pneumothorax is ineffective when the sternum is elevated above the anterior surface of the heart. For this reason, some surgeons provide sternal lift retractors to increase the retrosternal space and provide better exposure.[37] Articulating stabilizers passed through a subxiphoid port can stabilize the anterior surface of the heart to facilitate grafting.[38] Ventricular function is evaluated with TEE before termination of cardiopulmonary bypass. At the end of the procedure, the double-lumen endotracheal tube is changed to a single-lumen endotracheal tube over a tube exchanger. Robot-assisted, beating-heart coronary artery bypass grafting can be safely accomplished with appropriate patient selection. Obese patients (see Chapter 71) might benefit from total endoscopic coronary artery bypass graft surgery, as the robotic procedure does not increase the rate of intraoperative or postoperative complications when compared with the traditional procedure.[39] Cost effectiveness data comparing robotically assisted total endoscopic coronary artery bypass graft surgery with the traditional approach are not available.

BOX 87-3 ***Exclusion Criteria for Robotically Assisted Endoscopic Coronary Artery Bypass Grafting***

- Contraindication to one-lung ventilation
- Ejection fraction < 30% or decompensated heart failure (NYHA class III or IV)
- Moderate to severe aortic and mitral valve disease
- MI in preceding 30 days or MI requiring emergent CABG or postinfarction angina
- Calcified or intramyocardial LAD artery or diffuse LAD artery disease
- Large heart within left chest
- Morbid obesity (BMI > 35 kg/m^2)
- Severe peripheral vascular disease
- Severe noncardiac health issues
- Previous thoracic surgery, pleural adhesions, or radiation therapy of mediastinum or thorax

BMI, Body mass index; *CABG,* coronary artery bypass graft; *LAD,* left anterior descending; *MI,* myocardial infarction; *NYHA,* New York Heart Association.

ATRIAL FIBRILLATION SURGERY

Atrial fibrillation is a common rhythm disturbance encountered in clinical practice (see also Chapter 68). The Cox maze procedure is often the first choice to treat medically resistant atrial fibrillation. Excellent long-term results occur with this procedure.[40] In this procedure, right and left atriotomies are combined with cryoablation to interrupt reentrant rhythms and to restore sinus rhythm. Traditionally, this procedure has involved median sternotomy and cardiopulmonary bypass. With the evolution of technology such as cryotherapy, microwave, and radiofrequency, new handheld devices have become available for use in minimally invasive surgery.

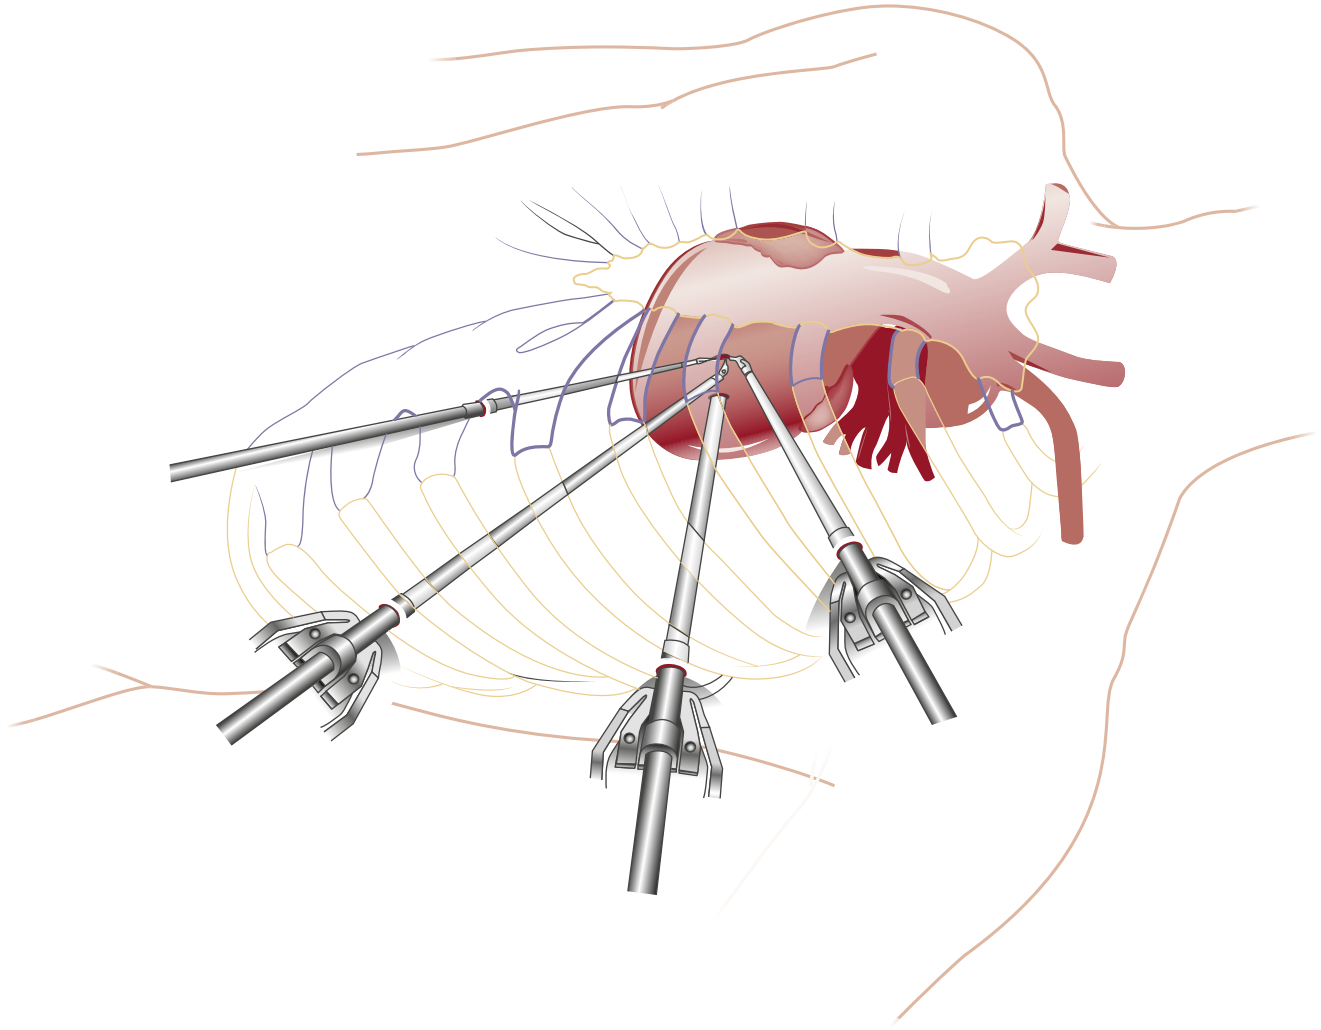

Figure 87-11. Incision ports for coronary artery bypass grafting. Trocars are placed in the third, sixth, and eighth intercostal spaces. Similar port positions are used for bilateral internal mammary artery dissection.

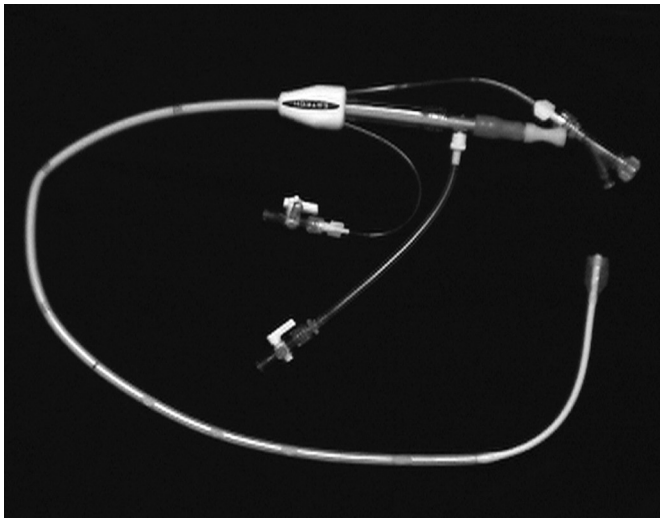

Figure 87-12. Remote Access Perfusion (Estech Systems, Plano, Tex.) catheter. The endovascular catheter has a cylindrical balloon for endovascular aortic clamping. The catheter provides anterograde perfusion of the aortic arch at a rate of 5 L/min and cardioplegia administration to the aortic root.

BOX 87-4 ***Contraindications to Use of Endovascular Cardiopulmonary Bypass System***

- Major vascular disease of iliac, femoral, and abdominal aorta found by Doppler ultrasound imaging
- Severe atherosclerosis
- Aortic diameter >4 cm
- Moderate to severe aortic valve incompetence

Many approaches have been used for minimally invasive atrial fibrillation ablation surgery. The approach using the da Vinci system via right minithoracotomy with peripheral cannulation and cardiopulmonary bypass is the most commonly used approach.[22] A total endoscopic approach on a beating heart also has been described.[41] Recently, a remote robotic navigation system (Sensei X; Hansen Medical, Mountain View, Calif.) has been developed for intracardiac catheter manipulation. In a small study, this system is equally effective while significantly reducing the overall fluoroscopy time when compared with manual catheter ablation.[42]

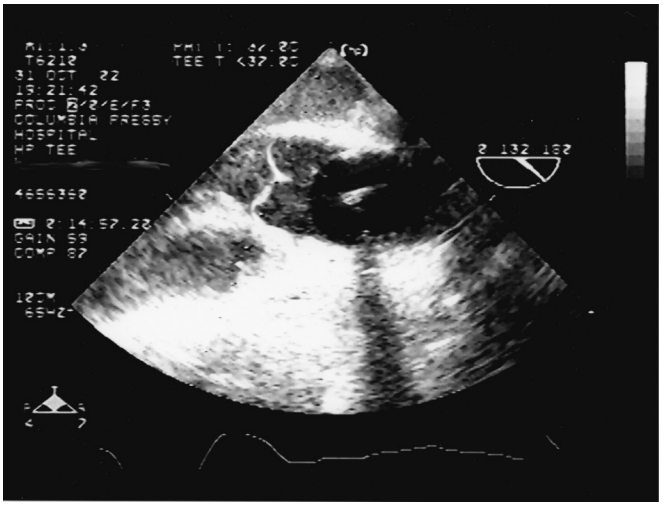

Figure 87-13. Ultrasound image of Remote Access Perfusion (Estech Systems, Plano, Tex.) catheter balloon in situ. Transesophageal echocardiography allows the anesthesiologist to keep track of the migration of the catheter balloon. The balloon should be positioned in the ascending aorta 2 to 4 cm distal to the aortic valve. Right radial pressure catheter signal damping can detect balloon malposition when occlusion of the innominate artery occurs.

In patients undergoing total endoscopic approach, the procedure is performed without cardiopulmonary bypass on a beating heart with the patient in the supine position. In addition to the standard monitors, invasive arterial and central venous pressures are monitored. A pulmonary artery catheter can be used in appropriate patients. After induction of anesthesia, the trachea is intubated with a double-lumen endotracheal tube, and its position is confirmed by a fiberoptic bronchoscope. A TEE probe is inserted to facilitate intraoperative cardiac monitoring and to rule out a clot in the left atrial appendage. External defibrillator pads are applied to the chest. After one-lung (left) ventilation is instituted, the right lung is collapsed, and the right hemithorax is insufflated with CO_2. Three, 1-cm port access incisions are made at the level of the third, fourth, and fifth intercostal spaces on the anterior axillary line for the robotic arms and the endoscope. The heart is then exposed after dissecting the pericardium and, using a microwave probe (Flex10; Boston Scientific, Natick, Mass.), a continuous circular lesion is produced encircling the pulmonary veins. Arrhythmias in the early postoperative period are treated with amiodarone and β-adrenergic blocker therapy.[41,43]

Outcome data in patients with a higher BMI are not available for this procedure. Cost effectiveness data on patients undergoing robotic atrial fibrillation surgery are also not available.

LEFT VENTRICULAR LEAD PLACEMENT

Some surgical groups have developed a total endoscopic robotic approach that involves the placement of right atrial and ventricular leads via standard transvenous approach, and the placement of left ventricular lead via small incisions in the left hemithorax.[44-46] The robotic approach was developed because of the high rate of immediate failure and late failure associated with the standard approach to left ventricular lead placement.[24] In patients undergoing the total endoscopic robotic approach, general anesthesia is induced after application of standard monitors and insertion of an arterial line. After induction of general anesthesia, the trachea is intubated with double-lumen endotracheal tube. The position of the endotracheal tube is verified with a fiberoptic bronchoscope. Subsequently, a TEE probe and a pulmonary artery catheter are inserted. The patient is placed in a posterolateral thoracotomy position. One-lung (right) ventilation is instituted. The left lung is excluded, and the left hemithorax is insufflated with CO_2 at a pressure of 8 to 10 mm Hg.

Robotic arms are inserted by incisions in the fifth and ninth intercostal spaces in the posterior axillary line, and the camera is inserted in the seventh intercostal space. The pacing lead is introduced through a working port and attached between the first and second obtuse marginal between the base and the apex. A second pacing lead is attached near the second obtuse marginal, and the pericardium is closed over the leads. Both leads are tunneled to an incision in the axilla and retested for threshold pacing requirements. The lead with the best threshold is connected to the pacemaker, whereas the other lead is capped and secured to the fascia for future use. If a right-sided pacing lead is needed, it is inserted transvenously at this time and connected to the biventricular pacemaker. This approach allows for reliable entry into the chest for left ventricular lead insertion, while allowing complete cardiac access for mapping.

No data are present on the difference in outcomes in patients with higher BMI undergoing this procedure. Cost effectiveness data on patients undergoing left ventricular lead placement surgery are also not available.

ROBOTIC-ASSISTED THORACOSCOPIC SURGERY

Although video-assisted thoracoscopic surgery (VATS) is well established, its use is limited to simple procedures. Few centers perform complex procedures such as pulmonary lobectomies and thymectomies using VATS.[47] Perhaps robotic surgery will be able to overcome some of the limitations of conventional VATS (see also Chapter 66).

Compared with minimally invasive surgery performed in other regions of the body, robotic-assisted thoracoscopic surgery (RATS) presents different challenges. The surgical challenges include rigidity of the chest wall and movement of heart, lungs, and mediastinum. The anesthesia-related challenges include prolonged one-lung ventilation and hemodynamic instability associated with CO_2 insufflation of the hemithorax.

Patient positioning plays a major role in exposing otherwise inaccessible areas, because mediastinal structures are heavy and mobile and change position in response to gravity (see also Chapter 41). Supine or slight lateral decubitus (raising one side 15 to 30 degrees) position is ideal for anterior mediastinum pathology. A 90-degree lateral position may be optimal for hilar masses and lobectomies. A nearly prone position can create better

exposure for posterior mediastinal masses.[48] CO_2 insufflation also has a big role in achieving adequate exposure by pushing the mediastinum to the opposite site, while compressing the lung away from the operative site. It also reduces fogging and removes cautery smoke. The disadvantage of CO_2 insufflation is hemodynamic instability.

As the use of robotics in surgery has increased, its role in thoracic surgery has evolved over the last few years. The procedures being performed include multiple esophageal procedures, including Heller myotomy, resection of esophageal masses,[49] and esophagectomy.[50] Other procedures being performed include lobectomies,[51] resection of mediastinal masses, and thymectomy.[47]

Whether outcomes are improved in patients with higher BMI undergoing this procedure is not known. RATS costs significantly more than VATS with similar complication rates; cost-effectiveness data are not available.[52]

UROLOGIC SURGERY

The first use of robotics in urology began in the late 1980s, when a robotic frame was developed for transurethral resection of the prostate (see Chapter 72). The frame was constructed to support the six-axes Unimate Puma robot (initially designed by Unimation, Danbury, Conn.). The safety of this device was derived from the steel circular frame that restricted and confined the robot to a precise arc of resection. Procedures could be performed more rapidly with a robotic instrument, and because hemostasis was required only once at the end of the procedure, there was less time for absorption of irrigation fluid. The Puma robot has been used to resect prostate tissue safely.[53]

The percutaneous access robot (PAKY-RCM; URobotics, Baltimore, Md.) was developed in 1996, and was later replaced by Tracker in 2003. This robot is used with fluoroscopy or CT guidance to improve the accuracy of needle placement in percutaneous nephrolithotomy and tissue biopsy. The AESOP system (discussed earlier) also has been used successfully in laparoscopic urologic surgery. The most advanced systems currently being used in urology are master–slave systems, such as the da Vinci Robotic Surgical System. The procedures that have been performed using da Vinci systems include radical prostatectomy,[54] radical cystectomy,[55] radical and simple nephrectomy, live donor nephrectomy, pyeloplasty, and adrenalectomy.[56]

ROBOTICALLY ASSISTED RADICAL PROSTATECTOMY

Guillonneau and Vallancien[57] were the first to show the feasibility and efficacy of laparoscopic radical prostatectomy. Since then, robotically assisted radical prostatectomy (RAPR) has become one of the most common procedures to be performed with robotic assistance. In 2011, more than 113,000 procedures were performed worldwide.[10] The learning curve seems to be much shorter with RAPR compared with the laparoscopic approach.

The most common technique used for RAPR seems to be the transperitoneal and antegrade approach, developed by Ficarra and colleagues[54] at the Vatikutti Institute of Urology (Detroit, Mich.). Outcome data, such as the transfusion rate, urinary continence recovery, erectile function, and oncologic outcomes with RAPR, compare favorably with those for laparoscopic or traditional retropubic approaches.[58-61] The operating times also can be similar to the traditional retropubic technique after the operator has learned the technique.

The plan for anesthetic induction for RAPR is similar to that of the open procedure. After inducing anesthesia, an arterial line can be inserted for blood pressure monitoring and frequent phlebotomy. Two large-bore intravenous lines should be considered when the potential for large blood loss is foreseen. Anesthesia can be maintained with a volatile anesthetic. Neuromuscular blockade is paramount in avoiding any movements by the patient while the surgical instruments are within the abdominal cavity. After placing the patient in the lithotomy position, pneumoperitoneum is created through an umbilical puncture needle, and the maximum pressure is set to 15 mm Hg. The trocar is inserted according to the standardized Heilbronn approach using a semilunar five-trocar arrangement, with a sixth in the suprapubic area.[62] A procedure with some modification of the Montsouris technique is used.[63] The patient is placed in steep Trendelenburg position to improve visualization in the surgical field. Because of the potential for long operative times, careful attention should be paid to patient positioning to prevent neuropathies (also see Chapter 41). Silicone gel pads should be placed at every pressure point. Some surgeons advocate tucking the patient's arms while the patient is awake to maintain optimal comfort and avoidance of neurapraxia.[63] Injury to the common peroneal nerve is one of the most common complications of lithotomy position. Other nerves at risk during lithotomy include the femoral, obturator, and sciatic nerves. Patients placed in an exaggerated Trendelenburg position are also at risk of developing brachial plexus neuropathies.[64] The effect of pneumoperitoneum can be attributed to increased intraabdominal pressure and hypercarbia. Some anesthesiologists use pressure-controlled ventilation to improve respiratory mechanics. In a small study of patients undergoing RAPR, pressure-controlled ventilation demonstrated no advantage over volume-controlled ventilation regarding respiratory mechanics or hemodynamic variables, except greater dynamic compliance and lower peak airway pressure. [65] Venous air embolism can occur in this procedure when the insufflation pressure exceeds venous pressure during the setting of a vascular injury. The incidence of venous air pressure is lower in RAPR when compared with an open procedure.[66] Steep Trendelenburg position and pneumoperitoneum can result in increased intracranial pressure. Despite increased intracranial pressure, cerebral perfusion pressure is usually maintained because of simultaneous increase of mean arterial pressure and central venous pressure.[67] Prolonged steep Trendelenburg position may be relatively contraindicated in patients with a history of stroke or cerebral aneurysm. Ophthalmologic injuries such as permanent vision loss, vision defects, and retinal tear have been reported after

RAPR.[64] The exact mechanism of ophthalmologic injuries is unknown. Some physicians, however, advocate for the use of an orogastric tube and lubrication of the eyes and closure of eyelids with tape or goggles to minimize the potential for gastric content causing eye contamination in the steep Trendelenburg position.

Urine output cannot be used as a measure of intravascular volume status because the bladder is opened during the procedure and the urine drains into the operative field. This can lead to overestimation of blood loss by mixing of urine and blood. Some institutions limit intraoperative intravenous fluids to reduce edema of the head and neck from positioning and to improve visualization in the operative field by reducing urine output. An endotracheal tube cuff-leak test is recommended before tracheal extubation in patients that have been subjected to prolonged, steep Trendelenburg position, because this position can result in airway edema and postoperative airway distress in some patients.[68] RAPR is associated with higher positive margin rate when compared with laparoscopic prostatectomy in patients with higher BMI.[69,70] Compared with laparoscopic prostatectomy, the higher cost of RAPR can be offset by the small gain in decreased risk of early harm and positive margin in high-volume medical centers.[71]

ROBOT-ASSISTED RADICAL CYSTECTOMY

Robot-assisted radical cystectomy (RARC) is an emerging alternative for treatment of invasive bladder cancer (see also Chapter 72). Using the six-port approach and the da Vinci system, pelvic lymphadenectomy and cystoprostatectomy are performed. The specimen is removed in a bag through a 5- to 6-cm suprapubic incision. Through this incision, the bowel is exteriorized, and a neobladder is created extracorporeally. Subsequently, urethroneovesical anastomosis is performed with robotic assistance.[72] RARC may have a less frequent rate of complications than in patients undergoing an open procedure.[73,74] Long-term oncologic results of RARC are still not available.[73] When the effect of complications is considered, RARC is more cost effective than open radical cystectomy; this effect is more pronounced in patients undergoing ileal conduit. [75]

The difference in outcomes in patients with higher BMI undergoing this procedure is not known. Cost effectiveness data for patients undergoing RARC are also not available.

GENERAL SURGERY

Robotic technology has defined itself in the field of gastrointestinal laparoscopic surgery.[1] The first surgical operation using robotic telemanipulation was a laparoscopic cholecystectomy performed in 1997 in Brussels, Belgium.[76] Robot-assisted surgical techniques permit the surgeon to provide the smallest possible incision and smallest surgical stress. This technology allows surgeons to work on a very small scale in cramped spaces. Virtually all gastrointestinal procedures have been performed safely by surgeons using this technology. Procedures most commonly performed include cholecystectomy, fundoplication, Heller myotomy, bariatric surgery, and colectomy.[77]

Robotic surgery overcomes some of the disadvantages of conventional laparoscopic procedures with three-dimensional imaging, elimination of motion reversal, motion scaling, and filtering of resting tremors, while offering an ergonomically comfortable position. Other reported advantages of robotic surgery over laparoscopic surgery are less intraoperative blood loss,[78] a short learning curve, superior imaging, and greater freedom of movement.[79] Robotic laparoscopic surgery also is associated with high patient satisfaction.[80] As long-term outcome data on laparoscopic robotic surgery are lacking,[78] the higher cost[81,82] and longer operating time[78] may prove to be a deterrent to some surgical programs.

ANESTHETIC CONSIDERATIONS

In the operating room, the usual monitors are used for the patient. Some clinicians advocate the placement of a second noninvasive cuff as an alternative should the first fail, when arms are "tucked" and not available for access during surgery. Bilateral peripheral intravenous access is valuable because the left upper extremity is not immediately available during the surgery. Anesthesia can be maintained with a volatile anesthetic. Neuromuscular blockade (see Chapter 34) is paramount in avoiding any movements by the patient while the surgical instruments are within the abdominal cavity. An orogastric tube and a urinary bladder catheter are placed. Eye lubricant and eye lid closure need to be assured. Convective-air body warmers are applied whenever possible.

In the supine position, the patient is prepared and draped, and the abdominal cavity is insufflated with CO_2 to a pressure not to exceed 20 mm Hg. The trocar for the camera is placed manually. Incision ports for Nissen fundoplication and cholecystectomy are shown in Figures 87-14 and 87-15. The side cart robot is brought very close to the patient's head to engage the other trocars with visual guidance from the robotic camera. Because of the proximity of the side cart to the patient's head, there is limited access to the patient's airway and neck, and the head must be guarded against inadvertent collision with the robotic arms when moving.[83,84] After the robot is engaged, the patient's body position cannot be changed. The surgical team should be capable of rapidly disengaging the robotic device if an airway or anesthesia emergency arises. As with any laparoscopic procedure that requires a pneumoperitoneum with CO_2, ventilator adjustments may be required to normalize the exhaled CO_2. Some surgeons argue that the benefit of invasive arterial monitoring does not outweigh the risks.[84] This issue should be considered for each patient based on a risk–benefit analysis.

GYNECOLOGIC SURGERY

Robotic surgery in gynecology was first described in 1999 for fallopian tubal anastomoses[74,75] after sterilization or tubal ligation. Robotic techniques are being used to perform gynecologic procedures, such as sacral

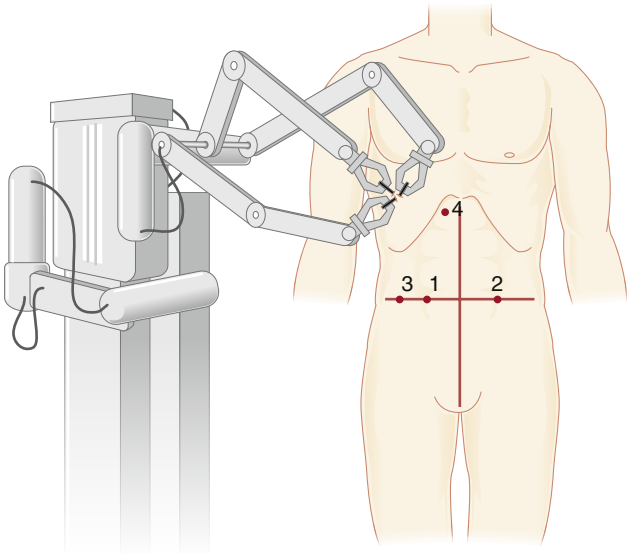

Figure 87-14. Numbered incision ports for Nissen fundoplication and location of the robotic arms.

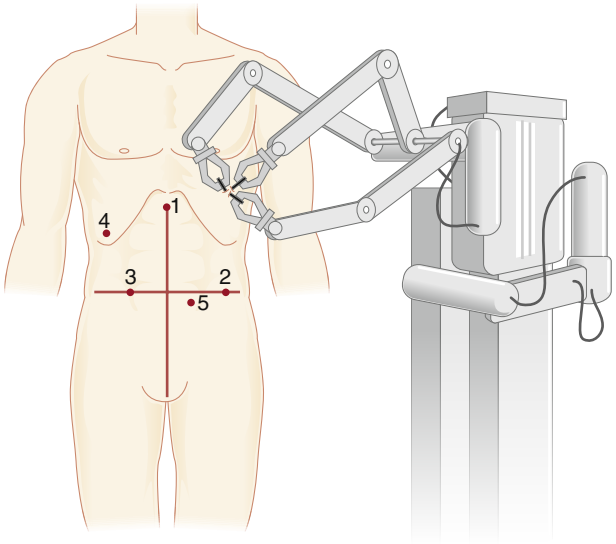

Figure 87-15. Numbered incision ports for cholecystectomy and location of the robotic arms.

colpopexy, myomectomy, treatment of endometriosis, simple and radical hysterectomy, salpingo-oophorectomy, ovarian cystectomy, and repair of vesicovaginal fistula.[76,77] In 2011, 146,000 hysterectomies were performed worldwide.[10] Despite the increasing popularity of robotic-assisted gynecologic surgery, there is little evidence to demonstrate lower incidence of complication when compared with open procedures.[85-87] Robotic gynecologic surgery is associated with similar morbidity, longer operative time, and higher cost when compared with open procedures.[82,86,87] The differences in outcomes in patients with higher BMI undergoing robotic gynecologic surgery are not known. Anesthesiologists should consider the physiologic effects of steep Trendelenburg position and pneumoperitoneum when providing anesthesia for these procedures. [88]

NEUROSURGERY

From the late 1980s to 1993, neurosurgeons investigated the use of robots to position resection probes and devices precisely within neural parenchyma to provide minimally invasive surgery and to protect normal tissue (see also Chapter 70). The da Vinci robot has been adapted to perform transnasal endoscopic skull base procedures, even though it was not designed for use in neurosurgery.[89] Robots such as NeuroMate (Renishaw plc, Gloucestershire, U.K.) have been developed to procure CT or MRI information to enable surgeons in performing accurate stereotactic procedures such as epilepsy surgery, performing biopsies, placement of ventricular reservoirs for chemotherapy, and placement of deep brain stimulator leads. [90-93] CyberKnife (Accuray, Sunnyvale, Calif.) is an image-guided, frameless, stereotactic radiosurgery system for treatment of spinal tumors. A major potential benefit of radiosurgical treatment of spinal lesions is that this can be performed in an outpatient setting, with rapid recovery.[94] The integration of various disciplines, such as robotics, machine intelligence, nanotechnology, and sophisticated computational networking, could revolutionize the practice of neurosurgery in the twenty-first century.

No data are present regarding the difference in outcomes in patients with higher BMI who are undergoing robotic neurosurgical procedures. Cost effectiveness data for robotic neurosurgery are not available.

ORTHOPEDIC SURGERY

The first medical application of robotics was in orthopedic surgery. There are two main types of robotic systems being used in orthopedic surgery: autonomous and haptic (see also Chapter 79). In 1992, Paul,[95] a veterinarian who worked in collaboration with International Business Machines (Armonk, N.Y.), developed a robotic system that could be used for hip replacement in dogs. The research collaboration resulted in the first surgical robot—ROBODOC (Integrated Surgical Systems, Davis, Calif.)—an autonomous robotic system. The earliest trials with ROBODOC were performed on patients undergoing total hip replacement. The femoral implant was placed into an axial canal of the proximal shaft of the femur. This femoral canal was formed with higher precision by a robot compared to the manual method.[95] The robot obtained its visual or coordinate cues from image-based information, such as from an MRI image or CT scan, and titanium pins placed in the femoral condyles and the greater trochanter. The robot recognized the three titanium registration pins and compared their location relative to the data obtained from CT. In this manner, the robot had a perfect sense of the position of the femur in three-dimensional space and could perform precise milling of the femoral canal. The remainder of the surgery proceeded manually. Autonomous robotic systems have fallen out of favor as they are associated with increased operating times and blood loss.[96,97] These systems are also associated with an increased risk of litigation.[98]

The Robotic Arm Interactive Orthopedic System (RIO; MAKO Surgical Corporation, Fort Lauderdale, Fla.) and Acrobot System (The Acrobot Company, London, U.K.) are examples of commercially available haptic robotic systems. These systems require active participation of the surgeon and use preoperative CT scans to create a three-dimensional model of the knee. The surgeon uses this model preoperatively to plan the sizing and placement of components and intraoperatively to "merge" the preoperative model with the actual anatomy of the knee. During the procedure the surgeon views the three-dimensional model of the knee on the monitor while manipulating the burr. The robotic arm provides auditory and haptic feedback, limiting the rotating burr to resect the bone within the preplanned cutting zone. Such haptic systems have a short learning curve and allow the surgeon to have greater precision.[99,100]

No data are present on the difference in outcomes in patients with higher BMI who are undergoing robotic orthopedic procedures. Robotic arthroplasty surgery has similar outcomes with significantly higher costs. [101]

SUMMARY

The use of robots in surgery is likely to increase in the future because of enhanced precision, multiple degrees of freedom, tremor filtering, and the ability to fuse preoperative (CT and MRI) and intraoperative images to guide the surgeon.

Although robotic systems have improved a great deal in dexterity, technically, much needs to be done to realize the full potential of this surgery. Current areas of research include the development of sensory input, and the ability to relay touch sensation from the robotic instruments to the surgeon. Some laboratories are also working to develop instruments for surgical anastomosis that requires no sutures. The possibility of automating some of these tasks in the operating room is another exciting and controversial idea. In the future, robots will be regarded less as mechanical devices and more as information systems. Robotic systems may also make long-distance consultation and guidance possible by experienced surgeons. The latest innovation in robotics is that of image-guided surgery, in which a surgeon is able to see in real time the scanner images superimposed on the surgical field. The human anatomy will be rendered translucent, and the exact location of any vital structure will be clearly visible. Preoperative diagnostic imaging in combination with virtual reality simulators will allow the surgeon to rehearse complex procedures in advance and to program the robot to avoid any vital structures during surgery.

Visualization systems are being developed that will improve surgery on mobile structures, such as the beating heart. Advances in motion gating technology will allow the heart to appear as if it were standing still. This will be done by properly timing a strobe light that is synchronized with the heart rate to achieve the proper virtual image of the heart standing still.[2]

Anesthesiologists need to be aware of this fast-changing field and the effects on anesthetic techniques and delivery. Initially, robotically assisted procedures increased the duration of general anesthesia. As surgeons gain expertise with robotically assisted surgery, operative times decrease dramatically. As the size and cost of robotic systems decrease and potentially improved outcome data become available, robotic systems are likely to become less of a marketing tool and more a technological innovation to improve patient care. As with all innovations, we make progress with optimistic caution.

Chapter 88

Anesthesia for Laser Surgery

VICKI E. MODEST • PAUL H. ALFILLE

Acknowledgment: The editors and publisher would like to thank Dr. Ira J. Rampil for contributing a chapter on this topic to the prior editions of this work. It has served as the foundation for the current chapter.

Key Points

- Lasers are characterized by wavelength, power, and duration of pulse.
- High-energy lasers (classification risk, Class 3 or 4) should be supervised by a laser safety officer.
- Laser energy can be transmitted at full strength at a distance from the source.
- Eyes are the most vulnerable organ.
- Laser goggles must be matched to the frequency of the wavelength and energy level.
- Airway fires are a significant risk when using lasers in or near the airway.
- High fraction of inspired oxygen concentration (FiO_2) significantly increases the risk of airway fires.
- Nitrous oxide (N_2O) is not a safe diluting gas for airway fire risk.

Laser is an acronym for *light amplification by stimulated emission of radiation*—a highly collimated beam of photons at a single frequency. Lasers are ubiquitous in the modern world and are increasingly used in the operating room (OR). Understanding the technology is important to safe anesthetic practice. Some of the same properties that make laser energy useful also make it a safety threat to both the patient and the staff.

Although any intense light source can cause biologic effects, lasers are unique in their precision. The critical features of laser light are the following:

1. Collimation—precisely aligned beam that can be seen on the moon
2. Coherence—light in phase
3. High-power density
4. Narrow spectrum of frequency
5. Can be pulsed for less than 10^{-11} seconds (femtosecond range)

Lasers were first developed in the 1950s with a history of conflicting primacy claims and protracted patent battles somewhat akin to the discovery of anesthesia. Its use in surgery followed shortly thereafter, but the extent of the applications continues to progress rapidly.

PHYSICS OF LASER

The original observation that electromagnetic radiation occurred only in discrete amounts, called *quanta*, was made by Max Planck,[1] for which the Nobel Prize was awarded in 1918. The energy of these quanta is proportional to the frequency of radiation:

$$E = h\nu$$

where h is Planck's constant (6.6×10^{-34} joule-seconds) and ν is the frequency.

Einstein's work on the photoelectric effect[2] (Nobel Prize, 1921) found that light was quantized (photons) and that transitions in electron energy states orbiting in an atom emit photons of characteristic frequencies. Certainly, the reverse is true—photons can raise electrons to higher energy states and can cause a current to flow. Because photon frequency (ν) and wavelength (λ) are related by the speed of light, $c = \nu\lambda$, Planck's postulation can also be expressed as:

$$E = ch/\lambda$$

Thus photons at a higher frequency (or shorter wavelength) have more energy.

Typical light sources such as the sun or an incandescent light bulb produce a range of wavelengths. This spectrum can be separated by a prism or rainbow. The atoms in a heated gas, for instance, have a spectrum of energies based on Boltzmann statistics. The photon radiation pattern changes with the temperature or the radiation source (hence the difference between the color spectrum of an incandescent bulb and daylight), but the pattern contains a range of frequencies (Fig. 88-1).

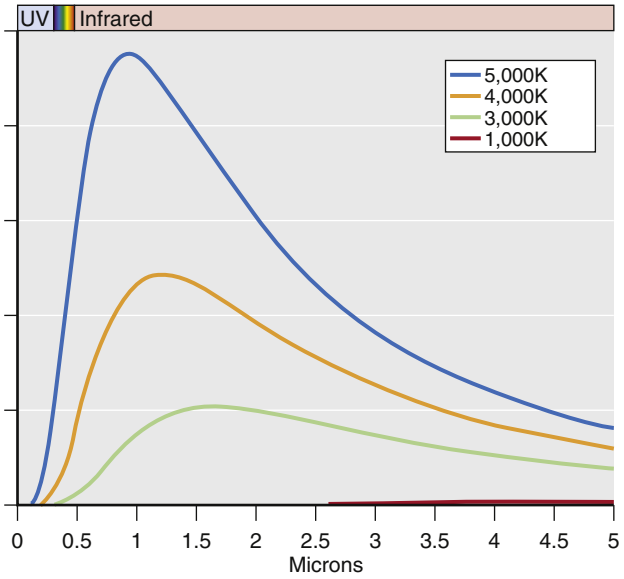

Figure 88-1. Higher temperature objects radiate at a higher intensity and shorter wavelengths.

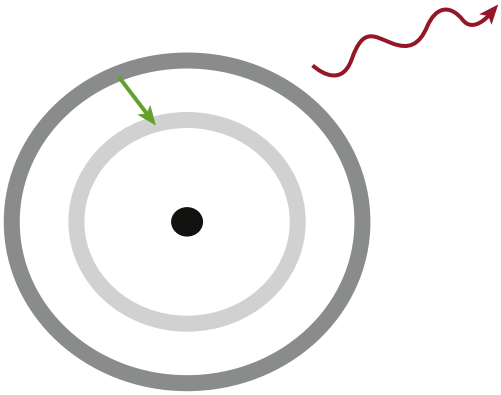

Figure 88-2. Spontaneous emission.

The laser phenomenon requires a detailed look at electron-photon interaction. Electrons orbit in atoms in discrete energy levels called *quantum states*. They can be pushed to higher energy states by collision with photons but will eventually return to the lower state emitting a photon. Because only specific energy levels are permissible, the emitted photon has only certain allowed energy levels and thus frequency. The phase and direction of photon emission is random in spontaneous energy transitions (Fig. 88-2). In the physical process of fluorescence, photons from higher energy light (or x-rays) cause excitation of the fluorescent atoms to glow at their characteristic frequency.

Lasers radiate not only in a narrow frequency but also with uniform phase and direction. Einstein proposed the phenomenon of stimulated emission based on theoretic arguments. Stimulated emission (as opposed to spontaneous emission) is a process during which an emitted photon triggers another excited state atom to emit at exactly the same phase and direction and energy level (Fig. 88-3).

Lasers are designed to amplify stimulated photon discharge, causing more stimulation and photon release. Typically, the laser cavity is mirrored at each end to reflect the emitted photons to increase the population of stimulated photons and thus the signal (an optical resonator); hence, the full explanation of the *laser* acronym: *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation.

Some subtlety exists in ensuring that the stimulation will be amplified. Stimulated photons have three possible fates: (1) escape as part of the working beam, (2) absorption by a nonexcited atom, or (3) stimulating an excited atom to emit as well. For a laser to amplify the photon discharge, the population of excited atoms must be larger than those in the ground state—*population inversion*. An external photon source (another laser or a flash lamp) or possibly a chemical means can induce the excitation. In practice, more energy states are involved (three- or four-level lasers), depleting the absorbing ground state. Other means of removing nonexcited atoms are possible, such as chemical dissociation (excimer laser) or gas separation.

TYPES OF LASERS

One method of categorizing the types of lasers is based on the physical process used. Even these broad categories have many nuances and are undergoing active development (Fig. 88-4).

- **Solid-state laser.** The lasing material is solid crystalline, similar to the first ruby laser, or a synthetic gem crystal known as *yttrium-aluminum-garnet* (YAG)—not to be confused with solid-state electronics, which includes diode lasers.
- **Gas laser.** Carbon dioxide (CO_2) and helium are common types. CO_2 is a particularly efficient type and is used for industrial metal cutting, as well as for medical uses.
- **Excimer laser.** A pair of disparate gas molecules forms a dimer in the excited state. The gas pair is usually a noble gas, such as xenon or argon, and a reactive halide, such as bromine or fluorine. The gases are complexed only in the excited state (under pressure with electron discharge) and rapidly dissociate after emission, preserving population inversion (i.e., the condition of having enough high-energy states distributed in a material that a chain-reaction of stimulated emission can occur). Their spectrum is in the ultraviolet range. In medical use, they function more by ablating tissue than causing a burn.
- **Dye laser.** An organic dye is used as the laser medium. These lasers have a large variety of wavelengths and high power. The wide spectrum available allows matching specific pigments (for tattoo removal), hemoglobin absorption, and a variety of skin lesions. The dyes and suspension media are often carcinogens, so care must be used in handling them.

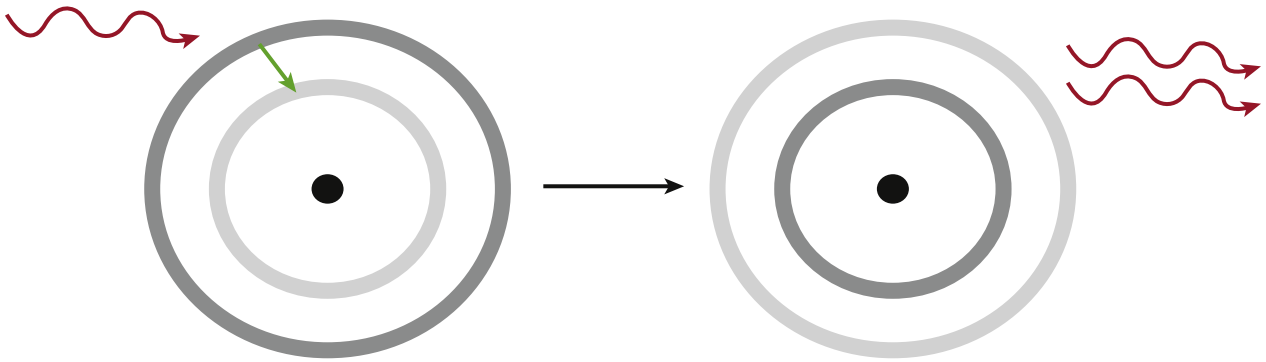

Figure 88-3. Stimulated emission. The emitted photon has the same direction and frequency as the triggering photon.

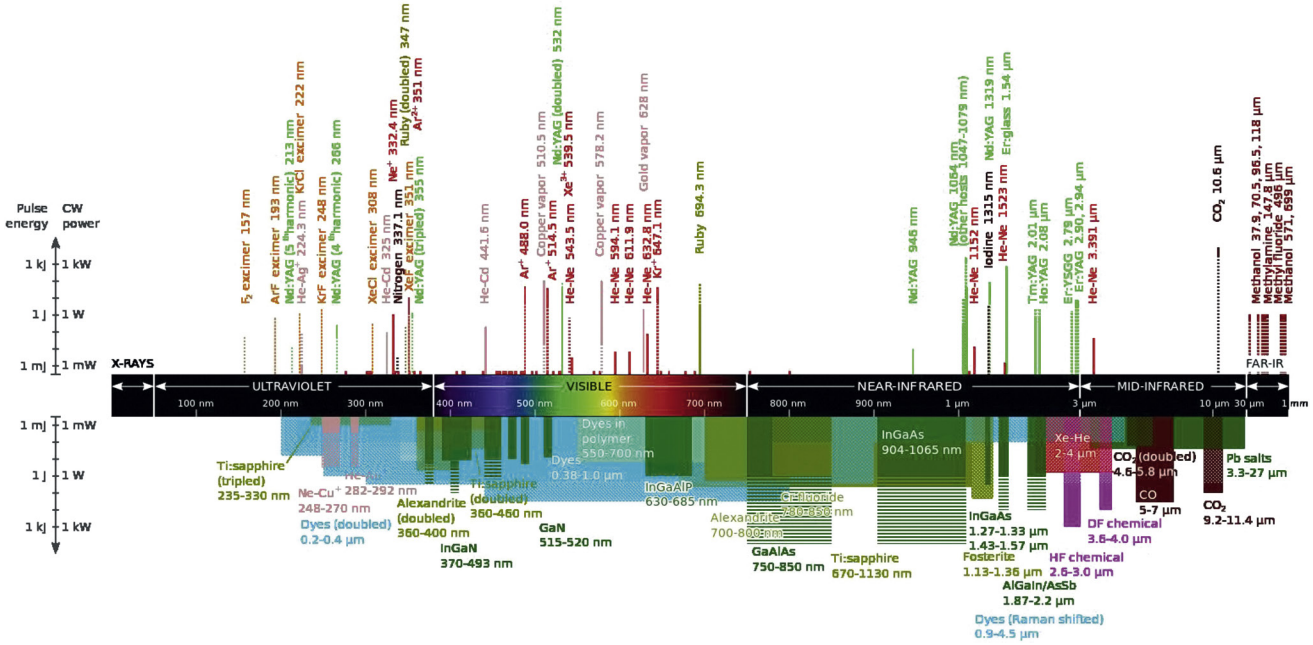

Figure 88-4. Commercially available lasers by power and wavelength. Power is shown in the vertical axis. Distinct frequency lasers are shown above, and wavelength ranges are below. *Blue,* Dye lasers; *green,* solid-state and semiconductor lasers; *red,* gas and excimer lasers. *(From Danh. Wikipedia Commons. <*http://en.wikipedia.org/wiki/File:Commercial_laser_lines.svg*> Accessed 11/22/2013.)*

- **Diode or semiconductor laser.** A specially constructed semiconductor layer on a silicon substrate can lase when electron and *holes* combine. The excitation can be from an optical or electrical source. These are now the most common lasers made and are used in consumer electronics (e.g., laser pointers, CDs, and DVD players), as well as sensors, pointers, and communication devices.

LASER MODES AND SETTINGS

There are a few *knobs* that can be adjusted for laser treatment.

1. Timing mode—continuous wave (CW) or pulsed. The length of pulse varies with the physics of the generating system but can be shortened by physical or electrical means (i.e., mode-locked). Interest in ultrashort length pulses—femtoseconds—is increasing.
2. Energy level. Specified in watts for continuous, and joules for pulsed. Lasers are typically used in two modes: continuous and pulsed.

CW lasers are produced from photons continuously escaping the amplification chamber. Several methods can produce pulsed lasers: (1) by either mechanically or electrically changing the reflection properties of the amplification chamber walls; (2) by using an intermittent pumping source to excite the lasing sequence, such as another pulsed laser or flash lamp; and (3) by mode locking, in which variations in phase are summed, causing interference patterns and allowing extremely short pulses.

BIOLOGIC EFFECT

Light has a biologic effect solely from absorption in tissue (Grotthus-Draper law), specifically by raising electrons to higher energy states that, in turn, can raise kinetic

energy (heat) or cause chemical reactions. Lasers have been applied to medicine since 1962.[3] The current uses are widespread and evolving. Boulnois categorized the biologic effects into four types.[4]

- **Electromechanical effects.** A pulsed laser causes a shock wave and thus an actual mechanical impulse. One common application is in stone lithotripsy for ureteral calculi. Laser lithotripsy using holmium:YAG (Ho:YAG) is at least as effective as extracorporeal shock,[5] and low-frequency high-power shocks are more effective in experimental models.
- **Thermal effects.** Similar to other surgical techniques (electrocautery from radiofrequency currents, harmonic scalpel), localized heat can cauterize and separate tissue, allowing bloodless incisions. Laser thermal effects differ little from other surgical sources[6] except that they can be more finely focused with high-energy density and delivered via fiberoptic strands. Bolliger found that airway lesions were well managed by laser, electrocautery, or argon plasma coagulation.[7] In some cases, laser coagulation may offer an advantage when laser frequencies that are absorbed by specific tissues such as the retina or hemangiomas are chosen. One treatment for port-wine stains involves pulse-dye tuned to hemoglobin, with surface dermal cooling to protect the surrounding tissue.[8]
- **Photoablative effects.** These effects come from the molecular disruption and ablation of tissue, with the resultant gases removing heat and protecting the surrounding tissue from thermal injury. Photoablative effects can be either at the microscopic level (femtosecond lasers for corneal surgery) or at a macroscopic level (photoselective vaporization of the prostate).[9]
- **Photochemical effects.** Photochemical effects are the newest area of interest and the least well proven mechanistically. Low-level laser therapy (LLLT) has been used in a wide variety of surgical and nonsurgical conditions. Various theories suggest that specific wavelengths can modify enzyme systems,[10] change electron transport and tissue oxidation states,[11] or be mediated via nitric oxide.[12] Although ongoing research is required, it is suggested that neurologic injuries may be effectively treated with certain wavelengths.[13]

COMMON LASER OPERATIONS

Defining the full scope of applications for lasers in surgery is difficult. In general, lasers are used for surface procedures and for endoscopic procedures during which the energy can be routed by fiberoptic bundles. Some of the more common laser surgical procedures are performed in dermatology, dentistry, laryngology, and ophthalmology.

DERMATOLOGY

The use of lasers in dermatology, from removal of lesions to wound care, has been long established and quite extensive.[14] Most procedures are office based, use topical analgesics, and do not involve anesthesiologists,[15] except possibly with children.[16]

DENTISTRY

The use of lasers in dentistry involves treatments for the discoloration of teeth, periodontal disease, and oral lesions.[17]

LARYNGOLOGY

The use of lasers in laryngology involves endoscopic resection of laryngeal cancers, either office based for smaller lesions[18] or with rigid suspension microlaryngoscopy.[19,20] Precise coagulation of vascular lesions without damage of the phonatory surface is another common application. Additionally, lasers are used in resecting papillomatosis (also see Chapter 85).[21]

OPHTHALMOLOGY

Lasers are extensively used, including with glaucoma surgery, during procedures in which very short pulses can target small cell clusters, for corneal shaping for vision correction,[22] and in retinal surgery with wavelengths that are transparent to the cornea but absorbed by pigmented retinal cells. Corneal surgery can be performed either by surface ablation of stromal tissue (typically with short-wavelength excimer lasers) or by creating subsurface flaps with femtosecond pulses at 1053 nm and allowing the microbubbles of plasma to separate tissue.[23] Most ocular surgeries are performed with topical or retrobulbar nerve–regional block and intravenously administered sedation. Low-level laser therapy can replace higher energy interventions in retinal disease (also see Chapter 84).[24]

RISKS OF LASER USE: STANDARDS AND REGULATIONS

SAFETY FRAMEWORK

Laser safety in the clinical setting is a multidisciplinary responsibility occurring at several organizational levels. Medical facilities are responsible for implementing safety programs and policies that adequately control the hazards associated with laser use.

In the National Academy Sciences Institute of Medicine report, "To Err is Human: Building a Safer Health System," *safety* is defined as "freedom from accidental injury."[25] Further, the National Patient Safety Foundation (NPSF) emphasizes that safety is a function of a coordinated effort that depends on interactions at many points and is not a result of an individual or a device.[26] The provision of safe laser use in the OR requires a team approach with the establishment of safe practices enforced by cooperative input and vigilance from all providers present (also see Chapter 109).

REGULATORY AGENCIES

A number of agencies oversee laser regulations, especially regarding its use in health care. The International

Electrotechnical Commission (IEC) is the body of the main standards, especially for Europe, but U.S. standards closely follow them. The guidelines come from an international technical committee (TC-76) with expert guidance from many organizations.[27] The specific IEC technical report is IEC 60825-8, "Safety of Laser Products—Part 8: Guidelines for the Safe Use of Laser Beams on Humans."[28]

Japanese guidelines are published by the Japanese Standards Association under JIS C 6802:2011, "Safety of Laser Products."

In the United States, laser safety guidelines are created by the American National Standards Institute (ANSI). The current laser safety guidelines are ANSI Z136.1–2007,[29] and the health care specific guidelines are ANSI Z136.3–2011.[30] Medical lasers are regulated by the U.S. Food and Drug Administration (FDA) under the Federal Food, Drug, and Cosmetic Act (FFDCA), Chapter V, Subchapter C—Electronic Product Radiation Control. The FDA publishes its standards (online) under Title 21, Chapter 1.J.1024.10.[31] The FDA regulations use the older class Roman numerals I through IV categories and include requirements for labeling and the need for various safety mechanisms.

Other than the FDA, no other mandatory federal agency standards or regulations specifically govern the safe clinical use of medical lasers, but accepted standards exists that facilities may voluntarily adopt and to which they may adhere. Several organizations focus on laser safety in general, including the FDA's Center for Devices and Radiological Health (CDRH), ANSI, the Occupational Safety and Health Administration (OSHA), and the nonprofit, Conference of Radiation Control Program Directors (CRCPD). Many states have regulations and guidelines as well. The FDA suggested a set of regulations in 1983 that have been adopted and modified by several states.[32] The CRCPD is attempting to establish a "Model State" standard.[33]

OSHA is the main U.S. agency that enforces safety and health legislation in the workplace. At present, OSHA does not have a comprehensive laser safety standard, but this organization publishes a technical manual on laser hazards,[34] endorses ANSI Z136.1–2007, and can issue citations attributable to the lack of compliance with other safety standards. The Joint Commission (TJC) (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) uses ANSI Z136.1–2007 and ANSI Z136.3–2011 as its guidelines. Under these guidelines, medical facilities appoint a laser safety officer (LSO) who is formally trained to administer the overall institutional safety program, which includes monitoring and enforcing the control of laser hazards. Currently, data regarding the incidence of laser-related injuries to patients and workers are incomplete. However, some safeguards to encourage reporting of potential safety breaches are in place, including (1) requiring laser manufacturers to report unusual incidents or injuries, and (2) the Safe Medical Devices Act of 1990, which mandates that clinicians report all serious injuries incurred from the use of a medical device.

Professional society taskforces have consensus statements that recommend how to prevent and manage OR hazards (also see Chapter 6). In 2008 and 2013, the American Society of Anesthesiologists (ASA) Task Force on Operating Room Fires issued practice advisories for the prevention and management of OR fires, with specific comments regarding lasers[35] (also see Chapter 109).

Considering the inherent risk in the medical application of lasers, state and federal safety guidelines and societal standards should be followed to ensure regulatory safety compliance, to provide a framework for identifying and controlling the risks of laser use, and to develop effective safety educational and training programs to better protect patients, employees, and property. Establishing a safe and compliant medical laser program requires access to standards and training. The Laser Institute of America (LIA) is an independent professional body, allied with OSHA,[36] that functions as secretariat of the ANSI standards. The LIA offers conferences and training materials and courses, including the certification for Certified Medical Laser Safety Officers.[37]

LASER RISK CLASSIFICATION

Lasers pose a safety risk to OR personnel. Because the beam is highly collimated, it can travel with minimal attenuation outside the intended surgical field either directly or by reflection. The likely biologic risk is for retinal damage because the structure of the eye concentrates the beam and has pigments tuned to visible wavelengths. Thermal effects (i.e., skin burns) come from heating with long exposures and high intensity and depend on local tissue susceptibility.

The current classification for laser devices from the IEC 60825-1 standard is based on safety risk. Four classifications, some with modifiers, cover safety and warning features (Fig. 88-5), the required level of training, and controls.

- **Class 1 lasers.** Are safe under all normal uses, even with optical magnification, although a strong lens might sufficiently concentrate the energy to cause damage. Class 1M is a subcategory for diffuse beams that could be harmful when viewed under magnification but not under expected conditions.
- **Class 2 lasers.** Are safe because of the blink reflex, which limits exposure to under one fourth of a second. A typical example is a laser pointer. Class 2M is safe for the same reason, as long as magnifying optics are not used. Class 2 lasers are confined to the visible range (400 nm to 700 nm) with any nonvisible emissions only at Class 1 levels. Class 2 lasers could be hazardous to patients in whom the blink reflex is suppressed.
- **Class 3 lasers.** Are split into two groups on the basis of intensity. Class 3R lasers are within five times the acceptable emission limit of Class 2 in the visible range and five times Class 1 outside that range. Class 3B is above that level and is able to cause direct ocular injury. Viewing reflections off matte surfaces are safe for Class 3 lasers.
- **Class 4 lasers.** Include high-powered lasers that can cause fire and injury even when viewing diffuse reflections.

Calculating actual exposure limits is complex. It depends on wavelength, intensity, duration, and type of injury (ocular versus thermal). Lasers used in medical

Figure 88-5. The International Electrotechnical Commission (IEC) laser warning label for Class 2 and higher.

facilities should have been classified by their manufacturer, unmodified, and properly maintained. As previously discussed, in the United States, medical lasers are regulated by the FDA under the FFDCA. Occupational exposure limits are set by OSHA, using guidelines from ANSI Z136.1–2007 for maximum permissible exposure (MPE) to the retina, based on wavelength and exposure time.

Many devices still in operation use the older classification scheme (ANSI Z136.1 or IEC 825), as do U.S. safety regulations. These are Roman numerals I through IV and roughly correspond to the current classes as listed:

- **Class I lasers.** Are safe under all conditions. Have very low power, or the laser is completely contained (e.g., CD players).
- **Class II lasers.** Are safe because of the blink reflex. Visible range with blink keeps exposure levels under one fourth of a second. Up to 1 mW.
- **Class IIa lasers.** Are safe for up to 1000 seconds of continual viewing.
- **Class IIIa lasers.** Are dangerous if viewed for longer than 2 minutes. May not be safe under magnification. Up to 5 mW power.
- **Class IIIb lasers.** Even momentary exposure can cause retinal damage, although indirect reflections should be safe. Laser goggles should be worn. Up to 500 mW.
- **Class IV lasers.** Are greater than 500 mW. Can easily cause ocular injury or burns. Even reflections off a matte surface can cause injury.

The revised ANSI Z-136.1–2007 guidelines now use the IEC Class 1 through 4 categories. In the ANSI Z-136.1–2007 guidelines, Class 3B and Class 4 handling should include key control, remote interlock connector, activation warning system (audio warning), window protection, protective goggles, training, and supervision by a laser safety officer (Table 88-1).

SPECIFIC LASER HAZARDS

The same properties that give lasers their clinical value also pose threats to patient and provider safety. These risks fall into three categories: (1) atmospheric contamination, (2) gas embolism, and (3) inappropriate energy transfer.

To place the relative safety risks in context, a review of laser safety databases for urologic procedures revealed that 46% of the reported incidents were machine problems (i.e., fiber breakage), followed by eye injuries, including permanent blindness. Seven deaths occurred, three from ureteral perforation and four from gas embolism.[38] As expected in this surgical population, airway fires were not represented.

ATMOSPHERIC CONTAMINATION: LASER PLUME

Tissue destruction during surgical laser procedures produces a complex particulate aerosol and smoke plume. Research confirms that this plume can contain compounds and toxic gases such as polyaromatic hydrocarbons, hydrogen cyanide, formaldehyde, benzene, and cellular material (dead and alive).[39,40] Fine particulates (mean size 0.31 μm; range 0.1 to 0.8 μm) and combustion by-products are easily dispersed throughout the respiratory tract. Animal studies link inhalation of the laser plume with pulmonary damage, which can lead to reduced mucociliary function, airway inflammation, interstitial pneumonia, bronchiolitis, and emphysema.[41-43]

The laser plume has in vitro mutagenic and teratogenic potentials. The mutagenic potential of the plume from a CO_2 laser on 1 g of tissue is equivalent to inhaling the smoke from three unfiltered cigarettes. This toxic potential is one half of that produced by electrosurgical units but is considerably more than that produced by Nd:YAG contact probes.[44]

Although controversial, the laser plume has the potential to transmit viable microorganisms into the atmosphere.[45-47] However, reviews have not found strong evidence of danger.[48] Viral DNA has been detected in plume from human papilloma virus (HPV)[49] in condylomas and skin warts,[50] but evidence for transmission to humans is weak. On its web site, OSHA notes that "no documented transmission of infectious disease through surgical smoke" has been published (see OSHA web site statement regarding Laser/Electrosurgery Plume: https://www.osha.gov/SLTC/laserelectrosurgeryplume/). A recent review of the literature assessing the infectivity of HPV in the plume is contradictory and scanty.[51] Inoculation of bovine papillomavirus (BPV) DNA from a surgical plume produced bovine fibropapillomas in three calves.[52] Other studies showed plume particle viability but no infectivity in susceptible cell lines.[53] Investigation into a laser surgeon's development of laryngeal papillomatosis, after laser treatment of a patient, revealed that the lesions in both the patient and the surgeon shared the same, albeit common, HPV serotypes.[54] A recent case report detailed two cases of HPV-induced airway cancers in surgeons using extensive lasering.[55] The incidence of HPV infection in laser surgeons specializing in the treatment of papillomas and condylomas is comparable to the incidence in the general public.[56] Human immunodeficiency virus (HIV) was not detected in electrosurgical smoke plume[57] in one study, and only noninfectious DNA fragments were found in a CO_2 laser plume from HIV-infected tissue pellets.[58]

Smoke evacuators are 99% effective at eliminating the plume when situated within 1 centimeter of the target site.[59] Accordingly, their use in the OR is strongly advised and supported by OSHA. The Centers for Disease Control and Prevention (CDC) states that surgical suction systems are not interchangeable with the preferred smoke evacuator suction unit.[60] In addition, using high-filtration masks that filter plume particulates down to 0.3 to 0.1 μm when dry is essential. Of note, viral particles are too small to be filtered reliably, and standard surgical masks filter particles as small as 3 μm.

EMBOLISM

The Nd:YAG laser system has been associated with venous gas embolism. Specifically, the gas coolant for the laser tip has been the responsible system element. During hysteroscopic surgery, while using an Nd:YAG laser, an accidental inflation of the uterine cavity by coolant resulted in deaths.[61] A sheathed quartz fiber (with coaxial coolant gas running) produced a massive and fatal gas embolism in another case.[62] Liquid (saline) coolant is a safer option during hysteroscopy, but fluid overload is possible.[63] If a coolant gas must be used, then CO_2 may be less harmful after embolization than nitrogen or air. Venous gas embolization has occurred at other sites, including tracheal tumor with an Nd:YAG laser,[64,65] during laparoscopic procedures,[66] and during nasal surgery using a CO_2 laser.[67] Continuous airway CO_2 monitoring may help with the detection of embolization. During laparoscopic surgery with CO_2 insufflation, mechanical hyperventilation should be adjusted to compensate for intraabdominal CO_2 absorption and cephalic displacement of the diaphragm, and a watchful eye must be maintained for the potential development of subcutaneous emphysema.

ENERGY TRANSFER TO AN INAPPROPRIATE LOCATION

Currently, medical lasers can all transmit an unattenuated and potentially destructive beam through air. If the

TABLE 88-1 SAFETY RECOMMENDATIONS FOR OPERATING VARIOUS CLASSES OF LASERS

	Classification						
Requirements Subclause	Class 1	Class 1M	Class 2	Class 2M	Class 3R	3B	Class 4
Laser safety officer 10.1	Not required, but recommended for applications that involve direct viewing of the laser beam				Not required for visible emission, but required for nonvisible emission	Required	
Remote interlock 10.2	Not required					Connect to room or door circuits	
Key control 10.3	Not required					Remove key when not in use	
Beam attenuator 10.4	Not required					When in use, prevents inadvertent exposure	
Emission indicator device	Not required				Indicates laser is energized for nonvisible wavelengths	Indicates laser is energized	
Warning signs 10.5	Not required					Follow precautions on warning signs	
Beam path 10.6	Not required	Class 1Ma as for Class 3B	Not required	Class 2Mb as for Class 3B	Terminate beam at end of useful length		
Specular reflection 10.7	No requirements	Class 1Ma as for Class 3B	No requirements	Class 2Mb as for Class 3B	Prevent unintentional reflections		
Eye protection 10.8	No requirements				Required if engineering and administrative procedures not practicable and MPE exceeded		
Protective clothing 10.9	No requirements				Sometimes required	Specific requirements	
Training 10.10	No requirements	Class 1Ma as for Class 3R	No requirements	Class 2Mb as for Class 3R	Required for all operator and maintenance personnel		

NOTE: This table is intended to provide a convenient summary of precautions. See text of this standard for complete precautions. From IEC 60825-1:1993+A1:1997+A2:2001 Safety of laser products, p. 108.

intended target is not accurately being sighted, then laser activation can result in injury to patients and OR personnel or damage to property. Laser ignition of any combustible fuel (e.g., surgical drapes, plastic endotracheal tubes [ETTs], ointment on the skin) may also occur either by unintentional direct beam strike or by reflectance and scatter of the beam off of specular surfaces.

TISSUE AND VESSEL PERFORATION

Off-target laser energy may perforate a viscus[68,69] or a blood vessel (if the vessel is too large to be cauterized: diameter >5 mm). Pneumothorax has been reported after a laser laryngeal procedure.[70] Of note, with an Nd:YAG system, the depth of tissue injury may not be immediately apparent. Complications such as viscus, tissue plane, or vascular perforation (with resultant complications) may not occur until edema and necrosis have become maximal several days postoperatively.

EYE INJURY AND EYE PROTECTION

Laser light, because of its special qualities of beam collimation, coherence, and high-energy density, poses optical safety hazards not associated with light from conventional sources. The extent of damage is determined by the laser irradiance, exposure duration, and beam size. The site of laser-induced ocular damage depends on the output wavelength. Visible and near-infrared light (400 to 1400 nm) can damage the retina. Argon, potassium titanyl phosphate (KTP):Nd:YAG, or ruby lasers are likely to focus on that structure with resultant rapid permanent damage to the retina.[71] Ultraviolet and far-infrared light is absorbed by the anterior structures. Infrared energy from a CO_2 laser causes corneal and lens injury.[72] With sufficiently powered lasers, permanent ocular damage can occur within a fraction of a second.

The blink reflex is too slow to guard against laser injury. Proper protective eyewear with side shields and appropriate filtering capabilities and optical density (specific for the type of laser to be used) are safety essentials for all present in the OR. The nonoperated eyes of patients should be taped closed and covered with saline-soaked opaque material or a metal shield.[73] CO_2 lasers emit far-infrared frequencies that are unable to pass through any clear glass or plastic lenses. Regular eyeglasses, fitted with side shields, may be sufficient protection, but contact lenses are not. All other lasers emit energy that requires specific colored lenses. Nd:YAG lasers require green-tinted goggles (which can make skin color assessment and monitor reading difficult), or clear lenses (Nd:YAG Protection Glass; Surgical Laser Technologies, Malvern, PA), which have a special coating opaque to near infrared. Argon or krypton lasers require amber-orange lenses, and KTP:Nd:YAG lasers require a red filter. The wrong eyewear will not protect. All protective eyewear must be donned before entering the OR. Glass windows in the unit must be covered during the use of lasers, and cautionary warning signs should be posted as described in ANSI Z136.3–2011 (also see Chapter 84).

LASER GOGGLES

Laser goggles need to be matched to the frequency of the Class 3 or Class 4 wavelength and still allow sufficient vision for safe medical care. In particular, it may be necessary to still see the weaker aiming beam at a different wavelength. IEC 60285-8 suggests that remote video observation may be an alternative to protective eyewear, as long as no risk of fiber breakage or the inadvertent direct exposure occurs.

Laser goggles are typically labeled with the wavelength and attenuation in decibels (dB) or optical density (OD). An OD of 6 at 1064 nm for Nd:YAG will attenuate the transmitted energy by $10^{-6.}$ The required OD should be calculated that reduces the maximum accessible emission (MAE) or power to below the MPE. Unfortunately, the goggles themselves may not physically withstand the laser strike.[74]

EN-207 is a more stringent IEC standard[75] that includes not only the degree of filtering but the resistance of the goggles to the laser itself, including reradiated energy. EN-207 markings include an *L number* that indicates the maximum power permitted (a logarithmic scale ranging from L1 through L10), and a DIRM modifier:

Marking	*Mode*
D	Continuous wave (cw)
I	Long pulse > 1 μs
R	Short pulse 1 ns to 1 μs
M	Femtosecond < 1 ns

The power limits are presented in EN-207 and differ for mode of operation (DIRM shown in the table above) and the wavelength range (180 to 315 nm, 315 to 1400 nm and > 1400 nm).

OPERATING ROOM FIRE

The ignition and propagation of fire requires a triad of components: ignition source, fuel, and oxidizer. All parts of the *fire triad* (Fig. 88-6) are ubiquitous in ORs and may

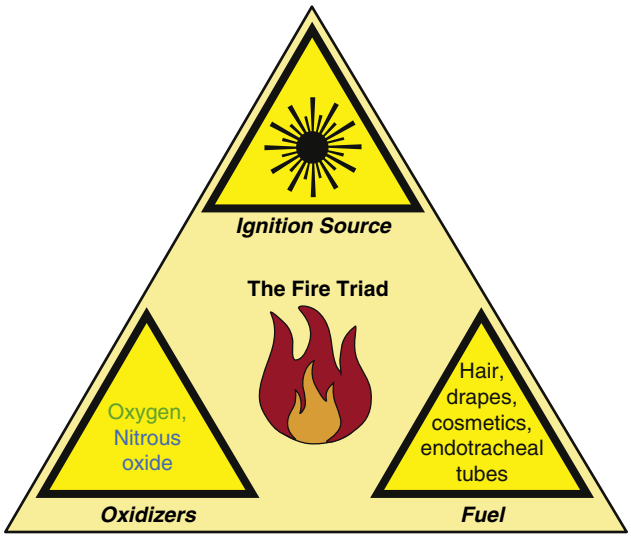

Figure 88-6. The fire triad.

be in close proximity of each other during laser surgeries. Lasers are highly effective and rapid sources of ignition.[76,77] Laser operators need to be well versed and compliant with the standards and codes in place for the safest practice during laser use. Given the right fuel, ignition may occur with oxygen as the primary oxidizer at 21% (room air) or at lower percentages in certain conditions.[78] Ignition potential is amplified in the presence of an enriched oxidizer concentration. This is true for either of the two prevalent OR oxidizers: oxygen or nitrous oxide (N_2O). Anesthesiologists and laser operators must work together to ensure the lowest possible fraction of inspired oxygen concentration (FiO_2) at critical points in all laser procedures. Common sources of fuel in the OR include the ETT and other plastic items, drapes and towels, and alcohol-based preparation solutions. Less common fuels include hair and skin ointments, which highlight the need for reminding patients to be ready for surgery with the face free of makeup and no products in the hair.

Although a feared complication, the actual incidence of surgical fires per year in the United States varies widely, depending on the report, and is not clearly defined. The Emergency Care Research Institute (ECRI), an independent nonprofit health service research agency, estimates between 550 and 650 surgical fires occur every year; an extremely small percentage of approximately 65 million annual surgical cases. Further, the ECRI reports that a high percentage of these surgical fires occur in the airway (34%) and head or face (28%)[79,80] A report from TJC gives the incidence of OR fires at 20 to 30 per year.[81] A report from 1984 that examined the complications associated with several thousand CO_2 laser surgeries reports the incidence of airway fires at 0.14%.[82] Even higher (and older) estimates on the incidence of ETT fires during laser procedures of the airway are 0.5% to 1.5%.[83,84] Surgical fire represents the most common major complication of endoscopic airway laser surgery and may result from direct or indirect laser beam contact with the ETT.[85] Smoldering particles of tissue from the surgical site can ignite an ETT.[86] In an otolaryngologic survey published in 2011, during endoscopic airway and tracheal surgery, a laser was the ignition source in 26 of 27 fires, 15 of which involved the ignition of an ETT and 7 of which had the FiO_2 at 0.21.[76] A survey of otolaryngologists reported on 100 fires, with electrosurgery causing 59%, lasers causing 32%, and light cords causing the remaining 7%. Supplemental oxygen was involved in 81%; in 31% of these cases, the ETT caught fire.[87]

INSPIRED OXIDIZERS AND OPERATING ROOM FIRES

When laser use is planned, the concentration of inspired oxidizers must be considered. Ignition is facilitated and combustion is more intense in oxidizer-enriched environments, which occurs with the use of either oxygen or N_2O. The risk associated with N_2O might not be readily apparent. In its resting state, N_2O has no free oxygen. An oxygen analyzer will reflect the dilution of oxygen by N_2O (with a lowered FiO_2) when the two gases are used together. However, N_2O easily exothermically dissociates, releasing heat and free oxygen. The fire risk of an oxygen and N_2O mixture should be considered equivalent to administering 100% oxygen. In an updated 2013 ASA Practice Advisory for the Prevention and Management of Operating Room Fires, the majority of the ASA taskforce members "…strongly agree that the use of nitrous oxide (N_2O) should be avoided in settings that are considered high risk for fire."[35]

Materials that resist ignition at a low FiO_2 may vigorously combust with an added oxidizer. As the temperature of the environment increases, the required FiO_2 needed to support combustion decreases. Flaming combustion can occur at warm conditions in oxygen concentrations as low as 14% to 16% (National Fire Protection Agency 921 Guide for Fire and Explosion Investigations 1998). The 2013 ASA practice advisory does not give a maximum allowable FiO_2 for procedures at high risk for fire but states that it should be "kept as low as clinically feasible…" to "…avoid hypoxia." Few clinicians would agree to allow laser use in the presence of an FiO_2 level greater than 0.4, or 0.5, which is considered dangerous in in vitro studies.[88] Most want the FiO_2 under 0.3 in high-risk fire settings. A 2013 analysis of the ASA Closed Claims database, which dates back to 1985, found that laser fires during general anesthesia occurred with inspired oxygen concentrations greater than 30%.[89] Analyses such as this one are used to establish *best practice* approaches to patient care.[90] As a consequence, many institutions have enacted policies mandating the use of safer ETTs and an FiO_2 below 30% for all intraoral surgeries with a provision to use an ignition source.[91] When available, diluting 100% oxygen with helium offers a small advantage over an air-nitrogen mixture attributable to its higher thermal conductivity that can delay the ignition of an ETT for a few seconds.[92,93] The index of flammability is reduced by only 1% to 2%.[94] Additionally, helium's lower density reduces the Reynolds number,* transition to turbulent flow, and thus increased resistance to flow, allowing the use of a smaller ETT.[95,96] Finally, reducing inspired FiO_2 does not protect from an increased airway oxygen concentration until expired concentration also decreases, which can take several minutes when low fresh gas flows are used.[97]

MONITORED ANESTHESIA CARE AND OPERATING ROOM FIRES

Surgical fire is the second most common injury that results in liability during monitored anesthesia care.[98] Oxygen-enriched environments are usually present in OR fires during anesthesia for upper body surgeries, which creates an exceedingly high-risk setting for fire because all three essential elements—ignition source, fuel, and oxidizers—are in close proximity.[99] Accordingly, in 2009, the ECRI and the Anesthesia Patient Safety Foundation (APSF) came out in support of guidelines for the use of oxygen administration during upper body surgeries.[80] Suggested for these procedures is the use of only nonoxygen-enriched air for any open delivery of gas via facemask or nasal cannula to the face when an ignition source will be present. If the spontaneously breathing patient,

*The Reynolds number is a dimensionless ratio of inertial and viscous forces, predicting the steadiness of fluid flow.

sedated or not, needs supplemental oxygen to maintain an acceptable oxygen blood saturation, then the airway should be secured with an ETT or laryngeal mask airway (LMA).[100] A theoretical concern is that supplemental oxygen, which is heavier than air, will be trapped in the drapes and pool around the patient's face and upper body.[101]

If a general anesthetic must be avoided, then the goal for using supplemental oxygen should be to use the minimum concentration of oxygen judiciously to maintain acceptable blood oxygen saturation. Simply lowering the flow of 100% oxygen to an open delivery site will not allow for control of the delivered FiO_2. However, predelivery blending of oxygen with air will do so.[102] A venturi apparatus is an option.[103] The ECRI recommends options such as the use of an oxygen blender or the use of a three-gas anesthesia machine that has a common gas outlet.[80] To attach the facemask or the nasal cannula tubing to the breathing circuit, a 5-mm ETT connector is attached to the Y-piece of the circuit.[100] The implementation of an *open face* draping scheme should be considered to dissipate the collection of added oxygen lingering around the surgical site.[104]

GENERAL ANESTHESIA AND AIRWAY FIRES

When the surgical site is within or near the airway, coordination between the anesthesia and surgical teams is essential to consider the need for an ETT, which tube type to use, the oxygen enrichment plan, and mode of ventilation. If intubation is planned, then varied intubation options exist and include an assortment of available ETTs and jet ventilation catheters. A few oxygenation-ventilation strategies include ventilating through a cuffed or tightly fitting ETT, either continuously or intermittently using a ventilator with apnea during episodic removal of the ETT to allow unobstructed access to the surgical field. Either supraglottic or infraglottic catheter positioning may be selected for jet ventilation. In addition, the choice of anesthetic must be considered. There are series using sevoflurane and spontaneous ventilation[105]; however, volatile anesthetics are not reliably delivered to the patient if jet ventilation is required, and the vapors can pollute the OR. Finally, although the volatile anesthetics currently used in clinical practice are nonflammable and nonexplosive in clinically relevant concentrations,[106] when exposed to flame, they may pyrolyse to potentially toxic compounds.[107] As such, the ANSI Z136.3–2011 standard conservatively recommends not using volatile anesthetics during airway laser surgery.

ETT fires have their own set of elevated risks for the patient and require swift corrective measures. With the right conditions and if properly managed, an ignited ETT may cause little if any harm. However, catastrophic injury may occur.[108,109] If ignited and combustion breaches the ETT with its centrally flowing reservoir of oxidizer, a *blowtorch* scenario in the airway can occur (Fig. 88-7). The potential for far-reaching thermal injury to the pulmonary tract exists. In addition, products of complete and partial combustion including smoldering debris, particulate matter, toxic gases, and compounds may cause further insult.

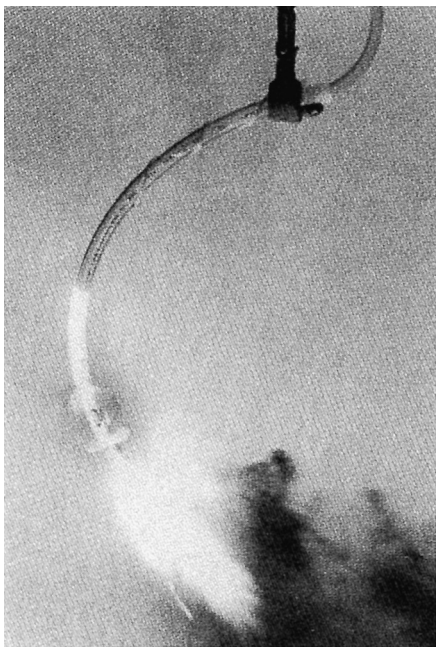

Figure 88-7. Blowtorch ignition of an endotracheal tube. *(No authors listed: Airway fires: reducing the risk during laser surgery,* Health Devices *19:109, 1990.)*

When using a laser near the airway, the updated 2013 ASA Practice Advisory strongly agrees that "laser resistant tracheal tubes [and catheters] should be used, and that the tube choice should be appropriate for the procedure and the laser…" If a cuffed tube is used, then the cuff should be filled with saline rather than air whenever feasible.[35] Methylene blue–dyed saline may help speed identification of cuff breaches.[110] Added protection from ignition may be achieved by using water-soaked sponges around the tube at the site of work and at the glottis. These sponges may seal leaks of oxygen around an ill-fitting ETT cuff, segregating the higher FiO_2 being delivered to the patient from the ambient air above the glottis and may protect the tube from laser strikes by adding a layer of water-saturated protection.

ENDOTRACHEAL TUBE COMPOSITION AND COMBUSTION-RELATED PROPERTIES

Standard polyvinyl chloride (PVC), red rubber, and silicone ETTs are candidates for use during laser procedures near the airway, but all are ignitable and require protective measures. Their dissimilar properties, reactions to various laser types, and by-products of combustion have been studied. Studies show that PVC easily absorbs far-infrared light and is vulnerable to CO_2 laser. Smith and colleagues[76] found a rapid (less than a 2-second) ignition of PVC ETTs exposed to 5 W CO_2 laser at 100% oxygen. Using a canine model, Ossoff and colleagues[111] studied CO_2 laser–ignited fires of PVC, red rubber, and silicone ETTs and found that all ignited into blowtorch scenarios in the setting of 1% halothane, 30% oxygen, and 70% N_2O. The effects of intraluminal fire on the larynx and trachea were assessed. Of the ETTs studied, the PVC type was not only the type that most readily ignited, but it

also deposited carbonaceous debris and caused the most severe burns and cellular damage. The PVC ETT also produces more toxic by-products of combustion, such as hydrochloric acid. The red rubber ETT was more ignition-resistant and produced less debris and tissue inflammation. Silicone ETTs took the longest exposure to ignite, but the finding of silica ash raised concern for possible remote development of silicosis. Other studies[82,112] have similar findings, except Ossoff[92] found red rubber ETTs were slower to ignite than silicone ETTs.

On the other hand, energy from Nd:YAG and visible laser light is not easily absorbed by clear PVC ETTs; however, if anything (e.g., blood, tissue, lettering on the ETT) disrupts the transparency, then energy will be absorbed at that point and will place the ETT at high risk for ignition. In a 1991 study, 1 minute of continuous exposure to an Nd:YAG laser at 70 W and 100% oxygen flowing produced no damage to the PVC ETT when aimed at the unmarked clear portion of a PVC ETT. However, when aimed at the ETT markings, ignition occurred at 2.6 seconds, and when aimed at blood or mucus, ignition occurred in less than 6 seconds.[113] This same research group and another demonstrated that none of the three commonly used ETT materials—PVC, red rubber, and silicone—are safe when exposed to Nd:YAG laser energies.[114,115]

LASER-RESISTANT ENDOTRACHEAL TUBE

Various strategies for the protection of ETTs from laser-strike damage have been evolving since the 1970s. Standard ETTs may be rendered more resistant to ignition by wrapping them with protective material, or the alternative is to use laser-resistant tracheal tubes (LRTTs), which are ETTs prefabricated with protective layering. In every case involving the use of lasers, the risk of airway fire must be considered and appropriate precautions taken if any appreciable chance of ignition is present.

The first ETT laser protection option was a do-it-yourself wrapping with laser-resistant materials. Flammable-resistant, smooth, and flexible tapes including aluminum and copper foil and metallic-coated plastic are typically used. These tapes are available through trade and craft stores and have proven to slow laser ignition.[116,117]

Although the practice of using metallic tapes to create LRTTs is well supported in the older medical literature, practitioners should realize that none of these products have FDA approval for this use. Practitioners opting to use the metal tapes to hand-wrap ETTs incur significant liability and patient safety risk. Even the one FDA-approved wrap, Merocel Laser-Guard Protective Wrap, is no longer marketed as a result of poor demand.

FDA-approved LRTTs are commercially available. These LRTTs vary in design and intended use. Some of these products are no longer on the market, including the Norton, Xomed Laser-Shield, and Bivona Fome-Cuff ETTs. The Xomed Laser-Shield was withdrawn from use after its involvement in three airway fires, one of which resulted in a death.[118] The Medtronic Laser-Shield II ETT (Medtronic ENT, Jacksonville, Fla) is a redesigned version of the Xomed tube. Some of the other currently available LRTTs include the Sheridan Laser-Trach (Hudson RCI/Teleflex/Medical, Research Triangle Park, NC), Rusch Lasertubus (Teleflex/Medical, Research Triangle Park, NC), and the Mallinckrodt Laser-Flex, now branded as the Covidien Laser Oral/Nasal Tracheal Tube Dual Cuffed Murphy Eye (Covidien, Mansfield, Mass).

The available LRTTs are made of metal or have a nonmetal tube core with a metallic overlay. The nonmetal core LRTTs are the following: (1) The Medtronic Laser-Shield II, which is intended for use with CO_2 and KTP lasers, is a silicone tube core wrapped with a flexible aluminum overlay topped by a fluoroplastic layer. It is a single-cuffed LRTT with dry methylene blue indicator in the unprotected silicone elastomer cuff. The covering is specified to withstand (in vitro) 35,000 W/cm^2 of CO_2 laser energy or 11,000 W/cm^2 of KTP energy for 3 minutes. In a laboratory test, a continuous laser beam at 20 W vaporized the fluoroplastic film, but the tube above the cuff did not perforate or ignite.[119] Blood on the surface of the tube did not result in ignition or burn-through, even when tested at increased beam power of 38 W.[120] (2) The Sheridan Laser-Trach, which is also intended for use with CO_2 and KTP lasers, is a red rubber tube core with a copper foil overlay. It has an unprotected single cuff. The tube above the cuff took 60 seconds to perforate when subjected to 40 W of continuous CO_2 laser, but it was readily ignited by a high-power Nd:YAG laser.[121] (3) The Rusch Lasertubus is intended for use with all medical laser types. It is has a central tube of flexible white rubber, "reinforced with corrugated copper foil and absorbent sponge" per product information provided by the manufacturer, Teleflex Medical, and has a dual cuff-inside-a-cuff system. Bench testing of this product by Teleflex Medical showed no damage to the tube integrity when exposed to a CO_2 laser at 20 W for 40 seconds. In independent testing, the area above the cuff withstood 90 seconds of a Nd:YAG laser set at 25 W and a CO_2 laser at 75 W.[122]

A metal LRTT is the Covidien Laser Oral/Nasal Tracheal Tube Dual Cuffed (Laser-Flex), and is intended for use with CO_2 and KTP lasers. It has an airtight flexible armored stainless steel shaft and two independent cuffs, positioned in series. It was shown that the shaft above the cuffs withstood 1 minute of a 69 W CO_2 laser. The shaft did not hold up to Nd:YAG laser at high power.[123] With the CO_2 laser set at 38 W, this tube ignited one out of four times when dry and had almost immediate combustion if blood was on the surface.

All LRTTs are merely *resistant* to laser damage. None, either metal wrapped or all metal, have protected shafts that are completely safe under all conditions, and all cuffed LRTTs have vulnerable cuffs and tips. LRTTs are no replacement for vigilant and thoughtful care by all present in the OR.

PROTECTION OF THE ENDOTRACHEAL CUFF

The thin pliable plastic or elastomeric envelope of the standard high-volume, low-pressure cuff found on ETTs and LRTTs is at risk for puncture from misdirected laser energy. If unrecognized, cuff punctures allow delivered gas, which is likely oxygen-enriched, to travel above the incompetent cuff and flood the surgical field, creating a high risk for an airway fire if using a laser. Other than the

Bivona Fome-Cuff, which is no longer available, no other cuffs remain inflated after puncture. If laser use near the airway is planned, then implementing cuff-protective strategies such as the following is essential: (1) Use saline to fill the cuff. A cuff puncture may extinguish a small fire. The updated 2013 ASA Practice Advisory notes that the majority of members and consultants strongly agree that "the tracheal cuff of the laser tube should be filled with saline rather than air, when feasible."[35] (2) Tint the saline in the cuff with methylene blue to act as an early marker of cuff puncture.[35] (3) Place the cuff as far away as possible (distal in the trachea) from the site of laser use. (4) Use moistened cotton pledgets or sponges to cover any exposed cuff. The usefulness of these practices in preventing or delaying cuff ignition from CO_2 laser exposure has been confirmed.[124,125]

JET VENTILATION

Optimal surgical conditions for procedures necessitating an unobstructed airway can be obtained with jet ventilation, which can occur from a supraglottic position (requiring no instrumentation of the airway) or through a flexible and small diameter jet ventilation catheter. In this mode of ventilation, Bernoulli's principle can explain the establishment of acceptable oxygenation and ventilation, despite the delivery of a relatively low volume of gas from the ventilator. Jet ventilation uses a high-pressure gas source to deliver a narrow high-velocity gas stream. This, in turn, creates a low-pressure microenvironment around the stream that causes the entrainment of surrounding gas. The entrained gas advances along with the primary gas stream, resulting in an additive effect and the delivery of a larger volume of gas to the patient. Concern about the potential absorption of carbon monoxide from the entrained laser plume by the patient during airway procedures prompted Goldhill and colleagues[126] to examine this possibility. They found no significant increase in carboxyhemoglobin during Nd:YAG bronchoscopy.

Jet ventilation, when used correctly and in accordance with safety precautions, has a low complication rate that includes the risk of barotrauma, pneumothorax, and crepitus. Concern existed over the potential for jet ventilation to cause distal bronchial seeding with active virus during laser resection of laryngeal papillomas. Shikowitz and associates[127] found no evidence of this in 96 patients who had multiple laser procedures. However, Cozine and colleagues in a multiinstitutional survey that examined 15,701 CO_2 laser airway surgeries found a higher rate of ventilatory complications with jet ventilation than with a standard ETT (Fig. 88-8), but the only fatality was caused by an ETT fire. The investigators concluded that no single mode of ventilation proved superior during laser surgery.[128]

During supraglottic jet ventilation, an intermittent gas stream is directed at the glottis through a small metal tube, such as a ventilating bronchoscope or even a 12-gauge blunt needle.[129,130] A retrospective review of 942 cases of microdirect laryngoscopy using endolaryngeal jet ventilation found only four complications.[127] Supraglottic jet ventilation has the advantage of using no flammable material in the airway during ventilation. However, oxygen-enriched air is free to flow back and enrich the air at the tissue targeted by the laser. Fires have been reported with this technique.[131]

A few catheter options exist for infraglottic ventilation. Rigid metal catheters that are nonflammable are available but cumbersome for the surgeon to work around. Nonmetal catheters used during laser procedures need to be appropriate. The Laser Jet catheter, made of polytetrafluoroethylene (Acutronic Medical Systems, Hirzel, Switzerland) and the Hunsaker Mon-Jet tube (product 7080100, Medtronic ENT, Jacksonville, Fla) are not flammable but can be deformed or punctured by CO_2 laser impact.[132]

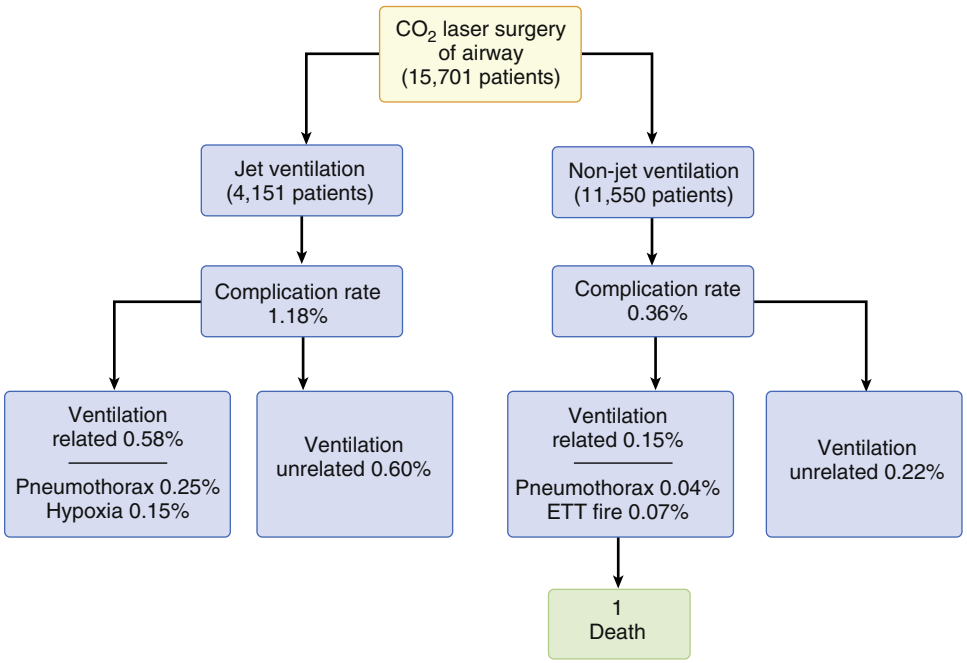

Figure 88-8. Complications of laser airway surgery. Pneumothorax was common with jet ventilation, but potentially lethal airway fires occurred with endotracheal intubation. *ETT,* Endotracheal tube. *(Data from Cozine K, Stone JG, Shulman S, et al: Ventilatory complications of carbon dioxide laser laryngeal surgery,* J Clin Anesth *3:20-25, 1991.)*

To further reduce obstruction of the surgical field by ventilatory appliances, perhaps all instrumentation could be removed by using spontaneous ventilation or intermittent apnea, with general anesthesia provided by nasal insufflation or bronchoscopic delivery of a volatile inhaled anesthetic[105,133] or an intravenous anesthetic.[100,134] Another common technique is modest hyperventilation, followed by intermittent tracheal extubation by the surgeon for periods of 90 to 120 seconds, during which time the laser is used.[135,136] Pulse oximetry adds a measure of safety by confirming adequate oxygenation from a denitrogenated pulmonary residual capacity during apnea.

OTHER CONSIDERATIONS

Although not specifically related to laser procedures in the airway, vagal hyperactivity often occurs during instrumentation of the trachea and during suspension laryngoscopy, in particular. Immediate recognition and treatment, which potentially includes the release from suspension and the intravenous administration of a vagolytic drug, are essential. Intense (deep) neuromuscular blockade is often a surgical need during laser on minute targeted areas in the airway. The paraneoplastic syndrome, occasionally observed with small cell and other types of endobronchial tumors, may lead to prolonged weakness after the administration of neuromuscular blocking drugs[137] (also see Chapters 52 and 53).

AIRWAY AND OTHER FIRES ON THE SURFACE OF THE PATIENT

In the event of a potential or actual OR fire, a timely and prompt response is imperative. Early warning signs of combustion need immediate communication to others in the OR and a full investigation. These signs may include suspicious odors, sounds, or visuals such as unexplained drape movements, flash, or discoloration of materials. If the patient is awake, then unanticipated complaints of discomfort or restlessness and moving on the table may be important signs. If a fire is detected, then the current ASA OR Fire Management Practice Advisory states that the event should be immediately announced, the procedure halted, and fire management tasks initiated.

The ASA OR Fire Management Practice Advisory and the ECRI have nearly identical algorithms for the essential steps of handling airway or other fires on the surgical patient[35,80] (see the ASA document for the complete Operating Room Fires Algorithm).[35] The essentials are provided:

Fire in the airway:

1. Remove the tracheal tube or breathing circuit fire. Hand it off to be extinguished and inspected.
2. Stop airway gas flow (consider disconnecting the circuit).
3. Remove all flammable and burning materials from the airway.
4. Pour saline or water into the patient's airway (to extinguish the fire and cool the tissues).

Nonairway fire:

1. Stop airway gas flow.
2. Remove drapes, flammable, or burning material from the patient.
3. Extinguish any burning items.

After the airway fire is extinguished:

1. Reestablish ventilation by mask. Avoid supplemental oxygen or N_2O, if possible.
2. Examine the ETT to evaluate whether fragments have been left in the airway. Consider bronchoscopy to assess injury and to remove foreign bodies.
3. Assess the patient's status, and devise a plan for ongoing care.[†]

After the nonairway fire is extiguished:

1. Assess the patient's status, and devise a plan for ongoing care.[†]
2. If not intubated, assess for smoke inhalation.

If the fire is not extinguished on the first attempt, then:

1. Use a CO_2 fire extinguisher.
2. If the fire persists, then:
   a. Activate the alarm system.
   b. Evacuate the patient, if feasible, and follow institutional protocol.
   c. Close the door to the OR.
   d. Shut off the medical gas supply to the OR.

[†] Assessment might include the involvement of other specialties. Perhaps a surgeon could perform a rigid bronchoscopy or bronchial lavage. Perhaps the trachea should be reintubated or a tracheotomy performed. A chest radiograph should be obtained. Pulmonary damage attributable to heat or smoke inhalation, or both, may necessitate prolonged tracheal intubation and mechanical-controlled ventilation. Humidification, bronchoscopy, and management of carbon monoxide or cyanide toxicity may be needed.[138] An expert consultation in burn management should be obtained to help evaluate and devise a plan for burns on the surface of the patient.

Chapter 89

Ambulatory (Outpatient) Anesthesia

IAN SMITH • MARK SKUES • BEVERLY K. PHILIP

Acknowledgment: The editors and the publisher would like to thank Drs. Paul F. White and Matthew R. Eng, who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The use of ambulatory surgery continues to increase, mostly as a result of less invasive surgery, improved patient selection and preparation, and an expansion in office-based practice.
- Few absolute contraindications exist to ambulatory surgery. Patients should not be excluded on the basis of arbitrary limits, such as age, body mass index, or American Society of Anesthesiologists physical status classification system.
- Effective preoperative assessment is required to evaluate and prepare patients and is essential for the delivery of safe, high-quality, and efficient ambulatory surgery.
- Many anesthetics and techniques can be used for ambulatory surgery. Of prime importance, experience and careful attention to detail are required to deliver high-quality rapid recovery with minimal side effects.
- Spinal anesthesia may extend the range of patients and procedures suitable for ambulatory surgery, but it requires the use of small doses of bupivacaine combined with opioids or short-acting local anesthetics to avoid prolonged recovery.
- Sedative techniques can facilitate a wide variety of procedures performed in the hospital, office, or remote settings. However, sedation is no safer than general anesthesia and requires the same standards of personnel, monitoring, and perioperative care as for patients undergoing general or regional anesthesia.
- Multimodal analgesia, using combinations of local or regional anesthesia, acetaminophen, and nonsteroidal antiinflammatory drugs, provide effective relief of pain. The reduced need for opioids decreases the incidence and intensity of adverse effects.
- Antiemetic prophylaxis should be based on individual patient risk. Multimodal regimens are required for patients and procedures known to be associated with increased risk for complications.
- Patients should be discharged with written information concerning aftercare, return to normal activities, follow-up evaluation, and a contact telephone number. This advice must include early warning signs and the appropriate action to take.
- Ambulatory surgery remains very popular with patients with infrequent rates of adverse events and complications. One important component of success in ambulatory surgery and anesthesia is minimal postoperative nausea and vomiting.

Ambulatory surgery has its origins in Glasgow, Scotland, where, between 1898 and 1908, James Henderson Nicoll performed almost 9000 ambulatory surgery procedures on children, nearly half of whom younger than 3 years of age.[1] Contrary to the prevailing philosophy, which advocated prolonged bed rest after surgery, Nicoll encouraged early mobilization and home follow-up by a visiting nurse to reduce high cross-infection rates and overcome bed shortages and financial constraints. A few years later, Ralph Milton Waters opened his Downtown Anesthesia Clinic in Sioux City, Iowa, allowing adult patients to return home within a few hours of difficult dental extractions, abscess drainage, or reduction of minor fractures.[2] Further progress was slow until the dangers of prolonged bed rest and the economic advantages of shorter stays began to be recognized toward the middle of the twentieth century. The first hospital-based ambulatory surgical units were opened in Grand Rapids, Michigan, in 1951 and in Los Angeles, California, in 1952, and somewhat later at London's Hammersmith Hospital in the United Kingdom in 1969.[3] At the same time, the first free-standing ambulatory surgery center opened in Phoenix, Arizona,[4] rapidly followed by many others across North America in the 1970s and 1980s.

The development of ambulatory anesthesia as a recognized subspecialty was enhanced by the formation of

the Society for Ambulatory Anesthesia (SAMBA) in 1984[5] and the British Association of Day Surgery in 1989. These and nine other national societies came together in 1995 to form the International Association for Ambulatory Surgery (IAAS), an umbrella organization dedicated to the worldwide promotion of ambulatory surgery.

Ambulatory surgery has expanded far beyond performing simple procedures on healthy patients. Currently, a broad range of major procedures are performed in patients who frequently have complex preexisting medical conditions. The availability of improved anesthetic and analgesic drugs minimizes the anesthetic side effects and facilitates the recovery process, as do the increasing availability of minimally invasive surgical techniques. Equally important has been a philosophical change that challenged outdated and conservative practices, demanding inpatient procedures. Ambulatory surgery now accounts for approximately 80% of the elective surgeries in the United States.[6] Ambulatory surgery also constitutes a large proportion of elective surgical activity in the United Kingdom and in many other countries, although rates for individual procedures still vary across countries in Europe.[7]

DEFINITIONS

Although ambulatory surgery is widely practiced, the precise definition can vary across countries and health care systems. For consistency, we have used the definition proposed by the cofounder of the IAAS: "A surgical day case is a patient who is admitted for investigation or operation on a planned non-resident basis and who none the less requires facilities for recovery. The whole procedure should not require an overnight stay in a hospital bed."[8] This definition requires the patient to be managed with the intention of same-day discharge from the outset, in addition to admission, operation, and discharge all occurring on the same calendar day. Including management intention in the definition ensures no incentive is provided to discharge a planned inpatient at short notice, who would be without all of the preparation and support that make ambulatory surgery such a high-quality form of care.

Short-stay surgery embraces all of the principles of ambulatory surgery and includes a postoperative overnight hospital stay. This may be because of significant comorbidities, lack of social support, or a procedure that is either too extensive or performed too late in the day to be compatible with same-day discharge. We have included short-stay surgery in this chapter because the objectives of minimizing physiologic disturbance to improve the quality of recovery and reduce the length of stay are the same as those of ambulatory surgery and much of the perioperative management is similar.

BENEFITS OF AMBULATORY SURGERY

The major incentive to perform more ambulatory surgery is the high quality of patient care it can achieve as a result of reduced tissue trauma, enhanced recovery with minimal adverse events, and the provision of effective postoperative analgesia, appropriate information, and postoperative support. Patients appreciate the more efficient scheduling of surgery, not requiring the availability of a hospital bed, and the comfort and convenience of recovering in the familiar home environment. Financial advantages exist to ambulatory surgery in eliminating the costs associated with overnight admission. In both the United States and the United Kingdom, procedures that are compatible with ambulatory surgery receive the same payment (from insurance companies and regional budget holders, respectively), irrespective of the length of stay. Therefore, if a patient does stay overnight, the extra costs are borne by the facility. In the United Kingdom, a few procedures currently attract a slightly higher level of funding when performed on an ambulatory basis,[9] to incentivize best practice and finance any necessary pathway redesign.

FACILITIES FOR AMBULATORY SURGERY

In the United States, the American Society of Anesthesiologists (ASA) provides guidelines on ambulatory surgical facilities,[10] including adherence to local regulations, staffing requirements, and minimum equipment standards. Quality standards are set and enforced by government regulation, licensing, or accreditation. In the United States and Canada, hospital-based ambulatory surgical facilities receive accreditation through The Joint Commission (TJC), Det Norske Veritas (DNV), and the Healthcare Facilities Accreditation Program (HFAP). Ambulatory surgery centers and office-based surgery locations can receive accreditation through the Accreditation Association for Ambulatory Health Care (AAAHC), American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF), or TJC. In the United States, the Centers for Medicare & Medicaid Services (CMS) has its own inspection program in addition to accepting accreditation decisions from the listed organizations.

A multitude of designs exist for ambulatory surgical facilities. Some have been purpose designed, and others have evolved by adapting existing facilities. The facilities delivering ambulatory care services also vary by country, but they can be broadly categorized into four models of care, each with its own advantages and disadvantages.[11]

HOSPITAL INTEGRATED

The simplest model of ambulatory surgery is one with shared inpatient surgical facilities, but with separate areas for preoperative preparation and recovery of ambulatory patients. This model of care was previously regarded as inefficient and brings the risk for ambulatory procedures being delayed or even canceled in favor of more major inpatient procedures or emergency pressures. However, by dedicating certain operating sessions to ambulatory surgery and using strict protocols, efficiency can be almost equal to that of a self-contained unit.[12] The design is very flexible, allowing the proportions of ambulatory and inpatient surgery to vary from day to day,

and, as new procedures are transferred to ambulatory surgery, it does not require all the equipment and skills of the operating room to be duplicated in a separate facility. It is also relatively inexpensive to expand the size of the preoperative and postoperative areas as ambulatory surgery grows.

HOSPITAL SELF-CONTAINED

These self-contained units are functionally and structurally separate from inpatient facilities with their own reception, admission areas, operating rooms, recovery areas, and administrative facilities. This design ensures functional separation from urgent and emergency work, yet all the backup facilities of the main hospital are readily available nearby. In many ways it is an ideal model of care; however, the capacity for ambulatory surgery is finite, and an inevitable need exists for duplication of operating room equipment and skills for procedures that are still commonly performed on both an ambulatory and inpatient basis.

FREESTANDING

Freestanding ambulatory surgery centers ensure complete separation from inpatient and emergency work. This improves efficiency and allows complete focus on ambulatory care. There is a risk of not being able to manage perioperative complications safely, although the typically good patient selection and preparation minimize this potential problem. However, unless the unit has some capacity for overnight stays, any unanticipated admission will need transfer to a nearby hospital, which somewhat limits the complexity of the patients and procedures undertaken. Ambulatory surgery centers vary from highly specialized, single-surgery facilities to multispecialty generalists, with a wide range of sizes.

OFFICE-BASED

Performing ambulatory surgery, diagnostic procedures, or both in a facility associated with a physician's office is a rapidly expanding area of care within the United States.[6] The main advantages are increased convenience for the patient and surgeon and smaller total procedure costs. Office-based services are much less regulated than ambulatory surgery centers, and especially unless accredited, they may have more significant equipment, personnel, and environmental limitations with lower ability to manage perioperative complications.

PATIENT SELECTION CRITERIA

SURGICAL FACTORS

The development of minimally invasive surgery, improvements in surgical technique and pain control, and the availability of shorter-acting anesthetics have dramatically increased the range of surgical procedures compatible with same-day discharge. The duration of surgery is now relatively unimportant, with the extent of surgical trauma being the more significant determinant. There should be no expectation of continuing blood loss, large perioperative fluid shifts, or the need for complex or specialized postoperative care. Surgical complications remain the single greatest cause of unanticipated hospital admission,[13,14] but provided these are infrequent and can be detected before discharge, ambulatory surgery should still be the plan. When discharge on the day of surgery is not possible, many patients require a single night in the hospital, making even more procedures suitable for short-stay surgery. In the United States and the United Kingdom, an overnight stay for an ambulatory surgery procedure receives no additional payment, so the extra costs are borne by the facility. The British Association of Day Surgery publishes a directory of over 150 different surgical procedures and suggests aspirational targets for the proportions of each that are suitable for either ambulatory or short-stay surgery.[15] A selection of these are shown in Table 89-1.

TABLE 89-1 SELECTION OF SURGICAL PROCEDURES THAT CAN BE PERFORMED ON AN AMBULATORY BASIS

Specialty	Examples of Surgical Procedures
Breast surgery	Excision or biopsy, including wide local excision, sentinel node biopsy, simple mastectomy, microdochotomy, and other operations on nipple
General surgery	Perianal fistulae, pilonidal sinus, hemorrhoidectomy, open or laparoscopic hernia repair, laparoscopic cholecystectomy, adrenalectomy, splenectomy, fundoplication, and gastric banding
Gynecology	Cervical surgery, laparoscopic tubal ligation, oophorectomy, hysterectomy, female incontinence surgery, and anterior and posterior repair
Head and neck	Dental procedures, excision of salivary glands, thyroidectomy, and parathyroidectomy
Ophthalmology	Cataract surgery, strabismus surgery, vitrectomy, nasolacrimal and all eyelid surgery
Orthopedics	Diagnostic and therapeutic arthroscopic surgery, anterior cruciate ligament repair, carpal tunnel release, bunion surgery, fracture reductions and removal of metalwork, lumbar microdiscectomy, minimally invasive hip surgery, and unicompartmental knee surgery
Otolaryngology	Myringotomy and tympanoplasty, rhinoplasty, procedures on nasal septum and turbinates, polypectomy, adenotonsillectomy, laryngoscopy, and endoscopic sinus surgery
Urology	Endoscopic bladder and ureteric surgery, transurethral laser prostatectomy, circumcision, orchidectomy, laparoscopic nephrectomy, pyeloplasty, and prostatectomy
Vascular surgery	Varicose vein surgery, dialysis fistula creation, and transluminal arterial surgery

Laparoscopic cholecystectomy is now a routine ambulatory surgical procedure in many countries, and increasingly same day discharge is seen as safe and beneficial with the use of many more advanced laparoscopic procedures, including fundoplication,[16] hysterectomy,[17] nephrectomy,[18] pyeloplasty,[19] and gastric banding.[20] Even complex procedures traditionally associated with a prolonged period of hospitalization have been performed on a short-stay basis, with some patients discharged the same day, including those undergoing awake craniotomy for tumor resection[21,22] and minimally invasive hip arthroplasty.[23] One series of 2000 patients undergoing laparoscopic Roux-en-Y gastric bypass for morbid obesity reported 84% being discharged within 23 hours, with a readmission rate of less than 2%[24] (see also Chapter 71). Patients undergoing less invasive procedures, such as diagnostic or therapeutic hysteroscopy, are leaving ambulatory surgery into the procedure room, outpatient clinic, or office. [25]

Postoperative pain and the ability to control it in the home environment is a major challenge for outpatient surgery. Discussed later in this chapter, high-volume local infiltration analgesia (LIA)[26] and the use of home delivery of local anesthetics through wound catheters[27] are helping to extend the boundaries.

Perhaps the greatest barrier to the development of ambulatory surgery is conservatism, based on an incorrect concern about serious complications that might occur after discharge. For example, despite convincing data that most primary hemorrhages are evident within 6 to 8 hours of tonsillectomy,[28,29] an overnight stay is still routine in some countries whereas others discharge 80% of patients or more on the day of surgery.[7] Similarly, ambulatory thyroid surgery was first shown to be safe and effective in 1986,[30] yet its widespread adoption has been slow,[31] predominantly because of concerns about bleeding and airway compromise. Such complications are rare, especially when surgery is undertaken by specialists who perform a high volume of cases, allowing short times to discharge to be achieved.[32] Performing thyroidectomy under local anesthesia also appears to increase ambulatory surgery rates,[33] perhaps because of the careful surgical technique required. In the case of breast surgery, concerns about postoperative psychological support has delayed transfer of mastectomy and other cancer operations into ambulatory care, although it is now recognized that early discharge improves the psychological well-being of these patients by minimizing the time away from home.[34] Challenging conventional wisdom also may be beneficial; for example, discontinuing the routine use of drains after mastectomy or axillary node clearance results in no significant increase in morbidity, including from wound seroma, while facilitating same-day discharge.[35]

MEDICAL FACTORS

In the past, ambulatory surgery has relied on relatively rigid patient selection criteria in the attempt to limit the occurrence of postoperative complications. In practice, however, most of these criteria predict the occurrence of treatable perioperative adverse events, but not the need for unanticipated admission or readmission.[36] Although an index combining age, length of surgery, and preexisting conditions, such as peripheral or cerebrovascular disease, can identify a group at higher risk for hospital admission, the specificity is poor and same-day discharge is still the most likely outcome.[37] Ambulatory surgery is very safe, with a perioperative mortality of less than 1 in 11,000,[38] better than that in the general population. The safety of ambulatory surgery continues to be excellent despite increasing surgical and patient complexity.[39-41]

Relatively few absolute contraindications now exist to ambulatory surgery. Patient suitability should be assessed on the basis of overall health, taking into account both the risks and benefits of early discharge, and certainly not determined by arbitrary limits, such as age, body mass index (BMI), or ASA physical status.[42] Chronic conditions should be relatively stable and must be optimally treated before any elective procedure, irrespective of the planned postoperative management. Many stable chronic diseases, such as diabetes, asthma, or epilepsy, are often better managed by patients, and ambulatory surgery facilitates this by easing the disruption to their daily routine.[42] A distinction should be made between preexisting conditions that will make a patient more difficult to manage on the day of surgery and those that increase the occurrence of late postoperative problems, thereby acting as a relative contraindication to ambulatory surgery.[43]

A good example is obesity, which is associated with numerous perioperative problems for the surgeon, anesthesiologist, and operating room personnel (see also Chapter 71). These may require the availability of experienced staff and specialized equipment, such as longer instruments and wider operating trolleys for safe care, but any risks are resolved soon after immediate recovery and are not prevented by overnight hospitalization. Obese patients benefit from ambulatory management with early mobilization, the use of short-acting drugs, and avoidance of opioid analgesia.[43] Obesity does not increase the rate of unanticipated admission, postoperative complications, readmission, or other unplanned contact with health professionals after discharge.[44] Even morbid obesity (BMI > 40 kg/m^2) is no longer considered an absolute contraindication to same-day discharge.[42] Obesity increases the likelihood of further comorbidities, but these should be evaluated in their own right.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) occurs in the general population but is much more common in obesity. Nonetheless, most cases can be managed safely and effectively on an ambulatory basis.[45] Perioperative problems, such as difficult endotracheal intubation and airway obstruction, should be anticipated.[46] However, patients undergoing more invasive surgery, especially involving the chest or airway, or those requiring large doses of perioperative opioids may be less suitable.[45] Difficulty may arise when OSA is suspected but has not yet been definitively diagnosed and treated. A simple questionnaire, supplemented with some basic measurements (e.g., STOP-Bang), can identify most patients at high risk for OSA,[47] who should then have the diagnosis confirmed and treatment instituted before surgery. In children, OSA is now one of the main indications for tonsillectomy and this has been seen as

a relative contraindication to ambulatory surgery. However, one recent study has shown that same-day discharge is still safe in the absence of other comorbidities.[48]

Age

Medical and social problems increase with age and should be evaluated and managed individually rather than applying an arbitrary upper age limit for ambulatory surgery (see also Chapters 80 and 93). The risk for death or readmission within 7 days of surgery in patients over 65 years of age are 41 per 100,000 and 2.53%, respectively.[49] Although somewhat more frequent than values from younger patients, the major risk factors appear to be very advanced age (older than 85 years of age), more invasive surgery, and recent inpatient hospital care.[49] The frequency of perioperative adverse cardiovascular events also increases with age. Overall, older patients had a twofold increase in the risk for intraoperative adverse cardiovascular events; however, this was seen not as a contraindication to ambulatory surgery but rather as indicating the need for more careful intraoperative management.[50] In contrast, the incidence of postoperative complications seems to be reduced in older patients.[50,51] In particular, older patients appear to experience far less postoperative pain, dizziness, nausea, and vomiting than younger patients[50, 52] and do not require a higher rate of unplanned admission or readmission. One study suggests a reduced incidence of postoperative cognitive dysfunction in older patients after ambulatory surgery compared to similar procedures performed on an inpatient basis,[53] presumably because of the use of short-acting anesthetic techniques and reduced separation from their familiar home environment.

At the other age extreme, the lower limit for ambulatory surgery may vary depending on the expertise and specialization of the individual institution. Premature babies have a higher risk for postoperative apnea, and hence ambulatory surgery may be inadvisable until they have reached an appropriate postconceptual age (PCA). Evaluation of several historic and retrospective studies suggests the risk for postoperative apnea is less than 5% once PCA exceeds 48 weeks, provided gestational age was at least 35 weeks, the infant was not anemic, and no apnea occurred in the recovery room.[54] However, because considerable variability exists in the incidence of apnea and the relatively small sample size of these studies, the postconceptual age at which risk becomes acceptably low is controversial,[55] with a value of 60 weeks most commonly taken as the cutoff for ambulatory management.[56,57] Caffeine administration appears to markedly reduce the incidence of postoperative apnea in babies who were premature,[58] but this is not seen as a substitute for careful patient selection.[56] Spinal anesthesia may offer advantages to infants who were premature undergoing abdominal surgery in the first week of life, but it is distressing to the infant and has a high (28%) failure rate.[59] Compared with older studies involving more soluble anesthetics, sevoflurane and desflurane were associated with lower rates of postoperative apnea after hernia surgery in infants born at less than 37 weeks gestation and under 47 weeks PCA.[60] Although no airway interventions were required to manage apnea, episodes still occurred throughout the 12-hour postoperative observation period and were equally common with either anesthetic.[60]

Cardiovascular Disease

Hypertension is the most common cardiovascular disease and has been a frequent cause for delay and cancellation of ambulatory surgery. Although hypertension is an important risk factor for long-term health, a meta-analysis of nearly 13,000 patients showed that it increased the risk for perioperative complications by only 1.35 times,[61] an amount that may be clinically insignificant. In ambulatory surgery patients, hypertension resulted in an approximate 2.5-fold increase in the risk for perioperative cardiovascular events,[51] but these were relatively minor. Hypertension is not an independent risk factor for perioperative cardiovascular complications if the diastolic pressure is less than 110 mm Hg.[62] Higher arterial blood pressures may predispose to perioperative ischemia, arrhythmias, and cardiovascular lability, but no clear evidence indicates that deferring surgery reduces perioperative risk. In the United Kingdom, surgery should not be canceled solely on the basis of increased arterial blood pressure.[61] In practice, poorly controlled hypertension is usually identified at the preoperative evaluation and can be treated before surgery is scheduled. Delaying surgery until hypertension is controlled is unlikely to be beneficial.[63]

Patients with known hypertension should continue to take their chronic medication, especially if these include β-adrenergic blockers. Angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists are sometimes withheld on the morning of surgery to prevent hypotension after induction of anesthesia.[64] Yet a transient and moderate decrease in arterial blood pressure will respond well to intravenously administered fluids and vasopressors. As β-adrenergic blockers should not be abruptly stopped,[65] patients may become less confused if they are advised to take all of their cardiac medications up to and including the day of surgery.[66]

Patients are generally unsuitable for ambulatory surgery if they have severe unstable angina that causes marked limitation of activity or pain at rest. In the absence of complications, such as arrhythmias or ventricular dysfunction, cardiac risk is not decreased beyond 3 months after myocardial infarction or revascularization procedures.[67] Exercise tolerance is a major determinant of perioperative risk[67] and the inability to climb a flight of stairs (~4 metabolic equivalent tasks [METs] of activity) is highly predictive (89%) of a postoperative cardiopulmonary complication.[68]

Patients taking anticoagulants and antiplatelet drugs require careful evaluation to balance the risk for perioperative bleeding against the risk in withholding therapy. For minimally invasive procedures, the international normalized ratio can be briefly decreased to the low or subtherapeutic range, with the usual dose of oral anticoagulation resumed immediately after the procedure.[65] If the risk for bleeding or thromboembolism is high, low-molecular-weight heparin can be used as bridging therapy.[69] Antiplatelet therapy should be continued for the recommended intervals in patients with bare metal and drug-eluting coronary artery stents, because premature

discontinuation is associated with a 25% to 30% risk for stent occlusion, which in turn has a more than 60% risk for myocardial infarction and 20% to 45% risk for death.[70]

SOCIAL FACTORS

In general, if a patient's living arrangements were adequate before surgery, they should also be suitable after surgery. Some adaptations may be necessary if the patient's mobility is severely compromised by their procedure—for example, by the use of casts. Access to a telephone to summon assistance is a minimum requirement, but is rarely problematic with the ubiquitous availability of mobile telephones. Patients usually live within a reasonable traveling distance of the surgical unit, but this may be impractical in rural or sparsely populated areas. Journeys of hundreds or thousands of miles are not unheard of in parts of Scandinavia after ambulatory surgery.[43] For patients who live far away, consideration should be given to the provision of emergency care close to home and for the comfort of the patient during the journey. Patients who choose to travel long distances after ambulatory surgery usually are very satisfied with their care.[71] Hospital hotels, which provide nearby accommodation but little or no nursing care, are a higher-cost alternative for the patient and have largely been abandoned as an impractical option.

A universal safety feature is to require all patients having surgery under general anesthesia or sedation to be discharged with a responsible adult escort and to have someone stay with them for the next 24 hours. If the 24-hour companion is mandated, patients often disregard postoperative instructions and send their escorts away if they feel well at home.[72] In the United States, it is standard practice to require that patients who have received other than unsupplemented local anesthesia be discharged with a responsible adult[10]; if not, surgery is postponed. A Canadian single-institution study reported discharging patients alone when their escort fails to arrive,[73] yet this practice did not appear to increase emergency room visits or readmission rates within 30 days. The Association of Anaesthetists of Great Britain and Ireland has suggested that an escort may be required in most (but not all) cases,[42] with exceptions when the surgery is relatively minor and anesthesia brief so the patient is not compromised by the sedative effects of anesthesia or analgesia by the time of discharge.[43] If patients are discharged alone, they should not drive themselves home[74]; several serious accidents have occurred, especially after the use of sedative doses of benzodiazepines.

PREOPERATIVE ASSESSMENT

THE ROLE OF PREOPERATIVE ASSESSMENT

An effective preoperative assessment process is essential for the delivery of safe, high-quality, and efficient ambulatory surgery.[63] Rather than trying to select specific, low-risk groups of patients, ambulatory surgery is increasingly seen as the default option for a wide range of surgical procedures, with inpatient care chosen only for those with insurmountable barriers to early discharge. Other than identifying this small group of patients, preoperative assessment is primarily required to evaluate and optimize patients and to provide appropriate information (Table 89-2). These assessment and optimization functions can be further distilled into two key questions: "Is there any benefit to this patient of being in hospital overnight after surgery?" and "Is there anything that needs to be done to enable this patient to be a day case?"[63]

MECHANISMS AND TIMING OF PREOPERATIVE ASSESSMENT

The timing of preoperative assessment is crucial, because it must be done early enough in the pathway to allow for any necessary investigations and optimization without delaying the planned procedure. This becomes increasingly difficult as the interval between the decision to operate and the date of surgery becomes shorter. Ideally, preoperative assessment should immediately follow the decision to operate, by providing a "one-stop shop." This type of service, in which preoperative assessment immediately follows the surgical consultation, is highly valued by patients,[75] although it can be difficult to manage because of variations in the demand for the service. An alternative is to use a basic screening tool to identify those patients who can proceed directly to surgery and those who require further investigation or management (Fig. 89-1).

A case can be made for all patients to be seen in a preoperative assessment clinic; however, in practice this places

TABLE 89-2 **THE FOUR KEY FUNCTIONS OF A PREOPERATIVE ASSESSMENT AND PREPARATION SERVICE FOR AMBULATORY SURGERY**

Function	Examples
1. Identify absolute contraindications to ambulatory surgery	Inability to identify a responsible caregiver other than for minor surgery with full and rapid recovery anticipated; severe uncorrectable cardiovascular disease
2. Identify need for optimization	Patient requires further investigation, therapeutic modification, or intervention to improve functional status; identify a friend, relative or neighbor to act as caregiver
3. Highlight issues for anesthesiologist or other staff (which may alter management but do not preclude ambulatory surgery)	Potentially difficult intubation necessitating advanced airway management skills; malignant hyperpyrexia–susceptible patient requiring trigger-free anesthetic; latex allergy; obese patient requiring operating table/trolley with high weight limit and extra width
4. Provide patient information	Written information on preoperative preparation, medication management, preoperative fasting, etc.

a major demand on resources and is also inconvenient for patients who may need to take additional time off work. Screening allows many patients to undergo assessment by telephone or questionnaire, with clinic attendance required only if unexpected problems are uncovered or if requested by the patient. When telephone assessment was chosen for all young healthy patients scheduled for minor breast surgery, only 2% of patients had problems identified that required further assessment in the ambulatory surgery center.[76] By using a computerized information gathering and triage tool, combined with some basic information about the planned procedure, approximately one third of ambulatory patients did not need to see an anesthesiologist before the day of surgery.[77] This approach eliminates the need for a face-to-face assessment before the day of surgery but does not eliminate an evaluation of the patient's medical information in advance of surgery. In contrast, advance face-to-face preoperative assessment is more advisable for older patients, in whom multiple comorbidities, polypharmacy, and social problems are all more likely.[78] Early discharge planning is also important for older patients, to address environmental issues that can be improved to support recovery.[79]

In the United Kingdom, preoperative assessment is usually performed by nurses working closely to protocols and supported by anesthesiologists who provide advice and personally assess the more complex patients.[80] In the United States, anesthesiologist-led, protocol-driven preoperative assessment is often used for healthy patients having minor procedures. However, these preoperative evaluation clinics are frequently used in U.S. hospitals, not just for ambulatory patients with more complex medical or surgical issues but also for the majority of the inpatient surgery that is admitted on the morning of surgery. More complex patients have their anesthesia preassessment performed by an anesthesiologist. A comprehensive preoperative history and physical evaluation by a nurse practitioner is often also provided in the preoperative assessment clinic for the surgeon. Using a nurse practitioner to assist in preoperative evaluation maintains patient safety and satisfaction, frees valuable resources, and increases staff satisfaction.[81] Appropriately trained nurses were just as effective as trainee medical staff in detecting information likely to influence subsequent patient management, but they ordered significantly fewer unnecessary tests.[82]

Patients generally rate their preoperative assessment clinic experience very favorably, with their greatest concerns relating to waiting times.[83] Scheduling appointments of approximately twice as long for patients of ASA physical status grades III and IV than for those of grades I and II reduced backlogs and reduced maximum waiting times for preoperative assessment to an acceptable level of about 10 minutes.[84]

PREOPERATIVE INVESTIGATION

The history and physical examination remain key elements of preoperative risk assessment, despite the availability of more sophisticated technologies.[67] In fact, most

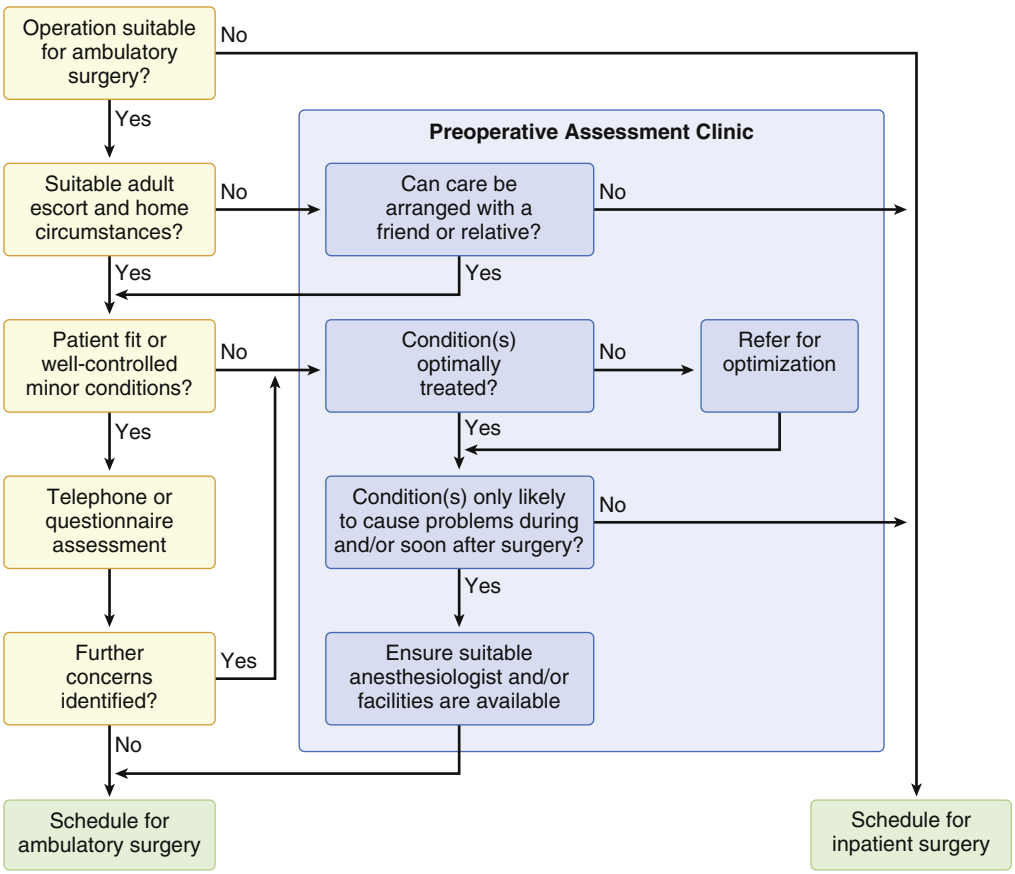

Figure 89-1. Flowchart illustrating the basic process for selecting patients for ambulatory surgery. The pathway incorporates a screening process for patients who may not require a full face-to-face assessment in the clinic. (Modified from Smith I, Hammond C: Day case surgery. In Radford M, Williamson A, Evans C, editors: *Preoperative assessment and perioperative management,* Cumbria, Calif, 2011, M&K Books, with permission.)

useful information can be obtained from the history, supplemented by simple observation of the patient.[85] Basic physical examination, such as routine chest auscultation, is often considered unhelpful in adult ambulatory surgery patients,[63,86] because findings that are unaccompanied by symptoms or functional limitation do not alter management. Although aortic stenosis may remain asymptomatic until it is quite severe, chest auscultation may be unreliable in its detection. In one high-risk population, 31% of patients without a detectable murmur nevertheless had some degree of aortic stenosis that was moderate or severe in 10% of cases,[87] whereas 31% of patients with a suggestive murmur did not have aortic stenosis on echocardiography. Ten patients with severe aortic stenosis (valve area 1 cm^2 or less, gradient 35 to 58 mm Hg) tolerated an unmodified anesthesia regimen for electroconvulsive therapy on 144 occasions without problems,[88] suggesting that ambulatory surgical patients with undiagnosed aortic stenosis may not inevitably be at excessive risk, when combined with appropriate procedure selection.

It is recognized that routine laboratory investigations are unhelpful because they mainly generate false-positive results or do not alter subsequent management.[89] In addition, such tests increase costs, are unpleasant and time-consuming for patients, and may lead to repeat testing with even further expense and delays. Consequently, many authorities recommend more selective testing, based on indications from the patient's clinical evaluation and demographics.[90,91]

Because comorbidities become more prevalent with age, more preoperative testing may be advocated for older patients.[91] However, even this may be excessively conservative. In patients 70 years of age or older, routine preoperative blood test results were not predictive of postoperative complications.[92] Although preoperative eletrocardiograms (ECGs) of patients over 50 years of age detected abnormalities, such as bundle branch blocks, predictive of postoperative myocardial infarction, the recordings did not provide additional predictive value to that obtained from the patient history.[93] One large pilot study demonstrated that the elimination of all preoperative testing resulted in no increase in adverse events in the perioperative period and did not alter the rate of unanticipated admission or readmission within 30 days compared to indicated testing.[94]

PATIENT PREPARATION

Preoperative assessment plays a fundamental role in preparing patients for their ambulatory surgery experience. This may include ensuring appropriate social support is in place, checking that preexisting conditions are optimally treated, and providing information.

PROVISION OF INFORMATION

Patients need to be informed about what will happen on the day of surgery, because a well-prepared patient is likely to be more relaxed and more satisfied with the service provided.[63] A well-informed patient is also more likely to comply with important instructions and protocols, such as fasting intervals and management of regular medications. Many patients are disproportionately worried about highly unlikely outcomes, such as death and awareness,[95] yet somewhat less concerned about more common consequences such as nausea, vomiting, and postoperative discomfort. The preoperative discussion should be able to allay the anxiety associated with unlikely risks. It was found that a specially designed website with text, animation, and video significantly increased patients' knowledge about anesthesia when compared with a combination of verbal and written information.[96]

Patients should be given specific information, preferably supplemented in writing, about how to manage their usual medications in the preoperative period. Some drugs (e.g., warfarin) should be stopped several days before surgery[69] and some hypoglycemic agents omitted before surgery.[97] However, other important medications should not be omitted.[66,70]

Information about medications should include over-the-counter and herbal products, which are commonly used but often regarded by patients as harmless and safe.[98] Despite some serious consequences and interactions associated with herbal medications,[99] not all practices specifically ask and advise patients about these products on a routine basis[100] (see also Chapter 40).

PREOPERATIVE FASTING

Almost universal agreement now exists that the safe fasting interval for clear liquids is no more than 2 hours, in contrast to 6 hours for light meals (see also Chapter 38).[101,102] These fasting intervals result in safe gastric volumes even in obese adults,[103] children,[104] and patients with diabetes and gastrointestinal (GI) reflux.[102] Indeed, a 2-hour interval is probably conservative, given that the stomach empties clear fluids exponentially, with a half-time of approximately 10 minutes.[105]

Despite guidelines based on decades of research, implementation remains poor, with many patients fasting for excessive periods and experiencing significant discomfort.[106,107] Rather than focusing on a minimum fasting time, patients should be encouraged to keep drinking until the latest time necessary for safety to reduce preoperative dehydration and its associated consequences.[102] In practice, this may mean asking patients to have a drink just before they leave home or even providing a drink on arrival if surgery is still more than 2 hours away. Advising patients to drink on the morning of surgery also makes it easier for them to take their medications. Practices such as chewing gum before surgery also may not be as harmful as previously suspected. No evidence exists of a clinically important increase in gastric volume associated with gum chewing in adults,[102] although in children it may promote gastric emptying and could also serve as a useful route for premedication[108] (see also Chapters 92 to 95 in the section on pediatric anesthesia).

Besides feelings of thirst and hunger, excessive fasting also results in hypoglycemia in significant numbers of patients, with 14% of fasted healthy female ambulatory surgical patients having an admission blood glucose value of 45 mg/dL (2.5 mmol/L) or less.[109] Preoperative oral carbohydrates have been shown to improve subjective

well-being, reduce thirst and hunger, and reduce postoperative insulin resistance, although convincing evidence of reduced length of stay is lacking.[102]

PREMEDICATION

Premedication traditionally refers to the administration of medications to relieve anxiety before surgery. However, the term encompasses any medication given in the preoperative period and therefore includes prophylactic analgesia and antiemesis agents, as well as drugs used to promote gastric emptying or counteract acid secretions.

Management of Anxiety

The use of anxiolytic premedication is now uncommon in ambulatory anesthesia,[110,111] probably because of concerns that these medications will delay recovery. In fact, a recently updated meta-analysis found no evidence that anxiolytic premedication delayed the discharge of ambulatory patients, although impaired performance in some tests of psychomotor function was found and the authors questioned the relevance of some of the older studies to modern ambulatory practice now that short-acting anesthetics are the norm.[112]

Anxiety is nevertheless common in ambulatory surgery patients,[110] with up to two thirds showing symptoms. A preoperative visit by an anesthesia provider reduces preoperative anxiety, but only if conducted immediately before surgery, rather than in the ambulatory surgery unit or in a preoperative clinic.[113] This finding must be treated with caution, however, because anxiety was high in all groups from this atypical population, with high stress levels and little of the usual perioperative family support.[113] Other studies have shown that a preoperative consultation more than 2 weeks before surgery can reduce patient anxiety and improve satisfaction, especially if the anesthesiologist was perceived as empathic.[114] Patient satisfaction was further improved when their intraoperative care was provided by the same anesthesiologist who performed the preoperative consultation.[114]

Anxiolytic Premedication

Given the high levels of reported anxiety, doubtless some patients will benefit from anxiolytic premedication, but what is the optimal regimen? Oral midazolam provided more anxiolysis than temazepam but also produced more sedation and amnesia, resulted in more oversedated patients, and delayed recovery.[115] Oral alprazolam produced comparable anxiety reduction to midazolam without causing amnesia,[116] but it also caused greater impairment of psychomotor function in the early postoperative period. Neither premedication delayed clinical recovery, but this may be a relatively crude assessment tool, because recovery primarily depends on other factors. Intravenous (IV) midazolam given shortly before induction of anesthesia reduced both anxiety and postoperative nausea.[117] Yet such relatively late administration will not reduce anxiety while the patient waits preoperatively and is more akin to a coinduction technique, which will be considered later. Intravenously administered midazolam may be useful in a patient who needs to have an uncomfortable procedure before surgery, such as mammographic needle localization, in which satisfaction with both the procedure and subsequent breast biopsy was improved.[118]

Anxiolytic premedication may have other possible advantages. Oral midazolam reduced preinduction of anesthesia heart rate and arterial blood pressure and also reduced the propofol dose required for induction of anesthesia[119]; however, the perception of anxiety was not reduced. Intramuscular midazolam improved self-reported postoperative psychological and pain recovery,[120] whereas oral diazepam reduced urinary catecholamine and cortisol levels in ambulatory surgical patients.[121] The clinical significance of these findings is unclear.

Premedication is more commonly used in children (see also Chapter 93). Premedication with oral midazolam 0.2 mg/kg reduced emergence agitation associated with sevoflurane anesthesia without significant delay in recovery,[122] and even a dose of 0.5 mg/kg does not delay recovery.[123] However, other patients have experienced delayed recovery at this dose[124,125] while not always having a reduction in anxiety.[125] Premedication with oral midazolam may itself provoke anxiety in children, but giving the child a small toy to play with first was effective in reducing this anxiety.[126] Unfortunately, the effect of the toy as an alternative to midazolam was not evaluated. Play therapy and distraction can be powerful tools in preventing anxiety in children, although achieving an adequate effect may require quite an elaborate approach. When two professional performing artists dressed as clowns entertained children during the preinduction period, using a variety of techniques including magic tricks, gags, music, games, puppets, word games, and soap bubbles, preoperative anxiety was reduced far more than could be achieved by midazolam premedication or the presence of a parent.[127] A preoperative educational program portrayed as a "Saturday morning club" also reduced anxiety,[128] although the authors questioned whether the benefits achieved were worth the time and resources required. A simpler and highly effective approach is to allow children to watch age-appropriate video clips or movies during anesthetic induction with IV (South Korea) or inhaled (Canada) techniques.[129,130]

Because of variable efficacy and the potential for delayed recovery, alternatives to benzodiazepine premedication have been sought. In children, oral transmucosal fentanyl reduced preoperative anxiety and postoperative agitation, but a high incidence of predictable side effects, such as postoperative nausea and vomiting (PONV) and delayed discharge, limited its usefulness.[131] Selective α_2-adrenergic agonists have potentially useful sedative and analgesic effects, yet despite years of study they still have no clearly defined role in ambulatory surgery in which their advantages outweigh the risks for adverse events.[132] Clonidine is commonly used in pediatric practice, particularly to reduce agitation during emergence,[133] but the promising results of clinical trials do not always translate well into routine clinical practice and its effects on induction anxiety are less persuasive.[134]

Analgesic Premedication

Ambulatory patients are commonly premedicated with prophylactic oral analgesia in the expectation of achieving analgesic levels in the early postoperative period. Because

the duration of action of acetaminophen (paracetamol) is relatively short (4 to 6 hours), it is unlikely to provide worthwhile postoperative analgesia, other than for an extremely short procedure. When patients received oral acetaminophen 1 g an hour before arthroscopic knee surgery, barely a third had plasma levels in the therapeutic analgesic range 30 minutes after arriving in recovery, whereas therapeutic levels were consistently achieved with intraoperative IV administration.[135]

The nonsteroidal antiinflammatory drugs (NSAIDs) are consistently more effective as analgesic premedicants. Some evidence indicates that NSAIDs have a small preemptive analgesic effect (i.e., they achieve a superior effect if given before rather than after surgery),[136,137] although one of the studies most strongly supporting this conclusion has recently been called into question.[138] Preoperative parecoxib followed by postoperative valdecoxib significantly reduced the opioid analgesic requirements and the incidence of opioid-related adverse effects after laparoscopic cholecystectomy.[139] As well as providing effective postoperative analgesia, etoricoxib premedication had an anesthetic-sparing effect during ambulatory ankle surgery.[140] Using a common dental model of postoperative pain, preoperative ibuprofen, diclofenac, and acetaminophen with codeine effectively controlled early postoperative pain.[141] Similarly, rofecoxib and ketorolac were equally effective in controlling postoperative pain after ambulatory surgery,[142] as were ibuprofen and ketorolac.[143] Sustained-release preparations of NSAIDs improve convenience by allowing earlier preoperative administration and a prolonged postoperative effect. Modified-release ibuprofen 1.6 g delayed the time until rescue analgesia was required after ambulatory third molar surgery in contrast to standard ibuprofen.[144]

Selective cyclooxygenase-2 (COX-2) inhibitors are no more effective and offer few advantages over traditional NSAIDs in ambulatory surgery, although they may be preferred by surgeons. Despite any inhibition of platelet function, the amount of blood loss seen during high-risk surgery, such as tonsillectomy, was not reduced in comparison to nonselective NSAIDs.[145,146] Attempts to limit GI adverse effects, which are rare in acute use, has introduced other side effects and led to some drugs being withdrawn.[147] Selective COX-2 inhibitors may be better tolerated in patients with aspirin-sensitive asthma.[148]

Several other drugs have been evaluated for premedication. Controlled-release oxycodone did not improve pain scores or reduce opioid requirements within 24 hours of ambulatory gynecologic laparoscopic surgery.[149] In combination with ibuprofen, pregabalin 150 mg reduced median pain scores at rest and in motion after gynecologic laparoscopic surgery, but did not reduce postoperative analgesic requirements.[150] Perioperative administration of pregabalin 75 mg provided short-lived pain reduction after laparoscopic cholecystectomy, and a meta-analysis confirmed limited analgesic benefit, no reduction in opioid side effects, and increased sedation from its use.[151] Even less effective was pretreatment with magnesium sulfate 4 g, which had no impact on postoperative pain or analgesic consumption in patients undergoing ambulatory ilioinguinal hernia repair or varicose vein surgery.[152]

Prophylactic Antiemetics

Patients at moderate-to-frequent risk for PONV should receive prophylactic antiemetics, which may be given after induction of anesthesia or as premedication, depending on the specific drug (see also Chapter 97). Preoperative steroids can provide both analgesic and antiemetic prophylaxis. Premedication with dexamethasone improved the quality of recovery with reduced nausea, pain, and postoperative opioid consumption and better return to normal activities after ambulatory gynecologic laparoscopic surgery,[153] but to achieve all these benefits required a dose of 0.1 mg/kg rather than the much less effective 0.05 mg/kg. For adults, this is approximately 8 mg of dexamethasone, which improved quality of recovery through reduced nausea, pain, and fatigue after ambulatory laparoscopic cholecystectomy.[154] The long-term side effect profile of this dose of dexamethasone has not yet been evaluated.

Antacid and Gastrokinetic Premedication

The incidence of aspiration of gastric contents is infrequent in fasted elective surgical patients. Despite improvements in several surrogate measures, insufficient evidence exists of clinical benefit (i.e., a reduction in morbidity or mortality from aspiration) to recommend the routine use of antacids, metoclopramide, H_2-receptor antagonists, or proton pump inhibitors before elective ambulatory surgery.[101,102] Patients who are receiving these medications chronically should take them before surgery. Patients who regularly suffer from significant acid reflux in the fasted state will also benefit from the head-up tilt position during induction of anesthesia. This approach also may be useful in the super-morbidly obese patient undergoing bariatric surgery, in whom the use of prophylactic proton pump inhibitors and sodium citrate may be considered.[46]

ANESTHETIC TECHNIQUES

CHOICE OF TECHNIQUE

Ambulatory surgery requires the same basic standards as inpatient surgery in terms of facilities, staffing, and provision of equipment for delivery of anesthetic drugs, monitoring, and resuscitation. Quality, safety, efficiency, and the cost of drugs and equipment are all important considerations in choosing an anesthetic technique for ambulatory surgery. The choice of specific anesthetic drugs or techniques should enable appropriate and controllable intraoperative conditions followed by rapid recovery with minimal side effects and a prompt return to normal psychomotor activity. Achieving these aims also requires careful attention to the details of analgesia, antiemesis, and fluid management and requires experienced staff to deliver a high-quality, efficient, and cost-effective service.

No single ideal anesthetic drug or technique for ambulatory surgery exists, and the choice depends on both surgical and patient factors. General anesthesia commonly remains the most popular technique with both patients and surgeons, in some cases despite clear benefits of local or regional anesthetic techniques.[155] Spinal anesthesia can be useful for lower extremity and perineal procedures,

but must be modified for use in the ambulatory setting by the use of low-dose techniques[156,157] or short-acting drugs[158] to prevent delays in discharge because of residual motor or sympathetic block. Infiltration of local anesthesia, peripheral nerve blocks, or both facilitate the recovery process by reducing postoperative pain and minimizing the need for opioid analgesics after general anesthesia and should be used whenever possible. Many ambulatory procedures also can be performed using local anesthetic techniques, supplemented, if necessary, with sedatives, or analgesic drugs, or both.

GENERAL ANESTHESIA

General anesthesia remains a popular choice with patients, surgeons, and anesthesia providers. Induction of general anesthesia is typically achieved with a rapid and short-acting IV anesthetic, although inhaled induction is often used in children and needle-phobic adults. IV drugs are also popular for maintenance of anesthesia, especially where the availability of target controlled infusion (TCI) systems simplifies delivery,[159] but the use of short-acting inhaled anesthetics, with or without nitrous oxide, is more common. No single anesthetic technique is clearly superior for ambulatory surgery. Other factors, such as the experience of the anesthesiologist, the use of adjuvant drugs, and the art of anesthesia, are still important to deliver the best quality care.[160]

INTRAVENOUS ANESTHESIA

Methohexital is occasionally used to induce anesthesia for ambulatory surgery in the United States, especially when propofol is in short supply, but is possibly no longer available in the United Kingdom. Thiopental results in prolonged postoperative sedation, especially after repeat administration for maintenance of anesthesia, and has little or no role in ambulatory anesthesia. The same applies to benzodiazepines and ketamine when used at the doses needed to induce general anesthesia. Etomidate is associated with myoclonus, pain on injection, and a high incidence of PONV. Although reformulation in a lipid solvent can reduce some of these disadvantages,[161] persisting concerns about suppression of adrenal steroidogenesis[162] have curtailed its use. The search for new and improved IV anesthetic drugs continues, with several promising compounds under evaluation.[163,164] However, for now, propofol remains the most practical IV anesthetic for ambulatory anesthesia.

Propofol

Propofol has many of the properties of an ideal anesthetic induction drug and is popular because it rapidly and smoothly induces anesthesia without airway irritation and results in a rapid recovery with an infrequent incidence of PONV[165] and a clear head. Propofol does have some disadvantages, however, including pain on injection, involuntary movements, transient apnea, and hypotension after induction of anesthesia. Numerous strategies have been proposed to reduce pain on injection, of which the most effective are the use of a large antecubital vein or pretreatment with lidocaine in conjunction with venous occlusion.[166] Alternative preparations of propofol, such as those containing bisulfite[167] or comprising medium- and long-chain triglycerides,[168,169] have had a modest or negligible effect in reducing injection pain, whereas some formulations significantly increase pain.[170] The addition of lidocaine remains more effective at reducing pain than the choice of propofol formulation.[171]

Some of the adverse effects of propofol can be minimized by reducing the propofol dose by coinduction with adjuvant drugs, the most common being midazolam. Pretreatment with midazolam 0.1 mg/kg allowed anesthesia to be induced with a decreased propofol dose and also attenuated the resultant hemodynamic changes.[172] A substantial decrease in the propofol dose can be achieved even when midazolam is administered up to 10 minutes before induction of anesthesia, a technique that also can make the induction experience for the patient more pleasant.[173] However, this approach may delay recovery. Midazolam 0.03 mg/kg, halved the required propofol dose but significantly impaired psychomotor recovery, even though awakening times were not delayed.[174] Coinduction with short-acting opioids, such as alfentanil, can improve the quality of induction and ease of laryngeal mask airway (LMA) insertion, but at the expense of an increased incidence of hypotension and prolonged apnea.[175] Similarly, fentanyl reduced propofol dose and improved conditions for LMA insertion, but also prolonged respiratory depression.[176] Furthermore, the use of 1 μg/kg[177] or fixed doses of 75[178] to 100 μg[179] of perioperative fentanyl increase the incidence of PONV. Giving an initial bolus of 30 mg of propofol reduced the total propofol induction dose to a degree similar to that achieved by 2 mg of midazolam.[180] This technique, which has been termed propofol autocoinduction,[181] can reduce propofol dose and hypotension to a degree comparable to that with midazolam pretreatment but without delaying recovery.

The pharmacokinetics of propofol allow it to be used as a variable rate infusion to maintain anesthesia, either in association with N_2O or combined with alfentanil or remifentanil as total intravenous anesthesia (TIVA). Recovery after anesthesia maintained with propofol is typically no faster compared to volatile anesthetics after an induction dose of propofol,[165] and initial awakening may be delayed compared to that with the shorter-acting inhaled anethetics.[189] These differences in emergence times are no more than 2 to 3 minutes[182] and so not of clinical significance. Recovery to home readiness may occur up to 15 minutes sooner after propofol than isoflurane but is no faster than sevoflurane or desflurane.[182] One consistent feature of propofol anesthesia is a less frequent incidence of PONV in contrast to the use of inhaled anesthetics.[165,182,183] However, even this benefit has been described as of doubtful clinical relevance, except when the baseline incidence of PONV is very frequent.[183] The reduction in PONV achieved by TIVA, specifically the use of propofol and the omission of N_2O, was similar to that produced by the use of single-drug antiemetic prophylaxis.[184]

Delivery of propofol is increasingly performed by TCI, which is commercially available in most countries except the United States.[159] In contrast to manual infusions, TCI makes the delivery of propofol easier, with

fewer interventions required by the anesthesiologist.[185] However, it does not improve the quality of anesthesia, shorten recovery time, or reduce adverse events[185,186]; although the quality of trials performed to date is poor, TCI systems calculate the predicted plasma propofol concentration and considerable variation exists between this and the actual measured value.[186] Further sources of error are introduced when the effect site, rather than the plasma concentration, is targeted.[187] Currently two different pharmacokinetic models are in commercial use, both derived from healthy subjects. The choice of model may make relatively little difference in the young, fit patient, but performance differs considerably in older patients[187] and neither model is reliable in the morbidly obese.[187,188]

INHALED ANESTHETICS

Volatile anesthetics remain the most popular choice for the maintenance of ambulatory anesthesia because of their ease of administration, controllability, and rapid emergence. Halothane and enflurane are now of historical interest only, and use of isoflurane has declined considerably as less-soluble, shorter-acting drugs have become available.

Sevoflurane

The low solubility and minimal airway irritation of sevoflurane make it a readily controllable, short-acting anesthetic for ambulatory surgery.[189] In contrast to isoflurane, sevoflurane resulted in significantly earlier awakening and orientation, caused less postoperative drowsiness, and facilitated earlier discharge by an average of 25 minutes.[182] Compared to propofol, orientation occurred earlier but the time to home readiness was similar.[182] The lack of airway irritation with sevoflurane means that rapid increases in inspired concentration are well tolerated,[190] facilitating control of anesthetic depth. This is in contrast to the cough reflex[191] and transient increases in heart rate and blood pressure, which sudden changes in isoflurane or desflurane concentration may provoke.[192]

Lack of airway irritation makes sevoflurane almost ideal for inhaled induction, which may be especially desirable in children and needle-phobic adults.[189] An 8% bolus induction of sevoflurane in adult patients can be faster than with propofol, with a similar rate of different side effects.[193] Sevoflurane induction also caused significantly less depression of mean arterial pressure than propofol in older patients and was equally as well accepted as an induction choice.[194] Using sevoflurane for volatile induction and maintenance of anesthesia (VIMA) has several benefits for ambulatory patients, but is associated with a greater incidence of PONV than when propofol is used for induction, maintenance, or both of anesthesia.[189] This appears to be in part due to coadministered opioids, which are rarely needed with VIMA, because omitting the opioids minimizes the problem.[177,193,195] In children, the rapid emergence from sevoflurane (and desflurane) anesthesia is associated with a high incidence of emergence delirium, especially if inadequate measures are in place to control postoperative pain.[196] Numerous strategies have been evaluated to reduce emergence delirium. Midazolam premedication is ineffective, but supplemental use of fentanyl 1 μg/kg, propofol, ketamine, and α_2-adrenergic agonists all reduce agitation to some degree.[133] Although emergence delirium is undesirable, it is not associated with any long-term consequences and does not delay recovery room discharge.[197]

Desflurane

With its low blood solubility, desflurane should be an ideal anesthetic for ambulatory anesthesia. However, meta-analysis of 25 randomized studies showed that patients receiving desflurane followed commands, had their trachea extubated, and were oriented only 1.0 to 1.2 minutes earlier than those receiving sevoflurane for up to 3.1 hours.[198] No differences were found in recovery room stay[199] or incidence of PONV.[198] Concerns about the more frequent incidence of airway irritation with desflurane may limit the rapidity with which anesthetic depth can be altered,[192] although relatively few problems were encountered in patients spontaneously breathing desflurane through an LMA when coadministered with fentanyl.[200,201] Although desflurane has lower fat solubility than sevoflurane, the rate of diffusion into the fat compartment is extremely slow with either inhaled anesthetic; therefore, lower fat solubility does not make the case for use of desflurane as the ideal agent for morbidly obese patients unless procedure length is very long. In practice, some studies of ambulatory surgery in the morbidly obese have found more rapid recovery after desflurane than sevoflurane,[202] whereas others found emergence and recovery to be similar with either drug.[203]

ANESTHETIC ADJUVANTS

Some adjuvant drugs are frequently administered to supplement the effects of general anesthesia and in an effort to reduce adverse effects.

Nitrous Oxide

Although N_2O is by far the oldest anesthetic drug still in use, its role is regularly questioned. N_2O is weakly emetogenic, yet its omission only significantly decreases vomiting when the baseline incidence is high and has no effect on nausea or the complete control of PONV.[204] This may be because the alternatives, specifically a higher inhaled anesthetic concentration or the use of supplemental opioids, also induce PONV. In addition, the risk for awareness resulting from the omission of N_2O is of a magnitude similar to any reduction in PONV,[204] somewhat reducing the usefulness of this strategy. N_2O retains a place in modern ambulatory anesthesia because its use improves the quality and safety of induction of anesthesia, facilitates faster recovery, and reduces overall costs.[205]

Opioid Analgesics

The indiscriminate use of opioid analgesics should be discouraged in ambulatory surgery to avoid PONV and unplanned admission.[206,207] Although long-lasting drugs such as morphine are especially detrimental, even the ultra–short-acting opioid remifentanil resulted in a 35% incidence of PONV when used with desflurane and multimodal prophylaxis, compared with only 4% when all opioids were avoided.[208] For minor to intermediate

ambulatory surgery procedures, the routine administration of as little as 1 μg/kg of fentanyl serves only to increase the incidence of PONV,[209] and its omission does not worsen postoperative pain, provided prophylactic analgesia is ensured with local anesthetic infiltration and preoperative NSAIDs.[177] However, small doses of fentanyl may be useful to provide additional analgesia toward the end of more painful procedures.

Opioids are an essential component of TIVA, but the antiemetic effect of propofol minimizes the incidence of PONV in contrast to the use of the same opioid with inhaled anesthetics.[210] Compared to alfentanil, remifentanil provides more effective suppression of intraoperative responses without prolonging awakening.[211]

Nonopioid Analgesia

For longer or more invasive procedures, IV acetaminophen given toward the end of surgery also can have a beneficial effect,[135,212] comparable to that of the opioid tramadol.[213] In a laboratory pain model using volunteers, the analgesic effect of acetaminophen was inhibited by commonly used 5-HT_3 antiemetic drugs, such as ondansetron and tropisetron.[214] However, a more recent study confirmed that no discernible interactions occurred under typical clinical conditions of use.[215] For shorter procedures, acetaminophen can be given orally before the anesthetic, at much lower cost.

Cardiovascular Drugs

Although intraoperative hemodynamic disturbances are usually managed by increasing the primary anesthetic concentration, administering an opioid analgesic, or both, it may be more appropriate to treat these responses with cardiovascular drugs. Using an infusion of esmolol as an alternative to alfentanil to control heart rate reduced emergence times after arthroscopy,[216] and substituting esmolol for remifentanil reduced nausea after gynecologic laparoscopy.[208] Using a combination of esmolol and nicardipine to blunt increases in heart rate and arterial blood pressure, respectively, prevented the need for increases in inspired anesthetic concentration and consequently shortened emergence and recovery times.[217] Ambulatory patients who received esmolol intraoperatively for hemodynamic control also had significantly smaller requirements for postoperative opioid analgesia.[217,218] Administration of a continuous infusion of esmolol during laparoscopic gynecologic surgery reduced sevoflurane consumption by 18%, shortened recovery room stay, reduced postoperative pain scores, and reduced fentanyl requirements.[219] In a similar study, an esmolol infusion decreased intraoperative remifentanil requirements and again resulted in lower postoperative pain scores and halved the dose of rescue fentanyl.[220] Labetalol may be a cost-effective alternative to esmolol for longer cases, especially in older patients, in whom it is less likely to cause inadvertent hypotension.[221]

Neuromuscular Blocking Drugs

Neuromuscular blocking drugs (NMBDs) may be used in ambulatory anesthesia to facilitate endotracheal intubation or to provide profound surgical relaxation (see also Chapter 34). Although several of the available compounds are suitable, muscle pain after administration of succinylcholine and concerns about residual neuromuscular block from intermediate-duration NMBDs after brief procedures have fueled the search for alternatives. The search for a nondepolarizing equivalent to succinylcholine has been unsuccessful. The most promising candidate to date, rapacuronium, was withdrawn from clinical use because of a frequent incidence of severe bronchospasm, although other factors such as inconvenient administration, declining use of endotracheal intubation, and large costs also contributed to its lack of commercial success.[222] The search for a rapid-onset, short-acting nondepolarizing NMBD continues with investigation of several fumarate compounds, which can be antagonized by L-cysteine.[223]

An alternative to short-acting NMBDs is terminating the neuromuscular blockade with sugammadex, which can rapidly and completely reverse rocuronium (or vecuronium) independent of the degree of residual neuromuscular block[224] (see also Chapter 35). Sugammadex is used in multiple countries outside the United States, but it is very expensive compared to neostigmine. Currently no reliable evaluations have been done on the cost-effectiveness of sugammadex in routine clinical practice. Although improved recovery times resulting from the elimination of residual neuromuscular block by sugammadex may potentially be cost-effective, this depends on the productivity of staff during the time saved and would probably require major changes to the workflow for actual benefits to be realized.[224]

Endotracheal intubation also can be achieved without the use of NMBDs, thereby avoiding all of their adverse effects. This practice is most common in children, for procedures in which airway protection is required but not prolonged muscle relaxation (see also Chapter 93). The optimum technique depends on personal experience and preference, but most commonly involves deep sevoflurane anesthesia[225] or propofol supplemented by remifentanil or alfentanil.[226] For adults, a dose of remifentanil 3 μg/kg with propofol 2 mg/kg is recommended,[227] but satisfactory conditions can be obtained with remifentanil 2 μg/kg, thereby reducing the side effects of bradycardia and hypotension.

AIRWAY MANAGEMENT

Many ambulatory surgical patients can be managed with an LMA, which results in a significantly less frequent incidence of sore throat, hoarseness, coughing, and laryngospasm compared to inserting a tracheal tube.[228] The LMA can occasionally cause pressure trauma to a variety of cranial nerves, in particular the recurrent laryngeal nerve, whereas hoarseness and vocal cord injuries are common after the use of endotracheal intubation during short-term anesthesia.[229] The LMA is relatively easy to insert with patients in the prone position,[230] making it a simple way of managing procedures such as pilonidal sinus repair or surgery to the short saphenous vein. Patients undergoing minor-to-intermediate surgery using a TIVA technique may sometimes receive oxygen through a simple Hudson-type mask (Fig. 89-2),[207] but most patients require a more secure form of airway such as an LMA.

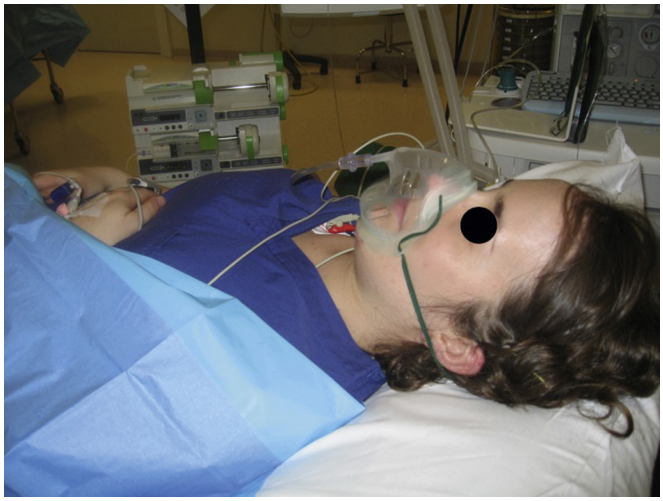

Figure 89-2. Patient receiving total intravenous anesthesia spontaneously breathing oxygen through a Hudson mask. (From Stocker ME, Philip BK: Adult general anaesthesia. In Smith I, McWhinnie D, Jackson I, editors: *Oxford specialist handbook of day surgery,* London, 2011, Oxford University Press, p. 63, with permission.)

Traditionally, endotracheal intubation has been advocated for laparoscopic procedures and surgery in obese patients, but further development of the LMA and more confidence in its use may be changing this. The ProSeal LMA (LMA, San Diego, Calif) has been modified to provide increased seal pressure, reduce gastric inflation, provide for gastric drainage, and, therefore, allow potentially better protection against aspiration of gastric contents while maintaining similar insertion characteristics.[231] At least one large consecutive series by an experienced user appears to support these benefits in routine clinical practice, without the constraints of a clinical trial.[232] During laparoscopic cholecystectomy, the ProSeal LMA provided adequate pulmonary ventilation without gastric distention in nonobese patients, although it was somewhat less effective than endotracheal intubation in the obese.[233] A useful clinical benefit is considerably smoother emergence with significantly less coughing. Use of the LMA for laparoscopic cholecystectomy remains controversial,[234] however, until the true incidence of regurgitation and the ability of the ProSeal LMA to protect against aspiration is better established.

Provided safety can be ensured, avoiding endotracheal intubation by using the ProSeal LMA for laparoscopic surgery appears to offer considerable advantages. In laparoscopic gynecologic procedures, the ProSeal LMA was associated with lower pain scores at 2 and 6 hours, with reduced analgesic requirements and less nausea at the same assessment points.[235] Similarly, in females undergoing gynecologic laparoscopic or breast surgery, it reduced the absolute risk for PONV by 40% and also reduced sore throats, analgesic requirements, and recovery room stay.[236] During laparoscopic gastric banding, the ProSeal LMA reduced the intraoperative stress response and also shortened recovery room stay and hospital discharge.[237]

Since the LMA patents expired, many manufacturers have introduced similar designs, but often using different materials to produce a low-cost disposable product. Often little or no data are available on the effectiveness or safety of these generic products.[238] Furthermore, the success of the LMA led to the development of many new supraglottic airways of myriad designs. Some of these may offer advantages in ambulatory surgery,[239] although little or no comparative data exist with the LMA. The manufacturers of new airways are currently able to market these without comparative trial data being available, because most of the regulatory requirements relate to manufacturing process and quality control, rather than efficacy and safety in clinical use.[240] Where comparative trials or case series do exist, they often lack power to provide a reliable estimate of the device's failure rate.[241] Comparative studies in children are even less common.[242] Anesthesiologists should therefore be wary of the claims made for new airway devices until they have been adequately evaluated.[243]

REGIONAL ANESTHESIA

Spinal Anesthesia

The use of spinal anesthesia makes ambulatory surgery accessible to some patients for whom the risks of general anesthesia are excessive (see also Chapters 56 and 57). It also increases patient choice, allows participation in intraoperative decision making (e.g., in sports injuries), and provides beneficial postoperative analgesia. Various ambulatory surgical procedures, such as prostatectomy, female incontinence surgery, and ankle and foot surgery, are well suited to spinal anesthesia.

The profuse availability of fine-gauge, pencil-point spinal needles has reduced the incidence of significant postdural puncture headache to 0.5% to 1%.[244,245] The main challenge now is to prevent prolonged motor block or impairment of joint position sense from delaying discharge. Although lidocaine has an appropriate duration for ambulatory surgery, its use in spinal anesthesia has virtually ceased as a result of a high incidence of transient neurologic syndrome (TNS).[246] Until recently, bupivacaine was the most obvious alternative, being devoid of TNS, but causing unacceptable delays in home discharge if used in standard doses.

For its acceptance in ambulatory surgery, bupivacaine spinal anesthesia needs to be "modified."[247] Reducing the dose of bupivacaine shortens recovery, whereas the use of patient positioning or the addition of adjuvants, such as fentanyl, ensures adequate analgesia for surgery. These techniques can be summarized as selective spinal anesthesia (SSA), defined as "the practice of employing minimal doses of intrathecal agents so that only the nerve roots supplying a specific area and only the modalities that require to be anaesthetised are affected."[248] SSA provides analgesia suitable for surgery, and light touch, temperature, proprioception, motor, and sympathetic function are all preserved.[248] This results in remarkable cardiovascular stability but can make the block difficult to test, and patient cooperation is important to the success of this technique.

A variety of SAA regimens have been described,[157] which typically permit discharge within a little over 3 hours after surgery.[249] The addition of fentanyl marginally delays

recovery and is associated with pruritus[249] (although most cases do not require treatment), but also reduces postoperative pain and analgesic requirements.[250] For unilateral knee arthroscopy, 4 to 5 mg of hyperbaric bupivacaine appears to be sufficient without adjuvants, provided the patient is kept in the lateral position.[250] Clonidine has also been used to supplement low-dose spinal anesthesia, but it may prolong motor block, exacerbate hypotension, and delay voiding.[132]

Spinal anesthesia may contribute to postoperative urinary retention. This is uncommon in low-risk patients, but may be more likely in older patients, with certain procedures and when more than 7 mg of bupivacaine is used.[247] The risk for urinary retention is particularly high after inguinal hernia surgery,[251] but simple infiltration anesthesia is often sufficient for this procedure and may be a more appropriate choice.[155,252]

New Drugs for Ambulatory Spinal Anesthesia

With the increasing popularity of ambulatory spinal anesthesia, some older local anesthetics have been reevaluated and, in some countries, marketed for spinal use. Of these, prilocaine, procaine, articaine, and 2-chloroprocaine appear the most promising, with mepivacaine largely discounted because of a high incidence of TNS.[158] Hyperbaric prilocaine has a faster onset and shorter duration than the plain preparation, with patients receiving 40 mg of 2% hyperbaric prilocaine being home ready in 208 ± 68 minutes.[253] This is comparable to discharge times reported with low-dose bupivacaine plus fentanyl,[249] although 13% of the patients receiving hyperbaric prilocaine required supplementation for inadequate analgesia toward the end of surgery, which was scheduled to last for less than an hour.[253] The duration of 2-chloroprocaine is even shorter, with recovery being significantly faster than that of low-dose bupivacaine[254] or articaine[158] and comparable to that of lidocaine.[255] Indeed, some have questioned whether the duration may be too short, especially where teaching and other logistical factors prevent surgery being undertaken in a predictably rapid time.[256]

Ambulatory spinal anesthesia that relies on short-acting local anesthetics should be compared with the cardiovascular stability of SSA. Prilocaine 20 mg combined with 20 μg fentanyl was associated with a lower incidence of clinically significant hypotension compared with bupivacaine 7.5 mg with fentanyl 20 μg.[257] The dose of bupivacaine and the dose of fentanyl used in both groups was somewhat higher than usual, however, and this is also the lowest dose of prilocaine to be successfully used in spinal anesthesia to date.[158]

Epidural Anesthesia

Epidural analgesia is seldom used in adult ambulatory anesthesia (see also Chapter 56). Although it allows the block duration to be extended by using a catheter technique, this is offset by the time required in establishing the block and less certainty of success, as well as the risk for inadvertent intravascular injection or dural puncture. In knee arthroscopy, recovery after 15 to 20 mL of epidural 3% 2-chloroprocaine was more rapid than spinal procaine with 20 μg fentanyl[258] and also had a decreased incidence of pruritus. Recovery after epidural 3% 2-chloroprocaine required fewer top-up injections and permitted discharge an hour sooner after ambulatory knee arthroscopy than with 1.5% epidural lidocaine.[259] However, the use of epidural 2-chloroprocaine has a more frequent incidence of back pain.[260]

In children, caudal epidural analgesia—for example, using levobupivacaine 0.5 to 1 mL/kg of 0.25 %—is popular for postoperative pain relief.[57] The technique is most useful for bilateral surgery or other situations in which the maximum safe dose would not permit an adequate volume for wound infiltration. After circumcision, caudal analgesia was no better than parenteral or systemic analgesia or dorsal nerve block in reducing analgesic requirements, nausea, or vomiting.[261] However, motor block and leg weakness were significantly more common in boys receiving a caudal block. The addition of clonidine[262] or dexmedetomidine[263] augments caudal analgesia, but concerns remain about the frequency of sedative and hemodynamic side effects and the risk for neurotoxicity.[132,262]

Intravenous Regional Anesthesia

Intravenous regional anesthesia (IVRA) (Bier's block) is a simple, reliable method of analgesia most commonly used in the upper limb, but sometimes also used effectively in the lower extremity.[264] In the United Kingdom and Europe, prilocaine is the preferred local anesthetic because of its high therapeutic index.[265] Lidocaine has also been used for many years[264] and appears to be a safe alternative.[266] Ropivacaine has also been extensively evaluated for IVRA. Compared to lidocaine, 0.2% to 0.375% ropivacaine resulted in prolonged and improved postoperative analgesia.[267-269] However, compared to prilocaine, ropivacaine's onset was slower, no useful prolongation of postoperative analgesia occurred, and ropivacaine plasma concentrations were more than double those of prilocaine, despite a 60% lower dose.[265]

IVRA was a cost-effective alternative to general anesthesia for outpatient hand surgery, being equally rapid to administer and with faster recovery and fewer postoperative complications.[270] However, analgesia was inadequate in approximately 11% of cases, which required supplemental local anesthesia, repeat of the block, and even conversion to general anesthesia. IVRA was also cost effective, and quicker to perform, compared to brachial plexus block, but with a 4.4% failure rate due to tourniquet pain.[271]

A variety of adjuvants have been used in IVRA to decrease tourniquet pain, improve block quality, and prolong analgesia after cuff deflation.[272] Opioids are relatively ineffective and cause nausea, vomiting, and dizziness after tourniquet deflation,[272] but several NSAIDs have been shown to be beneficial. Lornoxicam[273] decreased tourniquet pain and improved postoperative analgesia and tenoxicam improved postoperative pain,[272] but the effects of ketorolac are unclear after most of the evidence showing its efficacy in IVRA was withdrawn.[138] Dexamethasone improved both block quality and postoperative analgesia.[274] Similar results have been observed with the α_2-adrenoceptor agonist dexmedetomidine,[275, 276] whereas clonidine delayed tourniquet pain without improving postoperative analgesia.[277]

Other Local and Regional Anesthetic Techniques

A wide range of other regional anesthetic techniques can be used to facilitate ambulatory surgery or provide postoperative analgesia (Table 89-3).[278] The applicability of these techniques depends on the nature of the planned procedure, the patient, the preferences of the surgeon and anesthesiologist, and the skill and experience of the anesthesiologist performing the block. Benefits include excellent postoperative analgesia and reduced PONV, but this must be offset against pain and discomfort while performing the block, the difficulty of transitioning to satisfactory analgesia when the block wears off, and the risk for perioperative nerve injuries. Regional anesthesia may be contraindicated in patients with bleeding problems or those taking anticoagulants, as well as in patients with local infections. Regional anesthesia has a high failure rate in inexperienced hands, especially in the morbidly obese patient, although ultrasound guidance appears to improve the success rate of many blocks.[279] The use of ultrasound also can reduce pain during block placement,[279] but currently no conclusive evidence exists that it improves the safety of regional anesthesia.[280]

Simpler locoregional techniques may be more appropriate for some procedures. Intraarticular local anesthesia produces a moderate and relatively brief reduction in postoperative pain after arthroscopic knee surgery, but this is still considered to be of clinical significance in ambulatory surgery.[281] In many cases, simple wound infiltration may be as effective as central and proximal peripheral blocks and allows patients to mobilize more quickly.[282] Concerns about the possible risk for infection, or systemic toxicity resulting from large volumes of local anesthetic, appear unfounded in clinical practice.[282]

Infiltration anesthesia offers advantages for many ambulatory procedures and is the method of choice for inguinal hernia repair.[155] Several large series have confirmed excellent results with this highly cost-effective technique, with 79% of patients requiring oral analgesia for 7 days or less after surgery[283] and 91% of patients returning to normal activities within 5 days.[284] Repair under local anesthesia is not an independent factor for hernia recurrence, although this is influenced by the type of hernia and the level of surgical experience.[285] Infiltration anesthesia resulted in fewer medical and urologic complications after groin hernia repair than either general or regional anesthesia.[252] If spinal anesthesia is chosen for groin hernia repair, the anesthesiologist should be aware of the increased risk for urinary retention and other medical complications, especially in older patients.[252]

The concept of simple wound infiltration has been further developed into LIA, used for major orthopedic ambulatory surgery. This multimodal technique was originally developed for the control of pain after inpatient knee and hip surgery in Australia by Kerr and Kohan.[286] Their technique used a mixture of 300 mg ropivacaine with 30 mg ketorolac and 1.5 mg epinephrine diluted to 150 to 200 mL with saline, infiltrated into all the tissue planes of the surgical field over approximately an hour as the operation progressed. A catheter was placed into the wound to permit later repeat dosing. In the original series of 325 patients, mainly undergoing elective hip resurfacing but including some primary hip and knee replacements, pain was well controlled (numerical pain score 0 to 3) without morphine in two thirds of patients, most of whom could walk with assistance 5 to 6 hours after surgery; 71% were discharged, walking independently after a single night stay (Fig. 89-3).[286] These promising results have been confirmed in a blinded, randomized trial in patients undergoing unicompartmental knee arthroplasty, where a similar LIA regimen significantly reduced pain and opioid consumption and decreased the median

TABLE 89-3 SOME COMMON UPPER AND LOWER EXTREMITY BLOCKS USED FOR ADULT AMBULATORY SURGERY

Type of Block	Type of Surgery	Bolus Dose (Perioperative)*	Continuous Infusion	Patient-Controlled Regional Analgesia (PCRA)
Interscalene block	Surgery around the shoulder	Bupivacaine/levobupivacaine 0.25%-0.5%, 20-40 mL *or* ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/hr	Ropivacaine 0.2% 5 mL/hr
Supraclavicular or infraclavicular block	Surgery around elbow, wrist, and hand	Bupivacaine/levobupivacaine 0.25%-0.5%, 20-40 mL *or* ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/hr	Ropivacaine 0.2% 5 mL/hr
Sciatic nerve block	Posterior cruciate ligament repair, foot and ankle surgery	Bupivacaine/levobupivacaine 0.25%-0.5%, 20-40 mL *or* ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/hr	Ropivacaine 0.2% 5 mL/hr
Femoral nerve block	Knee arthroplasty, anterior cruciate ligament repair	Bupivacaine/levobupivacaine 0.25%-0.5%, 20-40 mL *or* ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.1% 5 mL/hr	Ropivacaine 0.1% 5 mL/hr
Paravertebral block (thoracic)	Breast surgery	Bupivacaine/levobupivacaine 0.25%-0.5%, 20-40 mL *or* ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/hr	Ropivacaine 0.2% 5 mL/hr

*Doses are approximations, with lower doses recommended when using ultrasound techniques. Depending on the type of surgery, multiple nerves may need to be blocked to get good postoperative pain relief. When using catheter techniques, disposable pumps with prefilled local anesthetics may be given to the patient with suitable written and verbal instructions.

From Gupta A, Smith I: Local and regional anaesthesia. In Smith I, McWhinnie D, Jackson I, editors: *Oxford specialist handbook of day surgery,* London, 2011, Oxford University Press, pp 93-108.

length of stay by 2 days, with 68% of patients discharged after a 1-night stay.[287]

A limitation of infiltration anesthesia in general is the relatively short duration of pain relief it provides, even with long-acting drugs such as bupivacaine. The encapsulation of bupivacaine into a biodegradable carrier offers the prospect of extended-duration local anesthesia (EDLA), which has demonstrated significant analgesic effects for at least 96 hours in pilot studies.[288] Several potential problems need to be solved before widespread application, however, including ensuring that the large doses of local anesthetic contained within the carrier are not rapidly released, leading to toxicity, or that the encapsulating materials do not break down into harmful products.[289] One extended-duration preparation of bupivacaine, Exparel, which uses an established liposomal-based drug delivery system (Lipo Foam, Contour^{MD}), is currently approved by the U.S. Food and Drug Administration (FDA). Early trial results report improved pain scores and reduced opioid analgesic consumption compared to plain bupivacaine during the first 24 to 48 hours or more after bunion surgery,[290] knee replacement,[291] and breast

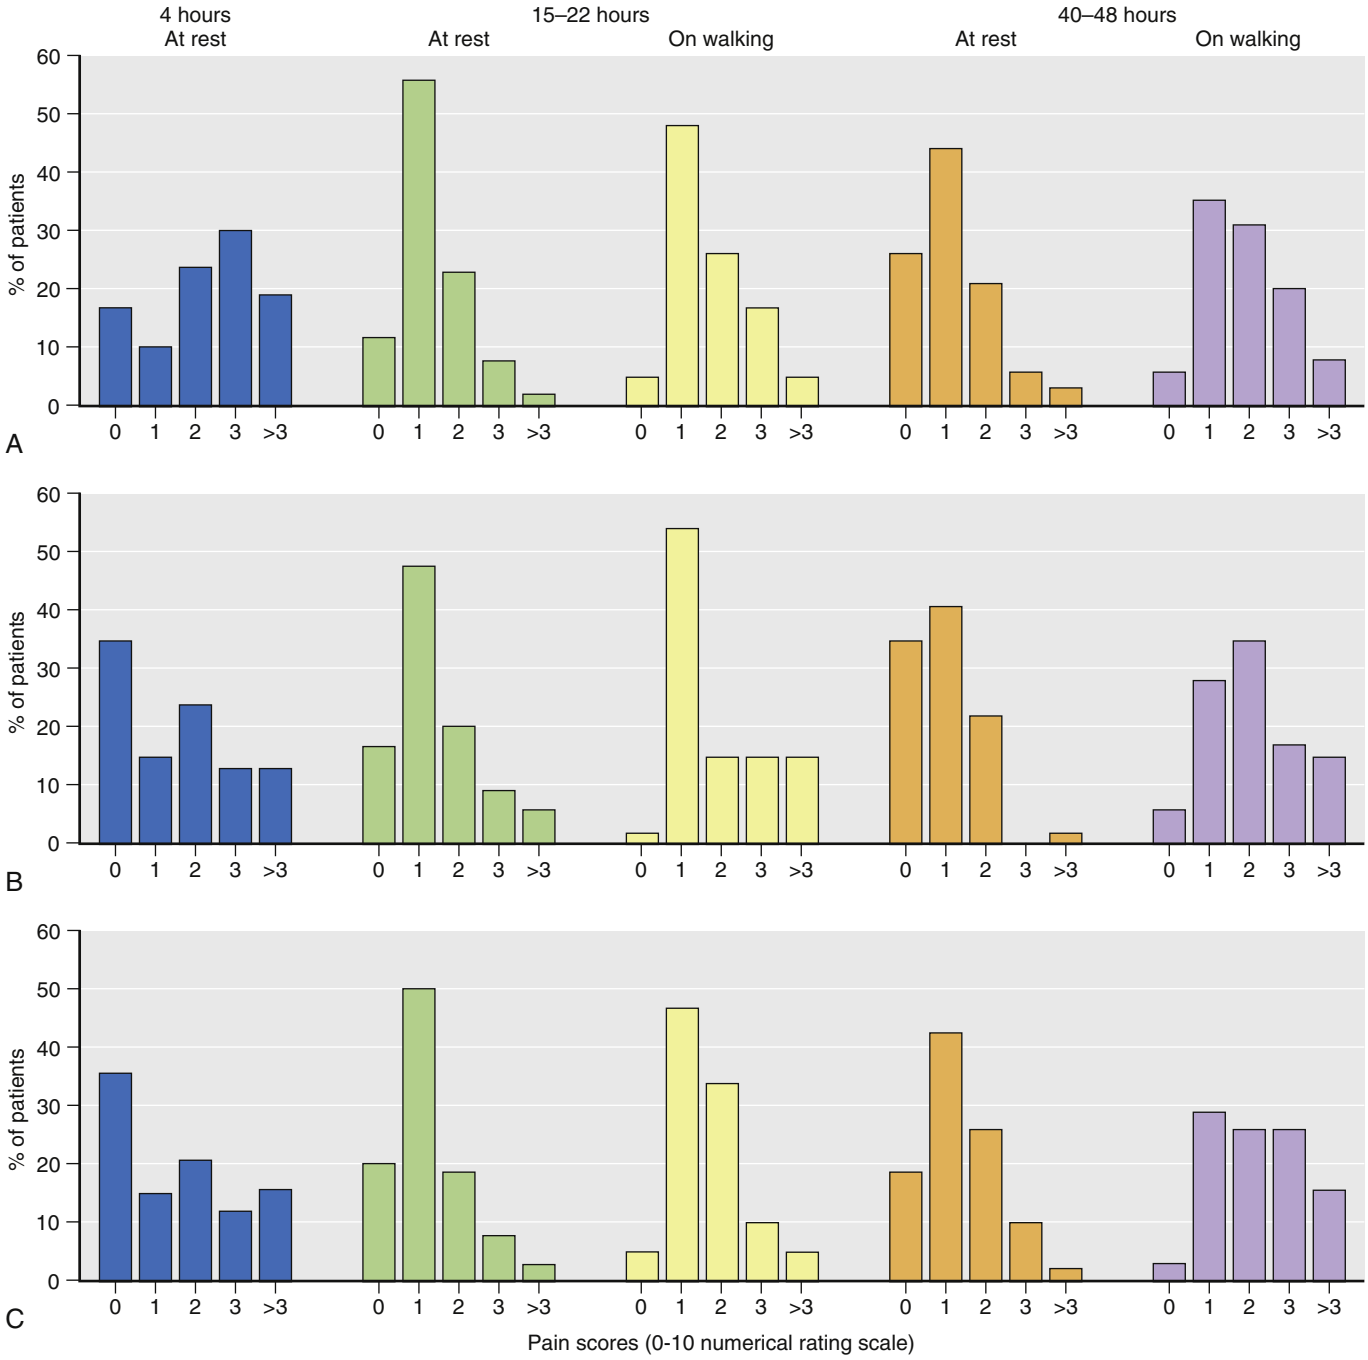

Figure 89-3. Numerical pain scores at various time points after hip resurfacing arthroplasty (**A,** n = 185), total hip replacement (**B,** n = 54), and total knee replacement (**C,** n = 86) in patients receiving local infiltration anesthesia. (Data from Kerr DR, Kohan L: Local infiltration analgesia: a technique for the control of acute postoperative pain following knee and hip surgery: a case study of 325 patients, *Acta Orthop* 79(2):174-183, 2008.

augmentation.[292] Myalgia was observed after Exparel in six patients in one study,[292] but a 2-year follow-up from the same group reported no long-term complications.[293]

Several naturally occurring alkaloid toxins, which may have the potential to provide longer lasting and safer local anesthesia, have been considered.[289] A preliminary study with neosaxitoxin, described superior analgesia compared to that with bupivacaine at 12 hours after laparoscopic cholecystectomy.[294] Catheter techniques also can extend the duration of effective local or regional analgesia, reducing pain scores, opioid-related side effects, and length of hospital stay, as well as improving patient satisfaction.[295]

SEDATION

Although some procedures may be performed with local or regional anesthesia alone, additional drugs are often required for anxiolysis to provide additional analgesia and to attain suitable operating conditions by helping the patient lie still in an appropriate position. The level of sedation required varies with each therapeutic, diagnostic, or surgical procedure and must be individually adjusted to achieve a balance of patient comfort and safety.[296]

The ASA defines three levels of sedation according to the responsiveness of the patient.[297] With minimal sedation a degree of anxiolysis is reached, but the patient is normally responsive and has a clear airway. During moderate (conscious) sedation the patient is more sleepy but responds purposefully to verbal or tactile stimuli. Spontaneous ventilation is usually adequate and interventions are not required to maintain a patent airway. With deep sedation, the patient can respond purposefully only to repeated or painful stimuli and may require a degree of airway or ventilatory support. Far from being discrete, these sedative levels lie on a continuum (Fig. 89-4), which becomes general anesthesia when the patient loses consciousness and is unarousable even with painful stimuli.[297] Careful monitoring is essential, and the standard of care for patients receiving sedation should be the same as for patients undergoing general or regional anesthesia and includes all of the usual aspects of anesthesia care.[298] Unfortunately, a widely held belief among physicians and patients is that sedation is a safer form of care,[299] but an ASA closed claims database analysis revealed that the risks for death or permanent brain damage are similar to those of general anesthesia.[300] Predictably, the greatest risk for harm comes from respiratory depression by opioids and sedative-hypnotic drugs, and many cases could have been prevented by better monitoring and improved vigilance.[301]

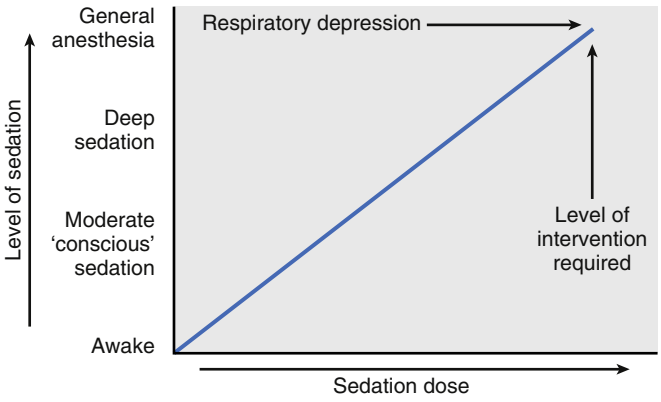

Figure 89-4. The continuum of sedation and general anesthesia. (From Ahuja M, Armstrong I. Sedation. In Smith I, McWhinnie D, Jackson I, editors: *Oxford specialist handbook of day surgery,* London, 2011, Oxford University Press, p 109, with permission.)

The U.S. term monitored anesthesia care (MAC) is sometimes erroneously used to describe sedation administered by an anesthesiologist. However, the ASA has a specific definition of MAC, which is a billing term used to describe an anesthesia service that includes all perianesthesia aspects of care.[298] MAC may include varying levels of sedation, including conversion to general anesthesia, when necessary. However, "if the patient loses consciousness and the ability to respond purposefully, the anesthesia care is a general anesthetic, irrespective of whether airway instrumentation is required."[298]

Choice of Sedatives

The specific requirements for supplemental sedative and analgesic drugs depend on the procedure undertaken, the skill of the operator in using local anesthesia, and the experiences and expectations of the individual patient. The use of pharmacologic agents can be reduced by sympathetic patient management at every stage, preoperative explanation, and the use of distractions, such as deep breathing, conversation, and listening to music.[299] Adjuvant drugs should be chosen to deliver those specific aspects that are required,[302] such as reduction of anxiety, sedation to relieve boredom or aid immobility, and analgesia for pain that is not amenable to further infiltration of local anesthetic.

Midazolam

Midazolam produces anxiolysis and dose-related hypnosis and is a popular component of sedation. It also produces marked antegrade amnesia. At times this may be beneficial, but it is not always welcomed by patients.[303] Midazolam is preferred to other benzodiazepines because it is water-soluble, does not cause venoirritation or pain on injection, is rapid-acting, and has a relatively short-elimination half-life of about 2 to 4 hours. As sole anesthetic, a single dose of 0.05 to 0.1 mg/kg allows reasonably predictable recovery after brief procedures, but individual responses are highly variable.[304] Recovery is also considerably slower if repeat or prolonged administration is required.

Propofol

Propofol is an excellent sedative-hypnotic for MAC because its pharmacokinetic properties result in a rapid recovery from the effects of a single bolus dose and a continuous infusion. Propofol is a relatively pure hypnotic, providing no analgesia and only moderate amnesia. Infusion rates of 25 to 75 μg/kg/min are typically used,[305] but the short duration of action facilitates titration to effect.

Because of the excellent conditions that can be achieved and the superiority of recovery compared with

that of midazolam,[306-308] demand for propofol sedation is growing rapidly in areas such as therapeutic endoscopy in which anesthesiologists have not traditionally been involved. Propofol can rapidly cause apnea, before loss of consciousness, even in sedative doses, and unintended transition to general anesthesia is a constant risk. The safety of nonanesthesiologist administration of propofol is therefore controversial. In the United Kingdom, the Royal College of Anaesthetists and the and British Society of Gastroenterology jointly state that propofol sedation for complex upper GI endoscopic procedures should be administered only by an "appropriately trained anaesthetist."[309] In the United States, the ASA also advocates propofol medicating "only by persons trained in the administration of general anesthesia,"[310] consistent with the package insert. However, the American Society for Gastrointestinal Endoscopy considers propofol use safe by anyone "proficient in the management of upper and lower airway complications, including manual techniques for reestablishing airway patency" and holding at least basic life support certification.[311]

Advocates of endoscopist-administered propofol claim a very low rate of airway complications (0.1%) and a mortality (4 in 646,080) less that that associated with endoscopist-administered midazolam-opioid sedation.[312] Their data also reveal a wide range for the frequency with which rescue airway support was required, suggesting considerable variation, either in technique or willingness to intervene to protect the airway.[312] When anesthesiologists administered propofol for patients undergoing endoscopic retrograde cholangiopancreatography (ERCP), deeper levels of sedation or general anesthesia were often intended and sedation-related adverse events were far more common (21%), especially in patients of higher ASA physical status classification, but were managed without adverse consequence or delay and high levels of patient and operator satisfaction were achieved.[313]

Fospropofol

Fospropofol is a water-soluble phosphate ester prodrug of propofol approved in the United States for sedation in adults in 2009, but not currently manufactured.[314] The pharmacokinetics of propofol liberated from fospropofol differ from intravenously administered propofol, with a slower onset of action and longer duration, but detailed pharmacology is lacking after the retraction of six key pharmacokinetic/pharmacodynamic studies because of an error in the propofol assay.[315] Fospropofol avoids the pain on injection of propofol, but is associated with paresthesia and pruritus.[314] Potentially, fospropofol should require less frequent dosing than propofol, but so far has only been studied in relatively short procedures. Conversely, titration to effect may be more difficult because of the lag during metabolism to propofol. The role of fospropofol in sedation is unclear at present, and the current license restricts its use to anesthesiologists.[314]

Analgesic Adjuvants

Opioids are useful for procedures in which pain cannot reliably be blocked with local anesthesia alone.[296] Compared to alfentanil in women undergoing breast biopsy, remifentanil resulted in lower pain scores during deep dissection and reduced the need for supplemental local anesthesia.[317] Remifentanil was a useful adjuvant to propofol sedation during transvaginal tape insertion[318] and in achieving optimal conditions for awake craniotomy,[319] surgery that is increasingly being performed as a day and short-stay procedure.[21, 22] Remifentanil produced lower pain scores than fentanyl in patients receiving propofol sedation during hysteroscopy, but did it not improve recovery or patient satisfaction.[320] For hysteroscopic surgery, paracervical block supplemented by a remifentanil infusion permitted earlier mobilization and discharge compared to TIVA, and the sedation technique was also preferred by a higher proportion of patients. Remifentanil is usually delivered by infusion, but intermittent bolus doses may be more effective for some procedures.[321]

Both clonidine and dexmedetomidine have potentially useful analgesic, anxiolytic, and sedative properties. The slow onset and offset of clonidine and frequent reports of cardiovascular instability, mean that neither drug has established a routine place in sedation,[132,322] although dexmedetomidine may be a useful analgesic adjuvant in awake craniotomy.[323] Ketamine improved analgesia when used to supplement propofol sedation, but an increase in PONV, psychomimetic side effects, and delayed discharge were observed at higher doses.[324]

Delivery of Sedation

Because of the varying needs to provide hypnosis, anxiolysis, analgesia, and amnesia, use of drug combinations are common during anesthesiologist-administered sedation. Preceding a propofol infusion with a small (2 mg) dose of midazolam improved anxiety, sedation, and amnesia for early intraoperative events with no detrimental effect on postoperative sedation, amnesia, or recovery times.[325] However, using drug combinations increases the risk for interactions, leading to adverse effects. At sedative doses, propofol and remifentanil each have only a modest effect on heart rate and arterial blood pressure, but their effect on respiration is strikingly synergistic, with the potential for severe respiratory depression.[326] Respiratory depression is also enhanced by the interaction of midazolam and remifentanil.[327] Antagonists of benzodiazepines and opioids may be useful in cases of unintended overdose, but should not be routinely relied on to reverse deep sedation because of their short duration of action, which may permit resedation before[328] or after discharge.[329]

As with TIVA, the stability and control of sedation regimens can be improved by using TCI systems.[330] Target concentrations of 0.5 to 2 μg/mL for propofol and 0.5 to 1 ng/mL for remifentanil are typical[296,322] but should be titrated to individual effect. Effective sedation is usually judged by clinical end points or scores. Bispectral index (BIS) changes with increasing sedation, but is too variable[331] to be useful routinely and was not effective as an end point for midazolam sedation.[332] BIS monitoring did not improve the quality of sedation or reduce the propofol dose or rates of hypoxemic, bradycardic, or hypotensive complications during ERCP.[333] However, BIS-guided TCI propofol may be useful in the management of patients with intellectual disability,[334] in whom clinical signs may be less reliable. Allowing patients to

adjust their own sedation level by patient-controlled sedation resulted in less propofol being used compared with a continuous infusion and was significantly more popular with patients.[335]

Inhaled sedation by a low dose of sevoflurane is an alternative technique that provides good control of sedation and rapid recovery.[336,337] However, it can be complicated by a frequent incidence of perioperative excitement and an increased risk for transition to general anesthesia.[338]

MONITORING DEPTH OF ANESTHESIA

Many devices are now available to monitor the hypnotic component of anesthesia as a supplement to our traditional reliance on autonomic signs (see also Chapter 50). Most monitor electroencephalogram signals, recorded either spontaneously or evoked in response to a stimulus, which are then processed into a dimensionless number, usually ranging from 0 to 100. Precisely which variables are recorded and how they are processed is proprietary information,[339] and the specific values corresponding to adequate anesthesia also vary among monitors.[340]

BIS was the first licensed monitor and is the most extensively studied, yet whether it can actually prevent awareness with recall remains controversial.[340] One of the largest studies to date revealed an effect that was only just statistically significant[341] but has been criticized for inadequate power, selection bias, and studying only a high-risk population.[342,343] A more recent and even larger study failed to show superiority of BIS over titration to end-tidal anesthetic drug concentration in preventing awareness,[344] also in a high-risk population. In ambulatory anesthesia, in which awareness is uncommon,[345] more interest has been shown on whether BIS and similar devices can reduce excessive anesthetic delivery, thereby improving the speed and quality of recovery and reducing costs. Two meta-analyses have shown that titrating anesthesia to achieve BIS values of 40 to 60 results in trivial (2 to 4 minutes) reductions in awakening times, shortens recovery room stay by just 6.8 minutes, and fails to facilitate earlier home discharge.[346, 347] BIS titration also produced a very modest reduction in PONV (32% versus 38%).[346] Despite reductions in anesthetic drug usage, the cost savings were substantially less than the disposable costs associated with BIS.[346] Monitoring with auditory evoked potentials achieved similar small reductions in drug usage and awakening times, comparable to those seen with BIS.[348,349] Discharge times were unchanged in one study[348] but were shortened by both BIS and auditory evoked potential monitoring in another study in a very similar population.[349]

Although a lack of clear clinical or financial benefit exists from depth of anesthesia-guided drug titration, genuine concerns have been raised about using these monitors for purposes other than those for which they were designed. Although anesthesia is usually adequate at values below 60, BIS lacks a high level of discrimination and some patients may form memories at values as low as 40.[350] Thus, titrating anesthesia, even to BIS values of 40 to 50, to reduce costs and recovery times, may unintentionally increase the risk for awareness.[339]

RECOVERY FROM AMBULATORY ANESTHESIA

Recovery is traditionally divided into three stages. Early, phase 1 recovery occurs in a postanesthesia care unit (PACU) and entails further awakening and management of pain and nausea, with monitoring of hemodynamic stability. Intermediate recovery continues in the phase 2 (step-down) recovery or in a separate ward area and ends when the patient achieves the criteria for home discharge (see later discussion). The phase 1 and phase 2 aspects of recovery may occur in separate locations or within the same room.

EARLY RECOVERY

The recovery room or PACU should be centrally placed to all operating rooms and requires the same standard of staffing and equipment as are provided for inpatients.[351] The PACU may be shared with inpatients in some facilities, but recovery times can be shortened dramatically if there is a separated phase 1 PACU dedicated to ambulatory patients.[11] In the United States, the ratio of nurses to patients is usually lower than in the inpatient PACU, typically 1:3, reflecting the lower acuity of postprocedural needs.[6] Patient care should be adequately transferred to the PACU nursing staff, relaying preoperative and intraoperative problems and postoperative instructions. The nature and frequency of monitoring in the PACU is determined by the nature of surgery and the state of recovery. Because ambulatory anesthetics are typically short-acting, supplemental O_2 administration may be unnecessary in the PACU,[352] provided the patient's saturation level of O_2 in hemoglobin (SpO_2) remains above 92% on air.

In the United Kingdom, patients may be discharged from phase 1 to phase 2 of recovery when they are awake and oriented, normothermic, able to maintain their own airway and ventilation, and demonstrate cardiovascular stability. Wounds should be reasonably dry, and pain and PONV should be minimal and adequately treated. This assessment is usually made on clinical judgment.[351] In the United States, transfer from phase 1 to phase 2 is commonly based on predefined, physician-determined criteria. Typical ambulatory criteria include being awake with stable vital signs, minimal pain, minimal nausea, and the ability to sit with minimal dizziness.[353] If more standardized data are desired, a scoring system can be used. The most commonly used system is the modified Aldrete score,[354] which assigns points on the basis of activity, ventilation, blood pressure, consciousness, and oxygenation (Table 89-4). Length of PACU stay is one of the key end points, along with awakening, orientation, and extubation times used to evaluate early recovery in ambulatory anesthesia research.

SECOND-STAGE RECOVERY

Second-stage recovery prepares patients for leaving the ambulatory surgery unit and taking over their own care. Patients should sit upright on trolleys or reclining chairs as an aid to mobilization. After low-dose spinal anesthesia, mobilization is usually possible within an hour of the return of full motor function, or about 2.5 to 3 hours after the start of spinal anesthesia.[156,355]

TABLE 89-4 MODIFIED ALDRETE RECOVERY SCORE

		Score*
Activity	Able to move four extremities voluntarily or on command	2
	Able to move two extremities voluntarily or on command	1
	Unable to move extremities voluntarily or on command	0
Respiration:	Able to breathe deeply and cough freely	2
	Dyspnea or limited breathing	1
	Apneic	0
Circulation:	BP ± 20% of preanesthetic level	2
	BP ± 20%-49% of preanesthetic level	1
	BP ± 50% of preanesthetic level	0
Consciousness:	Fully awake	2
	Arousable on calling	1
	Not responding	0
Oxygenation:	Able to maintain saturation > 92% on room air	2
	Needs oxygen to maintain saturation > 90%	1
	Saturation <90% even with oxygen	0

**The total possible score is 10; patients scoring ≥ 9 are fit for discharge from phase 1 recovery.*

BP, Blood pressure.

BOX 89-1 ***Criteria for Direct Admission to Second-Stage Recovery Unit, Bypassing the Postanesthesia Care Unit****

Patient should be awake, alert, oriented, and responsive (or return to baseline state).
Pain should be minimal (unlikely to require treatment with parenteral medications).
No active bleeding should occur (unlikely to require professional treatment).
Vital signs should be stable (unlikely to require pharmacologic intervention).
Nausea should be minimal.
No vomiting should occur.
If nondepolarizing neuromuscular blocking agent has been used, patient should now be able to perform a 5-second head lift or train-of-four monitoring should indicate no fade.
Oxygen saturation should be 94% or higher on room air (3 minutes or longer) or O_2 saturation should return to baseline on room air.

*During the follow-up period, the patient should be evaluated in the operating room, immediately before discharge, using the above criteria regarding recovery from anesthesia. To bypass the postanesthesia care unit, a patient must meet all of these criteria and, in the judgment of the anesthesiologist, be capable of transfer to the second-stage recovery unit.

From Apfelbaum JL, Walawander CA, Grasela TH, et al: Eliminating intensive postoperative care in same-day surgery patients using short-acting anesthetics, *Anesthesiology* 97:66-74, 2002.

FAST-TRACK RECOVERY

With the increased use of short-acting drugs and techniques, many patients will have already met the discharge criteria before, or by the time, they reach the PACU.[356] If this is the case, admission to the PACU will only generate unnecessary delay while further observations are performed. Instead, these patients may bypass phase 1 recovery and go directly to the phase 2 unit; this is known as fast-track recovery.

The modified Aldrete score can also be used to assess fast-track eligibility.[357] Because this score does not assess pain or PONV, which are traditionally treated in the PACU, White and Song[358] added two additional categories to derive their fast-track recovery score. Although using this score reduced the proportion of patients who met the fast-track criteria on PACU arrival, it also significantly reduced the number of patients who required parenteral analgesia or antiemetics in the step-down area.[358] Others have suggested a series of clinical criteria[359] that must all be achieved for patients to undergo fast-track recovery (Box 89-1). The criteria for transfer from phase 1 to phase 2 and the criteria for direct entry to phase 2 should be the same.

Fast-track recovery is the norm for patients who have had local anesthesia, but it is also appropriate for most patients receiving sedation[359,360] and low-dose spinal anesthesia in the United Kingdom.[156] Patients receiving general anesthesia also may be able to undergo fast-track recovery depending on the combined effects of procedure, anesthetic technique, duration of procedure, and the individual patient. After laparoscopic tubal ligation, 90% of women receiving desflurane, 75% receiving sevoflurane, but only 26% receiving a continuous infusion of propofol were judged eligible for fast-track recovery,[357] although actual recovery bypass was not attempted. In a more recent study involving more superficial surgery in which anesthesia was titrated to BIS, all patients receiving either desflurane or sevoflurane met fast-track recovery criteria on leaving the operating room,[361] although no patient actually bypassed the PACU in that facility.

Fast-track recovery is appealing because improved recovery provides the patient with a higher quality experience, enabling them to return toward normal in a more pleasant, comfortable, and facilitative environment. It also frees up the more intensive resources of phase 1 recovery for those patients who need them. Accomplishing fast-track recovery is complex. In one facility, despite high proportions of patients appearing eligible to bypass the PACU using the White criteria,[357,361] the same group actually achieved fast-tracking in only 35% to 53% of their patients.[362] The use of depth of anesthesia monitoring has been claimed to facilitate fast-track recovery,[363] whereas others have not found it advantageous.[364] Accomplishing fast-track recovery requires not only anesthesia recovery readiness, but also the support of a facility-based process, including nursing and surgeon participation and environment support. More productively, the current approach to fast tracking is not just the percentage of patients who completely bypass phase 1, but rather, it is to enable the fastest possible path for all patients through their recovery to discharge home.

The economic case for fast-track recovery should be considered separately.[365] In some cases, fast-track recovery has shortened overall recovery stay, comparable to,[366] or even longer than,[359] the time that would have been spent in the PACU. However, others have found no difference

in overall recovery time,[362] especially after laparoscopic surgery.[366] Achieving an adequate fast-track score can take almost 30 minutes after laparoscopic surgery, even when using cerebral monitoring to optimize anesthesia,[348] which could delay leaving the operating room. Nurses in the step-down unit are not always readily available to receive patients and often report patients arriving cold or without all the fast-track criteria actually being met.[367] Although fast-track recovery appears financially beneficial, actual savings will be made only if the PACU is not needed at all or if staffing levels can be reduced, which is not supported by the evidence to date.[365] One randomized trial showed that nursing workload and costs were simply shifted from one area to another, with no overall savings.[366] Fast-track recovery may still help to improve patient flow and may work best in small units that use staff flexibly between different areas.[365]

POSTOPERATIVE PAIN

The management of postoperative pain should begin well before the patient undergoes surgery. Patients need to have appropriate expectations about what they are likely to experience during their recovery (see also Chapter 98).[368] At preoperative assessment, patients should be provided with information about the likely extent and duration of pain after surgery. They should also be advised about simple measures to reduce pain, including advice to rest in a comfortable position, raising swollen limbs, use of heat or cold packs, and the benefits of distraction. Prevention is the mainstay of pain management, yet studies have shown that pain management after ambulatory surgery is often inadequate.[369] Common causes are a lack of adherence to analgesic guidelines and a failure to provide multimodal analgesia.[370,371] Too often there is overreliance on opioid analgesia, resulting in predictable adverse effects[372] that are second only to inadequate pain relief in causing unnecessary hospital admission.[369]

MULTIMODAL ANALGESIA

Multimodal analgesia relies on the additive or synergistic combination of drugs acting at various points on the pain pathway.[373] Typical combinations include local anesthetic wound infiltration or regional technique and routine NSAIDs, with small doses of opioids added as needed. Topical therapies also may be of some benefit, with both lidocaine and glyceryl trinitrate patches found to provide effective topical analgesia after a variety of ambulatory procedures.[374] Multimodal regimens are effective after several ambulatory surgical procedures.[375,376] An opioid-sparing effect exists for several drug combinations,[377] but most evidence is limited to an opioid plus one other drug, with little evaluation of true multimodal analgesia or attempts to identify optimal combinations.[371] Analgesic efficacy differs with the nature of surgery,[378] suggesting that multimodal analgesic regimens should be specifically tailored.[379] Nevertheless, reducing the opioid dose does decrease the incidence of PONV to a corresponding degree and may also reduce other opioid adverse effects, such as sedation, sleep disturbances, urinary retention, and respiratory depression.[372] As yet, no evidence indicates that multimodal analgesia improves long-term patient outcome[380] because of the small number of subjects studied and the infrequent incidence of adverse outcomes after ambulatory surgery.

RESCUE ANALGESIA

Despite prophylactic measures, some patients will experience pain on awakening after surgery. Milder cases may be amenable to treatment with additional oral analgesia, but more severe pain will usually require parenteral opioids. Fentanyl is commonly used for this purpose, and small boluses (20 to 25 μg) rapidly achieve analgesia. Compared to morphine, fentanyl results in more rapid control of pain and reduces the occurrence of PONV.[381] Rescue fentanyl also produced fewer adverse effects than oxycodone.[382] Administration of additional oral analgesia as soon as the pain is controlled will usually prevent a recurrence at a later stage of recovery. During the recovery period, pain should be assessed on a regular basis and treated according to protocols (Fig. 89-5).

PAIN MANAGEMENT AT HOME

In the United States, patients are often given prescriptions for postoperative analgesics, including weak opioids, preferably before surgery so the medications will be at home when the patient needs them. In the United Kingdom, patients may be given standardized take-home analgesic packs that can be dispensed from the ambulatory surgery unit, avoiding pharmacy delays. Typical take-home analgesia includes NSAIDs and acetaminophen combined with a weak opioid. Combinations of codeine-acetaminophen[383] and hydromorphone-acetaminophen[384] are effective after many ambulatory surgical procedures, although a proportion of patients are unable to metabolize codeine to its active form, rendering it ineffective.[385] Although a single preoperative dose of pregabalin produced modest improvements in pain after ambulatory surgery, continuing its use into the postoperative period added no further benefit.[151]

Managing Opioid Complications

Although multimodal techniques aim to minimize opioid use, strong opioids can be necessary as a rescue option after more invasive surgery. Analgesics such as morphine and oxycodone provide more intense and prolonged effects, but are associated with more intense and prolonged typical opioid side effects. Novel delivery techniques, such as iontophoretic[386] or nasal[387] fentanyl, may improve patient convenience but do nothing to reduce adverse effects. In addition to multimodal analgesia, attempts to limit these adverse effects have included the development of drugs such as tramadol, which combine opioid and nonopioid mechanisms of action. Tramadol is effective after ambulatory surgery,[388,389] but it is still associated with a frequent incidence of unwanted effects, including sedation, dizziness, and, particularly, PONV.[390] Tapentadol was recently licensed in both the United States and the United Kingdom. It has a dual action similar to that of tramadol, with

comparable efficacy to oxycodone but fewer GI adverse effects, such as nausea, vomiting, and constipation.[391] Unlike tramadol, it does not require metabolic activation or suffer from isomer-dependent pharmacodynamics.[147]

Combining oral oxycodone with naloxone (Targinact) antagonizes the GI effects, in particular preventing opioid-induced constipation, but has little effect on analgesia because first-pass metabolism prevents much naloxone from reaching the central nervous system.[147] Alvimopan is another peripherally acting MOP (formerly called mu opioid receptor) antagonist, intended to reduce opioid-induced constipation. However, peripheral MOP receptors also may partially mediate opioid-associated PONV, delayed gastric emptying, and urinary retention,[147] offering the hope that opioid analgesia without serious adverse effects may yet be a possibility.

Local Anesthetic Administration at Home

Sending patients home with perineural, incisional, and intraarticular catheters is a new and evolving area of postoperative pain management.[27] Patient-controlled regional anesthesia with an elastomeric balloon pump has provided effective analgesia and reduced pain intensity during mobilization when ropivacaine is delivered into a perioperatively placed wound catheter after subacromial decompression.[392] Although patients were kept in hospital for study observations and assessments, based on pain scores, the authors concluded that all patients in the active group could have been discharged within 2 hours of surgery. Another small pilot study showed excellent analgesia with continuous interscalene block, continued at home, allowing same-day discharge after a variety of shoulder operations, including open rotator cuff repair, subacromial decompression, and joint replacement.[393]

Recently, several institutions have described cases of chondrolysis that appear to be related to the use of postoperative intraarticular local anesthetic pain pumps.[394] In a series of 375 patients from one individual orthopedic surgeon, chondrolysis was observed only in cases in which either bupivacaine or lidocaine had been infused into the joint during the postoperative period.[395] Most local anesthetics, including bupivacaine, lidocaine, and ropivacaine, are chondrotoxic to human articular cartilage in vitro, and the risk may be increased with longer exposure to higher concentrations of local anesthetic, such as with a pain pump, compared to that associated with a single injection.[396] Consequently, the use of local anesthetic infusions after shoulder surgery has declined or stopped in many institutions.

A variety of infusion pump designs are available for local anesthesia infusions or patient-controlled regional anesthesia (PCRA) after discharge. Technical problems have been found with electronic pumps,[397] which seem to be unreliable for home use.[393] Patient satisfaction[397] has been reported with disposable elastomeric pumps, which are more reliable, although not all types function equally well and in vivo performance does not necessarily match results obtained in vitro.[398]

POSTOPERATIVE NAUSEA AND VOMITING

PONV occurs in as many as 30% in a general surgical inpatient population given no antiemetics (see also Chapter 97).[399] Some patients undergoing day surgery have a much smaller risk for symptoms, cited as less than 5%[50,400] for very minor surgery, with reduced requirement for intraoperative and postoperative opioids. However, in the same studies, other ambulatory surgery patients had a predischarge incidence of PONV as high as 41%. When the potential occurrence of emetic sequelae after discharge is included in the estimation of overall risk, some authors cite an overall incidence of more than 40%, even after receiving an antiemetic.[401]

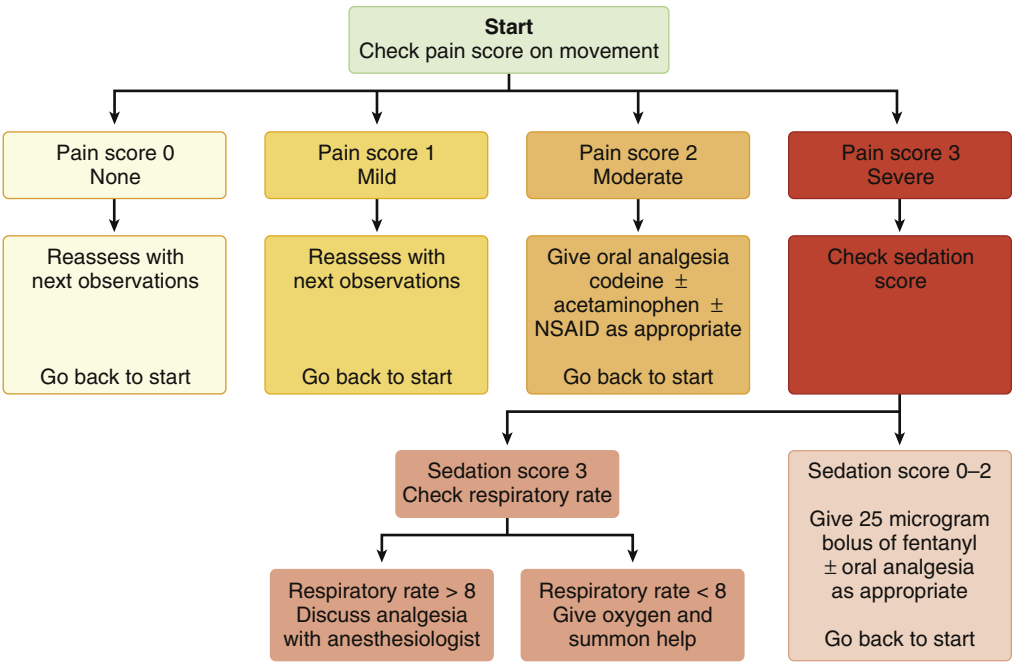

Figure 89-5. Example of a pain management protocol for ambulatory surgery patients. *NSAIDs,* Nonsteroidal antiinflammatory drugs. (Modified from Lipp A, Jackson I: Adult day surgery analgesia. In Smith I, McWhinnie D, Jackson I, editors: *Oxford specialist handbook of day surgery,* London, 2011, Oxford University Press, p. 133, with permission.)

RISK ASSESSMENT AND STRATEGIES

It might be expected that the management of PONV for ambulatory patients should involve universal multimodal pharmacologic prophylaxis to minimize the symptoms that might delay timely discharge or subsequent recurrence in the home environment. However, current recommendations[402] advocate a more focused approach toward the use of preventive pharmacotherapy, having first minimized baseline risk resulting from the use of generic emetogenic stimuli, such as the use of general anesthesia where regional techniques could be used, or if a general anesthetic is mandated, reducing exposure to volatile anesthetics, N_2O, large-dose neostigmine, and opioid-based analgesia. From there, individual patient factors should be identified to stratify relative risk. The scoring system originally derived from a cohort of ear, nose, and throat (ENT) patients by Apfel and colleagues in 1998[403] is popular because of its relative simplicity; yet debate continues regarding its applicability to ambulatory surgery patients, because the predicted risk for PONV (Table 89-5) seems to be overestimated in this population, presumably as a result of the original scoring system having been developed for inpatients in Europe. This seems to be confirmed in a subsequent paper by the same author,[401] where PACU rates of nausea were 19.9%, vomiting 3.9%, and nausea and/or vomiting 20.7% across a patient cohort with characteristics that would seem to predict greater risk from the original algorithm. However, when including postdischarge rates of PONV until the second postoperative day (Table 89-6), commensurate complication rates occur. Other scoring algorithms exist for prediction of risk for PONV in the ambulatory environment, but their relative complexity mandates the use of a calculator or computer.[400] A recent reevaluation of risk factors for PONV (see also Chapter 97)[404] reiterated the importance of those characteristics included in the original Apfel score,[399] but also included younger age and duration but not type of surgery.

Antiemetic treatment should therefore be tailored to assessment of likely risk for symptoms with the use of either unimodal or multimodal prophylaxis as indicated. The IMPACT study[184] demonstrated that ondansetron 4 mg, droperidol 1.25 mg, and dexamethasone 4 mg were equally effective in reducing the risk for PONV by an order of 25% and that using these two drugs together would be approximately additive (multimodal antiemetic prescription). Specifically, the prophylactic use of one of these drugs decreases the estimated risk for PONV from 60% to 44%; use of two drugs would further decrease the incidence from 44% to 33% and three drugs to 24%. The use of TIVA with propofol with the concomitant avoidance of N_2O had similar equivalence to the use of one antiemetic.[184] Simple measures, such as the routine administration of approximately 1 to 2 L of IV crystalloid fluids, reduce the incidence and severity of PONV, decrease dizziness and drowsiness,[405] and reduce postoperative pain in high-risk groups.[406]

ANTIEMETIC DRUGS

First-Generation Drugs

Metoclopramide is a dopaminergic (D_2) and serotonergic (5-HT_3, peripheral 5-HT_4 at higher doses) antagonist with gastric prokinetic properties that was first described in 1964. A meta-analysis of a standard clinical dose of 10 mg showed little evidence of pharmacologic benefit for PONV[407] and has led to a suggestion in recent guidelines for management of PONV in ambulatory surgery that other more effective antiemetics be used for first-line treatment.[402] However, more recent systematic reviews[408,409] have challenged these views, and a 10-mg dose may be considered. Higher doses, such as 20 to 25 mg, are more effective[410] but are associated with more akathisia.

Droperidol is a butyrophenone with an antiemetic effect resulting from dopaminergic receptor (D_2) antagonism that received a black box warning for the FDA-approved

dose of 2.5 mg[411] or greater because of potential QT interval prolongation. This and other side effects of droperidol, such as sedation and akathisia, were significant at higher doses than are commonly used for PONV prophylaxis,[411] which are typically 1.25 mg or less. Droperidol use is less in the United States since the black box warning was added but primarily for medicolegal reasons rather than because of concerns with efficacy or side effects. A recent meta-analysis[412] has confirmed the antiemetic action of low-dose droperidol. Supply in the United Kingdom was halted on the basis of a prediction of market nonviability by the manufacturer. Although the drug has been reintroduced in the United Kingdom, it has been little used in the ambulatory environment in this country as a result of perceptions of adverse extrapyramidal effects, particularly akathisia, even at 0.5-mg doses.[413,414] An Australian study evaluating the incidence of akathisia in 228 women undergoing ambulatory gynecologic laparoscopy reported a rate of 29% with administration of 10 μg/kg.[415]

Antagonists of the histamine H_1 receptor have a particular efficacy in the management of nausea and vomiting precipitated by vestibular pathways, with a documented benefit in the management of travel sickness and surgical procedures for strabismus or involving the middle ear. Dimenhydrinate (a combination of diphenhydramine and 8-chlorotheophylline that was added to reduce drowsiness) has an antiemetic effectiveness deemed similar to that of both droperidol and 5-HT_3 antagonists,[416] but potential adverse reactions from these antihistamines include marked sedation, dry mouth, urinary retention, and blurred vision as a result of associated muscarinic receptor antagonism. Meclizine, an H_1-receptor antagonist and anti–motion sickness medication, is minimally sedating, long-acting, and effective for treatment of PONV and for prevention of postdischarge nausea and vomiting (PDNV).[417] In the United States, it is inexpensive and available without prescription, making it an attractive postdischarge choice.

A transdermal scopolamine delivery system is also available. This patch was designed to deliver a total dose of 1 mg of scopolamine at a sustained, constant rate over a period of 3 days.[418] Numerous studies have shown transdermal scopolamine to be effective in reducing the incidence and severity of PONV and PDNV, with efficacy comparable to that of ondansetron or droperidol. It has a prolonged duration but the onset is delayed, becoming effective within 2 to 4 hours of applying the patch.[419] The slow onset can be overcome by applying the patch the night before surgery. Used in this way, the incidence of nausea and vomiting was reduced from 62.5% and 37.5% to 20.8% and 8.3%, respectively, compared to placebo after gynecologic laparoscopy.[420] In the United States, clinicians apply the patch preoperatively, knowing that onset of PDNV efficacy will be in the early recovery period.[418]

Adverse effects, particularly dry mouth but also somnolence, dizziness, and blurred vision, are relatively common but generally described as mild.[418,420]

Serotonin 5-HT3 Receptor Antagonists

The 5-HT_3 antagonists have played a substantial role in the management of PONV since their introduction in the 1980s, because of their relatively benign adverse reaction profile compared with those of the then available drugs. Their prophylactic use is more effective when given just before the end of surgery.[421] They are effective drugs for emetic rescue therapy, with ondansetron seeming to have a more preferential effect on vomiting (number needed to treat [NNT] = 4) rather than nausea (NNT = 7).[422] Although relatively well tolerated, their side-effect profile includes an increased risk for headache (number needed to harm [NNH] = 36) and elevated liver enzymes (NNH = 31).[422] All serotonin subtype 3 antagonists have also been associated with QT interval prolongation. More recently released serotonin 5-HT_3 receptor antagonists, such as dolasetron, granisetron, and palonosetron,[423] seem to exhibit similar characteristics with equal reduction of PONV rates in high-risk patients when used for prophylaxis, though the longer half-life of these drugs (8, 10, and 40 hours, respectively) may afford better protection against symptoms after discharge. In particular, palonosetron, by nature of its unique binding properties leading to internalization of the 5-HT_3 receptor[424] and a long half-life, may have a role in the management of postdischarge symptoms.[425] A large cost remains a significant barrier to use of the newer, nongeneric serotonin antagonists.

Steroids

Dexamethasone is an effective antiemetic at IV doses of 4 to 5 mg (depending on local formulation).[426] This steroid may act centrally to either modulate the release of endorphins or inhibit prostaglandin synthesis. Given its delayed onset of action, dexamethasone should be administered as early as possible *after* induction of anesthesia.[427] Prophylactic dexamethasone is also effective in reducing postoperative pain and improving the quality of recovery,[153,154] although at somewhat higher doses (typically 8 mg) than those required for an antiemetic effect.

Neurokinin-1 Antagonists

The role of tachykinins in the emetic pathway was first elucidated by immunohistologic studies identifying substance P in the dorsal vagal complex of the ferret, an area of the brain deemed essential in the vomiting reflex.[428] Subsequent research identified the potential value of specific antagonists to the neurokinin-1 receptor, at which substance P and neurokinins A and B interact both centrally and peripherally in the gut to suppress vomiting. Aprepitant was the first commercially released drug of this class. A preoperative oral dose of 40 mg has efficacy similar to that of ondansetron for the reduction of nausea, with a potentially superior effect in the suppression of vomiting for 48 hours after administration.[429] An IV prodrug formulation, fosaprepitant, was introduced in 2008 with a license for use in chemotherapy-induced nausea and vomiting, but as yet, no work has been done evaluating its role or value in PONV.[430] A multicenter study evaluating the use of oral rolapitant,[431] a competitive NK-1 antagonist with an exceptionally long half-life of 180 hours, suggested similar effectiveness in comparison with placebo and ondansetron (administered at induction) with early control of symptoms, but use of rolapitant similarly seemed to confer prolonged protection from postoperative emetic symptoms. Cost remains a barrier for this class of drugs as well.

MANAGING PERSISTENT NAUSEA AND VOMITING

The continuing symptoms that follow antiemetic rescue therapy require further clinical review. Consideration should be given to alternative causes for these symptoms, particularly hydration status, covert hypovolemia, or early infection. Review of vital signs (temperature, pulse, and arterial blood pressure), allied with clinical examination to exclude an association with concomitant worsening of abdominal pain, potential septic foci, or urinary retention, is important to exclude more sinister causes, before consideration is given to symptomatic relief.

Administering 20 mL/kg of an isotonic electrolyte solution reduces the risk for nausea and dizziness after ambulatory surgery and may have value in attenuating continuing symptoms.[405,432] Ephedrine 0.5 mg/kg intramuscularly is effective for prophylaxis and treatment, with efficacy comparable to that of droperidol and sedation scores lower than placebo.[433] No value exists in prescribing a previously used antiemetic drug within 6 hours of previous administration, but other second-line drugs may be considered should first-line management fail. These options include small-dose IV naloxone; propofol 20 mg; phenothiazines, including prochlorperazine, perphenazine, or small-dose promethazine (6.25 mg); or a neurokinin antagonist.

SPECIAL AREAS

OFFICE-BASED PRACTICE

Office-based anesthesia is a form of ambulatory anesthesia that is rapidly expanding in North America and some parts of Europe. Arguably, the first ambulatory surgery center in the United States (the Downtown Anesthesia Clinic in Sioux City, Iowa) was an office-based practice.[2] Simple, minimally invasive surgical procedures have been performed in physicians' offices for many years, using either local anesthesia or sedation. There is now a growing involvement of anesthesiologists, especially as the complexity of office-based surgery increases.

Advantages of office-based surgery include improved convenience for the patient, but the primary driver has been more control over scheduling and the work environment for the surgeon. The potential exists for significant profit going directly to the surgeon, but in addition, the lower overhead costs in this setting result in significantly lower overall costs for the procedure. For example, the total cost of a laparoscopic inguinal hernia repair was three and a half times greater when performed in a hospital setting compared with an office facility.[434] The costs of open hernia repair[434] and various rhinology procedures[435] were approximately 2.5 times less when performed in the office. However, legitimate concerns have been raised about the safety of office-based surgery. One comparative study showed a more than 10-fold increase in adverse incidents and deaths for procedures performed in a physician's office compared with an ambulatory surgical center.[436]

These disasters are often the result of unqualified or untrained individuals administering sedation in unsuitable or unaccredited facilities.[436,437] Deep sedation appears to be a considerable risk factor. From the ASA closed claims database, 40% of the deaths resulting from MAC occurred during facial and eye surgery, which are commonly performed in the office setting.[300] Hypoxia and hypoventilation resulting from oversedation was the most common cause of death, with poor vigilance, inadequate monitoring, and delayed resuscitation contributing to the deaths, half of which were judged to be preventable.[300] The common perception that sedation is safer than general anesthesia is not supported by these data.

In the United States, the regulation of office facilities is the responsibility of individual states, yet as of 2012, only a bare majority of states have such regulations.[438] Regulation does appear to improve safety, because no deaths were reported in a series of more than 23,000 cases from a fully accredited office staffed by board-certified anesthesiologists and surgeons.[439] Guidance on office-based anesthesia is available from the ASA and SAMBA,[440] and comprehensive recommendations from other organizations and experts have been published. Typical recommendations for safe office-based anesthesia are summarized in Box 89-2. In essence, the office setting must adhere to the same standards of care required in a hospital-based or freestanding ambulatory surgery facility. Strong safety processes must be in place, because the isolated office-based environment means that outside help is not immediately available.

The selection of patients for office-based anesthesia should adhere to robust guidelines for safe anesthetic care. Because perioperative complications are harder to manage in an isolated environment, selection criteria may need to be more restrictive than those currently advocated for ambulatory surgery in the hospital setting.[42] The selection

BOX 89-2 ***Summary of Office-Based Surgery Practice Guidelines Collated From U.S. Regulatory Bodies***

- Employment of appropriately trained and credentialed anesthesia personnel
- Availability of properly maintained anesthesia equipment appropriate to the anesthesia care being provided
- Documentation of the care provided as complete as that required at other surgical sites
- Use of standard monitoring equipment according to the American Society of Anesthesiologists policies and guidelines
- Provision of a postanesthesia care unit or recovery area staffed by appropriately trained nursing personnel and provision of specific discharge instructions
- Availability of emergency equipment (e.g., airway equipment, cardiac resuscitation)
- Establishment of a written plan for emergency transport of patients to a site that provides more comprehensive care should an untoward event or complication occur that requires more extensive monitoring or overnight admission of the patient
- Maintenance and documentation of a quality assurance program
- Establishment of a continuing education program for physicians and other facility personnel
- Safety standards that cannot be jeopardized for patient convenience or cost savings

process must include a matrix of procedure invasiveness, patient complexity, and the capabilities and comfort levels of the facility and its personnel.[440] Preoperative preparation should be guided by the same clinical acumen and common sense that drives the decision-making process at freestanding surgery centers, with any coexisting diseases under good control. Anesthetic techniques suitable for office-based surgical procedures are similar to those used for hospital-based and freestanding ambulatory surgery procedures. MAC remains common, although clearly a great challenge exists in "the judicious and skillful use of MAC anesthesia to achieve adequate sedation and analgesia for increasingly invasive procedures."[441] Increasingly a move toward light general anesthesia is occurring—that is, using an LMA or facemask for airway management.[442,443] Propofol, sevoflurane, and desflurane are all suitable within the office setting, although an anesthesia machine is required to deliver volatile anesthetics. Standard equipment can be installed in frequently used offices, and portable equipment has been developed for less frequent use.[437] Fast-track recovery is the ideal with patients who are awake, alert, and able to transfer themselves from operating room table to a reclining chair, thus facilitating room turnover in approximately 10 minutes and home discharge within an hour of awakening.[437] It is important to minimize PDNV.[444] Recommendations have been made for other outcome measures that should routinely be audited after office-based anesthesia.[440,445] The American Medical Association issued a set of Office-Based Surgery Core Principles to promote safety and quality of health care services for office procedures requiring sedation and anesthesia.[446]

In the United Kingdom, a similar practice of office-based dental anesthesia was in place for several decades. A series of anesthetic deaths in dental offices led to several reviews, culminating in recommendations that all anesthetics be administered by accredited anesthesiologists with specific training and experience in dental anesthesia, as well as recommendations regarding resuscitation equipment and the availability of drugs needed for emergency use.[447] Partly because of the high costs of equipment and maintenance, the net result was the movement of all anesthesia out of the dental office and back into the hospital environment.[448] Subsequently, office-based anesthesia has never developed in the United Kingdom. Minor surgery under local anesthesia is performed in some specially equipped primary care surgery centers, whereas the majority of procedures that are performed in offices in the United States are managed in hospital-affiliated day surgery units (DSUs), procedure rooms, or surgical outpatient clinics in the United Kingdom.

ANESTHESIA IN REMOTE LOCATIONS

Many surgical conditions that formerly needed treatment in a hospital outpatient operating room are now being managed by interventional procedures done by nonsurgeon physicians in radiology, cardiology, and endoscopy (see also Chapter 90). In many cases, deep sedation or anesthesia is still required, meaning the anesthesiologist has to move into unfamiliar and often hazardous environments. The problems associated with these diverse locations are considered in detail in Chapter 90, but because many of the procedures are performed on an ambulatory basis or require anesthetic management according to all of the usual short-stay principles, a brief description is required here. The basic sedative and anesthetic techniques already described are suitable for most cases, but the conduct of anesthesia is likely to have to be modified according to the specific environment.

Administration of anesthesia or sedation at remote locations is associated with significant risk.[449] Some of these risks are specific to particular areas (Table 89-7) but commonly include an unfamiliar environment; small, cramped, or dark rooms; restricted patient access; inadequate or poorly trained support; restrictions on patient monitoring; and inadequate resources. An analysis of ASA closed claims arising from anesthesia care in remote locations revealed that adverse events had a higher probability of death than those arising in the operating room[450] and were primarily caused by an adverse respiratory event (44%). MAC was the most common anesthetic technique, and respiratory depression secondary

TABLE 89-7 SOME HAZARDS ASSOCIATED WITH ANESTHESIA IN REMOTE ENVIRONMENTS

Area	Examples of Specific Hazards
Magnetic resonance imaging (MRI) scanner	Noise Strong magnetic fields; no ferromagnetic equipment within scanner Peculiarities of MRI-compatible equipment Remote monitoring may introduce delays (e.g., capnography) Risk for induced currents causing burns in coiled cables Compliance and dead space within extra-long breathing circuits
X-ray and interventional radiology	Radiation exposure; mobility limited by lead gowns Often low light levels Restricted access and unexpected movement of x-ray equipment Patients may have significant comorbidities Allergic reactions to contrast media Limited patient access in CT scanner
Endoscopy suite	Dark environment, limited access Patients may have significant comorbidities Risk for hemodynamic disturbance with bowel preparation or vagal stimulation Shared airway in upper endoscopy ERCP performed with patient in prone position with added hazards of radiology
General issues	Unfamiliar environment Old or unfamiliar equipment Emergency drugs and equipment may be rarely used or checked Lack of dedicated or trained assistance Scavenging may be difficult or absent

CT, Computed tomography; *ECRP,* Endoscopic retrograde cholangiopancreatography.

to oversedation accounted for over a third of the claims. Care that was substandard and preventable by better monitoring was implicated in the majority of claims associated with death.[450] In the United States, the CMS mandates that the chiefs of anesthesia services monitor and evaluate sedation practices throughout the hospital, and accrediting organizations, such as TJC and DNV, audit for compliance.

HOME READINESS AND BEYOND

PATIENT INFORMATION

Before discharge, patients should receive postoperative instructions concerning aftercare, their transition to normal activities, and any requirements for follow-up. These instructions should be in writing[451] because retention of information is impaired during early recovery from anesthesia,[452] and ideally they should be repeated to the patient's escort. Besides general advice, discharge information should include the early warning signs for the main complications of the specific procedure the patient has undergone[451] and the action to take should these occur.

CRITERIA FOR DISCHARGE

Discharge of the patient after ambulatory surgery and anesthesia is a physician responsibility in the United States,[10] fulfilled by physician-written discharge criteria (Box 89-3). Typically, patients should be oriented and comfortable with cardiovascular stability (including when standing) and problem-free wounds. Alternatively, discharge criteria may be incorporated into a scoring system, such as the Post-Anesthetic Discharge Scoring System (PADSS).[453] Voiding urine is no longer considered an essential prerequisite for discharge in those at low risk for urinary retention, even after spinal anesthesia.[454] For patients at higher risk, the bladder volume should be assessed by ultrasound scanning[455] and the patient managed accordingly (Fig. 89-6). Actual discharge is frequently nurse-managed,[451,456] provided patients have been managed according to an appropriate protocol and have met all the necessary discharge criteria.

BOX 89-3 ***Criteria for Facility Discharge at the Brigham and Women's Hospital, Boston, Massachusetts***

Alert and oriented to time and place
Stable vital signs
Pain controlled by oral analgesia
Nausea or emesis mild, if present
No unexpected bleeding from operative site
Able to walk without dizziness
Has been given discharge instructions and prescriptions
Accepts readiness for discharge
Adult present to accompany patient home

Courtesy B. K. Phillip.

No rationale exists for a minimum observation period after ambulatory surgery in most cases, although patients clearly must be observed for a sufficient period to ensure cardiovascular stability. One possible exception is tonsillectomy, in which a minimum observation period of 6 to 8 hours has been advocated to detect most primary hemorrhages.[28] However, even this has been challenged, with a 4-hour observation period[457,458] or less[459] regarded as safe.

AFTERCARE AND FOLLOW-UP

Appropriate aftercare is one of the main safety features of ambulatory surgery. Acute complications may be related to anesthesia or surgery, and patients should receive careful predischarge education about what may occur for both. All patients should be provided with a 24-hour telephone number for emergency contact. This is often the ambulatory surgery unit during the daytime, but it may be necessary to provide another number or better still to automatically transfer calls when the unit closes at night.[451] In the United States, patients are also routinely given their surgeon's office and answering service number to contact directly for surgical issues. Although the U.K. health care system includes primary care doctors, they have limited experience in potentially life-threatening early postoperative complications and should not be called first. If the patient's call to the facility or physician does raise concerns, it is important that the patient be brought back for early surgical review; going to the emergency department also can introduce unnecessary delay. Because the ambulatory patient is self-caring and likely to mobilize early, symptoms of surgical complications are noticed and reported sooner than if the patient were recovering in the hospital environment, allowing earlier detection and increased safety.

Follow-Up and Outcome Measures

Most ambulatory surgery units routinely telephone their patients on the first postoperative day. This allows measures to be recorded and audited. The ASA has developed a set of outcome indicators specifically for ambulatory and office-based surgery and anesthesia.[460] These include outcome events of interest for days 1, 14, and 30 and ongoing continuous quality indicators. The International Association for Ambulatory Surgery[461] has developed a series of indicators (Table 89-8) useful in the evaluation of the overall success of organizational performance, and these mirror the advice from other national specialist societies.[42,462] Lemos and Barros[463] further defined the value of outcome reporting in a range of domains subdivided into clinical, organizational, social, and economic factors[463] that allows the reporting of both individual and institutional performance (Table 89-9). Return-mail questionnaires can be used for patient follow-up after ambulatory surgery to help identify common sequelae that ambulatory patients should realistically expect to experience.[368] No matter how data are collected, it is important that information from quality indicators is fed back in an effective way to individual clinicians and clinical units to support continuous improvement.[464]

TABLE 89-8 **OUTCOME INDICATORS FOR AMBULATORY SURGERY SUGGESTED BY THE INTERNATIONAL ASSOCIATION FOR AMBULATORY SURGERY**

Indicator	Reason
Failure to attend the ambulatory surgery center/unit	Acute medical condition Decision of the patient Organizational reasons Other reason (explain)
Cancellation of the booked procedure after arrival at the ambulatory surgery center/unit	Preexisting medical condition Acute medical condition Organizational reasons Other reason (explain)
Unplanned return to the operation room on the same day	
Unplanned overnight admission	Surgical reasons Anesthetic or medical reasons Social or administrative reasons
Unplanned return of the patient to an ambulatory surgery unit or hospital	<24 hr >24 hr and <28 days
Unplanned readmission of the patient to an ambulatory surgery unit or hospital	<24 hr >24 hr and <28 days

Adverse Effects After Ambulatory Surgery

Minor adverse events are common after ambulatory surgery and anesthesia (86%).[368] Drowsiness is the most common effect persisting after discharge (62%), and aches and sore throat are common in intubated patients (47% and 49%, respectively). Headache (25%) and dizziness (20%) also occur, but nausea and vomiting after discharge are less common (17% and 7%, respectively). Patients may take 2 to 3 days before they are able to resume their usual activities.[368] Information about these known side effects should be incorporated into the preoperative patient education and in the United States may be incorporated in an anesthesia consent form.

Acute cardiovascular events (hypertension and hypotension, dysrhythmias, cardiac ischemia, and arrest) occur with an overall frequency of 2.9%, with greater risk in patients with preexisting cardiovascular morbidity; respiratory events (hypoxemia, laryngospasm, bronchospasm, aspiration, pulmonary edema, and pneumothorax) occurred in 0.1% of the study population, with increased risk in smokers, asthmatics, and the obese.[51] Unanticipated overnight admission has a worldwide reported incidence of between 1% and 6%. Caution is required in the use of this indicator as a standard to achieve, however, unless the reasons for the admission are documented.

TABLE 89-9 OUTCOME MEASURES IN AMBULATORY SURGERY

Category	Specific Outcome Measures
Clinical	Perioperative cardiovascular and respiratory adverse events
	Minor postoperative morbidity
	Pain
	Nausea and vomiting
	Other: Sore throat, headache, drowsiness
	Unplanned return to the operating room on the same day of surgery
	Unplanned overnight admission
	Unplanned return or admission to the Day Surgery Unity (DSU) or hospital:
	<24 hr
	>24 hr and <28 days
Organizational	Proportion of elective surgery performed as day case
	Accessibility to ambulatory surgery programs:
	Number of different procedures included
	Cancellation of booked procedures
	Failure to arrive at the DSU
	Cancellation after arrival at the DSU
Social	Patient satisfaction
	Functional health status and quality of life
Economic	Efficiency rate of operating room usage

From Lemos P, Barros F: Outcome measures. In Smith I, McWhinnie D, Jackson I, editors: *Oxford specialist handbook of day surgery,* London, 2011, Oxford University Press.

Although the indicator may provide evidence of inadequate preoperative assessment and patient optimization, differences in surgical case mix and complexity may explain any variation across institutions. Ultraconservative selection criteria could result in an extremely low overnight admission rate and inappropriately give the impression of a highly performing unit rather than one that was excessively cautious with patient selection. Cross comparison of this indicator with rates of ambulatory care as a proportion of all elective surgery, either by specialty or specific operation, could assist with interpretation.

Patient Satisfaction With Ambulatory Surgery

Patient satisfaction is a difficult metric to define, depending somewhat on the patient's expectation of care. Nevertheless, patient satisfaction is generally very high after ambulatory surgery. The patient experience was improved when facility staff was thought to be friendly and the surgeons discussed findings before discharge,[465] and these factors were perceived by postoperative ambulatory surgery patients as being more important than management of postoperative pain, starting the IV smoothly, and avoidance of delays. Others have found that provision of accurate information about the expected perioperative process is important; other factors that lead to higher satisfaction are effective postoperative analgesia, minimal emetic sequelae, staff courtesy and privacy in the unit, short waiting times before surgery, no perception of being rushed, postoperative telephone contact, and naturally, good surgical outcome.[461]

Chapter 90

Non–Operating Room Anesthesia

WENDY L. GROSS

Acknowledgment: The editors and the publisher would like to thank Dr. Paul E. Stensrud, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The non–operating room arena represents an expanding perimeter of the practice. As technology develops and patient acuity increases, non–operating room anesthesia (NORA) cases become more demanding in terms of both patient management and necessary resources.
- Financial and operational constraints create additional management challenges. Significant differences in practice result from the fact that NORA cases occur in places remote from the operating room (OR) and are performed frequently by medical proceduralists who are just now learning about the scope of anesthesiology practice. In addition, anesthesiologists are unfamiliar with the demands of providing an anesthetic in an environment in which radiation hazards are significant, equipment restricts mobility and access to patients, and changes to setups used in the OR are common.
- This chapter serves as a general guide to the cadence and focus of procedure performed outside of the OR, and highlights some of the adaptations, both cultural and practical, that are needed to provide a safe and optimal anesthetic.

OVERVIEW: DEFINING NON–OPERATING ROOM ANESTHESIA—WHAT IT IS AND HOW WE GOT HERE

Non–operating room anesthesia (NORA) refers to all procedures performed in off-site locations. NORA includes a very diverse set of procedures. Historically, cases managed outside of the operating room (OR) were minor, targeted, infrequent, and involved relatively stable patients and seldom required anesthesiology support. However, the current situation is very different. NORA cases now involve nearly every medical specialty, generate (in many hospitals) volume and revenue equivalent to that of the OR, and are as demanding of anesthesiologists as the most advanced surgical OR procedures. They constitute a major expansion of our practice perimeter and require the same (if not more) attention to operational efficiency, planning, rigor, and consistency with which the OR is managed.

The flood of NORA procedures now requiring anesthesia support has evolved from rapid technologic development and unprecedented increases in patient acuity as a result of aging and improved survival. NORA procedures include everything from minor to very major endeavors and range from day surgery cases to intense cardiac procedures requiring after care in the intensive care unit (ICU). Many NORA cases are performed on patients deemed "too sick for surgery"; in some cases, the patients are critically ill or unstable and therefore a need for advanced and specialized anesthesiology skills arises.

The purposes of this chapter are twofold. The first is to highlight the intrinsic, common, and unique characteristics of NORA cases that impose unusual constraints on anesthesiologists in the out of OR arena. The second is to present goals, methodologies, and pitfalls of interventions that may be unfamiliar to anesthesiologists. This chapter does not reiterate basic principles of anesthesiology practice described elsewhere in the book, nor does it describe the technical details of novel procedures. It should serve rather as a general guide to NORA procedures and the environment itself. The key to providing an optimal anesthetic (in or out of the OR) is thoughtful consideration of anesthetic options in the context of both the principles of the procedure and the physiology of the patient. No substitute exists for taking time to discuss the procedure and the patient with the medical proceduralist. This is not always easy, because—unlike surgeons—most medical providers are uneducated about anesthesia, are unfamiliar with the skill sets of anesthesiologists, and lack experience with many relatively rare but serious complications (e.g., loss of airway, allergic reactions). Many still consider anesthesiology support unnecessary because they do not normally think about the synergistic ramifications of moderate to deep sedation and complex procedures for an older, sicker patient population. This chapter equips anesthesiologists with a basic understanding and vocabulary with which to establish effective dialogue, in the hope of broadening our own horizons and helping to educate our colleagues about the benefits of collaborative practice.

NOVEL CHARACTERISTICS OF NORA CASES

NORA cases are characterized by three distinctive features: location, operator, and relative novelty. First, the procedure *never* takes place in a typical operating suite; second, for the most part (although not always) the operator performing the procedure is not a surgeon but rather a medical interventionalist or proceduralist; and, finally, the procedures and technologies used may be novel in one way or another. When anesthesiologists are faced with the need to provide services to nonsurgeons in non-OR locations, problems arising from scheduling inconsistencies, ad hoc requests, inadequate physical plant, poor communication, and resource limitations can obstruct expeditious resolution. The increasing incidence of medically complex patients needing urgent intervention but lacking periprocedural evaluation creates additional stress. An expanding need for anesthesiology services outside the OR presents an opportunity for us to reaffirm our skills and mission.

For many acute and chronic disorders, medical procedures now target the same problems and patients treated previously only with surgery. Some practitioners believe that noninvasive medical procedures are better tolerated than invasive surgical procedures. However, because noninvasive procedures are in many cases relatively new, long-term outcome studies are still lacking. But certainly for a rapidly broadening spectrum of acute and chronic problems, surgery in the OR is no longer the only potential route of treatment.

Medical and surgical procedures now demonstrate enormous overlap. Pulmonary embolism, for example, can be treated in the OR, in the catheterization laboratory, or in the interventional radiology suite. The ultimate choice of venue may be a function of acuity of presentation, but likely also depends on who the patient sees first and who is available.

As anesthesiologists, our mission is to safeguard the patient through the course of treatment, whatever the treatment is, and wherever it occurs. For the most part, history has placed us in the controlled environment of the OR, where we have organized schedules, protocols, and standards of behavior and communication. We have grown comfortable there, and perhaps a little complacent.

The perimeter of our landscape now expands beyond the familiar domain of the OR, where we enter the domain of medical practitioners—for example, interventional cardiologists, interventional radiologists, gastroenterologists, radiation oncologists, and electrophysiologists. It is our obligation to follow the need and import our clearly successful OR safety standards to new venues, patients, and practitioners. This means leaving some of the dogma of the OR behind and creating universal standards for broader practice. As the landscape changes, unusual and perhaps unforeseen obstacles are created. New venues pose physical, political, economic, and medical challenges that are often unanticipated. This chapter delineates the hurdles we face—from the most basic to the most complex and from the financial to the medical—and offers a perspective that is becoming more widely accepted. The goal is to promote awareness, encourage preemptive planning, and clarify the need for collaborative strategy design.

UNIQUE OBSTACLES: FROM PHYSICAL PLANT TO THE MEDICINE-ANESTHESIOLOGY CULTURE GAP

Non-OR procedure suites are constructed with the procedural operator in mind, without regard to the needs of anesthesiologists. They are often crowded and unfamiliar. Access to the patient may be inadequate. Almost universally, for example, procedure suites that use fluoroscopy for guidance are configured so that the C-arm limits access to the patient's head and obstructs direct communication between the anesthesiologist and the proceduralist. Hemodynamic and other monitoring may be controlled by someone outside the suite and may not be visible to the anesthesiologist. Lead screens may not be available, and when they are positioned to protect the anesthesiologist from radiation, pumps and intravenous lines may be inaccessible. The fluoroscopy screen is usually at 90 degrees to the person administering the anesthetic, so he or she cannot see the screen while standing behind the patient's head (the position we are used to in the OR). Often it is impossible to both have anesthesia equipment and monitors close to the patient and procedural equipment in the proper place.

In many cases, procedural suites are remotely located. Common electrical and mechanical malfunctions are not easily remedied because technical support is not nearby and additional supplies may not be accessible in timely fashion. This situation demands that care be taken *before the start of the procedure* to ensure that equipment is stocked and working and that backup options (emergency supplies, difficult airway equipment) are functioning and readily available. Certain procedure rooms require anesthesiologists to spatially reorient themselves and their equipment to adapt or reconfigure setups that are routine in the OR. This requires mindfulness about what we usually take for granted. Distraction of our focus away from patient care can be potentially disastrous in the face of novel or complex procedures.

Conversely, much equipment routinely found in traditional ORs is not present in medical procedure suites. Although anesthesiologists understand the need to import this equipment, medical proceduralists do not. For example, gas scavenging may be unavailable, oxygen and suction may be suboptimally placed, and monitoring equipment may not function properly because of interference with mapping systems or other electronic interfaces. Regardless of these preexisting conditions, it is the obligation of the anesthesiologist to understand and implement changes needed to administer anesthesia safely. To this end the American Society of Anesthesiologists (ASA) has formulated a statement regarding NORA locations that articulates minimum standards for all procedures performed in these areas,[1] but these standards are quite fundamental and may not fall within the reference frame of medical proceduralists.

Even more formidable than the physical constraints imposed by non-OR locations is the cultural mismatch that can dominate interactions between medical practitioners and anesthesiologists. Lack of mutual experience and vocabulary, extreme specialization, and unique financial and political motivators may contribute to poor

communication and misperception. Mutual goals are difficult to identify in these circumstances; medical interventionalists may find anesthesiologists obstructive, and anesthesiologists often find medical proceduralists cavalier. Many medical proceduralists do not understand the skill set of anesthesiologists, much less the intricacies or subtleties of administering an anesthetic—that is, they do not know what they do not know. Likewise, many anesthesiologists have only a basic idea (at best) about what is happening during the course of a noninvasive procedure and do not ask enough questions. They may have limited experience in a particular venue, the procedure may not be observable, and fluoroscopy screens may be out of the field of view or uninterpretable. Usually the proceduralist is unlikely to communicate the course of the procedure during the case. Anesthesiologists may be unaware of pitfalls and likely complications of the procedure; even though they would not undertake administering an anesthetic in the OR without understanding the surgery, they do this in non-OR locations without a second thought. Bridging the communication gap requires effort, but it is absolutely critical to optimizing outcomes.

Often proceduralists are consultants, enlisted by primary care providers who do not convey all relevant information. Even when all information is provided, specialization predisposes proceduralists to overlook general concerns and concentrate on their point of expertise; electrophysiologists, for example, might focus on the need for prompt treatment of tachycardia-mediated cardiomyopathy but be unaware of contributory problems and the extent to which they must be dealt with to avoid increased morbidity. Anesthesiologists might not think about how coughing on extubation might predispose patients who have had groin sheaths to serious hematomas.

When interventionalists undertake novel procedures using new technology, the situation can be even more troubling. The course of the procedure may be unknown, the timing and sequence of events may be unclear, and the focus of the procedure may change in midstream. When the proceduralist is unsure of what is happening, the anesthesiologist cannot possibly have all the information needed to administer a tailored anesthetic. Then, as technologic innovation accelerates, financial and political drivers come into play outside of the OR. Expensive new technology is desired by all, and equipment purchases can require enormous capital investments, which are depreciated over many years. Upgrading and maintenance constitutes an additional expense, and to justify the outlay, expensive equipment needs to be used. Ensuring that the appropriateness of the patient does not become secondary to the need or wish to use the latest technology sometimes requires insight from a physician with a different perspective. Anesthesiologists may find themselves in unusual non-OR locations administering anesthetics for noninvasive procedures that are long and complicated, although the same procedures performed invasively in the OR are shorter and relatively straightforward. This can be disconcerting, but it is integration of medical and surgical viewpoints, along with intellectual flexibility rather than adherence to dogma, that underlies the new collaborations that must be forged.

Surgeons realized long ago that effective performance of surgery required the administration of an appropriate anesthetic by another physician. They are thus accustomed to sharing their procedures with other medical practitioners. This is not yet always the case for medical proceduralists, who are used to working alone and ordering sedation by a nurse. As medical procedures become even more technically demanding and patient conditions more complex, medical proceduralists will find increasing benefit from the support of anesthesiologists. This requires collaboration and teamwork, but teams cannot function without mutual respect, excellent communication, common vocabulary, shared experience, and some truly overlapping competencies. Thus, argument exists for grouping medical specialists with specialty trained anesthesiologists who share a mutual knowledge base. Amalgamation of medical and surgical perspectives is mission critical in driving innovation and averting disaster outside of the OR. Unfortunately, this synergism is sometimes missing from the anesthesiologist-medical proceduralist dyad. Our hope is to broaden mutual understanding and nurture intellectual curiosity in the quest for the best possible patient management strategies. In pursuit of this goal, we can build on the outstanding record of improved patient safety and outcome that characterizes the history of anesthesiology.

FINANCIAL AND OPERATIONAL CONSTRAINTS

The impact of financial and operational infrastructure on the delivery of anesthetic care outside the OR is substantial. Because medical, financial, and operational constraints and priorities often become blurred, it is important to understand the difference between what does and what *should* drive the direction of program development. Unsettled questions about which patients require an anesthetic; when, where, and with how much notice; and who should pay how much for this type of support can remain unresolved or be inappropriately decided if financial discrepancy, political battles, and medical need are not prioritized or organized. The role of anesthesiologists may be central here, but the quality, safety, and efficiency of the care they deliver is a function of the environment as a whole.

EFFECTS OF PAYMENT SYSTEMS

Private health insurance evolved as hospitals transitioned from repositories for the impoverished and dying into institutions where people actually recovered from illness. Hospitalization plans, initially developed by hospitals in the 1930s, were a way to supplement the economic resources needed for growth and expansion. In those days, hospitals functioned as extensions of private offices in many ways. Since then, payment systems have become more bureaucratic and complex, but remain unsophisticated in terms of promoting care integration.

Medical optimization and financial efficiency are predictably not the end products of fee-for-service payments. As the population ages, care is increasingly specialized

and complex. The Medicare Payment Advisory Commission (MedPAC) reported that as of 2006, the average Medicare beneficiary saw five doctors per year and Medicare beneficiaries with three or more chronic conditions saw more than 10 physicians a year.[2] Now, new nonsurgical approaches to what were once surgical problems introduce an additional list of specialist providers and unanticipated outcomes to an already complex system. For patients whose care involved four or more doctors, MedPAC reported that 48% experienced medical errors, medication errors, or laboratory errors. As technology advances and the population ages, risks and benefits change and new genres of service emerge and expand. Imaging services, which have exploded across disciplines in the last decade, are now provided by radiologists, vascular surgeons, cardiologists, internists, anesthesiologists, and surgical subspecialists.[3] Traditional fee-for-service payment systems are not designed to ensure that the right treatment is performed on the right patient at the right time by the right physician in the right venue. The result is that groups of assorted medical proceduralists provide in-hospital care that is fragmented and isolated in terms of delivery and billing—perpetuated by silos of specialized care, despite the interdependent nature of specialty services. Coordination of care is needed, but this service is iatrogenic, unreimbursed, and often disregarded. Uncoordinated, fragmented care facilitates unpredictable need, duplication of service, variability of resource use, and inconsistent application of quality standards. Payment silos create misalignment of goals across specialties with similar focus, creating competition rather than collaboration among disciplines and pitting the interests of one set of providers against another and discouraging coordination of services.

In addition, because Medicare lags in its recognition of the impact of new technology on treatment cost and outcome, payment for new technology initially lags behind, thereby slowing rates of adoption. It then adjusts payments late, encouraging overapplication of new technologies in potentially inappropriate situations. The system is unable to keep up with an ever-expanding proliferation of new services, new sites, and new practitioners. Patients are left without advocates in the midst of a medical and financial maelstrom.

Anesthesiologists are particularly vulnerable to undercompensation in the silo scheme of payment structures, because they may be at the mercy of inefficient scheduling and unpredictable utilization rates. Additionally, many of the indirect services they provide are not billable. Preprocedure evaluation, postprocedure care, and periprocedural management services can be extremely time consuming but are not reimbursed. Fee-for-service systems encourage increased volume but do nothing to encourage care coordination or improved quality of care. Discussion of these issues is ongoing at national levels.[4]

Bundled payments, medical home models, and accountable care organizations are three avenues of reform intended to increase interdisciplinary collaboration and coordination of care between payment siloes within institutions. Herculean changes in political and philosophical underpinnings will be required for implementation, and it remains to be seen how effective these undertakings will be in improving care. In any case, financial infrastructure remains a key determinant of behavior. It is incumbent on anesthesiologists to remain at the forefront of new developments as demand for anesthesia services in less traditional arenas broadens in an environment that diminishes control over the revenues we generate.

OPERATIONAL CONSTRAINTS

It is quite clear that despite a multitude of publications condemning OR inefficiency and poor productivity, institutional tradition, idiosyncrasy, and surgical convenience continue to create havoc with OR scheduling practices and policies. Outside of the OR, medical proceduralists are themselves often highly specialized consultants who know little about the overall condition of their "referred" patients. They are also uninformed about the practice of anesthesiology and relatively inexperienced in working with another "support" physician. To make matters worse, the procedures are often ill defined or novel. All of these variables make scheduling non-OR cases extremely difficult. Key problems in scheduling and staffing non-OR cases include the following:

1. Non-OR anesthetizing locations are often adapted to the specific procedure being undertaken and the needs of the medical proceduralist. Unlike ORs, they are noninterchangeable.
2. Variability may be more problematic because the number of staff in any one non-OR venue is smaller and less flexible.
3. Block time may not be in place, and anesthesia cases can be placed anywhere on the schedule, making it difficult to utilize anesthesiology staff productively and increasing the likelihood of underutilized but deployed resources.
4. Non-OR procedures may take place far from the OR. Lack of storage space for anesthesia equipment may impose longer turnover time and the need for additional anesthesia technical services.
5. Many non-OR procedure suites perform procedures on patients referred from outside providers or services that are booked through a central scheduling office. Periprocedural evaluations are often very cursory or not done at all. This imposes an additional bottleneck for the anesthesiologist who may need to perform a preoperative evaluation before the procedure and cancel or delay cases at the last minute.
6. Because many non-OR procedures are novel, it is difficult to estimate the length of the procedure. Booking times may be unrealistic, and scheduling anesthesiology time may be difficult. Additionally, with new technology and noninvasive methods, it is very easy for the proceduralist to redirect or expand the procedure during the case.[5]

As a group, non-OR cases are more variable, less predictable, and, therefore, more difficult to staff cost effectively. Some of these difficulties are technical, but some are the result of cultural discontinuity and poor communication between anesthesiologists and medical proceduralists.

Effective management control of this arena requires the following at the very least:

1. If possible, establish a contract between the anesthesiology and procedural departments that encourages uninterrupted utilization of available time and minimization of differences between "staffed (contracted) time" and "productive time." In addition, it is worth considering a transfer price that confers cost neutrality to anesthesia departments while leaving open the option to bill for services to cover costs.
2. Include all non-OR cases within the electronic database for OR cases, so that resource deployment can be planned and modified as needed.
3. Create a block schedule that makes sense for the procedural area; that is, if the area tends to run late, then book an anesthesiologist to be there for those hours instead of running overtime on the days that more or longer procedures are done. Try to encourage productive utilization of anesthesiology contracted time.
4. Implement real-time scheduling. Calculate earliest start times, optimal arrival times, and adjusted preoperative fasting (nothing by mouth [NPO]) guidelines for all patients. Avoid having patients sitting in preoperative areas for extended periods because this overloads nurses and puts a hold on patients exiting procedure rooms while waiting for recovery area beds.
5. Improve specialized triage for scheduled outpatients in each procedural area by creating triage forms and staffing an intake office to minimize delays and cancellations. Create a situation in which specialists are invested in appropriate preprocedure evaluations.
6. Anesthesiology oversight of periprocedural triage and postprocedure recovery areas should aim to ensure both optimization of patient comorbidities and prompt treatment of postprocedure complications. Oversight includes unexpected admissions, longer than necessary recovery times, impact throughput, efficiency, length of stay, and medical outcomes in non-OR arenas just as they do in the OR.

Staff and non-OR locations can be scheduled in many ways. The principles outside of the OR are the same as they are in the OR. These are to reduce variability, schedule to avoid ad-hoc solutions as much as possible, and use real data when available (i.e., real-time scheduling for blocks). In addition, consideration of available time and productive time is important. Contracts should discourage situations in which procedural areas use their rooms at rates lower than those of the OR. Full schedules and adequate revenue collection should be incentivized; otherwise a subsidy of the anesthesia department is needed because the opportunity cost incurred is often significant. Without doubt the demand for non-OR anesthetics will increase. Whenever possible, proceduralists should be involved in scheduling schemes so they are invested in the process. The goal is to collaborate so anesthesiology goals are aligned with those of the proceduralists and integration of mutual competencies occurs. In this way, the value-added importance of the specialty can increase and outcomes improve.

TRANSITIONAL PRIORITIES FOR ANESTHESIOLOGISTS OUTSIDE OF THE OPERATING ROOM

As anesthesiology continues its steady integration into the world outside of the OR, new obstacles and new opportunities arise. Unusual procedural venues and practitioners who are unfamiliar with the scope and practice of anesthesiology challenge standard procedure. Adaptation requires that we confront, explain, reorient, and reinforce our traditional concepts of safe practice and standards of care. Anesthesiology as a specialty has improved OR safety enormously in the past 40 years, and as the scope of anesthesiology broadens, there is even more reason to redefine and remain steadfast in insistence on well-established standards of safe practice, which, although they are second nature to anesthesiologists, may be unfamiliar to medical proceduralists.

DEFINING INTERDISCIPLINARY SAFETY IN NON–OR LOCATIONS: STANDARDIZATION, RELIABILITY, AND COMMUNICATION

The unparalleled record of OR safety established by surgeons and anesthesiologists relies on standardized, routinized practice. Anesthesiologists depend on the predictable characteristics of ORs and of surgeries to optimize anesthetic outcomes and gauge the progress of procedures. All too often non-OR cases are not routine, the patients are not optimized, and the technology is novel. If communication is poor between proceduralist and anesthesiologist, the potential for error and poor outcome increases. Proceduralists would prefer to proceed without anesthesiologists and anesthesiologists are reluctant to be involved; everyone is fine except the patient. The establishment of safety and reliability outside of the OR should seek to parallel the same process that evolved in the OR and in other industries.

Frankel[6] and others have emphasized that environments that facilitate safety and reliability are characterized by the following:

1. Encouragement of continuous learning among all participants
2. A just and fair culture of accountability and responsibility
3. Support for teamwork
4. Data-based drive for safety and reliability
5. Effective communication and flow of information

Depending on the specific venue, NORA procedures may be performed in the context of routines, which differ from those used in the OR. Specialty-specific procedure units can accommodate each of the above with varying degrees of difficulty, depending on the medical, financial, and operational constraints and priorities in place. All of these elements are critical characteristics of a safe environment.

Continuous Learning

The inclusion of continuous learning as an element of process improvement comes from industry[7] but also applies to the context of multidisciplinary undertakings

in medicine. Each factor of production determines some piece of the final product, and because ultimately goal attainment is the sum of successful execution of smaller projects, optimization depends on encouragement of continuous improvement by all team members, *especially when this requires making an effort to understand what is going on in contiguous steps or stages of the process*. Data acquisition and analysis should drive process review, and team members should be encouraged to ask questions and make suggestions. Learning how to do things better as part of a team is not the same as learning how to do one thing better independently. Competition among interdependent facets of an organization may approach an asymptote when it comes to improving outcome or output. Continuous learning implies that improvement-seeking is multidimensional, involving both horizontal (across factors) and vertical (related to end product) processes.

Culture of Accountability and Responsibility

In a culture of accountability, individuals are held accountable for their actions but not for system failures. The relevance to medicine is that analysis of adverse outcomes should be open and disagreement should be managed so that resolution is a function of collaborative thought rather than assignment of blame or the application of power, bias, or tradition. This is especially difficult in environments that challenge the status quo because prevailing culture is changing. Anachronistic notions about "whose" unit or patient it is must be abandoned if interdisciplinary work is to move forward; these are precisely the settings in which accountability and analysis are necessary to improve interdependent functions. The launching and recovery of U.S. Navy aircraft is a well-known process in which this type of outcome-focused, nonpunitive review takes place.[8]

Support for Teamwork Structure

Support for a teamwork structure is a crucial foundation of successful interdisciplinary work. It requires that jobs are clearly defined, that debriefing occurs constructively and within a reasonable time frame, and that leadership take the required steps to ensure that what went well is repeated and what did not go well does not happen again. Fundamental to this is an attitude of mutual respect for other team members; this is often the most difficult for physicians to generate, because they are educated and trained to be self-sufficient, independent, and nondelegating. It is also necessary to recognize that teamwork does not mean sitting around a table patting each other on the back. "Virtuoso Teams"[9] are characterized by smart people who are opinionated, strident, and challenged by an acute need to perform. They get the job done by confronting each other and arriving at a mutually acceptable solution. Leadership is clearly important in this endeavor; conflict resolution and negotiation are key parts of the process.

An environment that supports *data-driven quests for safety and reliability* is critical if process improvement is to occur. As innovative technology develops and procedures become more complex, new operational paradigms will evolve as well. The safe and reliable administration of anesthesia in remote locations should be driven by data analysis, science, and patient evaluation, not by tradition, payment plans, or institutional politics. The acquisition of outcome data is a common undertaking in most institutions. Making these data accessible and available for improving medical care should be a priority, not a novel or difficult endeavor.

Effective Communication and Flow of Information

Effective communication including the flow of information is the most fundamental requirement for safe anesthetic practice outside of the OR. Novel interventions and technologies, unfamiliar to medical proceduralist and anesthesiologist alike, make it imperative that situational awareness, succinct and direct language, timely recommendation, and closed-loop communication are all included as components of the verbal interface between anesthesiologists and procedural operators. Add to this the increased likelihood that the patient has comorbidities that the proceduralist may be unaware of and the fact that the anesthetic may have ramifications for the procedure, and it becomes obvious that a simple *mis*communication or *non*communication can have tremendous effects on the outcome of the case. Even medically correct actions on the part of the anesthesiologist or proceduralist, if not communicated to the other party, can drastically alter outcome. If, for example, the anesthesiologist supports decreasing blood pressure but fails to tell the interventionalist, the proceduralist might continue under the assumption that all is well when in fact a search for retroperitoneal bleeding is more appropriate. Sometimes it is impossible for the anesthesiologist to see exactly what the proceduralist is doing because the fluoroscopy screen is not visible, the mapping is complex, or the intervention is very short and is obvious only to the proceduralist. In this case, the anesthesiologist may literally have to ask the proceduralist what he or she is doing; there is no shame in this. The shame lies in making an assumption when the facts are available for the asking. To create the same degree of safety and reliability outside of the OR as exists in the OR, compromise and adjustment of cultural and medical assumptions is required by all parties. Without good communication this cannot occur.

NEW NON–OPERATING ROOM ANESTHESIA SITES: WHAT IS ACCEPTABLE AND WHAT IS NOT

Potential sites for procedures performed outside of the OR continue to grow and must be assessed as possible anesthesia delivery sites in the context of both the focus and complexity of the intervention and common comorbidities of the patients to be treated. As technology develops, any procedure room outside the OR can become an anesthesiology delivery site. Although it is ideal for anesthesiologists to be involved during the construction of off-site procedure areas, this seldom occurs, and even when it does, the evolution of cases and the broadening of target-patient profiles can render even well-conceived units inadequate. Availability of adequate monitoring equipment is as essential outside of the OR as it is in the

OR, perhaps even more so. The ASA Standards for Basic Anesthesia Monitoring[10] may serve as a fundamental guide, but often specific procedures require more than basic monitoring. Sometimes, monitoring equipment, although present, may not be visible or accessible to anesthesiologists, rendering it useless and making additional equipment necessary. No matter what type or level of anesthetic care is provided, an anesthesia machine should be present (or readily available) in all NORA locations because conversion to general anesthesia is always a possibility. If the room cannot accommodate anesthesia equipment (for size, electrical, or other spatial reasons), it is not an acceptable site for the delivery of anesthesia. Standards of care outside of the OR should be consistent with those in the OR. As sicker patients are increasingly cared for in NORA locations, monitoring assumes critical status. Of course, there is nothing to prevent a service from starting a sedation procedure and then having a "code" when the patient fails conscious sedation, but the hope is that this will wane in coming years. Appropriate monitors increase the likelihood of early detection and amelioration of problems and undesirable outcomes. Because NORA sites are distant from centers of equipment storage and additional anesthesia help, it is critical that appropriate patient monitoring be in place so that problems are detected and solved early. Our success in establishing and maintaining unparalleled safety records in the OR result largely from the consistent use of appropriate monitoring equipment. It is never acceptable to sacrifice patient safety for the convenience or comfort of a proceduralist who may not be used to accommodating equipment space requirements or alarms. Flexibility, innovative thinking, and some explanation to medical proceduralists or technicians who may not understand the need for additional or duplicated equipment, may be required. Maintenance of safety standards is critical to the realization of an adequate anesthetic plan regardless of where it is carried out. In non-OR locations, where patients may require help from or transport to the OR, emergency procedures should be clearly stated and posted, along with phone numbers for accessing emergency help. Adequate preprocedure and postprocedure care space should be available to patients undergoing interventions and for those who receive an anesthetic. It is certainly standard of care that an anesthesiologist be available during the recovery period.[11]

MONITORING IN NON–OPERATING ROOM ANESTHESIA LOCATIONS

Physiologic monitoring is a core competency of all anesthesiologists and a critical feature of safe anesthesiology practice wherever the anesthetic is delivered (see also Chapter 44). Just as monitoring standards of care exist throughout the OR, they must be consistently in place in NORA locations as well. Some studies suggest that adverse events occurring outside of the OR may in fact be associated with more deleterious outcomes and serious injury than those in the OR because minimal monitoring standards are lacking.[12,13] Monitoring in NORA locations is often suboptimal because the need is not identified by anesthesiologists and medical proceduralists are not well informed about what is necessary. Short-sighted cost constraints often determine monitor purchasing. Until recently, pulse oximetry was the primary monitoring used to assess adequacy of oxygenation *and* ventilation, despite the fact that pulse oximetry has serious limitations in this regard. Several publications indicate significant misunderstanding among nonanesthesiologists using pulse oximetry to monitor patients outside of the OR,[14] and changes in ASA guidelines will help change the status quo. Anesthesiologists providing services outside of the OR, however, may find themselves explaining the shortcomings of pulse oximetry relative to capnography, particularly when discussions arise regarding purchase of new equipment for new NORA locations. Several excellent articles and websites are available as resources.[15] Over the last 20 years, capnography has become the standard of care for monitoring not only ventilation, but also circulation and metabolism[16-18] by directly measuring expired carbon dioxide levels and indirectly measuring production of CO_2 at the tissue level and delivery of CO_2 to the lungs. Despite broad utility and clear clinical superiority, capnography is not always available in non-OR locations. Its implementation may be a bone of contention because it is less familiar and misunderstood outside of anesthesiology circles, and it can be expensive to install. Even ICUs are commonly without the capability of using capnography in intubated patients. For cases in which patients are cared for by anesthesiologists, capnography equipment is bundled with the anesthesia machine. But when anesthesiologists are called to step in during failed sedation cases, the absence of capnography equipment can be life threatening and make case management very difficult.

PREPROCEDURAL EVALUATION FOR NON–OPERATING ROOM ANESTHESIA CASES: ADDITIONAL CONSIDERATIONS

Preoperative evaluation is an essential component of anesthesia practice, regardless of where the procedure is performed or who is performing it (see also Chapter 38). Increasingly, patients with serious comorbidities and significant compromise are scheduled to undergo procedures outside the OR. Often no possibility of optimizing these patients is available; they are slated for nonsurgical approaches because they are deemed "too sick for the OR." However, even a seemingly minor procedure can evolve into a disaster in an unstable patient. The ASA Guidelines for Preanesthesia Evaluation[19] of 2012, indicate that a preanesthesia visit should, at a minimum, include the following:

1. A patient interview that includes a physical examination and a review of medical, surgical, anesthetic, and medication history
2. Diagnostic laboratory tests and other relevant diagnostic information
3. Assessment of ASA status
4. Formulation of potential anesthetic plans and presentation of these to the patient

Because several studies have dispelled the notion that there is a body of routine testing that reduces anesthetic risk,[20,21] anesthesiologists should direct testing to areas

highlighted and indicated by the patients' history and the procedure they are to undergo. Many non-OR procedures are scheduled for patients who have not been seen by the interventionalist; therefore, gathering the information can be challenging, and sharing or discussing the information can prove even more difficult. If patients have numerous serious comorbidities, it may be more reasonable to send them to the preoperative evaluation clinic if one is available. If not, then an information-gathering exercise is required, or the proceduralist risks cancelation on the day of the procedure. Occasionally, periprocedural admission or consultation with a specialty service is required. Guidelines regarding preanesthetic evaluation can be found in this book (see also Chapter 38) and many others,[22] and those guidelines apply to non-OR locations as well. Additional concerns in non-OR locations make some comorbidities more problematic outside of the OR. For example:

1. Many procedure suites have beds with lower weight limits and less mobility than OR beds.
2. Procedure suites for fluoroscopy have beds that cannot be placed in Trendelenburg or reverse Trendelenburg position.
3. Anticoagulation status is often an issue, and guidelines may be extended for some procedures.
4. Renal status may change the course of the procedure or dictate the use of contrast.
5. During percutaneous procedures, bleeding may be occult, and the potential need for transfusion should be addressed preoperatively.
6. Percutaneous procedures often require that the patient remain still because they necessitate precise movements of catheters and wires. Patients with extreme anxiety, chronic pain, claustrophobia, mental disability, movement disorders, obesity, or obstructive sleep apnea (OSA) or those who are at the extremes of age may not tolerate lying on a table for long, even if the proposed procedure is not very stimulating. For these patients, deeper sedation or general anesthesia may be needed.

Current NPO guidelines for procedures are 6 hours for a light meal, 8 hours for a full meal, and 2 hours for clear liquids applied to patients without increased risk for aspiration (gastroesophageal reflux disease, gastric dysmotility, hiatal hernia, diabetes mellitus, bowel obstruction, or intraabdominal pathologic conditions).[23] This is often a bone of contention between anesthesiologists and medical proceduralists, who may not realize the ramifications of a full stomach or may insist that contrast or barium be administered before the procedure. Timely preprocedure evaluation and enforcement of clear standards for NPO can help prevent scheduling mishaps and unnecessary delays and cancelations. This may require educating the medical proceduralists and their staff.

GASTROINTESTINAL PROCEDURES IN THE ENDOSCOPY SUITE

Over the past 5 years, enormous growth in the number of gastrointestinal (GI) endoscopic procedures related to an aging patient population, increased awareness of cancer screening benefits, broad-based reimbursement for screening colonoscopies, and better technology is quite evident.[24] Increasingly complex procedures and higher acuity patients broaden the scope of challenges anesthesiologists face in caring for these patients and also increase the need for interdisciplinary input. The choice of anesthetic approach requires a thorough understanding of both the procedure and the comorbidities of the patient. Similarly, preprocedure evaluation and postprocedure care, which carry financial and operational constraints, assume greater importance. Historically, most endoscopists managed healthy patients undergoing minor procedures with moderate sedation administered by nurses. However, moderate sedation is often inadequate in the context of sicker patients for simple procedures or healthy patients for complex procedures. Therefore, this chapter discusses the focus and methods of common GI procedures, reimbursement issues that may affect practice, the frequent comorbidities associated with patients undergoing those procedures, and anesthetic approaches suggested by anesthesiologists with expertise in the area.

REIMBURSEMENT CONSTRAINTS

Rapid growth in the number of charges to Medicare and private insurance companies for anesthesiology support of colonoscopies provoked the attention of both Medicare and commercial payers to the point at which in 2008, a major insurance company amended its reimbursement policies,[25] stating that they would no longer pay for anesthesiologists to administer propofol for screening colonoscopies in routine cases. Costs would be reimbursed only if the patients had documented comorbidities that would likely contraindicate moderate sedation. The amendment was prompted by a huge increase in billing and significant regional differences with the use of propofol by anesthesiologists. Despite the fact that the list of acceptable comorbidities included more than 200 diagnoses, nationwide protests from patients and physicians prompted the carrier to delay and then cancel implementation of this policy change. The carrier's actions were prompted by an acute rise in billing, significant regional differences in the use of propofol for routine colonoscopies, and the growth of independent colonoscopy centers that churned out many patients per day facilitated by the use of propofol, which permitted very rapid turnover of cases. The finances of this situation continue to drive practice, and the debate continues. Anesthesiologists must continue to consider patient need and procedural requirements as the criteria by which anesthetic plans are formulated because the political and economic aspects of the debate will undoubtedly continue.

A broad spectrum of GI procedures takes place in the endoscopy suite, ranging from routine screening colonoscopies to complex endoscopic submucosal dissections. Each of these requires specific levels of anesthesia depending on the invasiveness and stimulation imposed by the procedure and the likely impact on the patient. The most common procedures are esophagogastroduodenoscopy (EGD), sigmoidoscopy and colonoscopy, and endoscopic retrograde cholangiopancreatgraphy (ERCP).

ESOPHAGOGASTRODUODENOSCOPY

EGD involves examination of the upper GI tract (esophagus, pylorus, and stomach) using a fiberoptic endoscope. The most difficult parts of the procedure for the patient include passing the scope into the esophagus and through the pylorus. Any interventions that occur during the procedure (biopsy, resection, dilation) should be discussed with the endoscopist before the procedure because they constitute additional stimulation. Important and potentially stimulating therapeutic undertakings during endoscopy include hemostasis, biopsy, stenting, dilation, and mucosal or submucosal dissection.[26]

Most patients tolerate this procedure well with opioid or benzodiazepine sedation, but for those at risk for obstruction or aspiration, children, or very anxious patients, general anesthesia may be the best alternative. Unfortunately, many patients presenting for EGD—those with severe gastrointestinal reflux disease, morbid obesity, asthma, or obstructive sleep apnea—are in this high-risk category. In some cases, thorough topicalization is all that is needed, but in some patients, this is inadequate for the procedure, and in some cases, is difficult to achieve. ProSeal laryngeal mask airways, which have a built-in gastric drainage port, permit the passage of a pediatric endoscope, and this approach may be the best option for children and other patients[27] who require general anesthesia and are appropriate for laryngeal mask airway use. As with all procedures above the nipple line that use cautery, precautions must be taken to reduce the potential for airway fires.[28] This subject is discussed in Chapter 55.

SIGMOIDOSCOPY AND COLONOSCOPY

Sigmoidoscopy and colonoscopy can be diagnostic or interventional and involve the examination of the lower GI tract, including either the sigmoid colon only or up to the distal ileum. This examination can be difficult for some, although most patients tolerate it with a combination of benzodiazepines and opioids. Interventions such as biopsies or polyp removal may require increased analgesia. Most anesthesiologists provide sedation with propofol; however, even in situations in which GI endoscopists are permitted to direct nurses to administer propofol, one study found that the mean bispectral index (BIS) score of patients was 59, indicating they were under general anesthesia.[29] Some gastroenterologists maintain that this depth of sedation or anesthesia allows for more thorough examination, but no data have indicated that a "better" examination is performed. Remifentanil has been compared with propofol in the context of sedation for colonoscopy. Although patients given remifentanil "recovered" earlier, they also had more nausea and respiratory depression than the propofol groups. When inhalational agents such as sevoflurane and nitrous oxide were compared with total intravenous anesthesia (TIVA), such as propofol, fentanyl, and midazolam in patients undergoing colonoscopy, the TIVA group emerged faster but had longer-lasting psychomotor impairment than the inhalational group.[30-32]

As with upper endoscopy, specific interventions during sigmoidoscopy and colonoscopy constitute additional stimulation, including introduction of the endoscope, colonic insufflation, advancement of the endoscope, and additional endoscopic intervention such as biopsy, polypectomy, stenting dilation, and mucosal resection.

The ability and need to titrate a drug quickly and appropriately drives the choice of anesthetic, and new studies looking at patient-controlled sedation pumps are under way. Studies of patient satisfaction and indicators of procedural success are ongoing, as are several trials of patient-administered sedation and other types of computerized pumps.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATGRAPHY

ERCP is a fluoroscopic examination of the biliary or pancreatic ducts accomplished through an endoscopically guided injection of contrast through the duodenal papilla. Patients are usually in the prone position. ERCP often requires precise intervention during the procedure; a patient who is gagging or squirming during the intervention invites disaster in terms of procedural outcome and airway or pulmonary and other organ compromise. Many patients who require ERCP are compromised. Their diagnoses include cholangitis, pancreatitis, bile duct obstruction, pancreatic cancer, and other significant comorbidities. Potentially stimulating interventional maneuvers during ERCP include hemostasis, stent placement, stone extraction, pancreaticobiliary visualization, laser lithotripsy, and sphincterotomy.

These are delicate and detailed interventions, and patient immobility is required. For this reason, many anesthesiologists prefer general anesthesia for ERCP. In addition, the patient's airway is effectively inaccessible to the anesthesiologist. Published data support this preference as well, procedural failure rates are twice as high for sedation patients as they are for general anesthesia patients, and the complication rate for general anesthesia cases may be lower.[33-34]

NATURAL ORIFICE TRANSLUMENAL ENDOSCOPIC SURGERY: THE NEXT FRONTIER?

Natural orifice translumenal endoscopic surgery (NOTES) represents an approach to abdominal and peritoneal procedures that integrates the perspectives of endoscopic medicine and minimally invasive surgery. The use of NOTES in humans is in the very early phases, and several cases have been reported of transvaginal and transgastric cholecystectomy.[35,36] Thus far these cases have required a pneumoperitoneum and general anesthesia; however, as technology improves, these parameters may change and NOTES procedures may take their place among the numerous other interventions performed outside the OR.

An example of a NOTES used by GI endoscopists to treat esophageal achalasia is peroral endoscopic myotomy (POEM). Esophageal achalasia is characterized by poor peristalsis of the esophagus in combination with increased muscle tone and incomplete relaxation of the lower esophageal sphincter (LES). Symptoms arising

from impaired entry to the stomach include nausea and vomiting, dysphagia, and/or pain. The POEM procedure has been developed as a minimally invasive procedure to correct achalasia by endoscopically insufflating the esophagus with CO_2 and then making an incision into the mucosa from the mid-esophagus (through the gastroesophageal (GE) junction) to 2 to 3 cm into the proximal stomach. During insufflation, patients may have an increase in $ETco_2$ that can be controlled using mechanical ventilation. Potential risks of insufflation range from subcutaneous emphysema to pneumothorax, pneumomediastinum, and pneumoperitoneum. This procedure commonly requires several hours and is best accomplished using general anesthesia with an endotracheal tube. This technique protects the patient from aspiration of gastric contents and allows the anesthesiologist to minimize the perils of CO_2 insufflation. As with all NORA procedures, vigilance, teamwork, and communication are vital to ensure not only the success of the procedure but the safety of the patient, as well.

INTERVENTIONAL PULMONARY PROCEDURES

Bronchoscopic interventions have grown to encompass many traditional surgical procedures performed in the OR. Not only are the patients at high risk in most cases but the procedures involve the airway, so the potential for disaster is high. Discussion, communication, and planning are particularly critical in this environment.

Common Bronchoscopic Procedures

Common bronchoscopic procedures include the following (see also Chapter 66):

1. Endobronchial stenting: placement of self-expanding metallic stents to treat stenosis
2. Endobronchial biopsy, laser treatment, and cauterization
3. Balloon dilation and cryotherapy

As technology advances and target populations broaden, new procedures are evolving. Several interventions that represent interesting amalgamations of preexisting technologies have made their way to the bronchoscopy suite, as follows:

1. Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA). This procedure is used to image the bronchial wall and adjacent structures. It allows ultrasonic visualization of mediastinal lymph nodes and other peribronchial lesions and therefore is a useful staging tool
2. Electromagnetic navigation bronchoscopy (ENB). This technique permits biopsy of endobronchial tissue that is not visible using computer software that creates a virtual multiplanar lung reconstruction from computed tomography (CT) data. A sensor probe and electromagnetic location board guides the operator to the appropriate location during the bronchoscopy.
3. Fiducial marker implant. Markers are placed before stereotactic radiosurgery via bronchoscopy or ENB.[37]

NOVEL ANESTHETIC CONCERNS

The site of intervention creates several special anesthetic considerations. Preoperatively it is important to review common comorbidities, which in these patients include obstructive and restrictive lung disease, cardiac disease, malnutrition, chronic aspiration, and tobacco and alcohol use. Although simpler procedures may be completed with sedation, complex procedures demand general anesthesia. Because a rigid bronchoscope is used during some aspects of these interventions, intravenous anesthetics are preferred. Instrumentation of the airway and insertion of biopsy or therapeutic equipment will compromise delivery of inhaled anesthetics to the patient and potentially pollute the procedure room. Propofol and remifentanil infusions are well tolerated and can be titrated to effect. Dexmedetomidine may be used as well. BIS monitoring may be helpful. Use of muscle relaxants is also preferred to prevent coughing and eliminate any chest wall rigidity. Muscle relaxation also facilitates introduction of equipment. The use of steroids during and after treatment has not been demonstrated to be effective in reducing edema; however, in cases in which general anesthesia is not used, the risk for aspiration is increased. In these cases the usual antiemetics and dexamethasone may be helpful.[38] Complications commonly encountered include airway obstruction, bronchospasm, bleeding, hypoxia, and airway fire (see also Chapter 88). Because potential complications are significant, patients should be observed in an appropriate unit postprocedure and, if needed, admitted to the hospital for observation.

ANESTHESIOLOGY FOR IMAGE-GUIDED INTERVENTIONS: EVOLUTION OF A NEW INTERFACE

Over the last several decades, radiology has redefined its historical character as a largely diagnostic specialty to one that now encompasses an expanded menu of interventional undertakings, in keeping with technologic development and patient need. The scope of procedures performed in interventional radiology settings is as broad as the number of diagnoses known to the medical profession and is expanding. In fact, not all interventional radiation procedures are performed by radiologists. Some take place in specialty areas with other names, such as catheterization laboratories, neuroradiology suites, CT scanners, magnetic resonance imaging (MRI), and even in ORs. Some are performed by interventional cardiologists or surgeons. For that reason we will discuss interventional procedures here in terms of their purpose and focus, rather than categorizing them by the location in which they are performed or the specialty of the person performing the procedure. The common characteristics shared by most of these interventions are that there are no surgical incisions; there is some type of imaging involved (fluoroscopy, ultrasound, CT, positron emission tomography [PET], MRI); and access to the organ, tumor, or vascular structure in question is through a small hole by wires or catheters. Beyond that, the array of available technologies and possible interventions (both diagnostic

and therapeutic) is astonishingly broad. Dogma aside, the scope and intensity of procedures undertaken in interventional suites rivals that of surgeries performed in any OR, and often, patients undergoing non-OR procedures are sicker than those undergoing conventional surgeries. Unfortunately, they often lack preoperative evaluation and are not medically optimized. Frequently non-OR patients become candidates for noninvasive procedures precipitously because they are felt to be too sick or too high risk for the OR or because the need for intervention develops urgently or emergently.

Understandably, this creates discomfort for anesthesiologists of a traditional mindset, but these are our patients too, and we are trained to deal with such situations. Given this scenario, it is imperative that anesthesiologists make the effort to understand as thoroughly as possible the planned course of the procedure (understanding that this can change midstream) and the nature and acuity of the patient's comorbidities, which may not be apparent to the proceduralist. As in the OR, the challenge is to preemptively think about how the prospective procedure will affect the patient's physiologic status and design a successful anesthetic plan for the case. However, the additional caveat, as with all non-OR anesthetics, is that this may require learning about a procedure, technology, or modality that may be novel, unfamiliar, or in clinical trial. Also, it may fall to the anesthesiologist to introduce the potential ramifications of the patient's comorbidities and anesthetic risks to the proceduralist in a constructive manner. Many interventional specialists are consultants, not involved in the primary care of the patients they are treating. They may be unaware of seemingly peripheral aspects of their patient's physical status that are in fact quite central to good outcome. Creating a clear, collegial, and workable path of communication between medical proceduralist and anesthesia provider is paramount. The need for anesthesia support may reflect the needs of the patient and not the complexity of the procedure. The interventionalist may be highly focused and technically oriented and may not understand the concerns of an anesthesiologist. Our mutual tasks are to understand what needs to be accomplished and to bring our skills to bear in a manner that bridges the knowledge gap, creating an atmosphere of safe and reliable interdisciplinary collaboration that optimizes outcome.

DIAGNOSTIC AND THERAPEUTIC INTERVENTIONS: NEW CHALLENGES

The need for anesthesia during minimally invasive procedures continues to grow as the scope of image-guided interventions broadens. As the population ages and technologic advancement marches forward, image-guided procedures will continue to supplement and perhaps replace conventional surgeries, especially for patients whose comorbidities make traditional surgical approaches risky. Image-guided procedures, although noninvasive, can cause pain and anxiety and carry the risk for potentially life-threatening complications. Anesthesiologists are called on to keep patients comfortable and safe and to facilitate optimal outcomes. Image-guided interventions may be diagnostic, therapeutic, or both. Many diagnostic procedures are short and tolerated well with nothing more than conscious sedation; however, for a compromised patient, even the most minor procedure can be problematic. Interventional procedure suites impose constraints not normally encountered in the OR. Additional considerations that emerge in these environments include unfavorable equipment layout, radiation exposure, occult bleeding risk, and contrast allergies.

EQUIPMENT LAYOUT

The layout in any radiology suite can be problematic for anesthesiologists because x-ray tubes and moving C-arms create a zone of inaccessibility around the patient's head and limit placement of the anesthesia machine. This necessitates the use of extensions on ventilator circuits and intravenous lines, increasing the potential for mishap. Infusion pumps, blood warmers, and other monitors must be placed far away from moving imaging equipment to prevent them from being knocked down or tangled during C-arm rotation and movement. In addition, imaging screens are often at right angles to the anesthesiologist, making it impossible to see what the interventionalist is doing or assess the progress of the case. Anticipating events is therefore difficult unless good communication occurs between the anesthesia and radiology staffs.

Radiation Exposure

Radiation exposure is a serious consideration for anesthesiologists, and steps must be taken to minimize it. Most exposure results from scatter of the x-ray beam. The specifics are not discussed in this chapter; however, excellent discussions and guidelines for optimization of radiation safety are readily available (see also Chapters 67 and 110). It is important that anesthesia staff wear properly fitting lead shielding, including thyroid shields and leaded glasses; use portable lead screens; and wear radiation badges that are monitored on a monthly basis. Even so, several recent studies indicate that exposure of anesthesia personnel to radiation is quite high and that the exposure of the head and face of anesthesiologists can exceed three times the exposure of radiologists[39] because of their position in the room. Unfortunately, anesthesiologists often have to dig through the available lead aprons worn by others because they are not yet considered part of the team. Many of the cases in which anesthesiologists perform are long and involve significant radiation exposure. Wearing someone else's lead shielding is uncomfortable. Lead shielding is only protective if it fits.

Related to the exposure problem is the need for the anesthesiologist to leave the room during specific imaging runs such as digital subtraction angiography (DSA). This can be planned and executed so that it does not interfere with the anesthetic or compromise safety, but it is definitely a novel aspect of NORA. Many anesthesiologists do not undergo consistent or repetitive training in radiation safety. All radiation exposure should follow the ALARA ("as low as reasonably achievable") principle. The radiation beam attenuates based on the inverse square of the distance from the radiation source ($1/^{d2}$).[40] Shortened exposure time, increased distance from the source of radiation, and barriers to radiation (lead shields) are three

ways in which to reduce exposure. Often, radiation time is under the control of the operator performing the procedure. Many of the new and more complex procedures involve prolonged exposure to radiation. As anesthesiologists' participation outside of the OR increases, our exposure to imaging increases, and this will become a routine part of our practice.

Contrast Material

Contrast material is commonly administered during interventions guided by imaging. Standard ionic, high-osmolality contrast agents are associated with dose- and concentration-dependent adverse reactions in 5% to 8% of patients. Anaphylactoid (idiosyncratic) reactions are unrelated to dose or concentrations administered.[41] Reactions can be severe and include laryngeal edema, bronchospasm, pulmonary edema, hypotension, and respiratory arrest or seizures. Oxygen, epinephrine, and bronchodilators are the recommended rescue regimen. For pretreatment of patients with a history of contrast reaction, steroids, and diphenhydramine are recommended. The use of low-osmolality contrast further reduces the risk for adverse reactions. Patients with renal insufficiency are at risk for contrast-induced nephropathy. These patients should receive preprocedure hydration and administration of N-acetyl cysteine before and after the procedure.[42]

Bleeding

Bleeding may be occult during percutaneous interventions and is a serious concern in patients receiving anticoagulation regimens (see also Chapter 62). Guidelines for optimizing coagulation parameters change frequently. For patients who do not undergo anticoagulation for other reasons, the international normalized ratio (INR) should be less than 1.5 and the platelet count more than 50,000. If possible, warfarin should be held for 5 to 7 days before the procedure, clopidogrel and aspirin for 5 days, and fractionated heparin for 12 to 24 hours. Heparin should be stopped 4 to 6 hours before the procedure. Nonsteroidal antiinflammatory drugs (NSAIDs), although less critical, should be held for 1 to 2 days, if possible.[43] It is not unreasonable to send a sample to the blood bank for any patient undergoing an interventional procedure. Of course, it is critical to communicate clearly with the interventionalist when hemodynamic parameters change or the initiation of blood pressure support becomes necessary.

VASCULAR INTERVENTIONAL PROCEDURES

Angiography, the general term for imaging of blood vessels includes arteriography and venography (see also Chapter 69). This involves the acquisition of images during injection of contrast material. In many institutions this technique has been replaced by CT angiography (CTA). DSA, a technique that imposes a contrast-injected image on top of a previously acquired noncontrast image, improves accuracy. Arteriography can be used to evaluate atherosclerotic and ischemic disease, define the arterial supply of tumors and vascular anomalies, and define traumatic injury. After diagnostic imaging, interventions using balloons, stents, or balloon-mounted stents take place. Follow-up arteriography is used to evaluate the result. In some cases, arteriography serves as a precursor to later surgery.

Thrombolytic therapy can be delivered to veins, arteries, or conduits that are thrombosed. The earlier the intervention the more successful it is likely to be. Various agents are used, including recombinant tissue plasminogen activator (r-TPA), urokinase, and others.[42-44] Thrombolytic therapy is generally contraindicated in patients with ongoing bleeding, recent bleeding, pregnancy, known allergy to thrombolytic agents, suspected aortic dissection, or the presence of a nonviable extremity.

Embolization therapy is used in a wide range of conditions, including trauma, hemorrhage, vascular anomalies, fibroids, aneurysms, and tumors. The goal is to occlude arteries or veins either temporarily or permanently. This can be done mechanically with coils, balloons, or glue; or with chemical agents that are temporary (gelfoam) or permanent (alcohol). In these cases, arteriography first defines and localizes the lesion and the embolic agent is then delivered to the appropriate place with imaging guidance.

For all of these vascular interventions, the nature of the case, the comorbidities of the patient, and the intricacy of the procedure will determine the need for and extent of anesthesia involvement. Complications to anticipate include bleeding during thrombolysis, undesired embolization of nearby structures during embolization, and vessel disruption. Depending on where the target vessels are, potential complications should be appropriately anticipated in terms of planning for physiologic sequelae and the need for blood products.

Venography or imaging of the venous system is used in the context of stent placements, inferior vena cava (IVC) filter placement or removal, pulmonary arteriography, embolization of pulmonary arteriovenous malformations (AVMs), thrombolysis, and selective venous sampling. Central venous angioplasty is most frequently undertaken in patients who have indwelling devices. IVC filters are placed to minimize the risk for pulmonary embolus arising from the migration of deep vein thromboses from the lower extremities or pelvic veins. Indications for IVC placement include high risk for pulmonary embolism, failure of anticoagulation or contraindications for anticoagulation, and allergy to anticoagulants. Both removable and permanent filters are available and can be placed via transfemoral or transjugular approach. For the most part, these procedures require little or no sedation; however, obese patients who cannot lie flat need anesthesia support (see also Chapter 71). Pulmonary arteriography is used less frequently than in the past because of the speed and reliability of pulmonary CTA; however, the procedure is useful when others are ambiguous to look for pulmonary AVMS or pseudoaneurysms, and to evaluate pulmonary hypertension.[44]

BILIARY AND HEPATIC INTERVENTIONS

Procedures to treat biliary or hepatic pathology are among the most challenging performed outside of the OR. Not only are the interventions themselves

painful, intricate, and technically demanding, but also the patients are often extremely compromised. Hepatic and biliary procedures include transhepatic cholangiography, percutaneous transhepatic biliary drainage, hepatic venography with hemodynamic measurement, liver biopsy and the creation of transjugular intrahepatic portosystemic shunts (TIPS procedure), and portal vein embolization (PVE). Patients scheduled for biliary procedures may present with jaundice, cholangitis, bile duct leak, or other related abnormalities. Clearly, significant comorbidities accompany these disorders. Contraindications for these procedures include bleeding diathesis, inability to tolerate contrast, and the presence of large hepatic arteriovenous malformations, significant ascites, and hydatid disease.

Biliary drainage is accomplished by placing the patient supine on the table, and inserting a long needle obliquely into the hepatic parenchyma. Contrast is delivered with the goal of imaging the necessary structures. Cholecystostomy tube placement is performed to improve symptoms in patients with acute cholecystitis but who are not candidates for surgery. Here, the gallbladder is imaged with ultrasound, CT, or fluoroscopy; the gallbladder is accessed through a needle that traverses the liver; and a drainage catheter is placed. For these procedures the choice of anesthetic depends entirely on the patient's habitus, comorbidities, and pain tolerance. Obese patients are difficult to image, and optimization of needle position also can be difficult (see also Chapter 71). Patients may present with a history of tolerance to pain medications and with compromised metabolism, which requires careful choice of drugs. Lying flat may be impossible for patients with ascites.

Hepatic venography and hemodynamic assessment are performed to assess suspected venous anomalies (Budd-Chiari) and quantitation of portal hypertension. Liver biopsies can be performed during these procedures. Access for these procedures is usually transjugular and involves needle insertion followed by wire access and insertion of a long vascular sheath. Many patients find this extremely difficult to tolerate. Hepatic venography and pressure monitoring is done through an angled catheter before it is advanced to wedge in the hepatic vein. A calculation of corrected sinus pressure, the difference between free pressure and wedge pressure, defines the degree of portal hypertension. Once the catheter is wedged, it provides an estimate of portal venous pressure.[45] The creation of a portosystemic shunt requires positioning of a needle advanced through the hepatic parenchyma and into the portal vein. The parenchymal tract is dilated with an angioplasty balloon and a stent is inserted. This is a painful and difficult procedure, vastly oversimplified here for clarity. It may be quite lengthy and general anesthesia is advisable. Indications for the creation of TIPS include repeated esophageal variceal bleeding refractory to medical treatment and intractable ascites. It is often used as a bridge to liver transplant. Contraindications to this procedure include preexisting hepatic encephalopathy and ongoing alcohol abuse, which preclude liver transplantation. Significant pulmonary hypertension, valvular heart disease, or heart failure contraindicates this procedure.[46] PVE is a relatively new technique designed to reduce blood flow in hepatic segments containing tumor, while encouraging hypertrophy of remaining hepatic tissue. The goal is to improve survival among patients undergoing resection of hepatic neoplasms by increasing postsurgical hepatic tissue mass. Embolization is accomplished with portal vein angiography and coils. Acute complications include bleeding, bile leak, pleural insults, and contrast reactions.

GASTROINTESTINAL AND GENITOURINARY INTERVENTIONS

Interventional radiologists perform direct-access GI procedures, the most common of which is the percutaneous gastrostomy tube (G-tube). Other variants include cecostomy and jejunostomy tubes. For G-tube placement, the stomach is distended with air via a nasogastric (NG) tube. Subsequent gastropexy is performed by some practitioners as a means of stabilizing the stomach; the stomach is entered with a needle and a wire and an appropriate tube is inserted and placed in the proper location. Acute complications include bleeding, violation of adjacent structures, and peritonitis. In many cases, these procedures can be tolerated with sedation.

Genitourinary (GU) procedures in the radiology suite focus on obtaining direct access to the renal collecting system. Dilation and stenting can be performed, and suprapubic cystostomy is also a procedure commonly performed in radiology suites. Nephrostomy tube placement is performed to divert urine in the face of obstruction from stones, tumor, or other obstructive pathology. In general, the technique involves injecting contrast, identifying the renal pelvis, accessing it, and inserting a tube.[47] Prone positioning of the patient is required, which generates an attendant list of potential anesthesia concerns, including airway issues, pain management, access, and more. Interventionalists may attempt to convince anesthesiologists that "less is more"; however, stimulation can be intense during these cases, and in general, it is worth thinking about the "what if" scenario—that is, deep sedation in a prone patient is difficult to advance to general anesthesia.

PERCUTANEOUS INTERVENTIONS FOR ONCOLOGY

Percutaneous interventions for oncology are relatively new and are rapidly expanding. Imaging guidance is achieved with CT, ultrasound, or fluoroscopy. Transarterial chemoembolization (TACE), percutaneous ablations (with radiofrequency, laser, cryoablation, or alcohol) can be directed at tumors and image-guided insertion of radioactive materials can be performed. Commonly, hepatic, kidney, lung, and adrenal lesions are targeted. Complications are similar to those of other percutaneous interventions; positioning depends on the site to be accessed. Often, general anesthesia works best for these procedures because the interventions may be intermittently painful, control of breathing may be optimal, and patient cooperation may not be compatible with the level of sedation required.[48]

PROCEDURES GUIDED BY COMPUTED TOMOGRAPHY, POSITRON EMISSION TOMOGRAPHY, AND MAGNETIC RESONANCE IMAGING

COMPUTED TOMAGRAPHY

CT is now a commonly used guidance modality for a broad array of percutaneous interventions, and CT fluoroscopy, which combines the improved imaging capacity of CT with the real-time imaging of fluoroscopy, is also widely used. CT is used to guide both diagnostic and therapeutic procedures. Diagnostic undertakings include biopsies and drainage of fluid collections; therapeutic interventions include tumor ablation and injections for pain management. Procedures occurring in the CT suite encompass the usual constraints of radiation exposures on operators and anesthesiologists, and patients are at risk for bleeding and contrast reaction. In addition, some special preprocedural considerations are important. Obese patients may not fit inside the scanner, and special (longer) needles and drains may be needed. Positioning in the scanner may be difficult, and the usual airway considerations apply, especially because it is nearly impossible for the anesthesiologist to have continuous access to the head. For the most part, biopsies performed under CT guidance can be accomplished with sedation, but when the stimulation is intense or repeated breath-holds are required, general anesthesia may be needed. For patients with significant comorbidities (obesity, pulmonary or cardiac compromise, chronic pain, or history of difficult intubation), securing the airway before the procedure is prudent.

Computed Tomography–Guided Biopsies

CT guidance is useful for obtaining biopsy tissue for cytologic or histologic examination. Needles range from 25 to 18 gauge, and the patient is positioned to minimize the distance from skin to lesion and maximize the safety of the approach. Liver biopsies are usually performed with the patient supine or slightly oblique, and retroperitoneal masses may require lateral decubitus or prone positioning. For the most part, it is helpful to the interventionalist if the level of sedation remains consistent throughout the procedure, so that large shifts in target location resulting from alterations in ventilation do not occur. However, levels of stimulation during these procedures can vary tremendously, presenting considerable challenge to the anesthesiologist if general anesthesia is not planned. Biopsies of carcinoid or adrenal tumors can be equally problematic, whether in the radiology suite percutaneously or in the OR. In both cases, stimulation of hormone release can precipitate severe hypotension or hypertension, which is difficult to manage. If pheochromocytoma or carcinoid are suspected, pretreatment should be considered.

Computed Tomography–Guided Therapeutic Interventions

CT–guided therapeutic interventions include catheter drainage, ablation of tumors, and injections for pain management. Anesthetic planning for these procedures requires understanding of patient comorbidities and the techniques of the interventionalists. Excellent communication between anesthesiologist and interventionalist is needed for coordination of procedure and anesthetic because unanticipated patient movement or interventional shortfall can have drastic consequences for procedural outcome.

Catheter Drainage

CT-guided abscess drainage has become common. Options include the modified Seldinger and trocar techniques. Although local anesthesia may suffice for superficial collections, the location of the fluid collection and the anticipated trajectory of the needle or trocar may be quite painful during the insertion or dilation phase. Before the procedure, the proceduralist and anesthesiologist should discuss the intended approach, potential anesthetic choices, and backup planning for transitioning to a deeper plane of sedation or anesthesia. Preemptive planning can make the difference between a smooth procedure with a good outcome and a prolonged, difficult intervention. Anesthesiologists should be prepared to treat potential complications, which can occur as a result of injury of surrounding structures.

Computed Tomography–Guided Ablation

A variety of ablation techniques are now used to target malignant neoplasms. Percutaneous injection of alcohol (95%) or phenol (6%) is used to target tumors. Alcohol can be instilled using needles or catheters, but the injection is usually quite painful. Large volumes of alcohol or inadvertent injection into a vascular structure can cause tachycardia and respiratory depression. Other ablation techniques involve the use of radiofrequency ablation, cryoablation, and microwaves. These procedures may be lengthy because they involve precise placement of applicators for the delivery of the ablation tool, whatever that may be. Reproducible breath-holds may be needed to facilitate placement. Radiofrequency ablation induces coagulative necrosis at temperatures above 50° C; the heating process can produce pain, whereas cryoablation is a less painful procedure.[49,50]

Computed Tomography–Guided Injections for Pain Management

Procedures for pain management include phenol and alcohol injections into a plexus, ganglion, or nerve (see also Chapter 64). Neurolysis is the intended outcome. Injection of steroids into joints for local pain management and mitigation of inflammatory processes is also performed. Many patients requiring these procedures are tolerant to pain medication. Body habitus may be an important factor in these patients as well, and depending on the source of pain, patients with cancer may be especially challenging in terms of attendant comorbidities.

POSITRON EMISSION TOMOGRAPHY AND POSITRON EMISSION TOMOGRAPHY COMPUTED TOMOGRAPHY

PET is an imaging technique used for diagnosis, staging, and follow-up of malignancies. Scanning is undertaken after injection of a radiolabeled glucose analogue fluorodeoxyglucose (18F-FDG), which is taken up by malignant cells preferentially and is not metabolized, thereby

serving as a tumor marker. FDG-PET is used to distinguish benign from malignant lesions, identify metabolically active portions of necrotic tumors, and monitor responses to treatment. The combination of positron emission tomography and computed tomography (PET/CT) provides both the metabolic information of PET and the anatomic precision of CT. PET/CT-guided intervention is an emerging modality.[51] For these procedures, patients are imaged beginning 60 minutes after injection. Imaging may require serial positioning, during which PET and CT images are acquired sequentially, so care must be taken to maintain consistent patient positioning throughout the image acquisition so that misregistration of image overlap does not occur. PET scanners include a long, mobile gantry that both limits access to the patient and requires that monitoring equipment be long enough to accommodate motion of the table. PET/CT suites represent another potential anesthestizing location. Whenever possible, anesthesiologists should be involved in the planning of these suites because wall-mounted gases, suction, and installed monitoring equipment must be strategically placed. It is likely in the future that PET will be used to augment CT-guided interventions; therefore, planning a space that will allow inclusion of anesthesiology equipment will ensure uneventful interventions and optimal outcomes.

MAGNETIC RESONANCE–GUIDED INTERVENTIONS

MRI is an ionizing radiation-free technique that uses magnetic fields and radio waves to create images. The quality of soft tissue images generated by MRI surpasses that of ultrasound or CT. MRI is still largely a diagnostic tool but is emerging as an interventional modality as well. Because MRI can acquire multiplanar, temperature-sensitive, and contrast-enhanced images, complete visualization of interventional implements such as wires or needles is possible.[47] Images quality is proportional to magnet strength. Field strength, measured in tesla units ranges from low (0.1 to 0.5 T), to medium (0.5 to 1.0 T), to high (1.5 to 3.0 T), to ultrahigh (>3.0 T). Imaging sequences can be manipulated to highlight tissue characteristics based on water content, vascularity, and presence of hemosiderin. The superiority of MRI-generated soft tissue images facilitates biopsy and ablation of structures that evade CT or ultrasound.[48]

Physical Constraints of Magnetic Resonance Imaging Suites

All equipment used in the MRI suite must be MRI compatible; that is, the equipment will not cause harm to the patient, affect image quality, or be affected by the MRI scanner. Objects containing iron or stainless steel become mobile projectiles in an MRI suite because of the magnetic field, regardless of their size. Therefore, special care must be taken to ensure that all equipment used in an MRI suite is unaffected by magnetic attractive forces, heating, or current induction. Similarly, patients themselves must be screened. Any implanted devices must be assessed for MRI compatibility. Patients with pacemakers, implantable cardioverter-defibrillators (ICDs) (see also Chapter 48), cochlear implants, pumps, nerve stimulators, or other metal objects such as aneurysm clips, metal fragments, or bullets, should not be scanned. These objects are subject to heating and movement. Increasingly, vascular clips, staples, orthopedic implants, heart valves, and other prostheses are nonferromagnetic and scanning of patients with these implants is possible. Monitoring devices are increasingly available in MRI-compatible format, as are interventional equipment, surgical equipment, and anesthesia equipment.[52] Detailed information regarding MRI safety is available in Chapter 110 and elsewhere.

Claustrophobic or large patients may be unable to tolerate being inside of an MRI machine, making even diagnostic procedures difficult for them. Newer MRIs combine a wider bore with high-field systems, improving accessibility and making it easier for patients to tolerate procedures. Because interventional MRI requires constant movement in and out of the scanner, typical interventions take much longer than the same procedures done elsewhere. Emergencies must be planned for because the MRI interventional suite may be isolated, and conventional emergency equipment may not be MRI compatible. Even a standard laryngoscope can become a deadly missile in an MRI suite.

Magnetic Resonance Imaging–Guided Interventions

In cases in which CT is inadequate, MRI may be useful because of its multiplanar capability. MRI has been used to guide breast and prostate biopsy and biopsy of other tumors not well visualized by other means. For the most part, local anesthesia and sedation suffice for these procedures. Tumor ablation using cryoablative technology can be performed in the MRI suite. This procedure can be done with ultrasound or CT as well, and the choice of MRI as an imaging modality indicates the need for precise soft tissue imaging. MRI also provides better visualization of tissue during freezing and thawing than CT or ultrasound, and MRI-guided cryoablation is safe and effective for liver, kidney, breast, and prostate tumors and in the treatment of uterine fibroids.[53] For these cases, repeated breath-holds may be needed, and the procedures may be lengthy. Pain is not uncommon during freezing and heating of tissues; therefore, general anesthesia may be required.

Bleeding is the most common complication after some of these procedures (also see Chapter 62). Thrombocytopenia is a rare but serious complication of extensive liver ablation. Extensive ablations can also induce myoglobinemia or myoglobinuria. Cryoablation of adrenal lesions can induce hypertensive crises as normal adrenal tissue responds to thawing.[54] MRI can facilitate the use of focused high-intensity ultrasound therapy by providing more precise imaging. Clinical trials of this technique are in progress. Temperature-sensitive MRI images can assess dosage of ultrasound, and gadolinium-enhanced MRI images can assess tissue response. MRI offers many potential advantages that may broaden the scope of current interventional procedures because of its capacity to provide improved imaging over that available with CT or ultrasound. The need to develop MRI-safe environments, equipment, and monitoring and to understand the limitations of sedation and need for anesthesia during long

and uncomfortable procedures are the next steps in extending the usage of this modality.

IMAGE-GUIDED PROCEDURES FOR SPECIALTY AREAS: NEURORADIOLOGY AND INTERVENTIONAL CARDIOLOGY

Neuroradiology and interventional cardiology are considered here as specialties because they each mirror areas that anesthesiologists have also chosen to designate as areas of specialization or fellowship training (neuroanesthesia and cardiac anesthesiology) (see also Chapters 68 and 70). The language of neurology, neuroradiology, cardiology, and interventional cardiology is part of the language of neuroanesthesia and cardiac anesthesia. Thus, the platform for clear communication exists and should be used to optimize procedural outcome. Of course, as alluded to earlier in this chapter, common vocabulary is necessary but not sufficient; mutual respect, a culture of safety and learning, and a functional teamwork structure are important elements of a successful unit.

Advances in neuroradiology and interventional cardiology have been incredibly rapid; technology has developed and target patient populations have broadened. In both of these areas, percutaneous approaches to formerly surgical problems have multiplied, as has the potential for the involvement of anesthesiologists. In many ways, the development of new techniques represent a "disruptive technology"[55] within the field of medicine and threatens to further blur distinctions between medical and surgical treatments. The unpredictable and demanding new landscape of novel interventional cases frequently elicit ad hoc responses from unsuspecting anesthesiologists. It is time for us to reevaluate dogma and use overlapping competencies to facilitate the success of new, cutting-edge interventions; these procedures are the future of the practice. Think of how it must be for an interventional radiologist, when discussing a new or complex procedure with an anesthesiologist, to be asked, "Why don't you just do this in the OR?" simply because the scheduling would be more convenient or the anesthesiologist would be more comfortable in an operating room? Scheduling conflicts must be resolved; everyone needs to compromise. If the OR is safer in our view, then it is incumbent on us to make the interventional suite safe as well, by explaining to the proceduralist what changes need to be made and why. No procedure is without risk, and comfort level or convenience should not drive practice standards.

PROCEDURES IN THE NEURORADIOLOGY SUITE

The field of interventional neuroradiology is relatively new. It has grown broadly and rapidly as a result of improved device technology (catheters, coils, and stents), better imaging techniques, and safer contrast media (see also Chapter 70). Cerebral angiography remains the gold standard for imaging the cerebral vasculature. Diagnostic cerebral angiography usually can be performed with conscious sedation, but interventional procedures require a broad range of anesthesiology because of the length of the procedure, delicacy and complexity of the technique, and need for a still patient. Certain procedures generate hemodynamic perturbations that require management by the anesthesiologist. On the other hand, some procedures (i.e., carotid stenting) can be done with the patient awake, to facilitate neurologic assessment. Anesthesia for each of these procedures must be considered in concert with patient comorbidities and status, on a case-by-case basis. Although the technical details of neuroradiology procedures are beyond the scope of this chapter (see Chapter 70), the basic focus and required steps in commonly performed interventions are outlined here.

GENERAL CONSIDERATIONS FOR ANESTHESIOLOGISTS IN THE INTERVENTIONAL SUITE

As with other areas outside of the OR, physical characteristics of the interventional suite affect anesthesia practice (see also Chapter 49). Equipment makes access to the patient's head difficult, radiation exposure must be considered, and contrast reactions must be anticipated. Because of the intricacy of the procedures, uncooperative patients and those with impaired consciousness or movement disorders should be considered candidates for general anesthesia. If time permits, arterial lines are advisable; if not, the neurointerventionalist can upsize a femoral sheath to permit arterial monitoring. Other neuromonitoring technologies can be helpful as indirect measures of cerebral perfusion; electroencephalography and somatosensory, motor, and brainstem evoked potentials have all been studied in this regard. Many neuroanesthesiologists use opioids, avoiding inhalational agents because of their confounding effects on electroencephalography and evoked potentials. As in the OR and other non-OR sites, the anesthesiologist and proceduralist need to be aware of each other's plan, progress, and complications.

ENDOVASCULAR TREATMENT OF CEREBRAL ANEURYSMS

Endovascular treatment of cerebral aneurysms achieves percutaneous isolation of aneurysms from the circulation by placement of a soft platinum coil within the aneurysm (see also Chapter 70). The procedure intraaneurysmal embolization may require placement of several coils. Several types of coils are available. Coiling procedures are least complex in aneurysms with a small, narrow neck. Coiling of wide-necked aneurysms requires the introduction of a stent; the coil is subsequently introduced through the stent.[42] Stent implantation, which requires preprocedure and postprocedure anticoagulation, increases bleeding risk. Therefore, stent- assisted coil embolization is limited to unruptured aneurysms. Endovascular treatment with coils demonstrated better outcomes than surgical clipping in patients who sustained a subarachnoid hemorrhage related to an aneurysm, but clipping improved resolution of cranial neuropathies.[56] Complications include aneurysm rupture or thromboembolism. If rupture occurs, heparin should be reversed with protamine (1 mg/100 International Units heparin)

and the arterial blood pressure decreased by the anesthesiologist. The usual course of action is to continue the coiling as quickly as possible. Thromboembolic events, usually platelet related, occur in 3% of cases and cause permanent neurologic deficit in 1.7% to 5% of cases [57] (see also Chapter 62). If a thromboembolic event occurs, the proceduralist will make an attempt to dissolve or remove the clot with either a mechanical device or intraarterial administration of a thrombolytic or antiplatelet agent. Some aneurysms have no neck or are inaccessible. This is the case most commonly with cavernous, petrous, extracranial vertebral, internal carotid, or giant aneurysms of the subarachnoid space. Treatment of these requires parent artery occlusion, which is possible only if good collateral flow exists. This requires a preliminary procedure known as a parent artery balloon test occlusion.[58] It involves first advancing a wire to the site of the proposed artery sacrifice. A neurologic examination is then performed, heparin is administered to prolong the activated clotting time, and a balloon is inflated to occlude the artery. Neurologic examination follows. In some institutions radionuclide enhanced cerebral vascular studies are undertaken. If the patient tolerates occlusion, coiling may proceed. If not, a surgical intracranial bypass may be required.

ENDOVASCULAR TREATMENT OF ARTERIOVENOUS MALFORMATIONS

AVMs in the brain are an area of direct connection between small arteries and the venous system without normally intervening capillaries. The usual presentation of this lesion is intracranial hemorrhage. Patients with AVM must be angiographically evaluated for the presence of associated aneurysms. This evaluation involves catheterization of selective feeder arteries to determine the precise source of the hemorrhage. Current therapy for cerebral AVM includes embolization, microsurgical resection, stereotactic radiosurgery, or combination treatment. Embolization preceding surgery can minimize bleeding and reduce AVM size. Small AVMs may be appropriate for endovascular treatment. Techniques for embolization of AVMs in the neuroradiology suite include the use of flow-directed microcatheters, solid occlusive devices, particulates, and liquid embolic agents. Complications include embolization of post-AVM vessels precipitating rupture, passage of embolic material into the pulmonary circulation, and microcatheter entrapment.[59]

INTERVENTIONAL NEURORADIOLOGY: ACUTE STROKE TREATMENTS

Acute stroke treatment has evolved significantly over the last 10 years. Intravenous r-tPA treatment has been replaced with intraarterial thrombolysis because it allows extension of the treatment time window from 3 to 6 hours, delivers a higher concentration of lytic drug to the target vessel, yields higher recanalization rates, and can be combined with other interventional techniques.

Initially a detailed cerebral angiogram is obtained and the level of occlusion is identified. A microcatheter is inserted over a microguidewire, contrast is injected, and the clot is localized. At this point, r-tPA is injected beyond the clot and the catheter is pulled back through the thrombus. If the occlusion persists, mechanical means of clot disruption or extraction are considered. This must be undertaken within 8 hours of the event. Several devices are available for retrieval or aspiration. Stent placement or angioplasty is also possible. A recent study of thrombectomy in patients treated within 8 hours demonstrated a recanalization rate of 57.3% of treatable vessels and 69.5% after adjunctive therapy. Thirty-nine percent of patients had favorable outcomes.[60]

Most patients with acute stroke are significantly compromised. General anesthesia is advocated. In addition, a narrow therapeutic window is available for interventions: 6 hours after the patient was last seen is normal for intraarterial thrombolysis and 8 hours for mechanical clot disruption. Often the anesthesia team has little time to gather preoperative information. A bolt or extraventricular drain may be necessary to measure intracranial pressure during the procedure.

INTERVENTIONAL CARDIOLOGY PROCEDURES: GENERAL CONSIDERATIONS FOR CATHERIZATION LABORATORY AND ELECTROPHYSIOLOGY LABORATORY

For the past 20 years, medicine has witnessed a crescendo of new procedures in interventional cardiology and electrophysiology (see also Chapter 68). The catheterization laboratory and electrophysiology laboratory—in terms of both volume and scope—define new specialties. In parallel, the need for anesthesiology involvement has increased. As new technology emerges into the medical marketplace, percutaneous treatment of structural heart disease has become part of the repertoire of interventional cardiologists, creating new and exciting opportunities for cardiac anesthesiologists. The anesthetic care of structural heart disease patients in the catheterization laboratory represents a new horizon for cardiac anesthesiologists, as does real-time echocardiographic guidance for placement of intracardiac closure devices. The role of cardiac anesthesiologist as co-proceduralist in this context is discussed later in an addendum to this chapter.

Similarly, the electrophysiology laboratory now offers expanded treatment options for patients with late-stage heart failure and complex arrhythmias. Because many of these procedures are long and involved, most are performed with general anesthesia or combinations of sedation and general anesthesia. Many patients have significant comorbidities. Often the proceduralists involved are unaware of the ramifications these present for procedural success, although this is changing. In this new and challenging arena, collaboration and planning between interventionalist and anesthesiologist are required to ensure patient safety and optimized outcome. A clear understanding of the procedure to be performed, possible pitfalls, and unique patient characteristics is necessary for the formulation of a safe and effective plan. As always, a common knowledge base and vocabulary facilitate integration of care.

THE LABORATORY ENVIRONMENT: UNIQUE CHALLENGES FOR ANESTHESIOLOGISTS

This section presents an overview of the laboratory environment(s), the evolution and future pathways of current practice(s), cases performed in each venue, and current anesthetic approaches. Invasive cardiology procedures performed in the cardiac catheterization laboratory include the following:

1. Diagnostic cardiac catheterizations and coronary interventions
2. Peripheral vascular diagnostic and therapeutic procedures
3. Amelioration of structural heart disease by the placement of intracardiac devices
4. Implantation of intraaortic balloon pumps and percutaneous left ventricular assist devices

Common electrophysiology laboratory procedures include the following (see also Chapters 48 and 68):

1. Electrophysiology studies
2. Atrial and ventricular radiofrequency ablation procedures
3. Implantation and removal of pacing and cardioverter defibrillator devices

These procedures potentially require the involvement of anesthesiologists if the patient has significant comorbidities. However, some ablations and electrophysiology studies and some device implants and removals can be performed with nurse-administered sedation. Some procedures are lengthy and technically demanding; some require that the patient be still. In such situations, preservation of hemodynamic stability and maintenance of a sedated or asleep state may indicate the need for a general anesthetic.

Catheterization laboratory and electrophysiology laboratory environments differ significantly from the OR. It is important for anesthesiologists to recognize the limitations of the venue and understand the flow of cases and responsibilities of ancillary personnel. Innovation and flexibility are necessary with respect to equipment availability and positioning and the nature and tempo of the anesthesiology-cardiology interface.

Electrophysiology and catheterization laboratories are built with separate control stations and procedure rooms. The control area is shielded from radiation and is the vantage point from which the progress of the procedure is recorded. An operator outside of the procedure room controls recording of data, patient monitoring, video recording and editing, and digital record keeping. Anesthesia equipment is not included in the array of controls outside the room. If robotic equipment is used, it is kept outside of the procedure room and catheter manipulations are made from there.

Room Configuration and Equipment Layout

Within the procedure room itself, cardiologists, anesthesiologists, nurses, and radiology technicians contribute to the care of care patient during the procedure. It can be daunting to know who is who and who is responsible for what. It is best to ask if unsure. In an emergency, understanding who is in charge of a life-saving therapy (i.e., defibrillator) can eliminate confusion and save lives. The procedure room includes fluoroscopy equipment (x-ray tube and C-arm), which usually surrounds the patient's head, making access difficult. The procedure table is mobile, and screens for viewing the procedure are at 90 degrees to the anesthesiologist. Sterile tables for the cardiologist, closets or portable storage units for various catheters, wires for the procedures, and blood analysis machines take up a lot of space. Anesthesia equipment (machine, cart, pumps, monitors), often an afterthought, is frequently pushed into the back of the room. Although lead screens hang from the ceiling to protect the cardiologist, no such protection is available for anesthesiologists, so portable lead screens, unwieldy and heavy, must be wheeled into the area between the anesthesia area and the fluoroscopy equipment. The anesthesiologist should become familiar with the contents of each procedure room, which varies across institutions, because usually things have to be moved, and moving the wrong thing can be problematic. Gas outlets and suction, monitors for vital signs, cardioverter-defibrillator, emergency medications, and airway equipment are critical and may not be optimally or even obviously placed. Longer tubing or extensions are needed for ventilator hoses, intravenous lines, suction, and more. Electrical outlets may not be sensibly located, and extension cords may be needed. Other equipment frequently found in these rooms may include ventricular assist devices, intraaortic balloon pumps, device programmers, and echocardiography machines. Space can become an issue during complex cases when a plethora of additional equipment is needed.

The fluoroscopy table and fluoroscopy equipment are controlled by radiology technicians and cardiologists. These move during the procedure to facilitate imaging, sometimes with no warning. As with all NORA locations, the local availability of extra equipment and an emergency airway cart becomes essential when the anesthesia workroom is not nearby. With cardiac patients, time can be critical. An anesthesia cart stocked with intravenous lines, medications, airway equipment, and medication essentials is important in the cardiac catheterization and electrophysiology laboratories. All personnel in the laboratory should be informed about the location and names of emergency equipment because the anesthesiologist may be alone and occupied during an emergency.

ANESTHESIOLOGISTS IN THE ELECTROPHYSIOLOGY LABORATORY

Clinical electrophysiology has redefined itself over the past 15 years (see also Chapter 48). Advanced technology and increased demand have driven exponential growth in the number of electrophysiology procedures. Additionally, the scope of these procedures has also dramatically changed from simple diagnostic procedures to major, life-saving, therapeutic interventions. More than 14 million Americans are affected by arrhythmias, and many of these patients require hospitalization and complex medical care. ICDs reduce mortality and morbidity for those with malignant tachyarrhythmias, and as a result, implantations and revisions of these devices have skyrocketed.[61]

The performance of many of these procedures now frequently mandates administration of general anesthesia because the procedures are long and many patients have comorbidities that make it unlikely they would tolerate a procedure under sedation. Optimal anesthetic planning requires the anesthesiologist to integrate patient comorbidities, nature of the arrhythmia, and tempo and framework of electrophysiology procedures. This section reviews the most commonly performed electrophysiology procedures.

ELECTROPHYSIOLOGY STUDIES

Diagnostic electrophysiology studies are usually undertaken in conjunction with either therapeutic procedures to evaluate and treat specific arrhythmias or device placements (see also Chapter 48). They can determine the electrophysiologic etiology of specific symptoms or events. Intracardiac recordings are made from catheters placed via femoral venous access into the high right atrium, bundle of His, coronary sinus, and right ventricular apex or right ventricular outflow tract. Arrhythmias are induced by programmed stimulation.[62] For these studies, sedation with benzodiazepines and short-acting opioids is usually sufficient. Drugs that may affect inducibility of certain arrhythmias should be avoided.

CATHETER ABLATION

Conduction abnormalities of many etiologies can generate rhythms that create hemodynamic instability and cardiac compromise. In general, these rhythms result in uncoordinated or ill-timed contraction; they are too slow, too fast, or mechanically abnormal. Bradyarrhythmias arise from either abnormal impulse generation or abnormal impulse propagation, which results in a slow rate. Tachyarrhythmias that are regular with a normal QRS include atrial flutter, atrioventricular nodal reentry tachycardia (AVNRT), and supraventricular tachycardia (SVT). Tachyarrhythmias that are irregular with normal QRS include atrial fibrillation and multifocal atrial tachycardia. Tachyarrhythmias with wide QRS include ventricular tachycardia and SVT with aberrancy.[63] Arrhythmias can have many etiologies, both metabolic and mechanical. Common electrophysiologic generators of arrhythmias include abnormal automaticity, anatomic reentry, and triggered activity. These abnormalities can be identified and treated using percutaneous catheter–based ablation techniques.

Catheter ablation is commonly used to treat SVTs, such as AVNRT, Wolf-Parkinson-White syndrome–related tachycardias, atrial flutter, atrial fibrillation, and ventricular arrhythmias in selected patients. Radiofrequency energy and cryotherapy are most commonly used for ablation. Both of these energy sources can be painful when delivered to target tissues.

Recent American College of Cardiology (ACC) and American Heart Association (AHA) Atrial Fibrillation Guidelines state that in patients with little or no left atrial enlargement, catheter ablation is a "reasonable alternative to pharmacologic therapy" to help prevent recurrence of atrial fibrillation.[64]

Radiofrequency catheter ablation is used for arrhythmias that are refractory to pharmacologic therapy and as a first-line treatment for other arrhythmias. The following arrhythmias can be treated with radiofrequency ablation: atrioventricular reentrant tachycardia, supraventricular arrhythmias associated with the Wolf-Parkinson-White syndrome, atrial ventricular reentrant tachycardia, atrial tachycardia, atrial flutter, idiopathic ventricular tachycardia, bundle branch reentrant ventricular tachycardia, right ventricular outflow tachycardia, atrial fibrillation with an uncontrollable rapid ventricular response (radiofrequency ablation of the atrial ventricular node and placement of a permanent pacemaker), and atrial fibrillation. Radiofrequency is also used as adjunctive therapy for recurrent ventricular tachycardia resulting from coronary artery disease or arrhythmogenic right ventricular dysplasia.[65]

During ablation procedures, catheters are placed throughout the cardiac chambers and programmed stimulation is performed from different sites to induce tachyarrhythmias. Complex mapping techniques localize the source of the arrhythmia to identify the exact intracardiac location to which the radiofrequency energy must be applied. Mapping techniques include activation mapping; pace mapping; entrainment mapping; anatomic fluoroscopy-based, three-dimensional electroanatomic mapping; three-dimensional noncontact mapping; and intracardiac echocardiography-guided anatomic mapping. Because of the precision required for mapping and applying radiofrequency energy, the patient must lie still during the procedure. General anesthesia ensures patient comfort and optimizes mapping. Paralysis should be avoided during radiofrequency ablation so that phrenic nerve stimulation can be performed to avoid injuring this structure. Remifentanil or sufentanil infusions can be administered in this setting.

Radiofrequency ablation procedures are becoming longer. Atrial fibrillation ablations often require 4 to 6 hours, followed by a 30-minute observation time after ablation with repeat stimulation (sometimes with pharmacologic agents as well) to ensure success of the procedure.[65]

Patients range from young and healthy to those with extensive comorbidities. Coughing, snoring, and partial airway obstruction are problematic for sedation and for the progress of the procedure. Snoring can precipitate swinging of the intraatrial septum, making transseptal catheter placement difficult. Ventilatory control with general anesthesia is preferable for obese patients, those with OSA, or those with potential pulmonary problems. Drugs that affect the sympathetic nervous system should be avoided, if possible, during mapping of ectopic foci and tracts. In patients with ventricular dysfunction, inotropic and vasoactive agents may be necessary to maintain hemodynamic stability during arrhythmia induction. Close communication with the cardiologist is necessary in these situations. Frequently, electrical cardioversion is necessary during the case.

ELECTROPHYSIOLOGIC DEVICES

Devices for the control or eradication of arrhythmias have diminished in size and increased in sophistication over the past 10 years (see also Chapter 48). More patients

qualify for device implants, and the number of procedures for implantation, revision, and upgrade of devices has grown. The two most common types of devices are ICDs and pacemakers.

Implantable Cardioverter-Defibrillators

ICDs have been demonstrated to be efficacious and safe in a number of large, prospective multicenter randomized trials in patients with coronary and no coronary heart diseases. Benefits accrue mainly in patients with depressed left ventricular ejection fractions of 35% or less.[66] Indications for ICD implantation as listed in the 2008 ACC, AHA, and the Heart Rhythm Society (HRS) guidelines have clearly been shown to prolong life and decrease the risk for sudden cardiac death for both primary and secondary ventricular tachycardia and ventricular fibrillation.[67] With the advent of smaller biphasic, transvenous ICDs and the experience gained over the years, it is now feasible for electrophysiologists to implant ICDs safely in the pectoral position in the electrophysiology laboratory. Local anesthesia combined with conscious sedation is used. The role of anesthesiologist is crucial if defibrillation threshold testing is done. This is especially true in patients who generally have significant comorbidities. Defibrillation threshold testing is commonly omitted because of the potential life-threatening risks of the procedure in unstable patients or patients with untreated coronary artery disease.

A new subcutaneous ICD (S-ICD), which eliminates the need for transvenous leads, is now available. Although the device detects and treats malignant VT and VF, it is incapable of providing antitachycardia pacing, advanced diagnostics, or radiofrequency interrogation with remote monitoring, and therefore is not appropriate for all patients. Implantation of these devices requires tunneling of the relatively large lead, and this can be painful enough to require deep sedation or general anesthesia.[67a]

Biventricular Pacing and Defibrillation Lead Placement

Cardiac resynchronization therapy with and without defibrillation systems are prescribed for both primary and secondary prevention of sudden cardiac death in patients with heart failure associated with both an ischemic and nonischemic etiology. The ACC/AHA/HRS guidelines gave cardiac resynchronization therapy with or without an ICD a class I indication for those with a left ventricular ejection fraction 35% or less with a QRS duration 120 msec or greater and drug-refractory New York Heart Association functional class III or ambulatory class IV heart failure who are receiving optimal medical therapy.[67]

Implantation of biventricular ICDs may be complex and lengthy because of difficulty positioning the left ventricular lead into the coronary sinus and great cardiac vein in the setting of distorted ventricular anatomy resulting from cardiac dilatation and advanced heart failure. In addition, valvular regurgitation can complicate lead positioning. Finally, lead dislodgement may occur immediately after lead placement, especially in patients with a large coronary sinus, further prolonging these procedures.

During any device placement, pneumothorax or coronary sinus perforation related to lead placement is possible. Coronary sinus perforation can immediately be recognized by contrast extravasation. Perforation of the coronary sinus or cardiac perforation related to ventricular or atrial lead placement may lead to the development of cardiac tamponade, which necessitates immediate pericardiocentesis. Paralytics should be avoided here, as well, so that lead placement, which results in diaphragmatic pacing, can be identified and avoided.

Many patients who qualify for these devices have multiple comorbidities, including a history of ventricular tachycardia or fibrillation, ejection fraction less than 30%, and coronary artery disease (these are indications for ICD placement). However, most of these devices are placed with mild to moderate sedation and standard monitors. Testing the device requires deep sedation or general anesthesia. ICD placement and testing can be accomplished without an arterial line. External cardioverter-defibrillator pads are placed on the patient at the beginning of the procedure. When testing ICDs, they serve as backup if the implanted device fails.

Some patients needing ICDs may benefit from placement of biventricular pacemakers used for cardiac resynchronization therapy. Patients scheduled for a biventricular pacemaker have extensive cardiac morbidity, including low ejection fractions, valvular heart disease, pulmonary hypertension, and right ventricular dysfunction. Patients may not be able to lie flat comfortably and can easily become hemodynamically unstable with sedation. Oversedation can lead to hypercapnia, which is problematic in patients with pulmonary hypertension or right ventricular dysfunction. The anesthesiologist should be available if needed to assist during the case.

ANESTHESIOLOGISTS IN THE CATHERIZATION LABORATORY

Anesthesiology in the catheterization laboratory reflects the evolving broad range of therapies performed in this venue (see also Chapter 68). Catheterization laboratories—originally the workplace of interventional radiologists (who were the "original" angiographers)—are home to interventional cardiologists, vascular surgeons, and others who practice a broad range of therapies, all of which use fluoroscopy and a host of ever more sophisticated interventional technologies. Procedures can be peripheral or cardiac and range from the stenting of narrowed or occluded vessels to the implantation of prosthetic heart valves. Anesthesiology involvement ranges from giving intravenous propofol to providing a full cardiac anesthetic and performing transesophageal echocardiography (TEE) during the case.

PERCUTANEOUS CORONARY INTERVENTIONS

Percutaneous coronary interventional procedures for patients with both stable coronary artery disease and acute coronary syndromes have grown in the past 10 years. Percutaneous coronary interventions (PCIs)

include coronary angioplasty (mostly performed immediately before coronary stenting) with both bare metal stents and drug-eluting stents, atherectomy procedures, and intracoronary thrombectomy procedures. PCI procedures are commonly performed in patients with 70% or greater intracoronary luminal atherosclerotic obstruction and demonstrated myocardial ischemia in the context of stable coronary disease. The major benefit of PCI is to reduce or relieve symptoms of ischemic heart disease and increase aerobic capacity.[68] No significant difference in total mortality, nonfatal myocardial infarction, or other major cardiovascular events were demonstrated between randomized patients treated with aggressive medical therapy or aggressive medical therapy plus PCI angioplasty with bare metal stenting.[69] But for patients who presented with acute coronary syndromes, PCI decreased mortality and recurrent myocardial infarction in contrast to medical treatment alone.[70]

PCIs can be performed with mild to moderate nurse-administered sedation under the direction of the cardiologist. Anesthesiologists are usually involved only when patients present with respiratory or hemodynamic compromise.

If acute patient respiratory or hemodynamic decompensation occurs, anesthesiologists are called emergently. In this circumstance, clear and direct communication with the cardiologist is required; management decisions usually need to be made expeditiously. Information such as medications given, intravenous access, and stage of the procedure must be made available. Access to the patient's head can be difficult because of the x-ray equipment, as mentioned previously. If an airway needs to be established, it may be necessary to temporarily move the table and fluoroscopy equipment and hold chest compressions. Placement of an endotracheal tube is preferred to a laryngeal mask airway (LMA) even in an elective situation because the constant movement of the equipment or cardiopulmonary resuscitation, or both, can dislodge the LMA. Obviously for patients who are acutely unstable, having an endotracheal tube is preferred, but if placement is difficult, an LMA can serve as a temporizing measure. During PCI, patients can be in a highly anticoagulated state, and a bleeding difficult airway is a nightmare in this context.

INTRAAORTIC BALLOON PUMPS AND PERCUTANEOUS VENTRICULAR ASSIST DEVICES

The intraaortic balloon pump (IABP) is a mechanical device inserted percutaneously into the aorta that increases myocardial oxygen perfusion and cardiac output (see also Chapter 68). The balloon, sitting approximately an inch distal to the subclavian artery, inflates and deflates in diastole and systole, respectively thereby delivering *counterpulsation*. This increases coronary blood flow and myocardial oxygen delivery, and cardiac output rises. The balloon pump is controlled by a programmed console, which inflates the balloon at varying time intervals chosen by the operator, linked to either an electrocardiogram trace or a pressure transducer at the distal tip of the catheter. Placement of IABPs is usually successful under conscious sedation unless the patient is compromised from a hemodynamic or respiratory standpoint, in which case the team would seek assistance from an anesthesiologist.

Percutaneous ventricular assist devices (PVADs) provide inotropic support during high-risk PCI, cardiogenic shock associated with myocardial infarction, or other left ventricular dysfunction. Several types of PVADs are available. The TandemHeart device (CardiacAssist, Philadelphia, Pa) is a percutaneous left-atrial to femoral bypass system consisting of a transseptal cannula, an arterial cannula, and an externally located centrifugal blood pump, which can deliver flow rates of up to 4 L/min.[71] An alternative percutaneous-based left ventricular assist device is the Impella Recover (Impella Cardiosystems, Aachen, Germany). This device comes in two sizes—a 2.5- and 5.0-L system—and uses a cannula inserted retrograde via the femoral artery into the left ventricle across the aortic valve. These pumps do not require transseptal puncture, are smaller and easier to implant, and incorporate a microaxial pump into the catheter system, thereby eliminating the need for extracorporeal blood. Cardiac output of either 2.5 L/min or 5.0 L/min can be achieved with the Impella devices.[72] Anesthesiologists are consulted for these procedures because the patients are unstable and/or present with a high likelihood of airway or hemodynamic compromise. Depending on the procedure and state of the patient, either sedation or general anesthesia can be used. These devices achieve cardiac outputs that can completely replace left ventricular function; blood flow may not be pulsatile, so pulse oximetry and noninvasive blood pressure cuffs may not work properly. However, invasive monitoring is available via the arterial cannulation used during the procedure. The choice of anesthetic, likely postprocedural care, and prognosis should be discussed with the cardiologist before the start of the case, if possible.

PERCUTANEOUS CLOSURE OF SEPTAL DEFECTS

The placement of intracardiac septal occluder devices requires general anesthesia if TEE is used to guide placement of the closure device (see also Chapters 46 and 47). If the cardiologist uses intracardiac or intravascular echocardiography, general anesthesia may not be needed. Several U.S. Food and Drug Administration (FDA)-approved devices are available for closure of atrial septal defects (ASDs). To date, however, no prospective randomized controlled trial has been done of percutaneous closure of patent foramen ovales (PFOs) in patients who have suffered from a cryptogenic stroke. The FDA has not approved the use of percutaneous occluder devices for the prevention of recurrent cryptogenic stroke in patients with PFO.[73] Insurance companies are increasingly unwilling to pay for these procedures.

The Amplatzer (AGA Medical, Golden Valley, MN) and the CardioSEAL (NMT Medical, Boston, MA) devices are routinely used in clinical practice. The Amplatzer Septal Occluder is a two-sided "clam shell" made up of two flat discs with a middle or "waist." The discs are made of nitinol (nickel and titanium) wire mesh and polyester fabric

inserts. The fabric inserts create a nidus for tissue growth after placement.[74] The CardioSEAL STARflex device consists of two self-expanding Dacron patch–covered umbrellas that attach to either side of the intraatrial septum. The umbrellas are composed of four central radiating metal arms attached to each other in the center. The device contains a self-centering mechanism comprising nitinol springs that connect the two umbrellas.[75] Closure of PFOs tends to be simpler than closure of ASDs. In patients with ASDs, it is important to clarify right ventricular function, pulmonary arterial pressures, and shunt to formulate an optimal anesthetic plan. Success rates for PFO and ASD closure range from 79% to 100%.[76]

These devices can also be used to close other types of defects, such as paravalvular leaks and muscular or perimembranous ventricular septal defects (VSDs) (either congenital or acquired). Reportedly, VSDs can be closed 96% of the time, with a 2% major complication rate with these devices.[77] Left to right flow is seen on TEE with these lesions. In patients with traumatic (post–myocardial infarction) VSDs, hemodynamic instability is not unusual and complications are common during closure attempts. Tissue integrity is frequently compromised, and placement of closure devices is difficult. Visualization of the defect and guidance of device placement can be challenging. Patients with post–myocardial infarction VSDs are more likely to have complications during closure of the defect.[78]

Complications of any device placement in the cardiac catheterization laboratory include air embolism, device embolization, malposition, thrombosis, embolization, arrhythmias, hypotension, valve dysfunction, cardiac perforation, and injury to nontarget cardiac structures. It is critical that these complications be recognized and dealt with expeditiously. Rapid and effective communication is critical. Untoward events may be evident initially to anesthesiologists if they are guiding the procedure with TEE.

Echocardiography is often used during the procedure to help guide placement and confirm a successful result. TEE can be performed by cardiologists, anesthesiologists, or ultrasound technicians, depending on institutional preference and availability of personnel. If TEE is used, general anesthesia will be necessary for the procedure. If a cardiac anesthesiologist administers the anesthetic, he or she can guide the procedure in a step-by-step fashion, integrating the guidance with anesthetic parameters. Although two-dimensional echocardiography is the most widely used imaging technique for preprocedural patient evaluation, three-dimensional imaging via echocardiography, multidetector row CT, and cardiac MRI can also help to delineate structural intracardiac details. Intraprocedural three-dimensional TEE is also available.[79] Intracardiac echocardiography (ICE) can be used to guide the procedure, but this must be performed by the cardiologist because the controls are at the groin and in the field. In cases in which TEE is not available or cannot be performed because of patient comorbidities, ICE is a reasonable alternative.

If arterial monitoring is needed and the cardiologist is not planning femoral arterial access, a radial arterial line should be placed by the anesthesiologist. Two intravenous lines (and/or a central line) should be available at induction if the patient is potentially unstable.

PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease affects approximately 8 million Americans (see also Chapter 69). The prevalence of this disease increases with age and occurs more commonly in African Americans. Intermittent claudication and rest pain are the principal symptoms. Claudication symptoms are due to insufficient arterial blood flow and leg ischemia. Symptoms include pain, aching, and a sense of fatigue or other discomfort that is relieved at rest. Symptoms are most often experienced in the muscle bed supplied by the most proximal stenosis. Buttock, hip, or thigh claudication is related to obstruction of the aorta or iliac flow. Calf claudication commonly is a result of either femoral or popliteal arterial stenosis, and either tibial or peroneal disease causes ankle or pedal claudication.[80]

According to ACC and AHA guidelines, percutaneous revascularization in patients with intermittent claudication should be considered when any one of the following circumstances is encountered:

1. Claudication symptoms significantly disable the patient.
2. The patient is able to benefit from an improvement in exercise.
3. Rehabilitation and pharmacologic therapy have not provided adequate response.
4. A favorable risk-to-benefit ratio to performing the procedure exists.
5. The characteristics of the lesion permit appropriate intervention at low risk with a high likelihood of initial and long-term success; and/or the patient has limb-threatening ischemia, as manifested by rest pain, ischemic ulcers, or gangrene.[81]

The anesthesiologist may be critical to the interventional cardiologist during a peripheral vascular intervention because many of these patients are unable to lie still during the procedure because of rest pain symptoms and other related comorbidities. In addition, the procedure itself may create painful transient ischemia and patient movement may reduce the likelihood of success.

PERCUTANEOUS VALVE REPAIR AND REPLACEMENT

Percutaneous technologies for the treatment of mitral regurgitation and aortic valve disease are presently available; development of devices and approaches is ongoing (see also Chapter 67). These procedures are a major addition to the repertoire of interventional cardiologists and represent exciting new overlap of surgical and medical therapies for structural heart disease.

Percutaneous Mitral Valve Repair

Currently, surgical repair is the most common procedure performed for the treatment of symptomatic mitral regurgitation or mitral regurgitation with impaired left ventricular ejection fraction (<60%). However, current techniques under investigation for percutaneous mitral valve repair include coronary sinus annuloplasty, direct annuloplasty, leaflet repair, and others.[82]

Devices that use the coronary sinus as a method of cinching the mitral annulus are investigational, and the safety and efficacy of this approach remains undetermined. Another approach involves percutaneous placement of a cliplike device (MitraClip, Abbott Vascular, Abbott Park, IL) that creates an Alfieri edge-to-edge repair (Evalve, San Francisco, CA). After a transatrial septal puncture, the clip is positioned in the center of the mitral valve orifice. The clip is opened, passed into the left ventricular cavity, pulled back to contact the mitral valve leaflets, and then closed to create a double-orifice mitral valve.[82] General anesthesia, fluoroscopy, and TEE to help guide placement of the device are part of the Evalve procedure.[76]

Percutaneous Aortic Valve Replacement (Transcatheter Aortic Valve Replacement)

Percutaneous aortic valve replacement or transcatheter aortic valve replacement (TAVR) is a relatively new treatment in the US for aortic stenosis. During the procedure, a replacement valve is crimped into a catheter and passed through the femoral artery to the aortic annulus. Rapid ventricular pacing is employed to minimize cardiac output while the prosthesis is deployed into the appropriate position after a balloon valvuloplasty. Transaortic and transapical insertions of transcatheter valves can also be performed by a multidisciplinary team in a hybrid OR setting. In the future, other variants of this procedure will likely evolve for placement of valves in other positions.

The concept of a transcatheter valve for percutaneous placement was initially presented in the early 1990s, and the first percutaneous heart valve for human use was developed by Cribrier and implanted in Europe in 2002.[83,84] In the United States, the Edwards SAPIEN valve received FDA approval in November 2011.[85] Two devices currently exist for percutaneous implantation; the Medtronic CoreValve (Medtronic, Minneapolis, MN) and the Edwards Lifesciences SAPIEN (Edwards Lifesciences, Irvine, CA). The CoreValve is a porcine pericardial self-expanding valve prosthesis sutured into a nitinol stent. The SAPIEN valve is a bovine pericardial prosthesis sutured into a balloon-expandable tubular metal stent.

In high-risk patients with severe aortic stenosis, transcatheter valve replacement was found to be "noninferior" to surgical aortic valve replacement at 1 year in terms of survival. However, the transcatheter procedure was associated with a higher risk for stroke than the surgical replacement at 1 year and a higher risk for major vascular complications at 30 days. More patients undergoing transcatheter replacement demonstrated improved symptoms at 30 days, but no significant between-group difference was seen at 1 year.[86,87]

Ongoing clinical trials are under way comparing surgical aortic valve replacement to percutaneous aortic valve replacement in patients who are candidates for cardiac surgery using newer generation percutaneous aortic prosthetic valves. As study results become available, percutaneous valve replacement may constitute a viable alternative to surgery for a patients who need valve replacement in whom the risk for cardiac surgery is unacceptable.

These procedures present a changing paradigm with respect to treatment of structural heart disease and the scope of interventional cardiology procedures. Procedures and patients are more complex. Medical and surgical approaches to cardiac care are beginning to overlap. Anesthesiologists must be prepared to treat this challenging patient population in new venues.

At our institution, all percutaneous valve repairs are performed under general anesthesia with fluoroscopic and TEE guidance. CTs are obtained before the procedure to define valve size and anatomy, and 3D TEE may be used during the procedure to affirm valvular anatomy before and after the prosthesis is placed. Patients are elderly, with severe valvular disease and attendant comorbidities. Communication and coordination of activities are critical.

During percutaneous valve replacements and repairs, the procedure room is crowded with staff and equipment. Planning for expected difficulties related to patient comorbidities and technical challenges is well worth the extra time. A team meeting before the procedure is worthwhile because elements of the patient's history often warrant interdisciplinary scrutiny and discussion. Two peripheral intravenous lines should be placed for infusions, and a Swan-Ganz catheter is recommended in compromised patients. Endotracheal intubation is required if TEE is used, and arterial monitoring is important because noninvasive blood pressure cuffs may not work when the patient is rapidly paced. Communication and visual accessibility to all imaging during the procedure is vital to successful placement of the device. Multiple attempts may be needed to ensure proper catheter and device placement with an acceptable result. Patients may develop hemodynamic instability, myocardial ischemia, or significant arrhythmias during the case. Constant communication between anesthesiologist and cardiologist is critical.

Transfemoral TAVR can be performed in a cardiac catheterization laboratory or hybrid OR. Enough space is required for general anesthesia, TEE, and cardiopulmonary circulatory support, in addition to the space required by the proceduralists. The percutaneous femoral approach requires adequate endolumenal diameters, but as technology develops, smaller sheaths and more flexible valves will become available. In the future, tortuous iliac vessels or high athermanous burden may not preclude a femoral approach.

For transfemoral cases, general endotracheal anesthesia is preferred, although institutions in the United States and Europe report successful outcomes with conscious sedation. Invasive arterial pressure monitoring and central access are needed. Planned extubation is reasonable assuming the patient's comorbidities and the course of the procedure warrant it.

Although institutions in Europe report successful TAVR outcomes using ICE and/or fluoroscopy alone, in our experience TEE plays a critical role (also see Chapter 46). Before any intervention, aortic stenosis with a trileaflet valve should be confirmed; TAVR cannot be performed with bicuspid valves. The degree of aortic insufficiency should be assessed before valvuloplasty; the presence of mild to moderate aortic insufficiency may be protective in severe new-onset cases after balloon aortic valvuloplasty. Ejection fraction, degree of mitral and tricuspid regurgitation, presence of mitral annular calcification and mitral stenosis, estimated pulmonary artery

pressures, and coronary artery takeoff location are also useful measurements. Accurate measurement of aortic annulus aids in choice of prosthetic valve size. During the placement of the valve, real-time echocardiographic guidance can assess positioning of the prosthesis. Following valve deployment, rapid assessment of valvular function, presence of leaks, and ventricular wall motion abnormalities are critical.

As technology improves, the flow of cases will change. Presently, however, at our institution, the following list constitutes the framework for transfemoral cases:

Critical Procedural Steps During Transfemoral Transcatheter Valve Replacement

1. Place intravenous line and A-line, induction.
2. Place PA line, larger access, cerebral Svo_2.
3. Conduct TEE discussion and expected and unexpected findings with entire team.
4. Access femoral vasculature: arterial sheath, contralateral transfemoral aortic occlusion balloon, and place transvenous pacer
5. Perform standard balloon aortic valvuloplasty: refine sizing and enlarge orifice.
6. Assess adequacy of rapid ventricular pacing.
7. Upsize sheath to (27 French) or appropriate introducer.
8. Advance transcatheter valve; assess position by fluoroscopy and echocardiography.
9. Deploy valve during rapid ventricular pacing.
10. Assess valve position and function.
11. Remove sheath and complete vascular closure.

Common Complications and Remedies

Vascular Disaster. Femoral vascular avulsion is possible on removal of the introducer sheath. Temporization of hemorrhage can be achieved with the distal aorta occlusion balloon residing in the contralateral femoral artery. This can prevent fatal hemorrhage in the event of a vascular catastrophe. If percutaneous access cannot be obtained, cut-downs or surgical access to the aortic bifurcation is possible. Vascular surgical repair is necessary in this situation. All of these potential eventualities demand the ongoing vigilance of the anesthesiologist.

Pacing Malfunction. Transvenous pacing is used to establish rapid ventricular pacing and a near-zero cardiac output state during ballooning of the aortic valve. If atrioventricular node dysfunction occurs after valvuloplasty or valve deployment, postdeployment pacing may be necessary. Poor communication during rapid ventricular pacing may be catastrophic. Loss of pacer capture during balloon valvuloplasty can place excessive traction on the native valve during balloon inflation; unexpected ventricular ejection can embolize the valve from the annulus during deployment.

Abnormal Valve Deployment. Valves left prepared on the balloon but not deployed for significant amounts of time may open improperly, causing significant aortic insufficiency. Deployment of an additional device (valve-in-valve) may be necessary in this case.

Hemodynamic changes may occur at a variety of points during the procedure. Communication among providers of different disciplines is essential. Patients respond idiosyncratically to balloon valvuloplasty; new-onset aortic insufficiency may require significant support and necessitate rapid valve introduction and deployment. Inotropic support may be necessary to maintain systemic blood pressure as balloons and crimped valves traverse the valve orifice. Invasive monitors typically reflect low cardiac output, falling Svo_2 and high pulmonary artery pressures. The authors routinely have boluses of epinephrine, norepinephrine, and vasopressin available in a variety of concentrations.

Device Embolization. Embolization into the aorta can occur as a result of ejection because of inadequate pacer capture or inappropriately high deployment. Once a valve is in the aorta, it is irretrievable endovascularly. Valves lodged in the descending aorta have been reported and are tolerated; however, a second valve must still be deployed in the aortic position. Valve loss into the ventricle may occur if deployment is too low. This result requires surgery for retrieval and may be fatal if comorbidities are significant.

Coronary Occlusion. Coronary occlusion is a potential problem if calcium or native aortic valve tissue occludes a coronary ostium. Prior coronary artery bypass graft with patent grafts is partially protective. Coronary guidewires may be placed in patients who are at higher risk. Skilled intervention is required to reopen occluded coronary arteries. Clear interdisciplinary communication is essential in the management of regional wall motion abnormalities, ST-segment changes, or hemodynamic compromise.

Need for Cardiopulmonary Bypass. Cardiovascular collapse during transfemoral procedures may require cardiopulmonary support. Institutional variability exists regarding the type of support planned; some institutions have a primed cardiopulmonary bypass pump in the room, even if the case is in a catheterization laboratory outside of the OR; others have percutaneous VAD support on standby.

Neurologic Events. Acute stroke is potentially detectable with unilateral changes in cerebral oximetry readings. The higher stroke rate of cohort A patients in the PARTNER trial was felt to be a result of both ballooning of the calcified native valve and the introduction of a large balloon and valve apparatus across the aortic arch. Anesthetics allowing for early neurologic assessment are preferred.

As patient acuity increases, safe and efficient care for the target population in the cardiac catheterization and electrophysiology laboratories is a concern for all anesthesiologists and cardiologists. Anesthesiologists are uniquely trained to care for this complicated patient population while permitting cardiologists to focus on the interventional procedure. Anesthesiologists, in collaboration with cardiologists, must establish guidelines for the interdisciplinary care of patients with complex issues in the cardiac catheterization and electrophysiology laboratories. Growing numbers of patients with more complicated health issues and an expanding arsenal of sophisticated technologies make it likely demand for these laboratory services will continue to grow. Collaboration between

cardiologists and anesthesiologists is increasingly necessary. Reframing the boundaries of medical specialties is the likely key to success. The goal is to enhance patient safety and improve procedural efficiency and outcomes while advancing the frontiers of medical care in expanding and exciting venues outside of the OR.

INTERVENTIONAL ECHOCARDIOGRAPHY ANESTHESIOLOGISTS AS CO-PROCEDURALISTS—THE ROAD AHEAD

As percutaneous interventions for structural heart disease increase in number and broaden in scope, the need for multidisciplinary input grows. Cardiac anesthesiologists traditionally perform TEE in the OR before and after cardiopulmonary bypass to diagnose structural problems and assess surgical repair. In the catheterization laboratory, growing usage of general anesthesia to support patients during complex procedures ideally positions cardiac anesthesiologists to perform this service in a new context.

Diagnostic echocardiography is important in the catheterization laboratory, as it is in the OR. However, the novel feature of TEE performed here (interventional TEE) is the need for step-by-step guidance of intricate and highly technical intracardiac manipulations[88] (see also Chapter 46). Fluoroscopy—the traditional imaging modality for interventional cardiology procedures—entails significant radiation exposure, requires the use of intravenous contrast, and can be temporally and spatially imprecise. Interventional TEE provides precise adjunctive imaging for placement or removal of intracardiac devices, placement of transcatheter valves, and repairs of paravalvular leaks or other structural defects. In addition, cardiac anesthesiologists understand imaging in the context of anesthetic care and are capable of manipulating hemodynamics as observation of cardiac function requires. Functional interpretation of structural defects can be critical as repairs are made. In the catheterization laboratory or hybrid OR setting, cardiac anesthesiologists become co-proceduralists, providing imaging, hemodynamic control, interpretation, and step-by-step guidance for interventionalists in the context of fixing abnormal cardiac anatomy. Real-time three-dimensional guidance during catheter placement, ballooning, or device implantation is an important and new component of interventional cardiology. This is a time-sensitive, high-acuity undertaking. It is relatively new in intracardiac imaging and for cardiac anesthesiologists; it defines an exciting and important role that goes a step beyond the job of maintaining homeostasis during the stress of surgery.

Interventional TEE is performed during septal occlusion, paravalvular leak repair, and transcatheter valve replacement. As in the OR, comprehensive interventional TEE examination begins with assessment of cardiac structure and function in the context of the proposed procedure, including the primary defect and any associated pathology. Effective communication among team members is critical because the value of interventional two-dimensional and three-dimensional TEE is lost if mutual understanding is absent. To this end, information from fluoroscopic and echocardiographic images can augment each other when unusual anatomy or clinical circumstances are observed. Data from each imaging modality should be discussed if contradictory interpretations arise.

Interventional TEE includes both two-dimensional and Doppler imaging complemented by three-dimensional and real-time three-dimensional datasets. It may be important to alternate between two-dimensional and three-dimensional imaging to clarify temporal and spatial details,[89,90] so that accurate placement of wires and catheters can occur. Closure of paravalvular leaks or stenting of stenotic pulmonary veins, for example, may require both types of imaging. Real-time three-dimensional imaging can clearly depict the proximity of equipment and devices to targeted defects by permitting rotation of acquisitions in all directions, thereby delineating structures in their native orientation. Although in the OR it is possible to correlate actual anatomy with TEE images while the chest is open and the patient is on bypass, this is not the case during percutaneous procedures. The accuracy of imaging and interpretation is therefore critical.

During TAVR, interventional echocardiography is important for optimization of valve placement and diagnosis of problems when they occur. After TAVR deployment, a comprehensive TEE is performed. Valve position is assessed, absence of coronary ostial occlusion is confirmed, valve gradient is measured, perivalvular and central leaks are assessed, and the need for any remedial activity is discussed. This requires the input of proceduralists and cardiologists alike.

As technology evolves, percutaneous procedures for structural heart disease will become more sophisticated. As devices improve, the target populations will grow. Patients with congenital, acquired, and surgically created defects will become eligible for treatment by interventional cardiology procedures. Interventional TEE has emerged as the newest evolutionary phase of cardiac anesthesiology.[91] The development of optimal, collaborative relationships between interventional cardiologists and anesthesiologists provides the foundation for a robust, multidisciplinary interface, thus establishing a basis for advancement of clinical practice and a place for anesthesiologists at the forefront of medicine.

THE ROAD AHEAD: TOWARD A COMPREHENSIVE STRATEGY

As technology evolves, medical procedures tend to become more complex. As the population ages and medical therapies achieve increased effectiveness, acute illnesses can become chronic. The current expansion of minimally invasive, nonsurgical approaches to disease will continue. Demand for anesthesiology services continues to escalate, but because procedural operators are largely medical and not surgical providers, requests for services do not necessarily parallel need. Thus, anesthesiologists are sometimes asked to attend patients who do not need their support, and conversely, are not asked to participate where presence is required until a crisis develops. Solutions to staffing problems become more complicated; efficiency and medical optimization become secondary to the goal of

getting through the day and the procedures to be done. When politics and finances increasingly dictate what they do and whom they treat, anesthesiologists must emphasize even further their mission of enhancing patient safety and comfort. Resetting the boundaries of practice to include medical specialties is critical to success.

It is clear that we must extend the recognized realm of our specialty beyond the limits of the OR. Inclusion of procedural areas within our practice requires a new model of service delivery. Not only are new markets emerging, but the financial rules are changing. We ought not allow our expertise to become discontinuous with current opportunities arising as a result of medical progress or risk allowing anesthesia services to become anachronistic. New, noninvasive approaches to surgical problems threaten to change the standards of where, how, who, and under what circumstances, surgical or percutaneous interventions may be performed.

Over the past 30 years, anesthesiologists revolutionized safety, reliability, and the scope of practice within the OR. The time has come for us to do likewise in non-OR locations. Seeing beyond the traditional role of anesthesiologists in the OR, we can create a niche broadened by services as critical care providers inside and outside the ICU, as surgical hospitalists and care integrators, and as innovators outside of the operating room. If these possibilities are ignored in the emerging market structure, we risk abdicating our real responsibilities to patients and to medicine. We must examine the productivity and sustainability of anesthesiology as a medical subspecialty. What, then, are the elements of an effective strategy?

Operational Effectiveness

Operational effectiveness is a crucial component of successful competitive strategy and financial sustainability. It implies innovation and the ability to manage a more successful, wider spectrum of activities than the competition. We must provide better, more flexible services that yield measurably better outcomes than the competition. For us, that competition includes (1) medical proceduralists who do not see the need for anesthesiologists, (2) other nonanesthesia providers, and (3) companies that design and produce machinery capable of administering drugs and interpreting monitoring equipment. "Better outcomes" are defined by evidence—that is, volume and quality data. Therefore, record keeping and data analysis must become an essential element of operations. In addition, operational effectiveness requires optimized resource management: planning is critical and ad-hoc management is unacceptable.

Costs, Uniqueness, and Value-Added

Anesthesiologists have the training and experience to deliver superior, integrated, cost-effective services outside the OR. In an era of increasing medical specialization and fragmentation of care delivery, particularly in the context of accountable care organizations and bundled payments, these are the critical indices of success.

Proper variable cost accounting demonstrates that the cost of patient care involving an efficiently deployed anesthesiologist is less than the cost imposed on the whole system by those (all too common) procedures that start without anesthesia personnel and end with an urgent, unanticipated call. The expense of (1) delaying a procedure, (2) stopping a procedure for inadequate or oversedation, (3) hospitalizing a patient, and (4) rescheduling and redoing the procedure is forbidding. But the costs are not always obvious because they are spread over multiple cost centers.

Institutions in which anesthesiologists practice and the medical and surgical departments they serve benefit from anesthesiology services. However, reimbursement to anesthesiologists may not parallel or indeed justify the investment. Little overlap exists in available time and productive time, and there are no rules. The non-OR would run as erratically as the OR would, were surgeons allowed to show up whenever they wanted, to book procedures 5 minutes before they started, and to change procedures or patients at the last minute.

Strategic Positioning

For anesthesiologists, strategic positioning occurs when the needs of customers and potential customers are satisfied with minimal cost to the anesthesiologist. Environmental scanning, context analysis, and other standard tools of market assessment serve to reconcile the mission of anesthesiology and revision of core competencies (product line) with the demand for them. The customers are not just patients; they are also medical proceduralists and third-party payers. If we can provide a safer, more comfortable, time-efficient, and cost-effective environment for proceduralists, the value of an anesthesiologist in attendance is clear. If we develop the bridge between medical and surgical treatment by facilitating hybrid procedures and interdisciplinary approaches, the overall value of our presence will be incontrovertible to proceduralists, patients, insurance companies, regulatory bodies, and government agencies.

Financial Silos and Teamwork

The certainty of increased insistence by third-party payers on integrated care requires collaboration and interdisciplinary effort. As accountable care organizations become widespread, bundling will become standard and integration will be expected by all insurers. Anesthesiologists will be forced to depend on the strength of relationships they forge with medical specialists. These will grow and develop only if the medical specialists recognize the value of anesthesiologists in attendance during their cases. Teamwork depends on improved outcomes and financial success.

Team building requires communication based on common experience and vocabulary—hence, the argument for grouping medical specialists with anesthesiologists who specialize in a specific type of surgery. Often medical specialists perform interventions with the same end goals as open surgeries, yet they lack the surgical perspective that many anesthesiologists acquire in the OR. Integration of medical and surgical perspectives can be, and has been, exploited for innovative solutions to new problems and to avert mistakes outside of the OR. The contribution of cardiac anesthesiologists to percutaneous device placement and congenital heart disease treatment in the

catheterization laboratory is a case in point. Similar participation in ultrasound-guided cases in the endoscopy laboratory and to interventional radiology cases is also possible. Teams bridge silos. Integration of reimbursement is coming. Why not be ready for it and organize ourselves preemptively?

Sustainable Strategy: Key Points

Effective strategy is one that maintains a dynamic and profitable market presence. Anesthesiologists have two related parallel sets of priorities: creating and maintaining a stable but flexible customer base and achieving financial sustainability.

Operational effectiveness will ensure that appropriate resource allocation permits innovation. Enhanced core competencies resulting from expanded medical training and presence outside of the operating room will provide a basis for the already needed enrichment of services. Team building will ensure that proceduralists understand the rationale for close cooperation and generate a foundation for better integrated finances. Reframing boundaries and elimination of silos will enhance integration, productivity, and the quality of care across the board. The overall strategy must be to make our specialty indispensable to customers and potential customers, while enhancing the lives of patients by improving outcomes and stimulating progress.

Our expertise will generate consistent reimbursement if we have the data to demonstrate the benefit of that presence. Our participation in non-OR procedures can stimulate and advance medicine just as development of the OR environment advanced the practice of surgery. As technology continues to proliferate and diversify, the distinction between medical and surgical approaches to treatment becomes blurred. The pursuit of innovation has always been characteristic of anesthesiologists. We must continue this work in new venues and work to build bridges if we hope to survive as a specialty.

The need is urgent for anesthesiology to adopt a broader, more business-like perspective as the practice continues to broaden medical know-how. If this opportunity and its associated intellectual challenges are ignored, the status of anesthesia, a key medical subspecialty, may be threatened. If the challenge is accepted, the practice of anesthesiology will be on the front lines of changing and advancing medical science. As this chapter goes to print, an unprecedented crescendo of emerging technology and ongoing innovation continues to defy status quo approaches to NORA cases. Some information presented here may already be outdated; proceduralists, locations, and equipment will continue to evolve. Regardless of the venue or the technique, anesthesiologists remain a critical and constant guardian of integrative medical perspective, patient safety and efficient procedural process. As we move beyond the OR, constant vigilance, dedicated teamwork, mutual respect and effective communication will continue to be the keys to success.

Chapter 91

Clinical Care in Extreme Environments: At High and Low Pressure and in Space

RICHARD E. MOON • ENRICO M. CAMPORESI

Key Points

- Hyperbaric oxygen exposure (breathing oxygen at increased ambient pressure, typically 2 to 3 ATA) causes an increase in arterial and tissue partial pressure of oxygen and no significant change in arterial pH or partial pressure of carbon dioxide.
- During hyperbaric oxygen therapy, cardiac output and pulmonary vascular resistance are decreased; systemic vascular resistance is increased.
- Acute illnesses for which hyperbaric oxygen is indicated include carbon monoxide (CO) poisoning (based on randomized controlled studies), gas bubble injury (gas embolism and decompression sickness), and soft tissue necrotizing infections.
- The decision to use hyperbaric oxygen to treat a patient with arterial gas embolism or decompression sickness should be based on clinical criteria, including the presence of symptoms, abnormal physical examination, or a history of arterial gas embolism within a few hours even in the absence of symptoms. Neither neurophysiologic testing nor radiographic imaging is useful except, rarely, to exclude other disorders.
- The decision to use hyperbaric oxygen to treat a patient with CO poisoning should be based on clinical criteria, including a history of impaired consciousness or other neurologic manifestation, pregnancy, or severe exposure (e.g., peak carboxyhemoglobin [HbCO] > 25%). The HbCO concentration correlates poorly with the severity of the illness and is generally useful only to make the diagnosis.
- Oxygen-induced seizures are rare and self-limited. Appropriate management includes discontinuation of inhaled oxygen. Chamber pressure should not be altered during the seizure because decompression while a seizure is occurring can result in pulmonary barotrauma (pneumothorax or pneumomediastinum) and arterial gas embolism.
- Pretreatment of patients with hyperbaric oxygen may ameliorate some of the adverse effects of cardiac surgery and invasive cardiac procedures (see also Chapter 67).
- The principles of treatment of acute altitude illness include descent and supplemental oxygen. If these options are not available, for acute mountain sickness or high-altitude cerebral edema, dexamethasone and acetazolamide are recommended. Recommended treatment of high-altitude pulmonary edema includes drugs that decrease pulmonary artery pressure, such as nifedipine, nitric oxide, or a phophodiesterase-5 inhibitor such as sildenafil.
- When providing anesthesia for otherwise healthy acclimatized patients at high altitude, the minimum amount of supplemental oxygen should be used to maintain arterial oxygen saturation close to baseline (not normal levels). Prolonged administration of oxygen in liberal doses may reverse acclimatization.
- As ambient pressure is altered, anesthetic vaporizers (except for desflurane) deliver a variable concentration but fixed partial pressure of vapor. Therefore, vaporizer settings do not need to be adjusted when delivering anesthesia in a hyperbaric chamber or at high altitude. Desflurane vaporizers deliver a fixed concentration and require upward adjustment at high altitude.
- Unexpected complications have occurred after anesthesia for minor procedures in primates following spaceflight. Physiologic and pharmacologic effects of neuraxial or general anesthesia during or after spaceflight are largely unknown, but they could include hypotension, resistance to nondepolarizing muscle relaxants and α-adrenergic agonists, and exaggerated hyperkalemia resulting from succinylcholine (see also Chapter 34).

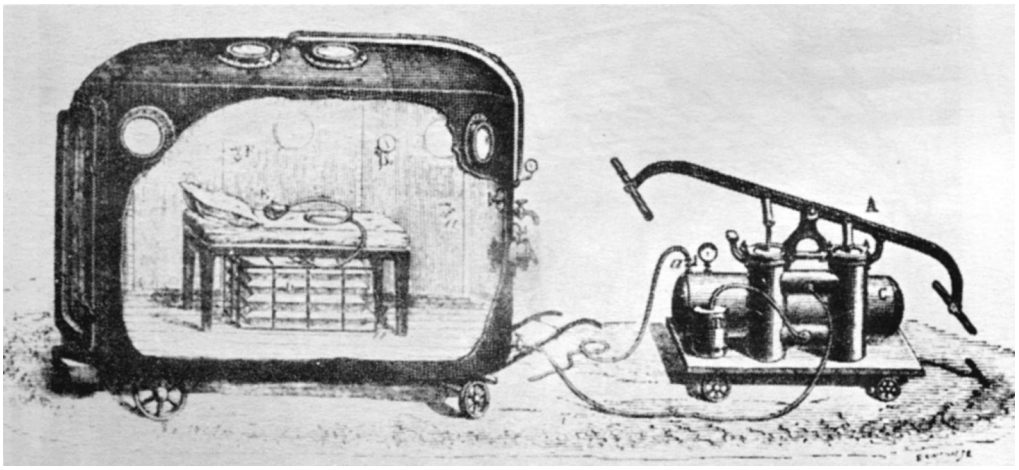

Figure 91-1. Mobile hyperbaric operating room described by Fontaine in 1879.[1] Nitrous oxide storage tanks can be seen under the operating table. Compressed to 1.25 to 1.33 atmospheres absolute with air (ATA), a nitrous oxide–oxygen mixture was provided to the patient. Breathing air in this chamber would have provided an inspired partial pressure of oxygen (PO_2) equivalent to 26% to 28% oxygen at 1 ATA.

Hyperbaric medicine began in the nineteenth century, when clinical improvement was observed after recompression of divers and compressed air workers who had decompression sickness (DCS). Hyperbaric air treatment was subsequently used for a variety of diseases, including tuberculosis, heart failure, emphysema, bronchitis, asthma, croup, whooping cough, anemia, anorexia, dyspepsia, leukorrhea, menorrhagia, neuralgic pain, and depression, without any scientific basis. An exception was the use by Fontaine in 1879 of a mobile hyperbaric chamber for anesthesia and surgery.[1] Compressed to 1.25 to 1.33 atmospheres absolute (ATA), a nitrous oxide–oxygen (O_2) mixture was provided to the patient (Fig. 91-1). Breathing air in Fontaine's chamber would have provided an inspired partial pressure of O_2 (PO_2) equivalent to 26% to 28% O_2 at 1 ATA. This was probably the first use of an increased PO_2 during anesthesia and certainly the first administration of hyperbaric nitrous oxide.

Use of O_2 at high pressure for the treatment of DCS had been suggested.[2] It was reported for the treatment of DCS,[3] but it remained an isolated medical curiosity until the early 1960s. A few indications, such as support of oxygenation in hyaline membrane disease of the newborn[4] and during open heart surgery,[5,6] were not useful. For other indications, such as carbon monoxide (CO) poisoning, arterial gas embolism (AGE), and DCS, hyperbaric O_2 treatment (HBOT) is effective, as evidenced by substantial clinical experience and randomized controlled studies. Indications are reviewed regularly by the Undersea and Hyperbaric Medical Society (headquarters in Durham, NC). This medical organization publishes an extensive bibliography with a list of indications for hyperbaric oxygenation that is updated every 2 to 3 years.[7] Laboratory and clinical data support the use of HBOT for a select number of acute and chronic illnesses (Box 91-1), and anesthesia providers are often called on to provide care of patients in this unusual environment.

Interest in the physiologic and medical aspects of altitude originated because of mountaineering and high-altitude balloon exploits in the nineteenth century.[8] An understanding of the physiologic response to altitude hypoxia has had wide application because increasing

BOX 91-1 ***Conditions for Which Hyperbaric Oxygen Is Effective***

Gas-bubble disease
- *Air embolism[7,83,85]
- *Decompression sickness[83,85]

Poisoning
- *Carbon monoxide[7,41,47-49,54,55]
- Cyanide[41]
- Carbon tetrachloride[323,324]
- Hydrogen sulfide[41]

Infections
- *Clostridial myonecrosis[7,100-103]
- *Other soft tissue necrotizing infections[7,102,103,325,326]
- *Refractory chronic osteomyelitis[7,93,327]
- *Intracranial abscess[7,328]
- Mucormycosis[329,330]

Acute ischemia
- *Crush injury[7,331]
- *Compromised skin flaps[7,332]
- *Central retinal artery occlusion, central retinal vein occlusion[333,334]

Chronic ischemia
- *Radiation necrosis (soft tissue, radiation cystitis, and osteoradionecrosis)[7,335-337]
- *Ischemic ulcers, including diabetic ulcers[7,11,338-342]

Acute hypoxia
- *Exceptional blood loss anemia (when transfusion delayed or unavailable)[7]
- Support of oxygenation during therapeutic lung lavage[104,105]

Thermal injury
- *Burns[7,343-346]

Envenomation
- Brown recluse spider bite[347,348]

Miscellaneous
- *Idiopathic sudden sensorineural hearing loss[349]

* Approved by the Undersea and Hyperbaric Medical Society as an appropriate indication for hyperbaric oxygen treatment.[7]

TABLE 91-1 RANGE OF TERRESTRIAL ALTITUDES

Altitude*		Ambient Pressure		
(ft)	(m)	(ATA)	(mm Hg)	Comments
		0.32	235†	Lowest pressure to which volunteers have been continuously exposed (hypobaric chamber study: Operation Everest)[350,351]
29,028	8,848	0.35	263†	Mt. Everest, Nepal: highest point on earth
20,320	6,194	0.45	345	Mt. McKinley (Denali), Alaska, United States: highest point in North America
19,521	5,950	0.49	372†	Aucanquilcha mine, Chile: highest altitude known to have been continuously inhabited by humans[352]; miners slept in a village at lower altitude ('Quilcha, 5334 m)
17,716	5,400	0.51	384	Everest Base Camp
17,060	5,200	0.54	409	Chacaltaya ski resort, Bolivia (elevation at the top of the ski hill, 5,422 m)
16,733	5,100	0.55	414	La Rinconada, Peru: highest permanently inhabited town
	5,050			Atacama Large Millimeter Array telescope, Chile; facility includes oxygen enrichment to 27%[353]
14,110	4,301	0.58	458	Pike's Peak, Colorado, United States[216]
13,796	4,205	0.60	460†	Mauna Kea, Hawaii, United States
		(0.57-0.63)	(433-479)†	(Keck Observatory)[354]
11,910	3,630	0.65	497	La Paz, Bolivia

10,430	3,179	0.69	525	Leadville, Colorado, United States: highest altitude incorporated city in North America (population 3000)[355]
9,321	2,841	0.67-0.68	507-516†	South Pole Station, Antarctica[356]
9,249	2,819	0.72	549	Quito, Ecuador
7,546	2,300	0.77	583	Mexico City, Mexico
5,280	1,609	0.83	633	Denver, Colorado, United States; Zermatt, Switzerland
4,500	1,372	0.86	650	Banff, Alberta, Canada; Kathmandu, Nepal
0	0	1.00	760	Sea level

ATA, Atmosphere absolute.
*Altitudes and barometric pressures are shown for Mt. Everest and several locations inhabited at least part time. Barometric pressures have been calculated using an algorithm developed by West,[357] except for values with a dagger
†which were obtained by direct measurement.[351]

numbers of people fly in aircraft, travel from low to high altitude, and live or work at higher elevations (Table 91-1). Significant effort has been devoted to techniques for prophylaxis and treatment of these illnesses.

The effects of space travel are mostly the result of microgravity, radiation, and confinement. Understanding these effects and developing tools to deal with sick or injured astronauts are paramount for the medical support of long-range space missions, such as to Mars.

PHYSIOLOGIC EFFECTS OF INCREASED GAS PRESSURE

INCREASED BAROMETRIC PRESSURE

Some effects of altered ambient pressure are summarized in Figure 91-2.

An increase in environmental pressure is accompanied by significant adiabatic heat production, whereas decompression generates cooling. This process results in an increase in chamber temperature during compression and cooling and precipitation of water droplets during decompression. These phenomena may limit the rate of compression in manned chambers to maintain temperature within a comfortable range.

Additionally, pockets of trapped gas within the body contract and expand on compression and decompression. Such pockets include gas in the middle ear and paranasal sinuses, intestinal gas, pneumothorax, and gas pockets within monitoring and life support systems. The changes in gas volume occur according to Boyle's law:

$$PV = \text{constant}$$

such that doubling of environmental pressure (P) causes the volume (V) of a gas-filled cavity to decrease by half. This effect also underlies one of the major beneficial effects of hyperbaric treatment of pathologic gas, as in AGE or DCS (see later).

A comparison of pressure units used clinically with those in common use in hyperbaric environments is shown in Table 91-2.

INCREASED PARTIAL PRESSURE OF OXYGEN

Breathing O_2 at increased ambient pressure leads to elevation of alveolar O_2 tension (PAO_2), which can be calculated according to the alveolar gas equation for O_2:

$$PAO_2 = FiO_2\,(P_b - PH_2O) - Pa_{CO_2} \cdot \left(FiO_2 + \frac{1 - FiO_2}{R}\right)$$

where FiO_2 is the fractional inspired O_2 concentration; P_{H_2O} is saturated water vapor pressure at body temperature (typically 47 mm Hg); P_{ACO_2} is alveolar partial pressure of CO_2 (P_{CO_2}), assumed to equal arterial P_{CO_2} (Pa_{CO_2}); and R is the respiratory exchange ratio (usually ≈0.8 at rest). From calculated values of PAO_2, arterial PO_2 (PaO_2)

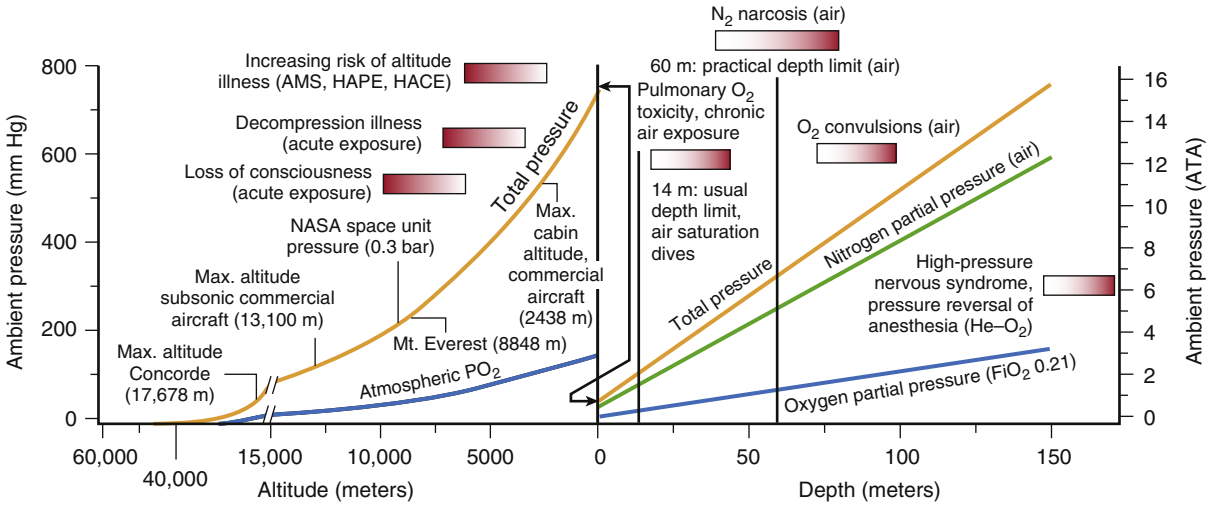

Figure 91-2. Ambient pressure as a function of altitude and water depth. Whereas ambient pressure increases linearly with depth, pressure and altitude are not linearly related. As air is inspired and humidified, a small and usually insignificant drop from atmospheric partial pressure of oxygen (PO_2) to inspired PO_2 occurs. At altitude, however, this decrease accounts for a greater proportion of the total ambient pressure. The PO_2 line in the water is shown for a constant fraction of inspired oxygen concentration (FiO_2) of 21%. At increasing depth, the inspired PO_2 eventually exceeds the pulmonary toxic limit (~14 m in depth) and the central nervous system toxic limit (~70 m in depth). The threshold for high-pressure nervous syndrome and pressure reversal of anesthesia (observed in nonnarcotic atmospheres) is 150 to 200 m in depth. The *shaded red bars* represent the depth or altitude ranges over which risk progresses from low *(light shading)* to high *(dark shading). AMS,* Acute mountain sickness; *HACE,* high-altitude cerebral edema; *HAPE,* high-altitude pulmonary edema; *He,* helium; *Max.,* maximum; N_2, nitrogen; O_2, oxygen.

TABLE 91-2 UNITS OF PRESSURE

Atmospheres Absolute (ATA)	Absolute Pressure (mm Hg)	Gauge Pressure (mm Hg)	Feet of Sea Water (fsw)	Meters of Sea Water (msw)
1	760	0	0	0
2	1,520	760	33	10
3	2,280	1,520	66	20
6	4,560	3,800	165	50

has been estimated, assuming that the arterial-alveolar (a/A) PO_2 ratio remains constant.[9] Whereas at 1 ATA the fraction of O_2 in arterial blood that is carried dissolved in the plasma is minimal, at elevated PaO_2 in the range of 1000 to 2000 mm Hg, significant quantities of O_2 may exist in dissolved form (Table 91-3).

Increased PaO_2 has at least four pharmacologic effects:

1. Increased blood O_2 content
2. Vasoconstriction
3. Antibacterial action, particularly against anaerobic bacteria
4. Inhibition of endothelial neutrophil adhesion in injured tissue

The increased arterial O_2 content underlies the rationale for administering HBOT for the treatment of ischemic conditions (e.g., ischemic nonhealing wounds). The elevation in PaO_2 leads to an increase in tissue PO_2, which can be estimated using transcutaneous PO_2 electrodes, even in ischemic tissue.[10,11] The second effect explains the effectiveness of HBOT in the treatment of traumatic edema (e.g., crush injury). The mechanism of HBOT-induced vasoconstriction appears to be the inactivation of nitric oxide as a result of increased production of superoxide[12] and possibly decreased release of nitric oxide from circulating S-nitrosohemoglobin.[12-14]

These two effects, increased O_2 content and vasoconstriction, lead to hemodynamic changes,[14,15] as shown in Table 91-3. A slight increase in mean arterial blood pressure also occurs. Studies of the effects of HBOT on myocardial contractility using denervated hearts[16] or autonomically blocked animals[17] have indicated no intrinsic effect. In intact animals or humans, heart rate and cardiac output are decreased and systemic vascular resistance is increased.[14,15,18] In both anesthetized dogs and awake humans, pulmonary vascular resistance is decreased.[14,19] At 2 ATA, 100% O_2 in conscious dogs has no effect on coronary flow,[18] whereas at 3 ATA, both coronary flow and myocardial O_2 consumption are decreased.[17] Cerebral blood flow is decreased by O_2 administration over a range of pressures,[12,18] whereas at 2 ATA, hepatic, renal, and mesenteric flows are unchanged.[18]

HBOT also has microcirculatory and cellular effects in various disease states (see later).

INCREASE OF INERT GAS PARTIAL PRESSURE

An increase of the partial pressure of the inert gas (usually nitrogen) present in a breathing mixture is associated with a narcotic-like effect, predictable by the Meyer-Overton hypothesis. Based on its solubility in olive oil, nitrogen

TABLE 91-3 **MEAN BLOOD ACID-BASE AND CARDIOVASCULAR RESPONSES TO ALTITUDE EXPOSURE AND HYPERBARIC OXYGENATION IN 14 NORMAL SUBJECTS**

Data from McMahon TJ, Moon RE, Luschinger BP, et al: Nitric oxide in the human respiratory cycle, Nat Med *8:711-717, 2002.*
ATA, Atmospheres absolute; *O_2,* oxygen; *Pco_2,* partial pressure of carbon dioxide; *PO_2,* partial pressure of oxygen.
*Assuming hemoglobin = 13 g/dL.

has 0.03 to 0.05 times the narcotic potency of nitrous oxide. At 3 ATA (breathing air), most people experience mild euphoria. At 6 ATA, memory loss and poor judgment may appear. At 10 ATA, some individuals lapse into unconsciousness. Nitrogen narcosis looks like alcohol intoxication; an increase in ambient pressure of 1.5 ATA appears to be similar to drinking one martini. Argon and, to a lesser degree, hydrogen, are narcotic-like, whereas helium has minimal if any such effect. In animals exposed to high partial pressures of nitrogen, evidence indicates activation of γ-aminobutyric $acid_A$ ($GABA_A$) receptors of dopaminergic neurons in the nigrostriatal pathway, thus leading to a decrease in dopamine release.[20]

ELEVATION OF ABSOLUTE PRESSURE

High-Pressure Nervous Syndrome

High pressure induces a constellation of symptoms consisting of tremor, ataxia, nausea, and vomiting that is known as the high-pressure nervous syndrome (HPNS).[21] It occurs at an ambient pressure more than 15 to 20 ATA and was first described during the compression phase of deep dives with a helium-O_2 atmosphere. HPNS is ameliorated by slow compression and addition of a narcotic gas (e.g., nitrogen) to the breathing mix.[22] The pathogenesis of HPNS may be related to an increase in striatal dopamine.[23]

Pressure Reversal of Anesthesia

Studies in animals demonstrated that high pressure has the tendency to reverse general anesthesia. Increases in ambient pressure in the absence of a narcotic inert breathing gas tend to decrease the effectiveness of both inhaled and intravenous anesthetic agents. At 50 ATA, a 20% increase in the 50% effective dose (ED_{50}) occurs in mice with a variety of inhaled anesthetic agents. At 50 and 100 ATA, the effective dose of barbiturates increases by 30% to 60%.[24] The ED_{50} for diazepam in rats is markedly reduced at 90 ATA in a helium-O_2 atmosphere.[25] At 31 ATA, the effective concentration for half-maximal effect (EC_{50}) of propofol for loss of righting reflex in tadpoles is increased by 19%, and at 61 ATA, it is increased by 38%.[26] Using the same technique, the EC_{50} for dexmedetomidine at 31 ATA is nearly double the value at 1 ATA, and it is increased 2.5-fold at 61 ATA.[27] At 80 ATA, the minimum alveolar concentration (MAC) of desflurane as assessed by response to a noxious stimulus is increased by 19%.[28] The mechanisms of pressure reversal may be secondary to physical chemical effects of pressure on membranes,[29] or they may be related to alterations in neurotransmitter release.[23] However, within the range of pressures used for HBOT (up to 3 to 6 ATA), the effects of pressure on sedative or anesthetic drugs are not clinically significant.

EFFECTS OF HYPERBARIC EXPOSURE ON DRUG DISPOSITION

A few studies have examined the disposition of drugs and drug effects at increased environmental pressures. Studies in awake dogs at pressures up to 6 ATA and ambient PO_2 up to 2.8 ATA showed that liver plasma flow decreased when either ambient pressure or PO_2 was increased. Plasma volume increased at 1.3 ATA and returned toward 1 ATA values during higher pressures. In the same studies plasma volume was inconsistently affected by ambient pressure, but it was reduced by increases in PO_2.[30]

Hyperbaria has no major pharmacokinetic or pharmacodynamic effect for most drugs up to 6 ATA. Up to 6 ATA pressure and 2.8 ATA PO_2, the pharmacokinetics of meperidine,[31] pentobarbital,[32] theophylline,[33] and salicylate[34] are unaffected.

Benzodiazepines, chlorpromazine, and lithium carbonate were used for the treatment of agitation, auditory and visual illusions, and paranoia in a previously normal subject participating in an experimental dive to 650 m (66 ATA).[35] The symptoms, poorly controlled with diazepam 120 mg/day and temazepam 60 mg/day, ultimately responded to chlorpromazine 300 mg/day. Lithium carbonate administered in conventional doses displayed normal pharmacokinetics. However, chlorpromazine appeared clinically to be appropriate. Whether the failure of benzodiazepines to elicit a desired therapeutic response was caused by the patient's condition or by a pressure-reversal phenomenon is not clear.

In summary, conventional parenteral drug dosing schedules may be followed safely under hyperbaric conditions at the pressures used for clinical treatment of patients with HBOT.

RATIONALE FOR THE TREATMENT OF SELECTED SPECIFIC SYNDROMES

CARBON MONOXIDE POISONING

Hemoglobin (Hb) binds CO with an affinity much higher (by a factor of ≈200) than that for O_2. This binding of CO with Hb to form carboxyhemoglobin (HbCO) has two major effects. First, the proportion of Hb that is occupied by CO molecules is unavailable for O_2 transport, thus resulting in a functional anemia. Second, the avidity with which the remaining Hb binds O_2 is increased (shift to the left of the Hb-O_2 dissociation curve). The results are a decreased ability to unload O_2 from blood to tissue at the capillary and therefore a reduction in tissue PO_2. Previously it was believed that these effects were solely responsible for the toxicity of CO. However, evidence has since been presented to show that the binding of CO to intracellular pigments (e.g., cytochrome a, cytochrome a_3, myoglobin) and oxidative stress may contribute significantly to the toxicity of CO.[36-44] CO exposure also triggers intravascular platelet-neutrophil aggregation and neutrophil activation.[44] These mechanisms result in toxicity to multiple organ systems, including brain and heart.[41,45] Immune-mediated effects have also been described.[46]

Clinical effects include headache, nausea, vomiting, dizziness, myocardial ischemia, loss of consciousness, and, during pregnancy, fetal distress. Persistent or delayed neurologic sequelae can occur, often after a clear window of lucidity.[47,48] Increased risk factors for persistent sequelae include older age (≥36 years) and longer CO exposure.[49]

The diagnosis of CO poisoning is made by a history of exposure (internal combustion engine exhaust, fire,

improperly adjusted gas or oil heating, charcoal or gas grills, or exposure to paint stripper containing methylene chloride, which is metabolized by the liver to CO). The diagnosis is confirmed by finding an elevated HbCO level in either arterial or venous blood. HbCO concentration in anticoagulated blood samples is stable for several days. Therefore, if HbCO determination is not available at a referring facility, the diagnosis can be confirmed using a blood sample obtained at the time of initial evaluation and transported with the patient. Fetal Hb (HbF) can produce a falsely elevated reading for HbCO on certain four-wavelength laboratory co-oximeters.[50] In the first few weeks of life, blood from normal infants may therefore falsely indicate 7% to 8% HbCO.

Actual HbCO levels measured on arrival in the emergency room correlate poorly with clinical status and should not be used as the sole criterion to determine the need for treatment. Because of the lower intracellular PO_2, elimination of CO from intracellular binding sites occurs more slowly. Significant mental obtundation, vomiting, and headache may remain even in patients with a normal HbCO level.

Brain imaging may reveal a variety of abnormalities in patients with CO poisoning, including hypodensities in the globus pallidus and subcortical white matter, cerebral cortical lesions, cerebral edema, hippocampal lesions, loss of gray matter and white matter differentiation, and white matter hyperintensities.[51-53] Except to exclude other pathologic processes, brain imaging is not useful for determining who should receive HBOT, but it may provide prognostic information.[51]

O_2 is the primary treatment modality for CO poisoning. High PaO_2 hastens the removal of CO from blood, as indicated by a reduced half-life of HbCO. Figure 91-3 shows the HbCO half-time in a series of CO-poisoned patients during normobaric O_2 administration; HBOT reduces the half-time even further, to approximately 20 minutes at 2.5 ATA[54] (Table 91-4). Additionally, the increased dissolved O_2 in plasma may support tissue oxygenation pending removal of CO from Hb and other proteins important for O_2 transport. Mounting evidence indicates that for poisoning in which neurologic symptoms occur, HBOT may decrease both early and late morbidity.[55] Although the results of one randomized prospective trial of hyperbaric versus normobaric O_2 revealed no apparent benefit of HBOT,[56] in four other trials HBOT resulted in improved outcome compared with treatment at 1 ATA[47,48,57,58] (Fig. 91-4).

Commonly used guidelines for the application of HBOT in CO poisoning include the following:

A history of neurologic impairment (including dizziness, loss of consciousness)
Evidence of cardiac abnormalities (ischemia, arrhythmias, ventricular failure)
An HbCO level that has been higher than 25%

TABLE 91-4 CARBON MONOXIDE ELIMINATION HALF-TIMES WHILE BREATHING AIR OR 100% OXYGEN AT 1 ATA AND AT 2.5 ATA

Breathing Gas	Mean Half-life (min)*	No. Subjects
Air, 1 ATA	214	10
Oxygen, 1 ATA	43	15
Oxygen, 2.5 ATA	19	10

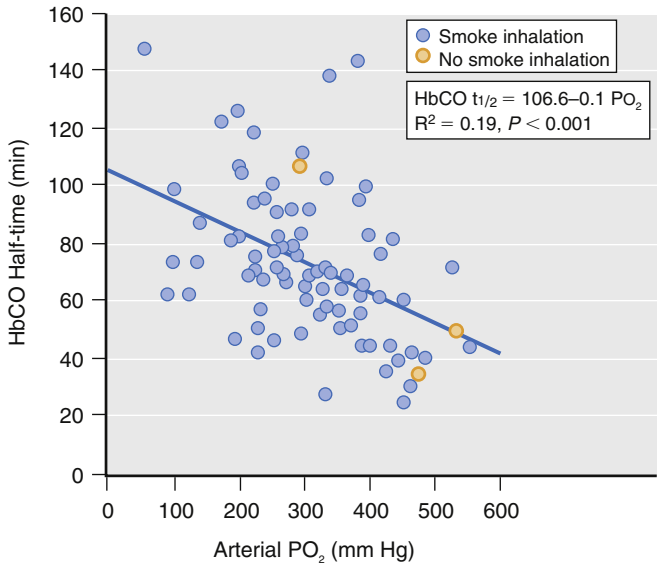

Figure 91-3. Elimination half-time ($t_{½}$) of carboxyhemoglobin (HbCO) in 93 carbon monoxide (CO)-poisoned patients. Although scatter are present in the data, it is apparent that CO dissociates from hemoglobin faster at a higher partial pressure of oxygen (PO_2). *(Redrawn from Weaver LK, Howe S, Hopkins R, Chan KJ: Carboxyhemoglobin half-life in carbon monoxide–poisoned patients treated with 100% oxygen at atmospheric pressure,* Chest *117: 801-808, 2000.)*

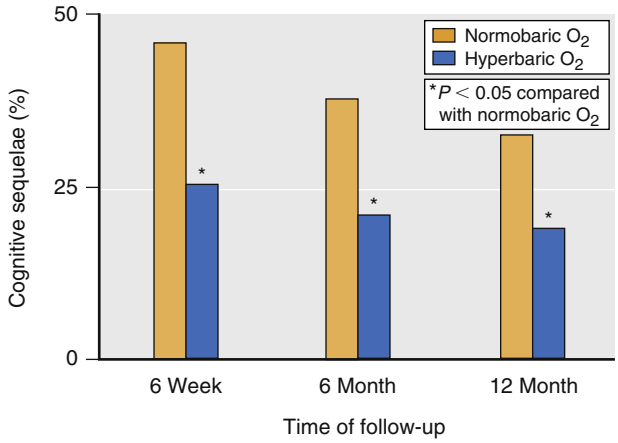

Figure 91-4. Cognitive sequelae in a randomized prospective trial of hyperbaric oxygen (O_2) in carbon monoxide poisoning. Cognitive sequelae were defined as any T score for a neuropsychological subtest more than 2 standard deviations (SD) below the mean of demographically corrected standardized T scores or if two or more T scores for subtests were more than 1 SD below the mean. If the patient reported difficulties with memory, attention, or concentration, then cognitive sequelae were defined as a T score on any neuropsychological subtest more than 1 SD below the mean of demographically corrected standardized T scores. *(Drawn from data reported by Weaver LK, Hopkins RO, Chan KJ, et al: Hyperbaric oxygen for acute carbon monoxide poisoning,* N Engl J Med *347:1057-1067, 2002.)*

Fetuses are particularly susceptible to CO toxicity. Pregnant women who fulfill the criteria just listed or in whom fetal distress is noted should be treated with HBOT. Case reports,[59-61] published series,[62,63] and a critical review[64] support the concept that inadequately treated CO poisoning is a serious risk to the mother and fetus, and the benefits of HBOT outweigh the theoretic risks to the fetus from HBOT. Potential adverse effects of currently implemented HBOT protocols have not been confirmed in clinical practice.

GAS EMBOLISM AND DECOMPRESSION SICKNESS

Introduction of gas into the arterial circulation (AGE) has traditionally been associated with scuba divers and attributed to pulmonary barotrauma during ascent from a dive while breathing compressed gas. However, it may also occur iatrogenically in several clinical circumstances, such as during cardiopulmonary bypass or as a result of inadvertent injection of air during a diagnostic arteriogram or hemodialysis (see also Chapters 67 and 90). Additionally, large amounts of gas may enter the venous system, for example during neurosurgical procedures (see also Chapters 49 and 70) with the patient in the sitting position, hemodialysis, major back surgery, total hip replacement, cesarean section, laparoscopy, intrauterine laser surgery, arthroscopy (from air escaping from faulty air-powered drill), and hydrogen peroxide irrigation or oral ingestion (from elaboration of gaseous O_2 from tissue and blood catalase). Venous gas embolism (VGE) can also occur when a central venous catheter is opened to air. Severe VGE has also occurred during orogenital sex after blowing air intravaginally.[65] VGE can occur in patients with adult respiratory distress syndrome (ARDS) who are being ventilated with positive end-expiratory pressure.[66] VGE in sufficient quantity may overwhelm the ability of the pulmonary vasculature to filter the gas, thus allowing bubbles to pass into the arterial circulation. Even small amounts of venous gas (e.g., VGE caused by decompression from diving) have been implicated in neurologic syndromes in scuba divers because of transatrial passage through a patent foramen ovale.[67,68]

The effects of gas embolism are not solely the result of vessel obstruction by bubbles. Bubble-endothelial interaction causes increased capillary permeability and extravasation of fluid,[69,70] as well as impairment of endothelial function.[71] Another effect was demonstrated in a model of AGE in anesthetized rabbits[72,73]: Small doses of intracarotid air may pass through the cerebral microcirculation yet produce vasoplegia, delayed reduction of cerebral blood flow, and neurophysiologic impairment. Because this reduction in blood flow is abolished in neutropenia, leukocytes are likely required for this effect.[74] This phenomenon of delayed reduction of cerebral blood flow may be responsible for the clinical observation of initial neurologic improvement after AGE, followed by delayed deterioration.[75]

A related syndrome that results from pathologic effects of tissue and blood gas bubbles is DCS, seen in aviators and compressed gas divers. The gas bubbles in these situations occur because of a decrease in ambient pressure at a rate sufficient to induce local inert gas supersaturation, with resulting formation of bubbles in situ from tissue stores. Symptoms of AGE classically consist of impaired consciousness, hemiparesis, or seizures, but they may be less severe. DCS most commonly manifests as any combination of joint pain, paresthesias, motor weakness, bladder or bowel sphincter dysfunction, vertigo, tinnitus, and hearing loss.[76,77]

Treatment principles for both forms of gas bubble disease, AGE and DCS, are the same in most instances. First aid includes therapy with O_2.[78] High PO_2 results in an increased rate of resolution of gas bubbles because of the resulting higher partial pressure gradient for diffusion of inert gas from the interior of the bubble into the surrounding tissue or blood. Intravascular bubbles cause endothelial leak, extravasation of plasma, and hemoconcentration.[69,79] Intravascular fluid resuscitation replenishes intravascular volume, reduces hemoconcentration, and facilitates microcirculatory flow,[80] actions that have been confirmed by both animal[81] and human observations.[69] However, excessive intravascular fluid administration can worsen pulmonary gas exchange in cardiorespiratory DCS (pulmonary edema from VGE), and aggressive fluid therapy is not indicated for isolated AGE.[80] Although capillary leak resulting from cerebral AGE can raise intracranial pressure (ICP), studies in anesthetized pigs showed that hyperventilation offers no benefit.[82]

HBOT is the definitive treatment for AGE and DCS.[83] The increased pressure causes a diminution in gas volume and thus further hastens resolution. The usefulness of HBOT for diving-related or aerospace-related gas embolism associated with rapid decompression is well documented.[84,85] HBOT may effect neurologic improvement even after many hours and sometimes days between the embolic event and treatment,[86-88] although some evidence suggests that severe abnormalities are less likely to resolve if not treated promptly.[89] Treatment of AGE is usually performed at ambient pressures from 2.8 to 6 ATA (see the later section on treatment schedules).

The decision to administer recompression treatment should be based entirely on clinical evaluation.[83] The only appropriate role of brain or spinal imaging (e.g., computed tomography [CT], magnetic resonance imaging [MRI]) is to exclude other pathologic processes such as hemorrhage, and only with a high degree of suspicion that bubbles are not the cause of a patient's symptoms. Patients with AGE should be treated with HBOT only if CT of the brain reveals air.[90] However, brain imaging of patients with AGE or DCS reveals abnormalities in only a minority of cases,[88,89] and the abnormalities on either CT or MRI are usually not specific. Neither the presence nor the absence of intravascular gas predicts response to hyperbaric treatment.[88,89] Nuclear imaging of the brain using single photon emission tomography (SPECT) or positron emission tomography (PET)[91] does not provide clinically useful information in the management of patients with bubble-induced neurologic injury.

ACUTE INFECTIONS

Anaerobic bacteria are especially sensitive to increased tissue PO_2. High O_2 tensions inhibit clostridial α-toxin

production.[92] Other mechanisms include reversal of hypoxia-induced neutrophil function,[93-95] enhanced macrophage interleukin-10 expression,[96] and antiinflammatory effects.[97-99] Evidence in favor of the use of HBOT in clostridial and nonclostridial infections is provided by clinical series and database analyses.[100-103]

SUPPORT OF ARTERIAL OXYGENATION

HBOT is a safe and effective method of supporting arterial oxygenation during therapeutic lung lavage, during which oxygenation must be maintained by the contralateral (nonlavaged) lung.[104,105] In our experience of more than 100 procedures, using this technique to treat arterial oxygenation has been uniformly successful with no resulting complications. A reversible simulation of pulmonary gas exchange during the lavage procedure can be provided by temporarily ventilating the lung to be lavaged with 5% to 6% O_2/balance nitrogen, which reduces PAO_2 in that lung to approximately the level of mixed venous PO_2 and confining O_2 exchange to the contralateral lung. Hypoxemia within 5 minutes predicts hypoxemia during the actual lavage.

MAINTENANCE OF OXYGEN TRANSPORT IN SEVERE ANEMIA

The ability of HBOT to increase arterial O_2 content in plasma to clinically useful levels may allow support of tissue O_2 delivery even without Hb. HBOT can therefore be used for temporary support of severely anemic patients pending availability of definitive therapy in the form of crossmatched blood (see also Chapter 61).

FUTURE DIRECTIONS

PREOPERATIVE HYPERBARIC OXYGENATION

Preconditioning is described as the application of an insult to activate endogenous protective mechanisms to lessen the morphologic and functional sequelae of a subsequent insult. *Ischemic preconditioning* is the application of a brief period of ischemia that activates endogenous protective mechanisms to reduce the damage from subsequent ischemic insults. Ischemic preconditioning was first described in canine myocardium and subsequently was shown also to exist in the brain. Since then, intense research in the field of pharmacology has ensued to identify other agents that lead to preconditioning, such as volatile anesthetics, lipopolysaccharide exposure, heat, central nervous system (CNS) seizures, hypoxia and hyperoxia, and, more recently, hyperbaric hyperoxia.

Several clinical trials have provided evidence that HBOT before cardiac or surgical procedures can improve outcome. Sharifi and associates described the use of HBOT to inhibit restenosis after percutaneous coronary intervention in acute myocardial infarction.[106] In 2005, Alex and associates observed that repetitive pretreatment with three sessions of HBOT at 2.4 ATA before on-pump coronary artery bypass graft (CABG) surgery reduced neuropsychometric dysfunction and modulated favorably the inflammatory response after cardiopulmonary bypass.[107] Yogaratnam and associates reported that preconditioning with a single session of HBOT at 2.5 ATA before on-pump CABG surgery improved left ventricular stroke work after CABG surgery while reducing intraoperative blood loss, intensive care unit (ICU) length of stay, and postoperative complications.[108] In patients undergoing on-pump and off-pump CABG, Li and associates demonstrated that HBOT preconditioning decreased the release of cerebral and myocardial biochemical markers. Patients in the on-pump group pretreated with HBOT had a reduced length of ICU stay and decreased use of inotropic drugs.[109]

The mechanism by which HBOT can be protective is not currently known, but it does not involve support of metabolism by increased tissue O_2 stores because tissue and blood oxygenation is dissipated within minutes after hyperbaric exposure. The etiology of cerebral injuries is probably multifactorial, including cerebral microemboli, global cerebral hypoperfusion, inflammation, cerebral temperature modulation, and genetic susceptibility.[110] The mechanism of protection therefore may include HBOT-induced oxidative stress resulting from increased reactive oxygen species generation, which could induce ischemic tolerance similar to ischemia and reperfusion. Alternatively, HBOT preconditioning may diminish ischemia-reperfusion damage by decreasing tissue leukocyte recruitment and activation, reducing tissue edema, protecting from cellular necrosis, reducing tissue apoptosis, and improving tissue outcome and preservation.[111,112] Another possible mechanism is upregulation of antioxidant enzymes, such as superoxide dismutase,[113] and possibly also heme oxygenase-1, as shown in a model of liver ischemia.[114] HBOT may be beneficial when administered before or after selected procedures. The role of HBOT in this setting needs to be determined by larger clinical trials.

STROKE

Several studies of middle cerebral artery occlusion in rats demonstrated beneficial effects of HBOT.[115-118] In an unselected case series of patients with acute stroke treated within 5 hours of symptom onset, some patients improved with HBOT in which arterial PO_2 was 1100 to 1300 mm Hg.[119] Several clinical studies have been conducted, with mixed results,[120] perhaps because of failure to start HBOT in a timely fashion[121] or to use of subtherapeutic PO_2. One double-blind study described improved outcome when HBOT was administered after acute stroke, a finding suggesting some effect on neuroplasticity.[122]

THERAPEUTIC SYSTEMS

The traditional method of administering hyperbaric therapy is with a multiplace chamber, which accommodates two or more persons (Fig. 91-5). Size may vary from a small, portable 2-person chamber used for transporting patients in the field to a chamber 20 ft or more in diameter in which 12 or more patients may be comfortably admitted, in addition to tenders. Multiplace chambers are compressed with

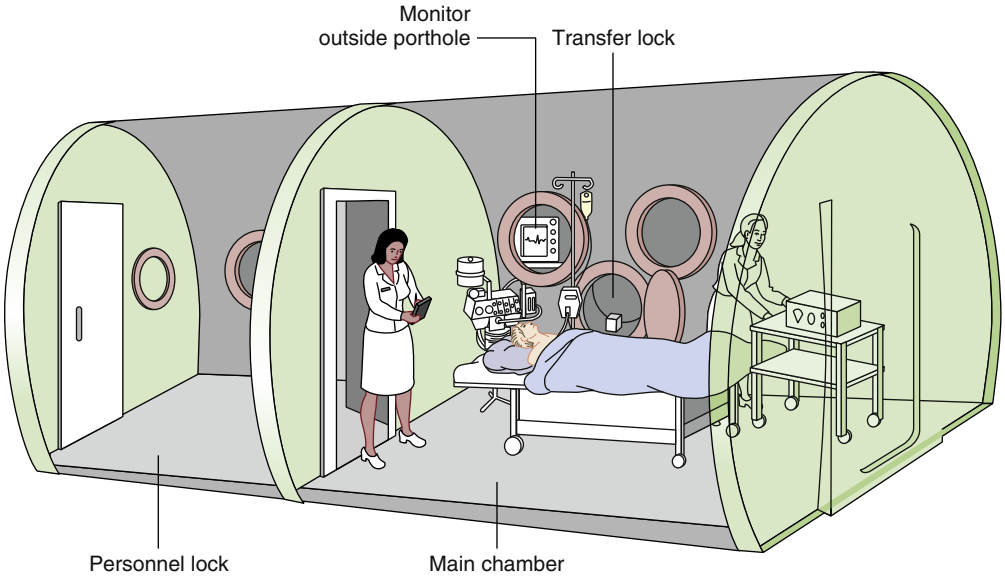

Figure 91-5. Multiplace hyperbaric chamber large enough for one or more patients and tenders. The chamber atmosphere is compressed air. The patient receives 100% oxygen by mask, head tent, or endotracheal tube. Monitors are usually kept outside the chamber because of electrical safety considerations. Monitoring is possible through a porthole. A personnel lock and a transfer lock allow physicians, nurses, or other personnel, in addition to medications, food, and blood samples, to be moved into and out of the chamber without repeated compression and decompression of the patient.

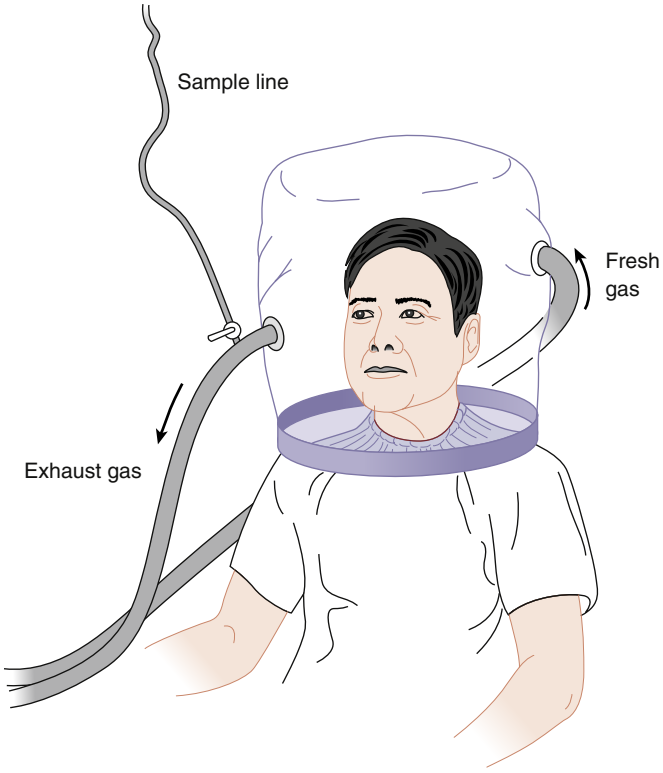

Figure 91-6. Head tent circuit for use in a multiplace chamber. Fresh gas (100% oxygen) flows at a constant rate (>30 L/minute) through the head tent. Exhaust gas may be either vented outside the chamber or recirculated through a carbon dioxide scrubber. The sample line attached to the exhaust hose allows monitoring of the patient's breathing gas.

air while the patient breathes O_2 with a head tent (Fig. 91-6), face mask, or endotracheal tube. Because of immediate access to the patient by accompanying nursing personnel or physicians, monitoring and resuscitative procedures are straightforward. However, multiplace chambers take up a lot of space and are expensive.

Figure 91-7. Monoplace chamber. This type of chamber has room for one patient or a tender with a small child. The patient is moved into and out of the chamber on a wheeled gurney. The chamber atmosphere is usually 100% oxygen. The chamber is constructed of transparent Plexiglas to allow observation. Through-hull penetrators in the door on the left can be seen and allow monitoring, intravenous fluid administration, and control of a ventilator inside the chamber. *(Photograph courtesy Dr. Lindell Weaver).*

Monoplace chambers are large enough to accommodate only one patient (Fig. 91-7), or a tender with a small child. The chamber wall in most types is manufactured of Plexiglas, thus facilitating close visual observation of the patient. The chamber is usually compressed with 100% O_2. The advantage of monoplace chambers is their relatively low cost and ease of installation. Chamber operation can often be implemented by connecting the O_2 inlet to the hospital supply. Operation is relatively simple, but the patient inside is not directly accessible. Monitoring is more remote, and emergency airway management is not possible. Development of pneumothorax during treatment, particularly tension pneumothorax,

can be fatal because pleural decompression with a needle or chest tube cannot be performed before decompression; however, this complication is extremely rare. A minor disadvantage of these chambers is that the ambient pressure limit is 3 ATA, and for practical reasons (psychological aversion to confinement), treatment times are limited. Moreover, intermittent periods of air breathing, to decrease the risk of O_2 toxicity during some types of treatment schedules (see later), require installation of an additional gas delivery system. Nevertheless, monoplace technology now permits intravenous fluid administration from outside the chamber, invasive intravascular monitoring, mechanical ventilation, and utilization of pleural drainage systems incorporating regulated suction.[123,124]

HYPERBARIC TREATMENT SCHEDULES

Ideally, a patient who has therapeutic indication for HBOT would be exposed for an unlimited time until the condition resolves. Unfortunately, several factors limit the dose and duration of HBOT:

O_2 toxicity
Decompression obligation for nursing staff (or other tenders) accompanying the patient
Adequacy of monitoring
Patient isolation and boredom in a confined environment

Treatment schedules are compromises between O_2 partial pressure and exposure time on one hand and O_2 toxicity and the other practical limiting factors on the other. The original schedules (or "tables") were developed by the various navies of the world to treat DCS and gas embolism in divers (Fig. 91-8).

U.S. Navy Table 6 prescribes an initial exposure to 2.8 ATA (equivalent to 60 ft of sea water [fsw], or 18 m of sea water [msw]), followed by slow decompression to 1.9 ATA (30 fsw) (Box 91-2; see Fig. 91-8). Periods of O_2 breathing are interspersed with 5- or 15-minute periods of air breathing to decrease O_2 toxicity (see later). This schedule remains the mainstay of treatment for DCS in multiplace chambers throughout the world. Incomplete relief of signs or symptoms can be treated with repeated applications of the U.S. Navy Table 6 protocol or a shorter treatment once or twice daily.

"Saturation" treatment consists of an extended exposure to increased pressure (e.g., 2.8 ATA) for an unspecified period of time (often 1 to 2 days) until manifestations have stabilized. Periodic O_2 breathing is given according to a recommended schedule as tolerated. Because saturation treatment results in a much larger degree of nitrogen uptake in both the patient and the tender, decompression must occur much more slowly, usually over 24 to 36 hours.[125] Although this therapy avoids the theoretic disadvantage of intermittent treatment—failure of resolution of gas bubbles—it is also considerably more labor intensive. Because hyperbaric chambers used for saturation treatments require additional hardware (e.g., CO_2 scrubbing capability) and personnel, their application outside military and commercial diving has been limited.

A schedule used for treatment of patients with clostridial myonecrosis or other life-threatening anaerobic

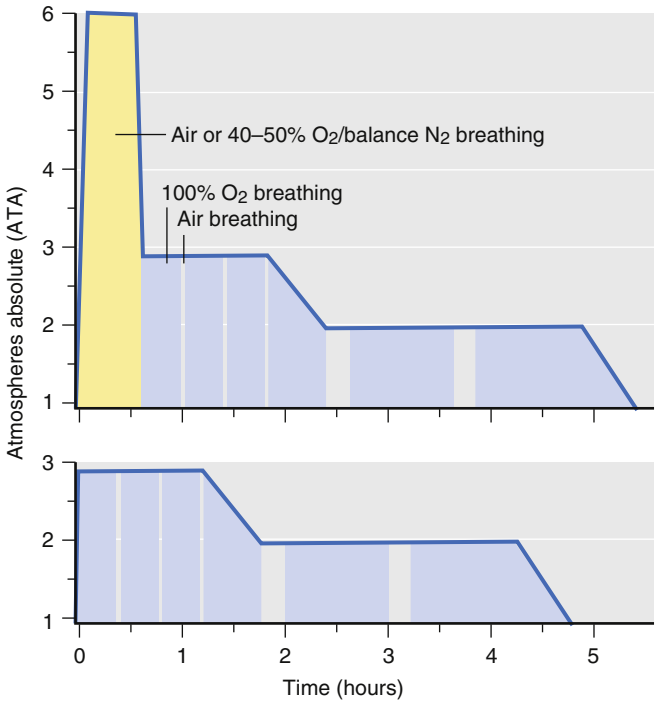

Figure 91-8. U.S. Navy treatment tables. **Top,** U.S. Navy Table 6a. This schedule is occasionally used for the treatment of arterial gas embolism. During the 30-minute period at 6 ATA, air or 40% to 50% oxygen (O_2) can be administered. **Bottom,** U.S. Navy Table 6. This table was originally designed for the treatment of decompression sickness, but it is now the most commonly used table for gas embolism as well. The *shaded areas* represent 100% O_2 breathing; the *white areas* represent air breathing periods (see Fig. 91-10). Further details can be found in the *U.S. Navy Diving Manual.* N_2, Nitrogen. *(From U.S. Navy Department:* U.S. Navy diving manual, *rev 6, vol 5: Diving medicine and recompression chamber operations, NAVSEA 0910-LP-106-0957, Washington, DC, 2008, Naval Sea Systems Command.)*

BOX 91-2 *Duke Modifications of the U.S. Navy Tables*

Standard air decompression
- Within 2 ft of standard Navy depth divisions, use the next greatest depth.
- Within 2 min of standard Navy time divisions, use the next greatest time.
- During decompression of the chamber after a compressed air dive, breathe 100% O_2 from an equivalent depth of 50 fsw (2.5 ATA) to the surface or for 15 min, whichever is shorter.
- Time for decompression
- 68-30 fsw (3.06-1.9 ATA): 3 min
- 30-20 fsw (1.9-1.6 ATA): 1 min
- 20-10 fsw (1.6-1.3 ATA): 1 min
- 10 fsw (or last stop) —"surface" (1.3-1.0 ATA): 5 min

Table 6 or 6A
- When U.S.N. Tables 6 and 6A are extended, the tender should breathe 100% O_2 for the last 30-90 min at 30 fsw (1.9 ATA) according to the number of extensions at 60 fsw (2.8 ATA): 30 minutes (no extensions), 60 minutes (1 extension), 90 minutes (2 extensions). 100% O_2 is breathed by the tender for the entire period of decompression from 30 fsw (1.9 ATA) to "surface" (1 ATA).

infections is shown in Figure 91-9. This schedule consists of 85 minutes at 3 ATA followed by a 33-minute decompression stop for the tenders at 1.3 ATA. This treatment schedule has been designed to maximize PaO_2 (and hence tissue bactericidal activity resulting from O_2) without an undue risk of hyperoxic seizures.

Treatment schedules for CO poisoning have varied. However, the proven efficacy of the schedule reported by Weaver (60 minutes at 3 ATA, 60 minutes at 2 ATA in addition to air breaks and compression-decompression time) supports the use of 3 ATA for at least the first treatment.[48]

Administration of HBOT to patients with chronic diseases (e.g., radionecrosis) is usually performed using shorter treatment tables at lower ambient pressure, most commonly 1 to 2 hours at 2.0 to 2.5 ATA (see Fig. 91-9) once or twice daily. At this lower ambient pressure, the risk of O_2 toxicity is minimal and treatments are well tolerated by most patients.

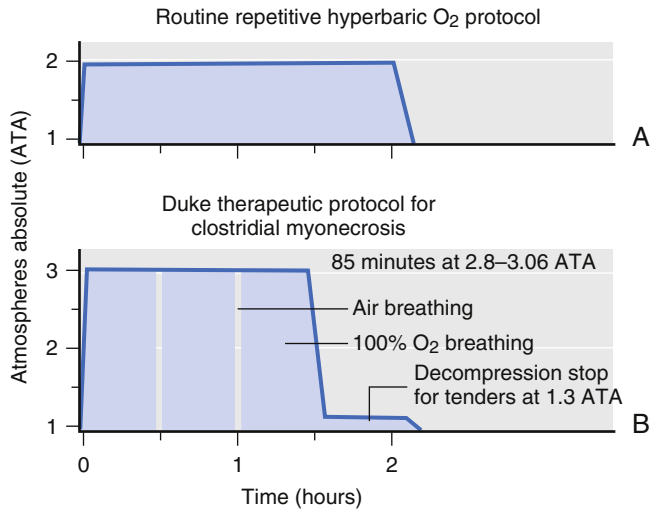

Figure 91-9. Examples of clinical hyperbaric oxygen (O_2) treatment schedules. **A,** The patient breathes 100% O_2 for 2 hours at an ambient pressure of 2 ATA. Generally, this schedule is used for repetitive treatment of chronic conditions (e.g., osteoradionecrosis). **B,** Therapeutic schedule often used for treatment of clostridial myonecrosis. The patient and tender spend 85 minutes at 2.8 to 3.06 ATA (3 ATA shown). The patient breathes 100% O_2, except during two 5-minute air breaks to reduce pulmonary and central nervous system O_2 toxicity. A decompression stop is made at 1.3 ATA, according to the U.S. Navy standard air decompression table. The stop is designed to facilitate safe decompression of the tender, who breathes air at 3 ATA.

SIDE EFFECTS OF HYPERBARIC THERAPY

OXYGEN TOXICITY

A wide body of evidence supports the notion that O_2 toxicity is caused by excessive production of oxygen free radicals (e.g., superoxide, hydroxyl radicals, and singlet oxygen). At high O_2 partial pressures, scavenging mechanisms can be overcome by increased rates of free radical production.[126] With the use of supplemental O_2 at 1 ATA, the manifestations of O_2 toxicity are almost exclusively confined to the lung; however, during hyperbaric O_2 exposure, other organs can be affected as well.

O_2 toxicity during HBOT can affect mainly the lung, the CNS, and the eye. Pulmonary toxicity in the conscious patient is heralded by symptoms of tracheobronchial irritation, namely, cough and burning chest pain. Prolonged exposure may result in a decrease in vital capacity and, if O_2 administration continues, ARDS. In the rare instances in which prolonged HBOT is indicated, the rate of development of pulmonary O_2 toxicity can be slowed by intermittent air-breathing periods ("air breaks") (Fig. 91-10).

O_2 toxicity is related to the PO_2 of the inspired gas. At 1 ATA, 100% O_2 is as toxic as 16.7% O_2 at 6 ATA or 2%

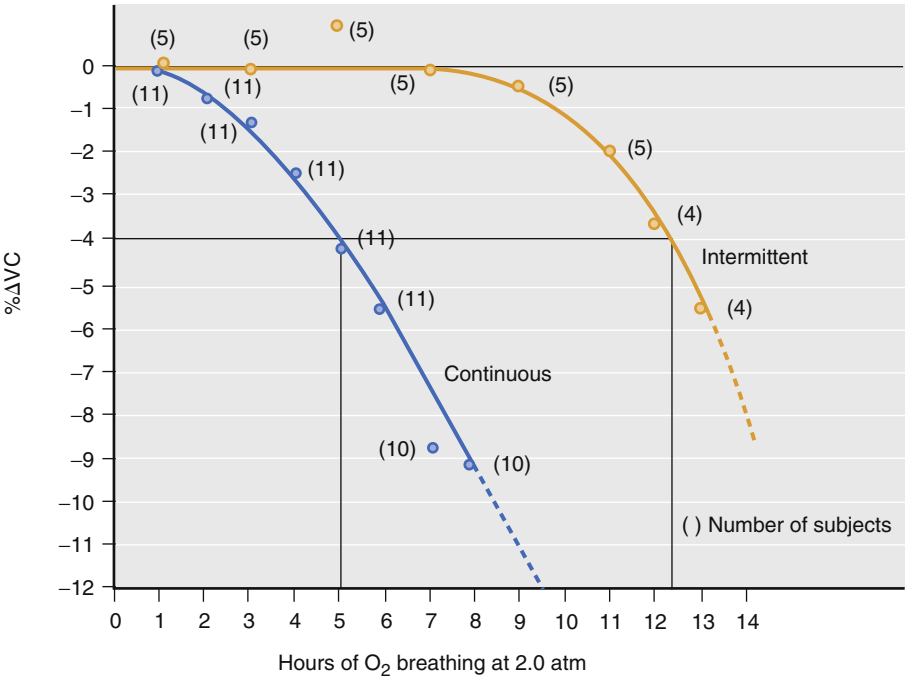

Figure 91-10. Decrease in vital capacity (VC) as a function of time breathing 100% oxygen (O_2) at 2 ATA in humans. The figure illustrates the value of intermittent O_2 (20 minutes O_2, 5 minutes air) versus continuous O_2 administration in the prevention of pulmonary O_2 toxicity. The numbers in parentheses represent the number of subjects tested. *(From Clark JM: Oxygen toxicity. In Bennett PB, Elliott DH, editors:* The physiology and medicine of diving, *Philadelphia, 1993, Saunders, pp 121-169.)*

O_2 at 50 ATA. One method of quantification of O_2 exposure is the unit pulmonary toxic dose, or UPTD.[127] In this system, the number of UPTD units is calculated by the following formula:

$$U = t \cdot \sqrt[m]{0.5/(P - 0.5)}$$

where U is the unit; t is the exposure time in minutes; P is the inspired PO_2 in ATA, and m is a slope constant that has an empiric value of 1.2. After 1425 UPTD units of O_2 exposure, an average 10% decrease in vital capacity occurs. After 2190 UPTD units, an associated decrease of 20% occurs. Complete reversal of vital capacity decrements as large as 40% of control has been observed after extended O_2 exposure at 2 ATA.[127]

Reanalysis of a larger data set than the one used for the UPTD model, which included those data, resulted in a different prediction equation:

$$\%\Delta VC = -0.009 \cdot (P - 0.38) \cdot t$$

where P and t are the same as for the previous equation.[128]

Using previously published data, Arieli and colleagues developed the following equation[129]:

$$\%\Delta VC = 0.0082 \cdot t^2 (PO_2/101.3)^{4.57}$$

where t is time in hours, and PO_2 is measured in kilopascals (kPa).

Although these algorithms may be useful as an approximate guide to safe O_2 exposures in populations, interindividual variability is such that they cannot be relied on to predict the development of pulmonary O_2 toxicity accurately for a specific patient.[130] Furthermore, O_2 toxicity can be modified by humidity,[131] circulating catecholamine and corticosteroid levels, leukocyte accumulation in the lungs (e.g., with pneumonia), and circulating endotoxin. A more useful guide to the development of pulmonary toxicity is the patient's symptoms, which include cough and inspiratory central burning chest pain. These symptoms do not occur during routine repetitive HBOT, but they may become evident during extensive O_2 periods at 2.8 ATA (e.g., when treating neurologic DCS). Asymptomatic persons usually have minimal or no change in vital capacity. Minor changes in forced expiratory volume in 1 second (FEV_1) reported during repetitive HBOT[132] are of uncertain clinical importance.

Some antineoplastic agents, such as bleomycin[133] and mitomycin C,[134,135] appear to predispose to fatal pulmonary O_2 toxicity (ARDS and respiratory failure) from what should otherwise have been well-tolerated doses of supplemental O_2. The risk of pulmonary O_2 toxicity from HBOT in patients with previous exposure to such agents is unknown, although we have treated several such individuals with a remote history of bleomycin treatment with repetitive doses of HBOT at 2 ATA for 2 hours (initially once daily, then increased to twice daily).[136] Occasional mild pulmonary O_2 toxicity symptoms such as retrosternal chest tightness did occur, but none of these patients experienced severe O_2 toxicity. Propensity to pulmonary O_2 toxicity engendered by these drugs appears to diminish a few weeks after their discontinuation.

CNS O_2 toxicity manifests as follows: nausea; vomiting; numbness; twitching; dizziness; olfactory, acoustic, or gustatory sensations; and, in its most severe form, nonfocal tonic-clonic seizures.[137,138] The probability of seizures increases with increasing PO_2 and time of exposure. In a study of 36 divers breathing 100% O_2 at 3.7 ATA, all experienced one or more of these symptoms within 100 minutes or less.[137,138] In clinical practice, convulsions in patients undergoing HBOT are rare at ambient PO_2 up to 2.5 ATA (typically 0.008% to 0.035% of treatments[139]), and the patients often have another predisposing factor (often hypoglycemia). The probability of a convulsion is also greater when O_2 is administered for acute indications such as CO poisoning.[140] Metabolic factors may reduce the seizure threshold, such as the administration of high-dose penicillin (e.g., for clostridial infection), sepsis, and hypoglycemia.

The treatment of hyperoxic seizures is immediate reduction of the inspired PO_2 until the seizure stops. Some physicians then routinely administer an anticonvulsant such as phenobarbital, phenytoin, or a benzodiazepine. It is generally recommended that the chamber should not be decompressed while the patient is actively convulsing because airway closure and failure to exhale during this period may cause pulmonary barotrauma. Hyperoxic seizures otherwise have no sequelae and rarely recur even if HBOT is continued. Thus, the occurrence of CNS O_2 toxicity should not preclude further HBOT. No evidence indicates that hyperoxic seizures are more common in patients with preexisting seizure disorders.

An acute effect of HBOT on the eye is narrowing of the visual fields,[141] which is generally observed only at a PO_2 of 3 ATA or greater and thus rarely, if ever, during routine HBOTs. A subacute or chronic ocular effect is a change in the refractive index of the lens that results in myopia.[142,143] Such refractive index change occurs during the course of intermittent HBOT over several weeks and usually resolves in a similar period of time. However, some patients may be left with residual myopia, particularly older patients.[144]

The risk of retrolental fibroplasia in the unborn child of a woman who may require acute HBOT during pregnancy could be a concern. Although many pregnant women have been treated with single exposures to HBOT (e.g., for CO poisoning), we are not aware of any subsequent occurrence of retrolental fibroplasia in the child. Pregnancy is not a contraindication to HBOT for appropriate acute indications (e.g., CO poisoning[60,62,64,145,146]) because the risk to the fetus of the underlying condition exceeds that of the treatment.

INERT GAS UPTAKE

Breathing air at high ambient pressure can result in nitrogen narcosis, a dose-dependent decrement in cerebral performance secondary to the anesthetic properties of nitrogen. This mostly occurs at ambient pressures exceeding 4 ATA, a treatment pressure that is used only for severe AGE or DCS. Nitrogen uptake can also theoretically result in DCS during or after decompression (see earlier). However, chamber decompression schedules are so conservative that this rarely occurs (most hyperbaric

facilities use U.S. Navy compressed air decompression tables[147]). Additional safety can be provided by requiring the patient to breathe 100% O_2 for a period immediately before and during decompression (Table 91-5). Rare episodes of DCS in hyperbaric tenders are usually minor, generally consisting of mild joint pain. Nitrogen narcosis and DCS could occur only in tenders in a multiplace hyperbaric chamber; patients breathe 100% O_2 and are therefore not susceptible.

BAROTRAUMA

As the ambient pressure is altered, the pressure within gas-containing spaces in the body must equilibrate with the ambient pressure or undergo a change in volume. Volume change can easily occur in compliant compartments such as the gastrointestinal tract, but if the free flow of gas into and out of containing spaces surrounded by a rigid shell (e.g., the lung, paranasal sinuses, and middle ear) is impeded, then tissue disruption and hemorrhage can occur. Indeed, the most common side effect of hyperbaric chamber use for patients is difficulty with middle ear pressure equilibration.[148] In awake patients, equilibration may be accomplished using several techniques, such as performing intermittent Valsalva maneuvers, swallowing while the nose is pinched, thrusting the jaw forward, or simply swallowing intermittently during compression. Patients with prior irradiation of the head and neck and acute respiratory tract infections are at particular risk. Equilibration may be facilitated by application of a topical nasal vasoconstrictor (e.g., oxymetazoline 0.05%, [Afrin]). For patients who cannot equalize despite these measures or for obtunded or tracheally intubated patients, myringotomy or tympanostomy tubes may be required. Theoretically, HBOT hyperbaric exposure in a patient with obstructed eustachian tubes could cause labyrinthine window rupture, but this complication has not been reported during HBOT.

Pulmonary barotrauma is most likely during decompression. Areas of regional hypoventilation could lead to pulmonary overpressurization and alveolar rupture, causing pneumothorax, pneumomediastinum, or AGE.[149,150] Pulmonary barotrauma during HBOT is extremely rare, probably because of the slow decompression rates typically used.

Although pneumothorax should diminish in size and resorb more quickly after compression, continuing leakage of air from the lung could result in tension pneumothorax during decompression.[149] Pneumothorax detected before HBOT is usually treated by insertion of a chest tube and water seal or Heimlich-type valve (in this instance, before monoplace chamber treatment, a chest tube should *always* be inserted) (see Chapters 66 and 81). Caution must be exercised when using certain commercially available pleural suction regulators, which can exert high negative pleural pressures during chamber compression.[151] Such excessive suction can be relieved by an attendant inside a multiplace chamber by activating the manual pressure relief valve on the chest drainage unit.

Despite these potential adverse effects of HBOT, major complications are extremely rare.[148]

PRACTICAL ASPECTS OF HYPERBARIC THERAPY

PATIENT MONITORING

Despite the changes in the acoustic properties of compressed air, blood pressure measurement may be performed without difficulty with a standard sphygmomanometer and stethoscope (see also Chapter 44). Aneroid pressure gauges are preferred to mercury to avoid contamination of the closed environment. Monitoring of the electrocardiogram and of intravascular pressures requires that transducer cables be plumbed through the chamber wall to preamplifiers outside the chamber. Standard intensive care monitors can be used to provide simultaneous measurement of arterial and pulmonary artery pressures and intermittent measurement of cardiac output by thermodilution. If pressure bags are used to drive continuous flow systems, they must be repressurized during compression and vented before or during decompression. Pulmonary artery catheter balloon ports should also be left open to the chamber during compression and decompression.

Defibrillation could generate a fire if sparking occurs or combustible materials are present in the vicinity of the paddles (see also Chapter 109). Sparking and heat

generation can be minimized by using a low-resistivity conductive gel between the electrodes and the skin[152] or preapplied conductive disposable pads.[153] To avoid pressure-related malfunction of the device, the defibrillator can remain outside the chamber and connected to the patient by through-hull high-voltage wiring. Despite the fear of causing fire, defibrillation has been performed in multiplace chambers numerous times without arcing, fire, or explosion.[154,155] Defibrillation cannot be safely performed inside a monoplace chamber compressed with O_2.

INTRAVENOUS FLUID ADMINISTRATION

In multiplace chambers, the air volume within the drip chamber shrinks during the compression phase of the HBOT and expands during decompression (which could force air into the intravenous line) (see also Chapter 59). Most intravenous infusion pumps work well inside a hyperbaric chamber at pressure (although electrical safety issues exist; see later). Glass bottles are best excluded from the chamber because of the possibility of explosive rupture during decompression.

Administration of fluids to patients inside a pressurized monoplace chamber requires an infusion pump capable of withstanding the pressure differential (up to 3 ATA or 1500 mm Hg pressure gradient across the chamber wall). Check valves can prevent unintended backflow of blood from the patient in the event of disconnection of the pump. Rigid arterial pressure transducer tubing helps to prevent kinking while the patient is inside the chamber.

ANALYSIS OF ARTERIAL BLOOD GASES AND VENTILATOR MANAGEMENT

Analysis of arterial blood gases from a patient inside a hyperbaric chamber can be erroneous (see also Chapters 63 and 103), for two reasons. At 1 ATA, O_2 tensions that exceed the ambient pressure are supersaturated; O_2 rapidly diffuses out of the blood, thus lowering its tension. An additional error (extrapolation error) results from the impossibility of accurate PO_2 electrode calibration at PO_2 values exceeding approximately 700 mm Hg. Blood gas tension measurement should therefore ideally be performed inside the hyperbaric chamber by using an appropriately calibrated analyzer. If such a capability is not available, rapid analysis at 1 ATA of decompressed samples can produce acceptably accurate values.[156]

Another approach is to estimate the hyperbaric PaO_2 based on measurements obtained at 1 ATA. Using a measured PaO_2 and PAO_2, the ratio of the two (PaO_2/PAO_2, or a/A ratio) is a constant.[9,157] On this basis, 1 ATA arterial blood gas values and the following equations can be used to predict PaO_2 at pressure.

The alveolar gas equation is required to calculate P_AO_2:

$$PAO_2 = (Pb - P_{H_2O}) \cdot FiO_2 - Paco_2 \cdot \left(FiO_2 + \frac{1 - FiO_2}{R}\right)$$

where Pb and P_{H_2O} are, respectively, ambient and saturated water vapor pressures, and R is the respiratory exchange ratio. If $FiO_2 = 0.2$, $R = 0.8$, and body temperature = 37 °C, then this equation can be simplified to

$$PAO_2 = (Pb - 47) \cdot 0.2 - 1.2 \cdot P_{CO_2}$$

Having calculated PAO_2 and measured PaO_2, the a/A ratio can then be obtained at 1 ATA. The predicted PaO_2 at increased ambient pressure while breathing 100% O_2 may then be obtained from this next equation:

$$PaO_{2(pred)} = a/A \cdot [(760 \cdot ATA - 47) - Paco_2]$$

where ATA is the chamber pressure in atmospheres absolute. Although as yet no dose-response curves for HBOT are available, a reasonable aim is to achieve PaO_2 greater than or equal to 1000 mm Hg for routine long-term therapy and to as high a level as possible for treatment of acute necrotizing infections (Fig. 91-11).

A better monitor of tissue oxygenation may be mixed venous PO_2 ($P\bar{v}O_2$), which, in the absence of left-to-right shunt, may be a reasonably accurate estimate of mean tissue PO_2.[158] Thus, a low value may indicate inadequate tissue oxygenation despite HBOT, as a result of insufficiently high cardiac output.

Normal values for pH and P_{CO_2} under resting clinical hyperbaric conditions are the same as they are at 1 ATA.[14] P_{CO_2} and hence pH do not change significantly in blood samples that are decompressed.

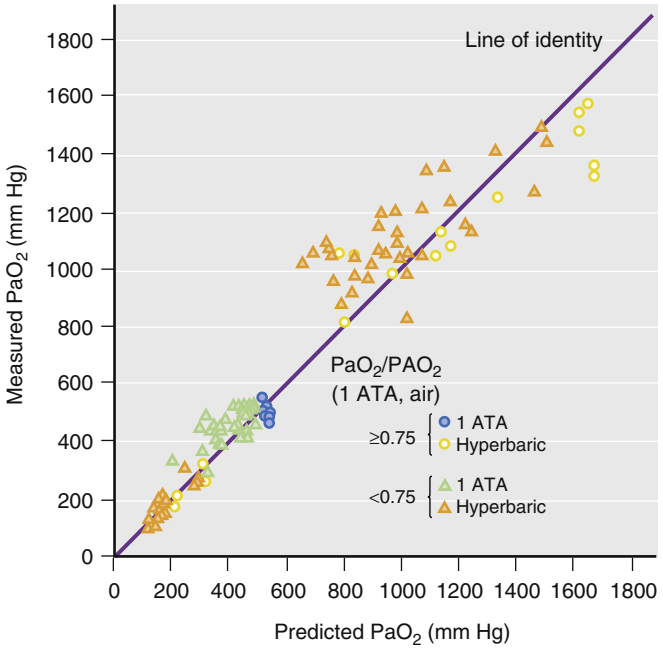

Figure 91-11. Measured versus predicted partial arterial pressure of oxygen (PaO_2) at increased ambient pressure. Predicted PaO_2 is calculated from room air arterial blood gases, assuming that the arterial-alveolar PO_2 ratio (PaO_2/PAO_2, or a/A ratio) is a constant. Data are shown both for persons with normal lungs (a/A ratio ≥ 0.75) and for patients with gas exchange abnormalities (a/A ratio < 0.75). It is evident that PaO_2 predicted in this way is close to the actual measured PaO_2. *(From Moon RE, Camporesi EM, Shelton DL: Prediction of arterial PO^2 during hyperbaric treatment. In Bove AA, Bachrach AJ, Greenbaum LJ Jr, editors:* Underwater and hyperbaric physiology IX. Proceedings of the ninth international symposium on underwater and hyperbaric physiology, *Bethesda, Md, 1987, Undersea and Hyperbaric Medical Society, p 1127.)*

Mechanical ventilation in a hyperbaric environment presents a variety of challenges (see also Chapter 103). The ideal requirements for ventilation include small size, no electrical requirement, absence of flammable lubricants, ability to operate on a volume-cycled basis over a wide range of tidal volumes and respiratory rates, minimal modification requirement for installation, and ability to provide positive end-expiratory pressure, as well as to ventilate in intermittent mandatory ventilation and assist/control modes.[159] Additionally, the ideal gas source to actuate the ventilator should minimize the risk of combustion caused by buildup of static electricity.

As ambient pressure increases, gas density is proportionately increased, whereas relatively little change occurs in gas viscosity. Therefore, in regions of turbulent flow (i.e., in the large airways) airway resistance increases. Measurements of respiratory conductance (the reciprocal of resistance) during tidal breathing[160] indicate that it varies with gas density according to the following formula:

$$G = G_0 \rho^k$$

where G is lung conductance at gas density ϱ, G_0 is the conductance at gas density 1.1 g/L (1 ATA), and κ is a constant that was found to have a mean value of –0.39. At 6 ATA, this equation predicts that lung conductance would decrease by 50%, which is equivalent to a doubling of pulmonary resistance. In addition, the higher gas density results in a less efficient distribution of ventilation, manifested by an increase in physiologic dead space.[161] The effects of these two phenomena include higher airway pressures during mechanical ventilation and an increased ventilatory requirement. If ventilator settings are not adjusted to compensate for the higher dead space, a rise in $Paco_2$ will occur.

Several types of ventilators have been used and tested in hyperbaric chambers (see also Chapter 103). Pressure-cycled devices have been used with some success because their compactness admirably fulfills the requirement for small size. However, continual adjustment of rate and cycling pressure is necessary with changes in ambient pressure. Volume-cycled ventilators seem to work well,[159,162] although at increased pressure some changes in rate may occur.

Two specific safety considerations exist. First, in any ventilator delivering enriched O_2, a possible fire hazard can result from O_2 buildup within the ventilator case or leakage of O_2 into the chamber. This hazard can often be offset by minor alterations (e.g., for a pneumatic ventilator, using air instead of O_2 to drive the bellows).[159] The risk of ignition can be substantially mitigated by purging the device with an inert gas such as 100% nitrogen (see later). Air-filled endotracheal tube cuffs tend to lose volume during compression and reexpand during decompression. Appropriate cuff inflation volume can be maintained either by manually adjusting the air pressure within the cuff during compression and decompression or by filling the cuff with water.

ATMOSPHERE CONTROL

Chamber atmosphere safety includes management of levels of O_2, CO_2, and trace gases. In a multiplace chamber, the patient must breathe as high a concentration of O_2 as possible (usually 98% or greater) while maintaining the chamber O_2 concentration close to 21% to minimize fire hazard. In some hyperbaric units, head tent O_2 concentration is routinely monitored. In others, the concentration is assumed to be high because of a high rate of O_2 flow through the head tent. Leakage of O_2 from head tents, masks, and ventilators tends to raise the chamber O_2 concentration. Typically an upper limit of approximately 23% is used as a criterion for ventilating the chamber with air or small volumes of 100% nitrogen until the O_2 concentration decreases.

Significant increases of inspired CO_2 concentration increase the risk of CNS O_2 toxicity. Therefore, a typical standard for the upper limit for head tent CO_2 is 1% "surface equivalent" CO_2, equal to a partial pressure of 7.6 mm Hg. Using a nonscrubbing (open-circuit) system, head tent O_2 flow rates of 40 to 60 L/minute (measured at chamber pressure) are usually adequate to keep CO_2 levels at such a level. Chamber CO_2 is usually limited to less than 0.5% "surface equivalent" (3.8 mm Hg).

Trace gases that may enter the environment include CO and hydrocarbons from improperly functioning compressors or from automobile exhaust that may be near the compressor air intake. Volatile gases such as alcohol vapor from skin disinfectant solutions and mercury vapor from spillage of sphygmomanometer columns may also pollute the atmosphere. Trace gas concentrations that are innocuous at atmospheric pressure can be toxic under hyperbaric conditions because their pharmacologic or toxic effects are related to partial pressure. Mercury in any form should be excluded from hyperbaric chambers because spillage can cause acute toxicity in chamber occupants.

Considerations of battery use may have implications for chamber atmosphere control, as well as fire hazards. All batteries release small quantities of hydrogen, although not usually in amounts that would be hazardous. Lithium–sulfur dioxide batteries carry a theoretic risk of sulfur dioxide discharge. Similarly, an objection exists to the use of mercury cells (now banned in the United States). Alkaline cells are considered safe, although temporary failure has been observed at extremely high ambient pressures (40 to 60 ATA).

FIRE HAZARDS

Although fires in hyperbaric chambers are rare, they are usually lethal. The effects of fire at elevated ambient pressure are so devastating, and the fire occurs so fast, that fire extinguisher systems may not be effective (see Chapter 88). The very real risk of fire in hyperbaric chambers has been illustrated by accidents in which chamber fires were started by a hand warmer, a sparking toy, and other sources of ignition carried into the chamber in the patient's clothing. Minimization of these risks involves the following:

Control of chamber O_2 concentrations (irrelevant in a monoplace chamber)
Minimizing the use of combustible materials within the chamber
Controlling sources of heat and spark
Having a chamber fire extinguisher system

The geometric increase in burning rate with increases in O_2 concentrations mandates careful monitoring of chamber O_2, as already noted. At increased ambient pressure, burning occurs more rapidly, even when O_2 concentration is 21%. Cotton garments are recommended because of their reduced risk of static electricity. Elimination of hair grease and humidification of the O_2 within the head tent can reduce the risk of hair ignition. Hydrocarbon lubricants (e.g., for stretcher wheels) can spontaneously ignite on contact with aluminum in the presence of high O_2 tensions and should therefore be replaced with nonflammable fluorocarbon lubricants.

Sources of sparks from electrically powered equipment should be minimized. Cigarette lighters, matches, and other sources of ignition should be excluded from the chamber. Plugging and unplugging electrical cables during hyperbaric treatments comprise a source of sparking that can be eliminated by taping all electrical plugs onto receptacles before compression. In multiplace chambers, the flammability of electrically powered devices (e.g., intravenous controllers) can be reduced by purging with 100% nitrogen through ports drilled in the covering, at a rate sufficient to keep O_2 concentration at a level that does not support combustion (typically at a flow rate of two to three times the internal volume per minute). Electrical systems used in monoplace chambers must comply with specific codes, which specify the types of switches, grounding, and insulation that can be used.[123]

Volatile anesthetics can be combustible at 1 ATA in high concentrations. However, isoflurane and sevoflurane Dräger vaporizers (Drägerwerk AG, Lubeck, Germany) have been tested up to 3 ATA using 100% O_2, with no evidence of spontaneous combustion at room temperature. Given the experience with halothane under hyperbaric conditions, without any reported fires, and the resistance to combustion in 100% O_2 at 1 ATA, in the absence of a source of ignition it is unlikely that any of the modern fluorinated anesthetics pose a fire safety hazard in the hyperbaric environment.

EVALUATION OF A PATIENT FOR SAFETY OF HYPERBARIC OXYGEN TREATMENT

In addition to ensuring that HBOT is indicated for the disease process in question, it is important to assess the patient in terms of general effectiveness and safety of HBOT. The following issues are pertinent:

Whether a sufficient elevation in PaO_2 can be obtained
Whether the patient can equilibrate middle ear pressure
Optimization of reversible obstructive lung disease and the presence of pulmonary bullae or blebs
Whether the patient is susceptible to claustrophobia

The calculation of predicted PaO_2 in the hyperbaric chamber was described previously. For example, a patient who has sufficient lung disease or injury that PaO_2 during treatment would not exceed 1000 mm Hg would probably obtain marginal benefit from HBOT unless the reason for HBOT is gas bubble disease.

The ability to vent the middle ears may be assessed before treatment by observing the tympanic membrane directly with an otoscope while the patient holds his or her nose or performs a Valsalva maneuver. Movement of the eardrums indicates a patent eustachian tube and the ability to equilibrate middle ear pressure. If otic barotrauma is unlikely to be avoided (e.g., with mental obtundation or the presence of an endotracheal tube) or because of a condition that may render the patient susceptible to inner ear injury (e.g., stapedectomy), myringotomy or tube placement can be performed before HBOT. The presence of pulmonary bullae or blebs represents a relative contraindication to HBOT because of the possibility of barotrauma, although a large clinical experience suggests that the risk is extremely low.

For patients requiring more than 20 to 30 HBOT sessions, periodic checks of visual acuity may be useful to assess hyperbaric myopia.

Because most hyperbaric chamber systems are small and cramped, patients who cannot tolerate enclosed spaces may require anxiolytic therapy to facilitate toleration of the HBOT.

DELIVERY OF ANESTHESIA AT INCREASED AMBIENT PRESSURE

A review of the problems of anesthesia under HBOT was published as a report to a committee of the American Society of Anesthesiologists.[163] This report explored various issues, including the potential for nitrous oxide to be used as a sole anesthetic.

Anesthesia while breathing spontaneously in a 100% O_2 atmosphere at 3 ATA was reported in the 1950s for radiation therapy.[164] The tracheas of patients were intubated after administration of pentobarbital 250 to 750 mg and meperidine 100 mg; some patients also received chlorpromazine 50 mg. Intubation of the trachea was performed after succinylcholine and topical anesthesia of the airway. Patients breathed spontaneously.

Anesthesia may be required as a procedure incidental to the hyperbaric exposure. Ross and associates discussed the challenges of anesthesia up to 35 ATA, to provide care for injured divers while in a saturation diving system (e.g., in North Sea oil fields).[165] These investigators suggested intravenous instead of inhaled general anesthesia because of the problems of pollution of the chamber environment. Regional anesthesia was recommended whenever possible. Neuromuscular blocking drugs should be titrated to effect because some degree of pressure reversal of the block can occur at approximately 10 ATA.

Since the 1960s, anesthesia has been performed at increased ambient pressure using a variety of drugs for carotid endarterectomy,[166] cesarean section,[167] therapeutic lung lavage for patients with alveolar proteinosis,[104,105] emergency surgery in a saturation dive,[168] open heart surgery,[169] and enhancement of the effectiveness of irradiation of carcinoma.[170]

Inhaled Anesthesia

Inhaled anesthesia of any type can pollute the enclosed chamber atmosphere with anesthetic gases, which may exert pharmacologic effects on medical personnel inside the chamber, particularly at high ambient pressures. Russell and colleagues reported nitrous oxide concentrations in chamber air of 2500 ppm; ventilation of the chamber

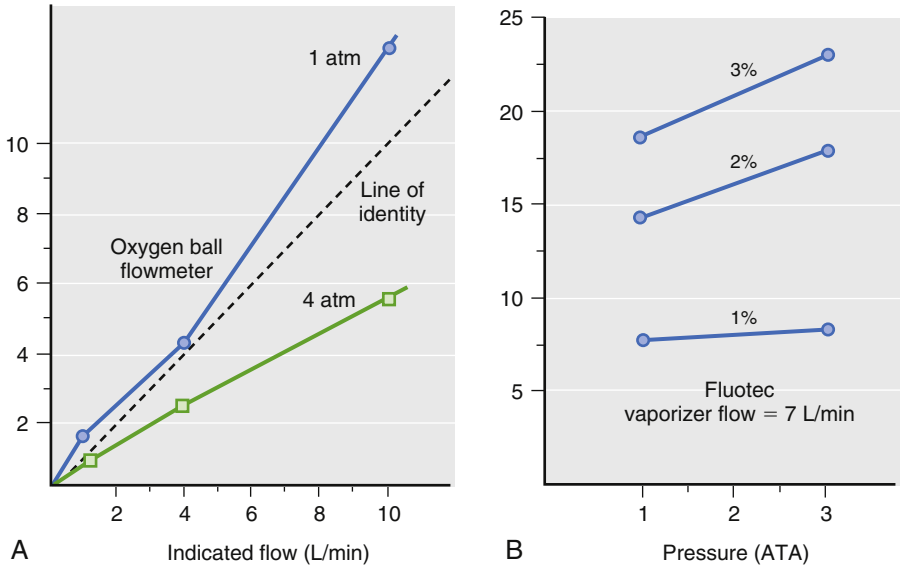

Figure 91-12. Performance of an anesthetic vaporizer system at increased ambient pressure. **A,** Flow characteristics of a rotameter system are shown. At 4 ATA, the actual delivered flow is less than 60% of the flow indicated by the rotameter. **B,** Fluotec vaporizer output in partial pressure of halothane as a function of ambient pressure. Only small increases in delivered partial pressure are evident at 3 ATA, at the 2% and 3% settings. *(From Committee on Hyperbaric Oxygenation:* Fundamentals of hyperbaric medicine, *publication no. 1298, Washington, DC, 1966, National Academy Press.)*

with air at a high rate (3500 L/minute of air) was required to reduce the concentration to 25 to 75 ppm.[171]

Nitrous Oxide. The increased ambient pressure in a hyperbaric chamber allows nitrous oxide to be used at partial pressures exceeding its MAC.[171-173] Although in both studies induction of anesthesia by nitrous oxide was rapid (<60 seconds), it was accompanied by tachypnea, tachycardia, hypertension, diaphoresis, muscle rigidity, catatonic jerking of the extremities, eye opening, and opisthotonus. After 2 to 4 hours of anesthesia, most subjects emerged rapidly from the anesthetic; however, the majority subsequently experienced nausea and vomiting, which was often severe (see also Chapter 97).

A potential problem associated with nitrous oxide anesthesia at high ambient pressures is the possibility that tissues could become supersaturated during decompression, thus allowing nitrous oxide bubbles to form during decompression. This complication was not observed by Russell and colleagues,[171] who used an empiric staged decompression schedule with a decompression stop for 30 minutes at 1.3 ATA while patients breathed 100% O_2. Bubble formation can occur without decompression if the patient breathes one gas while surrounded by an atmosphere of another gas that is more diffusible. For example, breathing air while in a helium-O_2 environment at 5 to 7 ATA can lead to urticaria and vestibular dysfunction.[174] The reason is rapid diffusion of helium into tissues that causes local inert gas pressure to exceed ambient pressure (isobaric gas counterdiffusion). This phenomenon can occur even at normal atmospheric pressure if a person breathes nitrous oxide–O_2 while surrounded by helium.[175] Therefore, nitrous oxide should never be administered in a helium-O_2 atmosphere.

Another risk of hyperbaric nitrous oxide is the dilutional effect of large volumes of dissolved gas entering the lungs during decompression, causing dilutional hypoxia. This situation can be prevented by administration of an O_2-enriched breathing mix for several minutes before decompression.

In patients who have recently engaged in scuba diving or have suffered DCS, nitrous oxide should be avoided, even at 1 ATA, because its administration may result in tissue or blood bubble growth and recrudescence of pain or neurologic symptoms. Neurologic symptoms can occur after nitrous oxide anesthesia and apparent spontaneous resolution of DCS.[176]

Halogenated Anesthetics. The effect of a volatile anesthetic agent on a patient is proportional not to the alveolar concentration but to the partial pressure of the anesthetic. For example, the effect of 1% halothane at 1 ATA (with a partial pressure of 7.6 mm Hg) is equivalent to a 0.5% concentration at 2 ATA (with the same partial pressure). The anesthetic concentration of an anesthetic-specific calibrated vaporizer varies with ambient pressure, but in a manner such that delivered partial pressure remains constant (Fig. 91-12). Because of the effect of increased gas density on this flow ratio, in practice the delivered partial pressure depends somewhat on ambient pressure. A slightly increased partial pressure of halothane delivered by a Fluotec vaporizer at 3 ATA has been observed (see Fig. 91-12).[163] Our testing of a sevoflurane vaporizer revealed delivery of a constant partial pressure of anesthetic up to the maximum tested ambient pressure: 3 ATA.

Rotameter flowmeters calibrated at 1 ATA will indicate falsely high values at increased ambient pressure because of the increased gas density. McDowell reported the following relationship for rotameter flow[177]:

$$\text{Flow}_{\text{actual}} = \text{Flow}_{\text{read}} \cdot \sqrt{\frac{\rho_1}{\rho_p}}$$

where $\text{Flow}_{\text{actual}}$ and $\text{Flow}_{\text{read}}$ are the actual and scale reading flows, and ϱ_1 and ϱ_P are the gas densities at 1 ATA and P ATA, respectively. This inaccuracy in rotameter performance up to 4 ATA has been confirmed by other investigators (see Fig. 91-12).[163]

Intravenous Anesthesia

Intravenous anesthetics behave similarly and are unlikely to be affected within the usual clinical range of ambient

pressure (see Chapter 30). No alteration in the pharmacokinetics of either meperidine[31] or pentobarbital[32] is evident at ambient pressures up to 6 ATA. For therapeutic lung lavage, we have provided general anesthesia at ambient pressures up to 3 ATA by using conventional doses of ketamine and benzodiazepines or propofol and narcotics with nondepolarizing muscle relaxants.

Regional Anesthesia

Regional anesthesia is likely to be both safe and effective in a hyperbaric environment by avoiding the requirement for mechanical ventilation (see Chapters 56 and 57). A bowel resection was performed at an ambient pressure 6.75 ATA in a helium-O_2 environment by using local injection of lidocaine supplemented with parenteral meperidine.[168] Extreme care should be taken to ensure sterile technique because of the propensity for enhanced bacterial growth in the warm, humidified environment of a hyperbaric chamber, particularly during saturation chamber exposures.

EFFECTS OF ALTITUDE

Approximately 140 million people worldwide live permanently at altitudes greater than 2500 m,[178] and possibly equal numbers of people visit high altitudes each year, many of whom will require medical care. Therefore, a need clearly exists for anesthesia and critical care practitioners to understand the physiology of this environment.

Unlike the relationship between ambient pressure and water depth, the relationship between pressure and altitude is nonlinear (see Fig. 91-2). The physiologic effects of altitude exposure are mainly attributable to reduction in the following three variables: inspired PO_2, ambient pressure, and gas density. Extreme or prolonged altitude exposure may be accompanied by additional factors, which may modulate physiologic responses, such as hypothermia, exertion, dehydration, sunburn, and polycythemia. Pregnant women and individuals with hypoxic conditions such as cerebrovascular disease, congenital heart defects, coronary artery disease, and hypoxic lung disease may carry additional risks that require medical evaluation.[179]

HYPOXIA

Physiologic Changes

The major reason for hypoxemia at high altitude is the reduction in inspired PO_2, augmented by the failure of erythrocytes in the pulmonary circulation to equilibrate fully with alveolar gas (diffusion nonequilibrium)[180] and increased ventilation-perfusion $\dot{V}_A/\dot{Q}$ mismatch.[181]

The acute blood gas and heart rate responses to acute hypoxia are shown in Tables 91-3 and 91-5. Heart rate and cardiac output are increased.[182] Systemic vascular resistance is decreased, and pulmonary vascular pressure is increased.[183] A corresponding increase occurs in organ blood flow, including cerebral blood flow. Hypoxia also induces hyperpnea (from increased breathing rate) to a degree that varies considerably among individuals.

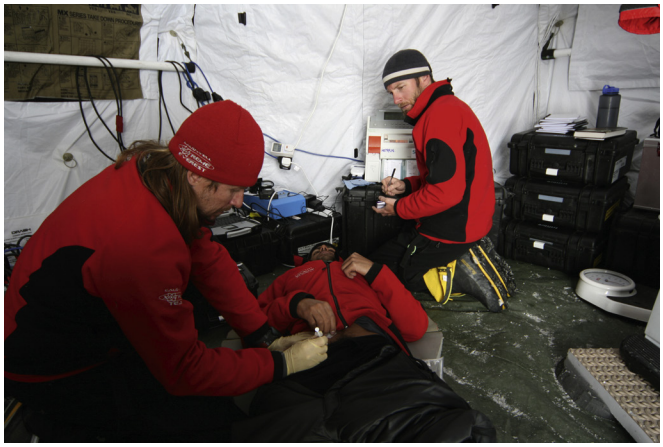

Figure 91-13. Obtaining blood gas sample from the femoral artery at 6400 m (barometric pressure 350 mm Hg) during the Caudwell Xtreme Everest field expedition. Measured values have been reported by Grocott.[359] *(Photograph courtesy Caudwell Xtreme Everest.)*

End-tidal P_{CO_2} measured in one subject breathing air at the summit of Mt. Everest (barometric pressure 263 mm Hg) was 7.5 mm Hg, whereas PAO_2 was 37.6 mm Hg.[184] Arterial blood was obtained near the summit in a later expedition (Fig. 91-13). This hypocapnia has several effects. It results in an increased affinity of Hb for O_2 (leftward shift of the Hb-O_2 dissociation curve), which enhances oxygenation of blood at the lung while simultaneously interfering with transport of O_2 from tissue capillary to mitochondrion. The overall effect on O_2 transport is beneficial.[185]

Hypoxemia may be particularly accentuated during sleep. Figure 91-14 depicts continuous pulse oximetry during transition from sleep to wakefulness at a simulated altitude of 4572 m in a hypobaric chamber, thus demonstrating periodic breathing and cyclic oscillation of saturation of peripheral oxygen (SpO_2). Individuals with moderate obstructive sleep apnea at 1 ATA are at risk of severe central sleep apnea at high altitude.[186]

Acute exposure to altitudes in the range of 4000 to 5000 m causes a decrease in arterial PaO_2 to approximately 40 mm Hg and in arterial Hb-O_2 saturation to approximately 75%. Acute exposure to mild hypoxia appears to have only minor effects on CNS function. Crow and Kelman found no decrement on free recall and visual scanning when normal subjects were exposed to a simulated altitude of 3658 m (inspired PO_2 92 mm Hg).[187] Severe hypoxia can cause encephalopathy and loss of consciousness. A measure of this phenomenon is the effective performance time (EPT), defined as the amount of time the individual is able to perform useful flying duties.[188] At 5500 m altitude, the EPT is 20 to 30 minutes, which is reduced to 2.5 to 3 minutes at 8500 m and to 1 to 2 minutes at 9100 m.

Gradual exposure to high altitude or long-term exposure results in a series of adaptive changes that allow individuals to function extremely well and do substantial physical work at altitudes at which newcomers can barely function. For instance, Mt. Everest has been climbed by adapted individuals without the benefit of supplemental O_2, whereas acute exposure to such an altitude would result in rapid loss of consciousness. Subjects exposed to a progressively lower barometric pressure, reaching

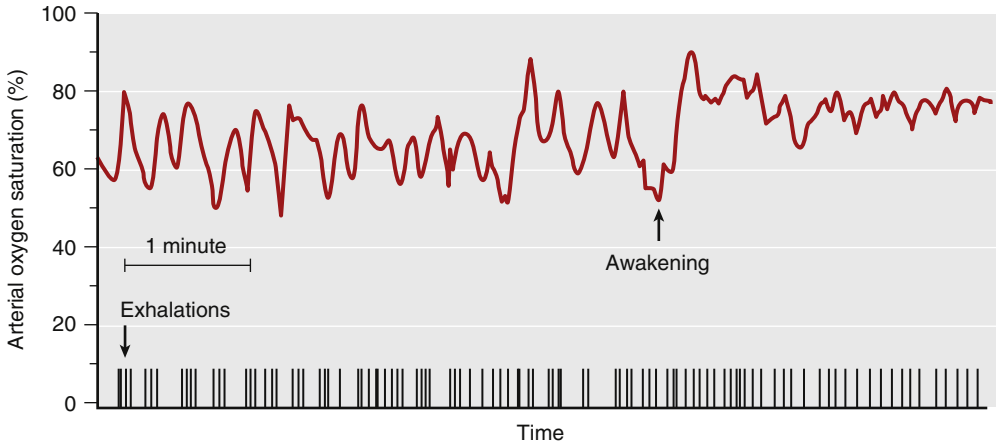

Figure 91-14. Pulse oximetry and breathing pattern (spikes at bottom represent exhalations) are shown in this subject in a hypobaric chamber at a simulated altitude of 4572 m. During sleep, periodic breathing and oscillatory alterations in saturation of peripheral oxygen (SpO_2) change after waking up to a more regular breathing pattern and a steady SpO_2.

to simulated altitude of 8848 m in a hypobaric chamber over the course of 40 days, were able to work on an exercise ergometer at 120 W while their mean PaO_2 was only 30 mm Hg (arterial Hb-O_2 saturation 58%).[189] In the same study, blood Hb concentration increased from 13.5 to 17.0 g/dL (hematocrit increased from 40.4% to 51.9%). The development of polycythemia may be one of many mechanisms by which tolerance to hypoxia occurs. However, the mechanisms of adaptation are still incompletely understood.

One of the adaptive mechanisms is a gradual reduction in plasma bicarbonate,[189] preceded by a decrease in cerebrospinal fluid (CSF) bicarbonate,[190] which tends to offset the initial respiratory alkalosis. After a 40-day simulated "climb" of Mt. Everest in a hypobaric chamber, resting serum bicarbonate had decreased from 22.2 to 9.9 mM; pH had increased from 7.43 to 7.56.[189] Other adaptive changes include increases in hematocrit and capillary density, as well as undoubtedly other mechanisms as yet undiscovered.

Despite the adaptive mechanisms, careful neuropsychological testing of subjects before and after mountaineering expeditions to extreme altitudes of 7000 m or greater have shown evidence of mild persistent performance impairment.[191,192] Such neuropsychological impairment after prolonged extreme altitude exposure is correlated with a brisk hypoxic ventilatory response,[191] possibly resulting from enhanced cerebral vasoconstriction and reduced brain O_2 delivery.

Effect of Maternal Hypoxia on the Fetus

Data on the fetal effects of maternal hypoxia are sparse (see Chapter 77). However, using changes in fetal heart rate (FHR) as an end point, the fetus is relatively resistant to moderate degrees of maternal hypoxia. Administration of 15% O_2 (inspired PO_2 = 108 mm Hg, equivalent to 2500 m altitude) for 4 minutes to five primigravid women at 36 to 38 weeks of gestation resulted in an increase in FHR of only 2 to 3 beats per minute.[193] The same investigator observed no change in FHR after administration of mixtures as low as 10% O_2 (inspired PO_2 = 71 mm Hg, equivalent to 5300 m altitude) for 20 minutes in 8 of 28 pregnant women. Administration of 10% O_2 for 10 minutes to pregnant women at 35 to 41 weeks of gestation had no significant effect on FHR, heart rate variability, or Doppler velocimetry in the umbilical and middle cerebral arteries of the fetus.[194] Acute hypoxia of this magnitude appears to exert no detectable effects on the healthy fetus because of augmentation of uterine blood flow; thus, it is unlikely that acute exposure to altitudes up to 2500 to 3000 m would have any adverse fetal effects.

Additional adaptations to long-term altitude exposure specific to pregnant women include an increase in placental capillary volume and a reduction in villous membrane thickness.[195] Infants born at high altitude, even as high as 4329 m, have scalp vein O_2 tensions similar to values obtained from infants born at sea level.[196] Consequently, a significant reduction in maternal O_2 delivery can be tolerated without any impact on fetal O_2 consumption.

Infants Born at High Altitude

As with adults, SpO_2 decreases with increasing altitude, but it also depends on activity (lower during sleep), postnatal age (Fig. 91-15), and race[197] (see also Chapter 77). Perinatal hypoxia appears to predispose to a blunted hypoxic ventilatory drive in adulthood.[198]

At sea level, pulmonary artery pressure decreases to normal levels within 24 hours after birth, whereas at high altitude, pulmonary artery pressure often remains elevated for several weeks or throughout infancy.[197] In a series of 35 consecutive infants born at term in Leadville, Colorado (altitude 3179 m), during the first 3 months of life 17% experienced elevated pulmonary artery pressure or respiratory distress requiring supplemental O_2 or mechanical ventilation, or both.[197] In infants born at high altitude, the transition to adult circulation occurs more slowly, with increased frequency of patent foramen ovale and patent ductus arteriosus.[199] Patent foramen ovale was present at 6 months in 7 of 16 infants studied after birth in La Paz, Bolivia (altitude 3700 to 4000 m).[200] Acute hypoxia after birth (15% O_2 administration) in preterm infants paradoxically produced hypoventilation, periodic breathing, and apnea.[201] Infants with trisomy-21 (Down syndrome) are at increased risk of high-altitude pulmonary edema (HAPE; see later).[199] Perinatal pulmonary hypertension seems to predispose to exaggerated hypoxic pulmonary vasoconstriction in adulthood.[202]

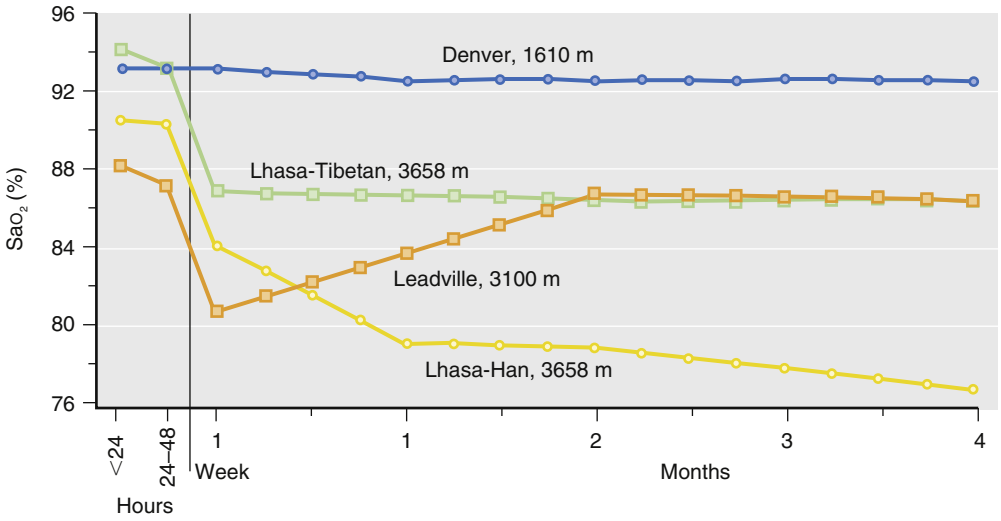

Figure 91-15. Pulse oximetry in infants born at various altitudes. In infants born in Lhasa (altitude of 3658 m), Han Chinese children have progressive arterial desaturation whereas Tibetan infants, following a slight drop shortly after birth, have a stable saturation of peripheral oxygen. Sao_2, Arterial oxygen saturation. *(Redrawn from Niermeyer S: Cardiopulmonary transition in the high altitude infant,* High Alt Med Biol *4:225, 2003.)*

Effects of Altitude on Children

Although SpO_2 is lower at higher elevations, children who reside at altitudes up to 3000 m generally maintain arterial O_2 saturation (Sao_2) higher than 90%.[203] Normal children who travel to altitudes up to 3500 m exhibit changes in cardiorespiratory function similar to changes seen in adults.[204] Exaggerated hypoxemia at high altitude can suggest previously undiagnosed cardiorespiratory anomalies, such as Pierre-Robin syndrome or tracheomalacia-laryngomalacia.[199]

Altitude Illness

Altitude illness consists of a group of subacute and chronic syndromes, the underlying pathophysiology of which is triggered by continuous exposure to hypoxia. These syndromes are described here. Further information can be obtained from detailed reviews.[205-208] The Wilderness Medical Society has published guidelines for the prevention and treatment of acute altitude illness.[209]

Acute Mountain Sickness. The most common symptoms of acute mountain sickness (AMS) are headache, decreased appetite, nausea and vomiting, insomnia, ataxia, and peripheral edema.[210] AMS can occur after several hours of exposure to elevations greater than 2500 to 3000 m, although some people are more susceptible and can experience it at lower altitudes. Approximately 25% of visitors to ski resorts in the Rocky Mountains of the United States (altitude 1920 to 2960 m) develop AMS.[211]

Pharmacologic prophylactic measures against AMS in mountaineers include slow ascent (≈300 m/day) or "staging," in which several days are spent at an intermediate altitude of approximately 2000 m.[209,210] Pharmacologic prophylactic measures include the administration of acetazolamide,[212] which is believed to work in part by augmenting the ventilatory response to hypoxia as a result of the ensuing bicarbonate diuresis.[213] However, other purported mechanisms include tissue respiratory acidosis, improved sleep quality from a reduction in periodic breathing (paradoxically because its inhibition of the carotid body response to CO_2), and diuresis.[214] The effective dose range is 250 to 750 mg orally daily begun the day before ascent.[205,209,215]

Figure 91-16. Portable Altitude Chamber at Everest Base Camp. The pressure inside the bag can be raised to 2 psig (approximately 100 mm Hg) by using a foot pump. This effectively reduces the "altitude" for the occupant of the chamber and thus raises the partial pressure of oxygen (PO_2). These bags can be used to treat altitude illness when neither oxygen administration nor true descent is feasible. *(Photograph courtesy Caudwell Xtreme Everest.)*

Although most individuals recover spontaneously after several days at high altitude, AMS can be treated effectively with O_2 and descent. A descent of only 500 to 1000 m usually leads to resolution of AMS. Simulated descent using a portable inflatable hyperbaric chamber (Gamow bag or similar) operated by foot pump is also effective (Fig. 91-16). Depending on the altitude, inflation of such a chamber to only 2 psi (100 mm Hg) produces a decrease in equivalent altitude of 1500 to 2000 m.[205] AMS also responds to dexamethasone in a dosage of 4 mg every 6 hours, although symptoms may occur as soon as it is discontinued.[216,217] Ginkgo biloba has also been used, with mixed results.[218,219] Insomnia associated with AMS responds to treatment with acetazolamide. Sedative-hypnotic drugs can depress ventilation and exacerbate hypoxia and should therefore be used cautiously. Both zolpidem (10 mg orally) and zaleplon (10 mg orally) improve sleep quality at high altitude, and neither appears to depress ventilation in healthy young subjects.[220,221]

AMS symptoms could conceivably result from hypoxemia at sea level. The headache associated with obstructive

sleep apnea and opioid-related headache may be caused by a form of "AMS" secondary to hypoxemia caused by respiratory depression.

High-Altitude Pulmonary Edema. HAPE is much less common than AMS but more serious. It occurs in a small percentage of unacclimatized, susceptible people within a few days of reaching altitude.[183] A hemodynamic pathophysiology for HAPE is suggested by its tendency to occur when pulmonary vascular flows or pressures are particularly high (e.g., in the lung contralateral to unilateral absence of the pulmonary artery).[222] Measurements in patients with HAPE have revealed pulmonary hypertension, normal pulmonary artery wedge pressures, but elevated pulmonary capillary pressures (assessed using the single occlusion method[223]). Bronchopulmonary lavage fluid in subjects with HAPE has a high protein content, implicating an increase in permeability or alveolar-capillary disruption.[224-226]

Prophylaxis against HAPE includes slow ascent. People with known predisposing factors such as unilateral absence of the pulmonary artery should avoid high altitudes. For climbers with known HAPE susceptibility, prophylactic measures may include nifedipine (20 mg slow-release formulation every 8 hours),[227] tadalafil (10 mg twice daily), or dexamethasone (8 mg twice daily).[228] Inhaled salmeterol also appears to be an effective prophylactic agent.[229] Whether acetazolamide prevents HAPE has not been established by randomized studies; however, it is probably at least partly effective based on animal studies and its augmentation of PaO_2 during hypoxia.[230]

Treatment of HAPE consists of descent or supplemental O_2, or both.[205] If descent is impossible or O_2 is unavailable, pharmacologic reduction in pulmonary artery pressure should be initiated. Nifedipine (10 mg sublingually), followed by 20 mg of a slow-release preparation administered orally every 6 hours, has been successful in HAPE.[231] Pulmonary artery pressure can also be lowered in patients with HAPE by using hydralazine, phentolamine, or inhaled nitric oxide.[231-234] Other suggested treatments include agents that could lower pulmonary artery pressure (e.g., prostaglandins[235] and phosphodiesterase inhibitors such as sildenafil[235]) or facilitate alveolar fluid clearance (e.g., β_2-adrenergic agonists,[229] recompression in a Gamow bag,[205] and application of expiratory airway pressure[236]).

High-Altitude Cerebral Edema. High-altitude cerebral edema (HACE), the rarest but most lethal form of high-altitude illness, is a clinical diagnosis made when a patient with AMS or HAPE has ataxia or altered consciousness.[237] Physical findings in patients with HACE may include papilledema, retinal hemorrhages, and, occasionally, cranial nerve palsies.[238] Focal abnormalities in the corpus callosum detected with MRI have been reported.[239] The pathophysiology of HACE is unknown. It has been hypothesized that individuals who develop AMS and HACE have a limited capacity to accommodate the associated increase in brain volume that accompanies the rise in cerebral blood flow during hypoxemia.[205,240]

Treatment of HACE is a medical emergency and ideally should include evacuation or descent and administration of supplemental O_2. Although a reduction in altitude of 500 to 1000 m is usually effective for AMS, treatment of HACE may require descent to a lower altitude. Use of a Gamow bag may also be effective. Recommended adjunctive treatment includes dexamethasone (8 mg immediately, then 4 mg every 6 hours). If descent is not possible, acetazolamide (250 mg twice daily) may also be effective.[205]

Chronic Mountain Sickness (Monge Syndrome). Chronic mountain sickness has been defined as a clinical syndrome that occurs in natives or long-time residents at altitudes higher than 2500 m. This illness is characterized by excessive erythrocytosis (female patients, Hb ≥19 g/dL; male patients, Hb ≥21 g/dL), severe hypoxemia, and, in some cases, moderate or severe pulmonary hypertension, which may evolve to cor pulmonale leading to congestive heart failure.[241] Other manifestations include headache, dizziness, breathlessness or palpitations, sleep disturbance, fatigue, localized cyanosis, burning in the palms of the hands and soles of the feet, dilatation of the veins, muscle and joint pain, loss of appetite, lack of mental concentration, and alterations of memory.[241] The diagnosis requires the exclusion of other conditions that may produce hypoxemia, such as cyanotic heart disease and chronic lung disease. Clinical improvement and increased work capacity often result from phlebotomy, at least transiently, and descent to lower altitudes relieves the symptoms completely. Other suggested modalities for treatment of chronic mountain sickness include angiotensin-converting enzyme inhibitors, the D_2 dopaminergic receptor antagonist domperidone, acetazolamide, and the respiratory stimulants medroxyprogesterone and almitrine.[242] Both nifedipine and sildenafil may be effective to reduce pulmonary artery pressure.[242]

REDUCTION IN AMBIENT PRESSURE

Acute ascent to altitude in an aircraft can cause DCS resulting from the reduced barometric pressure and supersaturation of nitrogen. Although symptoms have been reported to occur after rapid ascent in aircraft to only 2437 m,[243] DCS usually occurs only in aircraft in which the cabin altitude is higher than 5000 to 6000 m,[244] which typically occurs only in military planes. Exposure to lower altitudes, including the cabin altitude of commercial aircraft (2400 m or less) within 12 to 24 hours after a scuba dive can also precipitate DCS.[245] To reduce this risk, it is the practice of individuals who are planning rapid decompression to low ambient pressure (e.g., military pilots, astronauts) to denitrogenate their tissues by prebreathing 100% O_2 for periods ranging from a few minutes to several hours, depending on the altitude of the planned exposure. Nevertheless, DCS has been described even in pilots following appropriate prebreathing procedures.[246,247]

A lower ambient pressure implies a reduction in gas density, which results in lower breathing resistance. The effect of ambient pressure from 0.5 to 5 ATA on airway

resistance in normal subjects can be estimated by either of the following equations[248]:

$$R_P/R_0 = 0.57 + 0.44 \cdot P_{ATA}$$

or:

$$R_P/R_0 = P_{ATA}^{0.59}$$

where P_{ATA} is ambient pressure in ATA, Rp is airway resistance at ambient pressure, and R_0 is airway resistance at 1 ATA. For example, at an ambient pressure of 0.5 ATA (5486 m), airway resistance is reduced by approximately 20%. Under resting conditions, differences in breathing pattern during altitude exposure, compared with a similar degree of hypoxia at sea level, are minor.[249]

OTHER ENVIRONMENTAL STRESSES AT HIGH ALTITUDE

Individuals at high altitude are subjected to low temperature, wind, and ultraviolet radiation. The effects of hypoxia may therefore be compounded by hypothermia, dehydration, frostbite, and sunburn. On the basis of a seemingly higher incidence of stroke,[250] thrombophlebitis, and pulmonary thromboembolism[251] at high altitude, investigators have suspected that prolonged hypoxic exposure may cause a hypercoagulable state.[252] Indeed, rapid exposure to high altitude in a hypobaric chamber has been associated with a decrease in partial thromboplastin time[253] and an increase in prothrombin fragments 1 and 2, thrombin-antithrombin complex, and factor VIIa activity.[254]

ANESTHESIA AT HIGH ALTITUDE

General Principles

Because of the reduced ambient PO_2 at high altitudes, the risk of perioperative hypoxia is likely to be magnified, particularly in newcomers to altitude. Opiates depress both the tachycardia and hyperpnea that normally occur in response to acute hypoxemia. Slow recovery of consciousness and postanesthetic headache have been reported after anesthesia using thiopental with air or nitrous oxide.[255] When ventilation was assisted or controlled during the anesthetic regimen and when postoperative supplemental O_2 was administered, these complications did not occur. This finding suggests that intraoperative or postoperative hypoxemia may be a pathophysiologic factor. In contrast, long-term residents at high altitude may be more tolerant of hypoxemia; in such individuals other considerations may be important, including a higher hematocrit, pulmonary hypertension, and lower Pa_{CO_2} and bicarbonate concentration.[189] To prevent renal retention of bicarbonate, which reduces ventilatory drive, patients requiring controlled ventilation should have their Pa_{CO_2} maintained at baseline value rather than in the traditionally normal range. Similarly, maintenance of PaO_2 within the sea level normal range results in loss of adaptation and difficulty in readapting the patient to breathing room air.

Increased oozing of blood from surgical wounds at high altitude has been reported,[256] and it is attributed to higher venous pressure, blood volume, vasodilatation, and increased capillary density. Camporesi reviewed the topic of anesthesia at both high and low ambient pressures.[257]

Anesthesia Equipment

Fluotec Mark II and Dräger Vapor halothane vaporizer performance has been compared at sea level, 5000 ft (1524 m), and 10,000 ft (3048 m) altitude.[258] At any given setting the delivered percentage of halothane increased with altitude; however, its partial pressure remained constant. Therefore, when these devices are used at a given vaporizer setting, the anesthetic agent is delivered at a constant potency regardless of altitude (see also Chapter 29).

The effect of altitude on floating-bobbin or floating-ball gas flowmeters has also been examined.[258] At 10,000 ft (3048 m) simulated altitude, both nitrous oxide and O_2 flowmeters underread the actual flow rate. The percentage error progressively increased up to 4 L/minute, at which point both flowmeters were approximately 20% in error. A hazard may therefore arise when a low flow of O_2 is mixed with a higher flow of nitrous oxide. Unless an O_2 analyzer is available, the delivered percentage of O_2 may be significantly lower than that calculated on the basis of the flowmeter readings.

Venturi-type gas mixing devices tend to deliver higher concentrations of O_2 at high altitude than they do at sea level[258]; at 10,000 ft (3048 m) altitude, a mask designed to deliver 35% O_2 at sea level actually delivered 41% O_2.

Sedation

Standard sea level doses of sedative-hypnotics may produce increased respiratory depression at high altitude in unacclimatized subjects (see Chapters 89 and 90). A small dose of oral ethanol (50 g, producing an estimated blood alcohol concentration of 65 mg/dL, which was without ventilatory effect at ground level) increased blood P_{CO_2} by a mean of 1.5 mm Hg after acute ascent to 3000 m.[259] Both diazepam (5 mg orally) and temazepam (10 mg orally)[260] have measurable effects on respiration at 3000 m. In contrast, temazepam (10 mg orally) improved sleep quality and reduced the number of desaturations during sleep in partially acclimatized mountaineers at 5300 m.[261] The difference in the studies is probably explained by different degrees of acclimatization to altitude. During acute altitude exposure in healthy young subjects, neither zolpidem (10 mg orally) nor zaleplon (10 mg orally) adversely affected SpO_2 during sleep.[220,221]

General Anesthesia

Bandolz-Frank reported approximately 900 general anesthetic cases in La Paz, Bolivia at an altitude of 12,000 ft, with few problems.[262] For adults, anesthesia induction was performed using a short-acting barbiturate such as thiopental, followed by ether or intravenous procaine maintenance, mostly with spontaneous ventilation. The respiratory stimulant nikethamide was sometimes required to reestablish ventilation after barbiturate induction. During the 1933 British Everest expedition to Mt. Everest, to facilitate fixation of a fractured clavicle a brief general open-drop chloroform anesthetic was administered at 14,000 ft altitude to a Tibetan, and it caused

cardiopulmonary arrest. After external cardiac massage and intracardiac injection of the respiratory stimulant nikethamide, breathing and circulation returned. An hour later, the patient had recovered sufficiently to smoke a cigarette.[263] Other examples and a review of anesthetic agents delivered at high altitude are provided by Firth and Pattinson.[263]

The potency of anesthetic gases is proportional to their partial pressure. Therefore, as barometric pressure is reduced, fixed concentrations of inhaled anesthetics have lower potency. At an altitude of 3300 m, a significant reduction in efficacy of 50% nitrous oxide was observed in reducing pain threshold in normal volunteers[264] (Table 91-6). Successful induction of general anesthesia with halothane in a hypobaric chamber was reported at a barometric pressure of 375 mm Hg (equivalent altitude = 5490 m).[265] Recovery was rapid and uneventful.

Because supplemental O_2 may not be available in some mountain locations, it may be imperative to choose an anesthetic technique that is least likely to suppress ventilation. Ketamine anesthesia with spontaneous ventilation was reported in 23 patients requiring general anesthesia at an altitude of 1830 m.[266] Two patients developed significant, although brief, desaturation, which resolved quickly. The authors concluded that this form of anesthesia is a practical method in a rural hospital setting at high altitude without access to supplemental O_2.

Ketamine (total dose 1 to 6 mg/kg) after intravenous premedication with atropine 0.02 mg/kg and midazolam 0.05 mg/kg was reported in a consecutive series of 11 patients (American Society of Anesthesiologists Physical Status 1 to 2) requiring general anesthesia for short procedures at Kunde Hospital in Nepal (3840 m) (Fig. 91-17).[267] Nine patients required reduction of dislocations or fractures, 1 patient (9 years old) required suturing of a facial laceration, and another patient required drainage of an abscess. The induction dose of ketamine was 1 mg/kg intravenously administered over 1 to 2 minutes, followed by additional incremental doses, titrating to effect. Baseline SpO_2 on room air was 86% to 91%. O_2 was administered in 3 of 11 cases through an O_2 concentrator if SpO_2 fell below 80% for 1 minute and was not correctable by forward jaw thrust or vocal and tactile stimulation. Both low-altitude residents required supplemental O_2 for 20 minutes during recovery, whereas only 1 of 9 high-altitude residents required O_2. Use of ketamine was reported at even higher altitude (4243 m), for control of postpartum hemorrhage in a 22-year-old woman.[268] Deep general anesthesia was obtained with only 25 mg of

TABLE 91-6 **EFFECT OF 50% NITROUS OXIDE ON PAIN THRESHOLD IN NORMAL VOLUNTEERS AT ALTITUDE***

Altitude(m)	Barometric Pressure (mm Hg)	Increase in Pain Threshold(%)	Side Effects
0	760	71.5	3 subjects, nausea; 2 subjects, semicomatose
1,460	636	40.0	None
3,300	517	19.0	None

*Pain threshold was measured in 20 subjects at each altitude by applying pressure to the anterior aspects of the tibia using a spring balance. Simulated altitude exposures were in a hyperbaric chamber. At increasing altitudes a fixed concentration of nitrous oxide is progressively less effective.

Data from James MFM, Manson EDM, Dennett JE: Nitrous oxide analgesia and altitude, Anaesthesia *37:285-288, 1982.*

Figure 91-17. Kunde Hospital, Nepal (altitude 3840 m), the site of the published series of general anesthetics described in the text.[267] The photograph depicts Dr. David Murdoch assisted by Kami Temba Sherpa. *(Photograph courtesy Dr. Lynley Cook.)*

intravenous ketamine (≈0.5 mg/kg), which induced 5 minutes of apnea, requiring airway manipulation and supplemental O_2. The total dose of ketamine required for the 20- to 25-minute procedure was only 50 mg. The authors attributed the exaggerated response to a low dose of ketamine to a combination of hypoxemia and hemodynamic instability.

Compared with lowlanders at 300 m, high-altitude natives anesthetized at 3500 m above sea level (mean preoperative SpO_2 88.5%) appeared to require significantly larger amounts of propofol when administered with fentanyl.[269] The highlanders also had a lower resting heart rate, and heart rate responses to surgical stress were significantly attenuated.

Regional Anesthesia

Spinal anesthesia has been reported to result in an unacceptably high incidence of dural puncture headache,[255] possibly because of chronically increased CSF pressure, dehydration, and altered sensitivity of the altitude resident's CNS ICP changes.[255] Headaches were not reported in 20 young native mountain dwellers in whom CSF samples were obtained with 25-gauge needles.[255]

Perioperative Supplemental Oxygen

At high altitude, PAO_2 is normally increased by hyperventilation induced by the hypoxic ventilatory drive. Administration of anesthetics or narcotic analgesics, both of which blunt the hypoxic ventilatory drive, may therefore precipitate hypoxia. The resulting hypoxic symptoms of irritability, confusion, and restlessness may be misinterpreted as being caused by pain, and misguided administration of additional narcotics would only compound the problem. Analgesic-induced respiratory depression was reported as a likely cause of death in a Sherpa who had débridement of frostbitten fingers at 4300 m altitude.[265] Therefore, if opiate analgesics are administered, supplemental O_2 may be required.

Monitoring

O_2 analyzers, both electrochemical and paramagnetic, measure PO_2 rather than O_2 percentage (see also Chapter 44). Thus, if the display is in "percent," the actual percentage will be falsely low unless the analyzer is calibrated at that altitude. Nevertheless, it is the PO_2 that is physiologically important. Clinical CO_2 analyzers similarly measure partial pressure. Because end-tidal P_{CO_2} at high altitude is within the normal range (or somewhat low), readings are unaffected by altitude.

Air evacuation in an unpressurized or partially pressurized aircraft engenders expansion of the gas volume in enclosed spaces such as tracheal tube cuffs and pulmonary artery catheter balloons.

AIR TRANSPORT OF CRITICALLY ILL PATIENTS

Important issues during air transport of critically ill patients include the challenges of monitoring and intervening in an environment with limited space and resources, as well as those pertinent to altitude itself[270] (see also Chapter 81). A decrease in ambient pressure causes expansion of fixed gas volumes such as in an endotracheal cuff and pneumothorax. Volumes increase 20% and 45%, respectively, at 5000 and 10,000 ft (1524 and 3048 m) altitude, and they may require adjustment of cuff pressure. It would also be expected that the volume of pneumocephalus would similarly increase and cause a rise in ICP. This issue was examined in a review of 21 patients with posttraumatic pneumocephalus who were evacuated by military transport (8 hours flying time) at a cabin altitude of 5000 to 8000 ft from Iraq to Landstuhl Regional Medical Center in Germany. Two patients had intraventricular drains. None of the patients experienced sustained clinical neurologic deterioration during transport or within 24 hours after arrival at the destination.[271] The patient with the most severe brain injury had baseline ICP of 25 to 30 mm Hg and experienced only transient ICP elevations during takeoff and during level flight, each of which resolved spontaneously. Provided the cabin altitude is within the range usually experienced during commercial flight (see later), the mild decrease in arterial PO_2 can be managed with supplemental O_2.

In a review of 19,228 urgent civilian transports of adult patients within Ontario, Canada, by either fixed wing aircraft or helicopter, at least one critical event occurred during 5% of the transports.[272] Hemodynamic deterioration was the most frequent critical event, occurring in 3.2% of transports. Accidental extubation was uncommon (0.1% of cases); however, airway interventions occurred in 0.7% (intubations, laryngeal mask insertions, or cricothyroidotomies). The success rate for first-attempt intubations was 64.5% for oral and 75.0% for nasal. Needle thoracostomies were performed in 63 instances (0.33%). Cardiac resuscitation (mostly chest compression, defibrillation, cardioversion, or external pacing) was performed in 1.25% of cases.

COMMERCIAL AIR TRAVEL

Clinical Effects of Aircraft Flight

During commercial aircraft flight, the pressure within the cabin is mandated to be no less than the barometric pressure at 8000 ft altitude (typical cabin altitude 1500 to 2438 m). During flight, the ambient air PO_2 would fall from 159 mm Hg at sea level to as low as 118 mm Hg. One publication reported observations during commercial flights that indicated a cabin altitude sometimes reaching 8549 ft.[273] The ensuing mild hypoxemia Sa_{O_2} (usually >90%) is generally well tolerated by normal individuals, although altitude-related symptoms such as discomfort and fatigue can occur.[274] Small increases in pulmonary artery pressure have been described in normal individuals,[275] with clinically significant changes in susceptible individuals.[276] Changes in ambient pressure can induce otic and sinus barotrauma and pain resulting from expansion of intestinal gas. Motion sickness is now rare. More serious manifestations that have been attributed to immobility and possible hypoxemia include phlebothrombosis.[277,278] Airborne spread of communicable diseases has also been reported.[278] Medical guidelines for air travel have been discussed in review articles.[279,280]

Prediction of Oxygenation During Commercial Flight

Patients with impaired gas exchange resulting from chronic obstructive pulmonary disease or restrictive disease during flight may experience significant hypoxemia,[281,282] as well as symptoms of dyspnea, edema, wheezing, cyanosis, and chest pain.[283]

To predict the effect of altitude on arterial oxygenation, the patient can be exposed to simulated altitude in a hypobaric chamber with assessment of SpO_2 and/or arterial blood gases. Alternative measures include administering a hypoxic gas premixed to produce the same inspired PO_2 as air at the target altitude (typically 15% O_2)[284] or supplying a Venturi mask designed to deliver 35% to 40% O_2 with 100% nitrogen.[285,286] Prediction algorithms based on sea level blood gas values have also been used with success.[287] Predicted PaO_2 at altitude ($PaO_{2\ alt\ (predicted)}$) can be predicted from ground level blood gases ($PaO_{2\ GL}$, $PaCO_{2\ GL}$), ground level calculated alveolar PO_2 ($PAO_{2\ GL}$), and altitude alveolar PO_2 ($PAO_{2\ alt}$) using the following equation:

$$PaO_{2\ alt\ predicted} = PAO_{2\ alt} \times (PaO_{2\ GL}/PAO_{2\ GL})$$

Systematic testing of a number of other prediction equations has been reported.[286,288] Incorporation of SpO_2 measured after a 6-minute walk test may provide greater predictive accuracy.[289]

Patients with baseline hypoxemia resulting from lung or heart disease may be considered for in-flight O_2 administration.[290] Procedural details have been reviewed by Stoller.[287]

In-Flight Emergencies

One to 75 in-flight medical events per million passengers have been reported by commercial airlines.[291] The most common are syncope, gastrointestinal complaints, minor trauma, and cardiac, pulmonary or neurologic issues. Emergency care of severely ill passengers is facilitated by medical kits that are carried aboard all U.S. commercial aircraft requiring a flight attendant. In addition, automatic external defibrillators are aboard all U.S. commercial planes with a payload exceeding 7500 pounds. In-flight deaths are extremely uncommon (0.01 to 0.8 deaths per million passengers). In a study of 1 year's (1999 to 2000) experience of a U.S.-based airline, it was estimated that an onboard physician was available during approximately half of all flights.[291] Guidelines for assessment of in-flight emergencies have been outlined by Silverman and Gendreau.[279] A system of ground-based physicians is available for consultation and to assist with decisions regarding flight diversion.

MEDICAL CARE IN SPACE

PHYSIOLOGIC AND MEDICAL ISSUES DURING SPACE FLIGHT

For a few minutes during launch of a space vehicle, gravitational force increases as the space craft accelerates to orbital speed (typically 4 G for the Russian Soyuz). During the period in space, the major physiologic stress on astronauts is the absence of gravitational stress (microgravity). This phenomenon results in an increase in left ventricular end-diastolic volume, paradoxically accompanied by a decrease in central venous pressure.[292] The central redistribution of blood causes facial edema and initiates diuresis, and thence plasma volume depletion (up to 20% or more), which persists until after landing.[293] Shortly after attaining orbit, most astronauts experience self-limited dizziness, drowsiness, nausea, and vomiting.[294] During reentry, astronauts are reexposed to increased G force without the benefit of an anti-G suit. This is typically 4 to 5 G for the Soyuz craft, but it can be as high as 6 to 7 G. To increase plasma volume, astronauts routinely consume 4 L of an electrolyte fluid within 4 hours before reentry. Nevertheless, after landing astronauts typically experience some degree of orthostatic intolerance,[295] and they often have a recurrence of nausea and vomiting.[294] Postural hypotension has been attributed to hypovolemia, decreased muscle tone in the legs, enhanced endothelial nitric oxide synthase expression, and down-regulation of α-adrenergic receptors.[296] Reduced ventricular mass has been observed after several days in orbit,[297] and it may be caused by cardiac atrophy[298] or dehydration.[299] Skeletal muscle atrophy occurs even after short missions.[300]

Cabin pressure in the space shuttle and the International Space Station is 760 mm Hg. However, during extravehicular activity (EVA), space suit pressure is 4.3 psi (222 mm Hg). During EVA, astronauts prevent hypoxia by breathing 100% O_2, although the reduced pressure engenders the potential risk of DCS.[301] To decrease the probability of bubble formation by reducing tissue nitrogen content, the astronauts have a 100% O_2 prebreathing period of approximately 4 hours. If the suit were to become disrupted during EVA, the astronaut's ambient pressure would quickly drop to zero, causing hypoxia and generalized bubble formation, referred to as *ebullism* (body fluids boiling as a result of ambient pressure lower than saturated water vapor pressure).

Gravitational unloading causes loss of calcium from bones. During long space flights, this loss could produce significant osteoporosis. This problem, along with the resulting hypercalciuria and increased probability of nephrolithiasis, constitutes a major obstacle to human interplanetary travel.

Emergency care during space includes numerous challenges, including the effect of fluid volume changes on drug disposition, hypovolemia, difficulties with applying mechanical force (e.g. for intubation), and limitations of supplies and expertise.[302] For acute medical conditions that cannot be adequately treated on board the International Space Station, evacuation of an astronaut by Soyuz may take up to 24 hours. Hypovolemia secondary to hemorrhage may not be adequately treatable because of limited quantities of supplies, and hypotension could be exacerbated by preexisting volume loss and increased G forces during reentry. Air-fluid interfaces in intravenous fluids generate bubbles (Fig. 91-18). Thus, intravenous fluid bags must be degassed before flight, and bubbles must be removed by in-line filtration. The physiologic effects of general or regional anesthesia in microgravity are unknown. Because conventional anesthesia vaporizers require gravity to confine the liquid to the bottom of the reservoir, a different design would be required for

Figure 91-18. Air in the bag of intravenous (IV) fluid in microgravity with an infusion pump. The lack of a gravitational field makes it impossible to remove gas in the usual way. IV fluid bags must be degassed before flight, and bubbles must be removed by in-line filtration. *(Courtesy National Aeronautics and Space Administration.)*

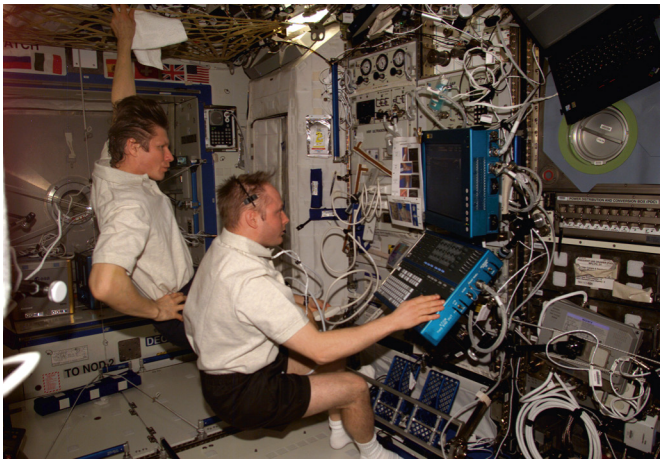

Figure 91-20. Testing diagnostic ultrasound on the space shuttle. Astronaut Mike Finke is operating the ultrasound device while being guided by a ground-based physician. *(Courtesy National Aeronautics and Space Administration.)*

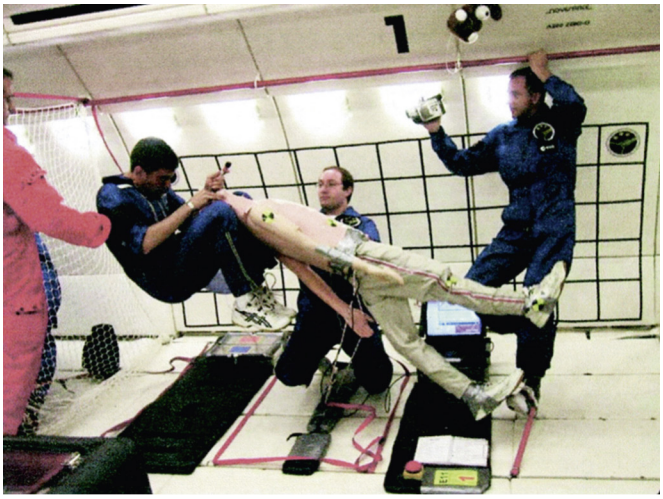

Figure 91-19. Tracheal intubation of a free-floating mannequin in microgravity. The intubator stabilizes the head by holding it between his knees. *(From Groemer GE, Brimacombe J, Haas T, et al: The feasibility of laryngoscope-guided tracheal intubation in microgravity during parabolic flight: a comparison of two techniques,* Anesth Analg *101:1533-1535, 2005, with permission).*

use in space. Additional practical limitations include the need to prevent pollution of the enclosed environment by volatile anesthetics or exhaust O_2 (fire hazard).

Tracheal intubation may be difficult because of facial edema. The laryngeal mask airway (LMA), cuffed oropharyngeal airway, and intubating LMA have all been successfully demonstrated in microgravity simulated in a neutral buoyancy tank.[303] Studies using secured mannequins during short periods of microgravity in an aircraft have demonstrated successful intubation using laryngoscopy and standard tracheal tube (Fig. 91-19), Combitube (Nellcor, Pleasanton, Calif.), and an intubating LMA.[304,305] However, tracheal intubation in microgravity by a nonphysician using conventional laryngoscopy is frequently unsuccessful.[304] All intubation techniques require that both the patient and the intubator be secured.[304] Gastroesophageal reflux is more common in microgravity; thus, aspiration during general anesthesia may be more likely.

On-board diagnostic tools are being developed, such as for remotely guided ultrasound examination (Fig. 91-20). The challenges of providing anesthesia in space have been outlined by Komorowski and colleagues.[306]

Remote robotic surgery has been considered a substitute for an on-board surgeon. Indeed, a robotic laparoscopic cholecystectomy was successfully performed on a patient in Strasbourg, France by surgeons operating from New York City. The total delay time between movement initiated by the surgeon and detection on the monitor was approximately 155 msec.[307] A surgical center at McMaster University in Hamilton, Ontario, Canada successfully performed several telerobotic surgical cases at North Bay, 250 miles away, by using an Internet link with a delay of 135 to 140 msec.[308] The limit of the acceptable time delay is believed to be approximately 330 msec. Whether training or technology will allow this technique to be expanded to permit surgery during interplanetary flights (with a much longer delay time) is unknown.

PHYSIOLOGIC AND MEDICAL ISSUES AFTER RETURN TO EARTH

Medical challenges may extend into the period after landing. After 14 days in space, to obtain biopsies, two rhesus monkeys were administered general anesthesia (ketamine 10 mg/kg intramuscularly; then 1% to 1.5% isoflurane for 3.5 to 4 hours) by a competent veterinary anesthesiologist within 24 hours after landing. One animal aspirated during emergence and could not be resuscitated. Three hours after recovery, the other inexplicably developed lethargy and facial edema.[309] From this experience, it can be inferred that well-accepted standard-of-care techniques may not be safe when anesthetizing astronauts shortly after space flight.

Several specific challenges have been elucidated. Details can be found in two excellent reviews.[310,311] Some issues most pertinent to anesthetic risk are as follows.

Hypovolemia and Adrenergic Hyporesponsiveness

Following flight, many astronauts experience orthostatic intolerance. This is in part the result of hypovolemia, but it is also caused by a dysfunctional adrenergic response.[312] In astronauts with postflight orthostatic intolerance, the pressor response to phenylephrine is not different from the preflight response; however, it is attenuated compared with astronauts who are tolerant of acute orthostasis.[313] Cardiovascular deconditioning, ventricular atrophy, and changes in arterial stiffness may also play a role.[298,299,314,315] The immediate postflight hemodynamic response to general or neuraxial anesthesia could include unexpected hypotension, but to date is this is unknown.

Electrolyte Disorders

Reductions in both serum potassium and magnesium have been reported after some space missions,[316,317] possibly in response to decreased dietary intake. Hypokalemia has been blamed for cardiac arrhythmias observed during Apollo 15.[318]

Hyperkalemic Response to Succinylcholine

Skeletal muscle atrophy resulting from immobilization and disuse causes proliferation of acetylcholine receptors, increased sensitivity to succinylcholine (see Chapters 34 and 35), and decreased cholinesterase activity.[319] Based on data from patients with neuromuscular disease and immobilized limbs, resistance to nondepolarizing neuromuscular blocking drugs may occur.[320] Use of succinylcholine in immobilized ICU patients has been associated with exaggerated hyperkalemia and cardiac arrest.[321,322] Investigators have suggested that skeletal muscle atrophy in astronauts may put them at a similar risk.[311]

SUMMARY

Increasingly widespread use of HBOT to treat critically ill patients has created a demand for individuals skilled in using this technology. Planning and design of monitoring capabilities will enable optimal control of hemodynamics and oxygenation. Patient safety in this environment can be achieved with careful attention to detail, which includes patient selection and monitoring and chamber procedures. Optimized treatment schedules will evolve from studies of mechanism of action and further clinical trials. Advances in prevention and treatment of O_2 toxicity may allow more prolonged therapy than can currently be safely administered and hence a more aggressive approach to ischemic and infectious syndromes.

The decreases in ambient pressure and ensuing hypoxia associated with acute high-altitude exposure result in well-described physiologic changes that are often associated with clinical symptoms. Methods for prophylaxis and treatment have been described. Safe anesthesia at high altitude requires some modification of sea level techniques, not only because of the hypoxia and reduced ambient pressure, but also because suboptimal equipment may be available under mountain conditions.

Anesthesia in space poses unique challenges that may extend even beyond return to earth.

Chapter 92

Regional Anesthesia in Children

CHRISTOPHE DADURE • CHRYSTELLE SOLA • BERNARD DALENS • XAVIER CAPDEVILA

Acknowledgment: The editors and the publisher would like to thank Dr. Bernard J. Dalens, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The application of regional anesthesia in pediatrics has increased in the past 30 years.
- Regional anesthesia represents a major therapeutic option for preventing and treating pain in pediatrics both intraoperatively and postoperatively.
- In recent years, the use of peripheral nerve blockade instead of the neuraxial approach has reduced the incidence of adverse effects.
- More regional anesthesia procedures in children are being described in terms of efficacy and safety.
- The development of devices and techniques specifically for pediatric use has facilitated their routine use.
- Peripheral catheter techniques are becoming routine practice.
- The efficiency and safety of these techniques may facilitate early ambulation with improved pain management and includes treatment at home and improved rehabilitation of children.
- Traditionally, nerve stimulation is the gold standard for locating nerves and plexuses. However, ultrasound guidance is increasingly used for regional anesthesia in children.
- The benefits of the ultrasound-guided regional technique are visualization of targeted nerves and spaces and the spread of injected local anesthetic.
- The use of ultrasound guidance for performing peripheral nerve blocks permits the decrease of local anesthetic doses, decrease in number of punctures, and increase in the onset time and duration of sensitive block.
- To avoid local or systemic toxicity, the dose of local anesthetic, in terms of volume and concentration, should be carefully calculated.

Pediatric regional anesthesia is commonly used in adjunction with general anesthesia and plays a key role in the multimodal approach of pain management in surgical and nonsurgical pediatric patients and provides excellent postoperative analgesia. The development of needles and catheters for pediatric patients has made the use of these techniques easier and safer. Large retrospective and prospective studies confirm the infrequent rate of complications and no major sequelae with regional anesthesia in children, especially with peripheral nerve blocks. The use of long-acting local anesthetics with less cardiotoxicity, as well as ropivacaine or levobupivacaine, increases the safety of these procedures in children. Virtually all techniques of nerve blockade have been evaluated in pediatrics, thus allowing precise definition of their indications, contraindications, and adverse effects. This chapter describes these approaches in detail.

Continuous peripheral nerve blocks are one of the most recent developments in regional anesthesia in children. Local anesthetics in a single-shot procedure have a limited duration of action, sufficient for some pediatric surgeries but insufficient in many cases of major surgery. Major pediatric orthopedic surgery causes significant and prolonged postoperative pain, making continuous peripheral nerve blocks very important.

Ultrasound imaging techniques represent the second transformation in regional anesthesia (see also Chapter 58). The advantage of ultrasonography is to make visible the spread of the local anesthetic. Without doubt, ultrasonographic guidance improves the quality of regional anesthesia blockade, allowing both the adjustment of needle positioning in case of inappropriate spread and the reduction of local anesthetic dose in children.

RELEVANT DIFFERENCES BETWEEN CHILDREN AND ADULTS

ANATOMIC DIFFERENCES

Change in Body Size Resulting From the Growth Process

The most obvious difference between children and adults is body size. "Normal" full-term neonates weigh 3 to 3.5 kg,

with a height of 50 cm, and within 10 to 15 years they will multiply their weight by more than 12 (>1200%) and their height by more than 3 (>300%). During the early stages of development the spinal cord occupies the spinal canal entirely, but later the growth of vertebrae exceeds that of the cord,[1] and the last spinal nerves, the cord, and its envelopes are "attracted" within the spinal canal. At birth the dura mater ends at the level of the third or fourth sacral vertebra and the cord (conus medullaris) at the L3 or L4 level. It is only at the end of the first year of life that the adult level is attained—that is, L1 for the conus medullaris and S2 for the dural sac.

Anatomic relationships and landmarks are constantly changing throughout infancy and childhood, which interferes with regional procedures and requires good knowledge of developmental anatomy and the assistance of accurate techniques for localization of anatomic spaces and nerve trunks.

Congenital malformations, genetic disorders, and consequences of fetal and neonatal asphyxia (cerebral palsy) are frequent and specific to the pediatric period. They result in abnormal development and deformities of bone, joint, and neurologic structures that tend to worsen during childhood.

The main pediatric anatomic and physiologic factors that can influence indications for or performance of regional block procedures are listed in Table 92-1.

Delayed Ossification of Bones and Fusion of Sacral Vertebrae

Bones of neonates, including vertebrae, are mostly cartilaginous. Sharp needles can easily traverse them because cartilage offers little resistance to penetration, and ossification nuclei can be severely damaged, thus compromising further bone and joint development. Consequently, bone contact should be avoided as often as possible during block procedures, especially in infants. This cartilaginous structure also allows easy penetration of x-rays and ultrasound.

Development of Flexures of the Spine

At birth, a single spinal flexure is present and the orientation of epidural needles is the same regardless of the intervertebral space. Flexures, however, are not fixed, and they can be easily counteracted by forced flexion almost throughout childhood because of persistent spinal flexibility, which is a major advantage in the pediatric period (in addition to the absence of osteophytes).

Loose Attachment of Fasciae and Fluidity of Epidural Fat

Fasciae and perineurovascular sheaths are loosely attached to underlying structures (e.g., nerves, muscles, tendons, vessels). This allows extended spread of local anesthetics, resulting in high-quality nerve blockade regardless of the technique but also, occasionally, undesirable spread to distant nerves or anatomic spaces. The epidural fat is very fluid in infants and young children (up to 6 to 7 years of age). This fluidity combined with the loose attachment of the sheaths surrounding the spinal roots favors consistent leakage of local anesthetics injected within the epidural space; therefore, comparatively large volumes of epidural local anesthetics (up to 1.25 mL/kg) are required to reach desired levels of anesthesia.

Delayed Myelinization of Nerve Fibers

Myelinization begins during the fetal period in cervical neuromeres and extends cephalad and caudad,[2,3] but the process is not finalized before the twelfth year of life. Myelinization is especially poor in infants; the lack of fully developed nerve fibers is the main reason why they are unable to walk. A major pharmacologic consequence of this condition is that local anesthetics can penetrate and block nerve fibers more easily. Diluted solutions of local anesthetics provide the same quality of nerve blockade as with at least twofold more concentrated solutions in adults. Onset time is shortened, but, on the other hand, duration of blockade is reduced because trapping of local anesthetics within myelin with subsequent progressive release is reduced and because local circulation and, therefore, vascular absorption are greater in infants.

PAIN PERCEPTION

Somatic pain is a subjective sensory experience resulting from the intermixing of three main components[4]: motivational-directive, sensory-discriminatory, and cognitive-evaluative. The motivational-directive component is conveyed by unmyelinated C fibers ("slow" pain or "true" pain). It leads to protective reflexes such as autonomic reactions, muscle contraction, and rigidity. C fibers are fully functional from early fetal life onward. Connections between C fibers and dorsal horn neurons are not mature before the second week of postnatal life. However, nociceptive stimulations transmitted to the dorsal horn by C fibers elicit long-lasting responses,[5,6] probably as a result of extensive depolarization of surrounding neurons in response to the production of large amounts of substance P. As the number of dorsal horn receptors to substance P decreases during the first 2 weeks of life, this exaggerated response of neonates to nociceptive stimulation progressively disappears. The inhibitory control pathways, which are immature at birth, develop concomitantly.

Painful procedures during the neonatal period modify subsequent pain responses in infancy and childhood,[7] depending on the developmental stage of the infant (full-term versus preterm) and the infant's cumulative experience with pain. With later noxious procedures, full-term neonates react with heightened behavioral responsiveness, whereas preterm neonates react with a damped response. When analgesic drugs (local anesthetics or opioids) are administered before painful procedures, infants demonstrate less evidence of procedural pain and a reduction in the magnitude of long-term changes in pain behaviors.[7]

A major difficulty in assessment, and, at times, even identification of pain in children pertains to the inability of young patients to communicate with their caregiver and precisely express their distress and discomfort. During the past 2 decades, pediatric pain has received considerable attention, and reliable age-related pain scales have been developed to evaluate both the severity of pain and the efficacy of its treatment.

TABLE 92-1 MAIN ANATOMIC AND PHYSIOLOGIC FACTORS IN THE PEDIATRIC PERIOD THAT CAN INFLUENCE THE SELECTION OR PERFORMANCE OF A REGIONAL BLOCK PROCEDURE

Pediatric Factors (Mainly Infants)	Resulting Danger	Implications for Regional Anesthesia
Lower termination of spinal cord	Increased risk for direct trauma to the spinal cord	Avoid epidural approaches above L3 whenever possible.
Lower projection of dural sac	Increased risk for inadvertent penetration of the dura mater	Check for cerebrospinal fluid reflux, including during caudal approaches. Favor low approaches to the epidural space.
Delayed myelinization of nerve fibers	Easier intraneural penetration of local anesthetics	Onset time is shortened, and diluted local anesthetic is as effective as more concentrated anesthetic in adults.
Cartilaginous structure of bones and vertebrae	Reduced resistance to penetration by sharp needles	Avoid use of thin and sharp needles; use short and short beveled ones instead.
	Danger of direct trauma and bacterial contamination of ossification nuclei compromising further bone or joint growth	Do not apply excessive force on needle: if resistance is felt, stop trying to insert the needle farther.
Lack of fusion of sacral vertebrae	Persistence of sacral intervertebral spaces	Intervertebral sacral epidural approaches can be performed throughout childhood.
Delayed development of curvatures of the spine	Cervical lordosis (3-6 mo) Lumbar lordosis (8-9 mo)	Same orientation of epidural needles is appropriate whatever the spinal level before 6 mo of age; then adapt needle orientation to spinal flexures.
Changing axis of coccyx and absence of growth of sacral hiatus	Sacral hiatus comparatively smaller with increasing age	Identification of sacral hiatus becomes more difficult after 6-8 yr (increased failure rate of caudal anesthesia).
Delayed ossification and growth of iliac crests	Tuffier line, which joins anterior superior iliac spinous processes, crosses the spine at L5 or lower in infants.	This line passes over L5-S1 interspace instead of L4-L5 interspace.
Increased fluidity of epidural fat	Increased diffusion of local anesthetic up to 6-7 yr of age	Excellent blockade after caudal anesthesia can be achieved up to 6-7 yr of age.
Loose attachment of sheaths and aponeuroses to underlying structures	Increased spread along nerve paths with danger of penetrating remote anatomic spaces and blocking distant nerves	Larger volume of local anesthetic is required for epidural blocks because of leakage along spinal nerve roots. Smaller volume of local anesthetic is necessary to produce excellent peripheral blocks.
Enzymatic immaturity	Slower metabolism of local anesthetics (usually compensated by other enzyme pathways)	Increased mean body residency time and half-life, with accumulation (especially after repeat injection and continuous infusions of local anesthetic), are characteristic.
Increased extracellular fluids	Increased distribution volume and mean body residency time of local anesthetic (and most medications)	Decreased C_{max} occurs after single injection but accumulation occurs with repeat or continuous injections.
Low plasma protein content (HSA and AAG)	Competition at nonspecific HSA binding sites Limited capacity of specific binding of local anesthetic by AAG, resulting in increased plasma concentration of the free fraction	Increased unbound free fraction of all local anesthetic occurs, with greater danger of systemic toxicity
Increased cardiac output and heart rate	Increased regional blood flow resulting in increased systemic absorption of local anesthetic	Increased systemic absorption of local anesthetic occurs (decreased T_{max} and shorter duration of blockade). Increased efficacy of epinephrine. Vasoconstriction reduces absorption (thus toxicity) and prolongs duration of blockade.
Sympathetic immaturity, diminished autonomic adaptability of the heart, smaller vascular bed in lower extremities	Hemodynamic stability during neuraxial blocks	Fluid preloading and use of vasoactive agents are unnecessary.
Delayed acquisition of body scheme and conceptualization, anxiety	Inability of patients to locate precise body areas Concept of paresthesia not understandable Difficult cooperation	Nerve and space identification requires application of location techniques independent of patient's cooperation. Heavy sedation or general anesthesia is required in most patients (especially when a "dangerous" technique is planned to avoid detrimental consequences of panic attacks at a critical phase of the block procedure).

AAG, α_1-Acid glycoprotein; C_{max}, peak plasma concentration; *HSA*, human serum albumin; T_{max}, time to reach C_{max}.

PHARMACOLOGY OF LOCAL ANESTHETICS AND ADDITIVES

Two main factors influence pharmacologic properties of medications in children: (1) immaturity of some enzyme pathways and their replacement by other biochemical pathways and (2) progressive increase in body surface area concomitantly with the growth process. Drug prescriptions made according to body surface area are the same as (or in simple ratio with) adult dosing.[8] However, body surface area is not easily obtained and, in practice, doses are calculated according to body weight and require constant adaptation as the child grows up; dosage errors are not infrequent.

Local Anesthetics

Chemical properties and mechanisms of action of local anesthetics are detailed elsewhere in this book (see also Chapter 36); they are basically the same during the pediatric period and only pharmacokinetic properties may notably differ, especially in neonates and infants.[10]

Local Fixation

Schematically, local fixation is reduced and spread is increased in infants in contrast to the occurrence in adults, especially within the epidural space, because the epidural fat is more fluid and less densely packed. The main consequences are (1) shorter onset time of action, (2) more extended longitudinal and circumferential spread of local anesthetics, and (3) shorter duration of action because of reduced secondary release from local binding sites.

Regional Spread Toward the Target. The target of local anesthetic action is voltage-dependent sodium channels located within nerve fibers. Nonionized molecules can achieve penetration of only biologic membranes, and the speed of the process depends on the number and thickness (increasing with age) of sheaths.

Systemic Absorption and Distribution

Plasma Protein Binding. Nonionized local anesthetics cross almost freely the capillary wall close to the injection site. Because cardiac output and local blood flow are two to three times greater in infants than in adults, systemic local anesthetic absorption is increased accordingly and vasoactive agents such as epinephrine are very effective in slowing systemic uptake.

Once they have penetrated within the vascular bed, local anesthetics undergo plasma protein binding mainly to human serum albumin (HSA) and α_1-acid glycoprotein (AAG), or orosomucoid. HSA has a low affinity for local anesthetics, and many pharmacologic agents can compete at available binding sites. Furthermore, plasma levels of HSA are low during the first months of life, especially in premature and fasted infants; thus, the protection offered by HSA against systemic toxicity of local anesthetics is low and decreases postoperatively. The affinity of AAG for local anesthetics is 5000 to 10,000 times greater than that of HSA, which makes AAG very effective to protect the patient from systemic toxicity (which depends on the unbound free form of local anesthetics). However, again, plasma concentration of AAG is very low at birth (0.2 to 0.3 g/L) and does not reach adult levels (0.7 to 1.0 g/L) before 1 year of age.[11-13]

Because plasma concentration of the two proteins able to bind local anesthetics are low at birth, the free fraction of all local anesthetics is increased in infants; therefore, the maximum doses of all aminoamides must be significantly reduced in this age group even though the plasma concentration of AAG increases postoperatively, except in case of liver insufficiency.[13] On the other hand, the stress of surgery, particularly in infants with infection or in an emergency surgery, the plasma levels of orosomucoid may increase.[11] The increase in plasma orosomucoid concentration can change the proportion of free fraction of ropivacaine, increasing the plasma concentration of the bound fraction of this molecule and thus protecting from the systemic toxicity of local anesthetic.[14] These phenomena can largely reduce the potential risk of local anesthetics after a single injection by retaining their plasma concentration within the safety margins.

Red Cell Storage. Once in the bloodstream, local anesthetics distribute to red blood cells, which retain 20% to 30% of the total dose, depending on the anesthetic and the hematocrit. Red cell storage usually has a minor impact on the pharmacokinetics of local anesthetics except in the following situations:

- In neonates: High hematocrit values (which may exceed 70%) and enlargement of erythrocytes (physiologic macrocytosis) result in consistent "entrapment" of local anesthetics, thus lowering peak plasma concentration (C_{max}) values after a single injection but increasing secondary release, thus increasing the half-life of all local anesthetics.
- In infants: Physiologic anemia reduces red cell storage and its protective effect against systemic toxicity of local anesthetics (after a single-shot injection only) when the plasma protein binding sites are saturated—that is, close to toxic blood concentrations.

Absorption From the Epidural Space. Absorption has been rather well evaluated in the epidural space. In children and infants, the same kinetics of absorption is reported, but the younger the patient, the less accentuated is the biphasic shape of the plasma concentration curve. The peak plasma concentration and the slope of the decreasing concentration curve are increased,[15] whereas the time (T_{max}) to reach C_{max} remains basically unchanged; for example, the T_{max} of bupivacaine is approximately 30 minutes regardless of the patient's age.

Ropivacaine is a remarkable exception. After caudal or lumbar epidural injection, T_{max} is prolonged up to 2 hours in infants and C_{max} is increased.[16] This atypical pharmacokinetic profile may be explained by factors such as enzyme immaturity, slower systemic uptake, and decrease in distribution volume.[17,18] Intrinsic vasoconstrictive properties of ropivacaine also may play a role in the same way as addition of epinephrine. This significant increase in both C_{max} and T_{max} values must be kept in mind because surgeries in infants are brief and the young patient may have left not only the operating room but also the postanesthesia care unit (PACU) less than 2 hours after the caudal or epidural procedure was performed—that is, before peak plasma concentration was reached.

Importantly, levobupivacaine displays a similar pharmacokinetic profile. After caudal injection of levobupivacaine 2 mg/kg in infants younger than 2 years of age, the C_{max} range is 0.41 to 2.42 μg/mL (0.91 ± 0.40 μg/mL), which is higher than the C_{max} reported after caudal injection of the same dose of racemic bupivacaine.[19] T_{max} values also are delayed (50 minutes versus 30 minutes) in infants younger than 3 months of age as a result of reduced plasma clearance.[20]

When repeat injections are considered, the epidural dose must be reduced to keep C_{max} values in the same range as that resulting from the first injection. For the second injection, the following recommendations can be made:

- Reduce the dose to one third of the initial dose and do not inject it less than 30 minutes (lidocaine, mepivacaine, prilocaine) or 45 minutes (bupivacaine, levobupivacaine, ropivacaine) after the first injection

or

- Inject half of the initial dose, but 60 minutes (lidocaine, mepivacaine, prilocaine) or 90 minutes (bupivacaine, levobupivacaine, ropivacaine) after the first injection.

If reinjections are necessary, dosing should be further reduced to half of the second dose (i.e., one sixth of the initial dose) while respecting the same delay as for the second injection.

Continuous infusions aim to produce a steady-state concentration at the twenty-fourth hour postoperatively. This goal is easily achieved in adolescents with infusion rates of approximately 0.3 mg/kg/hr of bupivacaine and levobupivacaine or 0.4 mg/kg/hr of ropivacaine.

In infants, infusion rates must be reduced,[21,22] not exceeding 0.2 mg/kg/hr with bupivacaine (or equipotent doses of other local anesthetics) in infants younger than 4 months and 0.25 mg/kg/hr in older infants. Infants younger than 4 months (occasionally up to 9 months) may develop systemic toxicity even at these "safe" infusion rates with racemic bupivacaine because no steady-state plasma concentration is reached, even at the forty-eighth hour. In this age group, levobupivacaine[23] or ropivacaine[24] instead of racemic bupivacaine is preferred because stable plateau concentrations are obtained from the twenty-fourth hour onward.

Absorption From Other Injection Sites. Absorption of local anesthetics deposited along mucous membranes is increased in infants.[9] Mucosal topical anesthesia has long been considered contraindicated in this age group. However, the technique can be safely used with certain precautions—selection of specific transmucosal patches[25] or sprays with diluted lidocaine[26,27] and recognition that topical lidocaine exaggerates laryngomalacia.[28]

After cutaneous application of EMLA (lidocaine and prilocaine) cream, peak plasma concentrations occur 4 hours later and remain low[29]—less than 200 ng/mL for lidocaine and less than 131 ng/mL for prilocaine, even in infants younger than 6 months of age.

Absorption of local anesthetics from compartment blocks (e.g., fascia iliaca, umbilical, ilioinguinal, pudendal blocks) follows the same biphasic curve as for the epidural space.[30-33] Because of the extended surface of absorption, injection of highly concentrated solutions of local anesthetics often leads to high, occasionally potentially toxic peak plasma concentrations, especially with 0.5% ropivacaine,[33] whereas use of more diluted solutions results in rather low plasma concentrations.

Absorption from peripheral conduction blocks also follows a similar biphasic curve with different C_{max} and T_{max} values depending on the local anesthetic, the addition of epinephrine, and the site of injection; the more distal the injection, the slower is the absorption process (as in adults).

Pulmonary Extraction. After they have reached the venous bloodstream and undergone plasma protein linkage and erythrocyte storage, aminoamides reach the right cardiac cavities and then the pulmonary circulation, from which they are extracted by the lung. Their plasma concentration in pulmonary veins and then in systemic arterial circulation (especially coronary and cerebral arteries) is consistently decreased. Thus, pulmonary extraction represents a temporary protection against systemic toxicity. However, certain medical conditions suppress this protective effect. Some medications such as propranolol decrease pulmonary extraction in a clinically relevant way. Also, children with right-to-left shunts undergo considerable increase in arterial plasma concentration of local anesthetics because of pulmonary bypass; even with small doses of local anesthetics they can develop systemic toxicity.[34]

Distribution Volume. After intravenous (IV) injection, distribution volume at the steady state (Vdss) is 1 to 2 L/kg for all aminoamides (Table 92-2). After administration at other sites, calculated distribution is increased, often considerably, because of the "flip-flop" effect, especially for long-lasting local anesthetics. In infants and neonates, owing to higher extracellular fluid content (Table 92-3), the distribution volume of all local anesthetics is greater than in adults, the consequences of which are (1) significant decrease in peak plasma concentration of all local anesthetics, thus decreasing the danger of systemic toxicity after a single dose, and (2) accumulation with reinjections, which increases drug plasma concentration and elimination half-life while concomitantly decreasing clearance.

Hepatic Extraction and Clearance of Aminoamides. Short-acting local anesthetics undergo high hepatic extraction (0.65 to 0.75 ratio for lidocaine), which depends mainly on hepatic blood flow and not much on their plasma concentration. Only limited pediatric data are available for levobupivacaine. After a single injection, the clearance of levobupivacaine increases during the first months of life, but during continuous infusion (even with 0.0625% levobupivacaine), it tends to decrease almost to the same extent as for racemic bupivacaine, and plasma concentrations do not reach a plateau.[20]

Placental Transfer. In pregnant women, placental extraction may consistently affect tissue distribution of local anesthetics. Protein binding influences placental transfer. The concentration ratio between umbilical venous blood and maternal arterial blood is approximately 0.73 for lidocaine, 0.85 for prilocaine, but only 0.32 for bupivacaine. Chirality may play a role, too, at least for bupivacaine, because placental transfer of dextrobupivacaine exceeds that of levobupivacaine but only with solutions containing

TABLE 92-2 AGE-RELATED DIFFERENCES IN PHARMACOKINETIC PARAMETERS OF AMINOAMIDES

Local Anesthetic	Protein Binding (%)	Vd_{ss} (L/kg)	Clearance (mL/kg/min)	Elimination Half-Life (hr)
Lidocaine				
Neonate	25	1.4-4.9	5-19	2.9-3.3
Adult	55-65	0.2-1.0	11-15	1.0-2.2
Mepivacaine				
Neonate	36	1.2-2.8	1.6-3	5.3-11.3
Adult	75-80	0.6-1.5	10-13	1.7-6.9
Bupivacaine				
Neonate	50-70	3.9 (±2.01)	7.1 (±3.2)	6.0-22.0
Adult	95	0.8-1.6	7-9	1.2-2.9
Levobupivacaine				
Infant	50-70	2.7	13.8	4
Adult	95	0.7-1.4	28-39	1.27 ± 0.37
Ropivacaine				
Infant	94	2.4	6.5	3.9
Adult	94	1.1 ± 0.25	4-6	1.15 ± 0.41

TABLE 92-3 VARIATION OF BODY FLUID DISTRIBUTION BY AGE GROUP

Distribution of Body Fluids	Preterm Neonates (%)	Full-Term Neonates (%)	Infants (%)	Children (%)	Adults (%)
Total body fluids	80-85	70-75	65	55-60	50-55
Intracellular	20-25	30-35	35	35-40	40-45
Extracellular	55-60	45	30	20-25	20

epinephrine.[35] Most aminoesters undergo such a rapid plasma hydrolysis that placental transfer is not an issue. Tetracaine and cocaine, the hydrolysis of which is slow, are used only for topical applications or (tetracaine only) spinal anesthesia; systemic uptake is slow and plasma concentrations remain extremely low and, thus, are not issues again for placental transfer.

Metabolism. Aminoesters are rapidly hydrolyzed by plasma cholinesterases. This enzymatic activity is low at birth (but no adverse clinical consequences are to be feared) and gradually reaches adult levels by 1 year of age.[36] Chloroprocaine is eliminated at the fastest rate (4.7 mol/mL/hr), procaine at a slower rate (1.1 mol/mL/hr), and cocaine at only 0.3 mol/mL/hr. Procaine and chloroprocaine are also metabolized, in part, by hepatic cholinesterases.

Aminoamides are metabolized within the liver, where they are subjected to two types of enzymatic reactions. Phase I reactions occur first, during which oxidation of the amide link is achieved within hepatic microsomes by the cytochrome P (CYP)450 enzyme superfamily, then phase II reactions, during which glucuronic acid or aminoacid residues are appended to phase I metabolites, produce atoxic and hydrosoluble compounds, which are thus easily eliminated from the body.

CYP450 enzymatic activities are reduced during the first months of life. Bupivacaine is mainly metabolized by CYP3A4 in adults, but this enzyme is defective in infants. However, fetal CYP3A7 remains very active in infants, thus allowing metabolism of bupivacaine to be almost as effective as with CYP3A4.[9] Ropivacaine and levobupivacaine[20] are metabolized by CYP1A2, which is not fully functional before the third year, and, to a minor extent, by CYP3A4. This enzyme immaturity is clinically relevant but with limited consequences (lower clearance, delayed T_{max} and, for ropivacaine only, increased C_{max} but within clinically acceptable levels): it does not preclude administering these local anesthetics in neonates and infants.

Phase II reactions, especially glucuroconjugation, are immature at birth and remain so until the third year of life. However, other conjugation pathways such as sulfoconjugation are active and quite effective during the first months of life.

Elimination Half-Life. Elimination half-life ($t_{½}\beta$) depends on both distribution and metabolism. It can be calculated using the formula below (*Cp* is the plasma clearance and *Vdss* the distribution volume at the steady state):

$$t_{1/2}\beta = (0.693 \times \text{Vdss})/\text{Cp}$$

Basically $t_{½}\beta$ is the same in children older than 1 year of age and adults, mainly because the increase in Vdss is compensated by concomitant increase in Cp (related in part to higher hepatic blood flow in children, whose liver accounts for 4% of body weight, versus only 2% in adults). Before the age of 1 year, Cp is low and elimination half-life of all local anesthetics is prolonged (see Table 92-2), thus favoring accumulation with repeat injections. Nevertheless, Bricker and colleagues[37] measured no consistent differences in pharmacokinetic parameters between infants and adults.

Systemic Toxicity. Clinical signs of neurologic toxicity have been reported with plasma concentration ranging from 7 to 10 μg/mL for lidocaine or mepivacaine and 1.5 to 2 μg/mL (intraoperatively) to 2 to 2.5 μg/mL

(postoperatively) with bupivacaine. However, plasma concentrations of bupivacaine higher than 4 μg/mL have been reported without evidence of clinical toxicity. From studies in adult volunteers, the following thresholds of toxicity of the unbound form of local anesthetics have been defined:

- 0.3 μg/mL for unbound bupivacaine
- 0.6 μg/mL for unbound levobupivacaine or ropivacaine

Because plasma protein binding is lower in infants, hazards of systemic toxicity might be increased, the more so as cardiac toxicity is usually concomitant with, not preceded by, central nervous system toxicity. For further information on local anesthetics, see Chapter 36.

Opioids

Elimination half-life of neuraxial opioids is considerably increased in neonates and infants.[38] After epidural injection, morphine reaches its peak concentration in plasma within 10 minutes, but this concentration is very low and unable to provide clinically relevant analgesia.[39,40] Elimination half-life from cerebrospinal fluid (CSF) is similar to that from plasma, but CSF concentrations are very high after epidural injection; therefore, it takes 12 to 24 hours before they decrease below minimal effective concentrations (near 10 ng/mL). Consequently, vital parameters of children given neuraxial opioids must be monitored for 24 hours and are not eligible for outpatient surgery. Usual doses of neuraxial narcotics are listed in Table 92-4. Short-acting lipid-soluble opioids (fentanyl, sufentanil) can be used, but, as in adults, they do not significantly prolong postoperative pain relief unless repeat injections are given or a continuous infusion is established. Their analgesic effect is mainly a systemic effect, and the patient may experience acute respiratory depression (sudden apnea); this condition is very different from the progressive and delayed respiratory depression, preceded by generalized pruritus, sedation, and bradypnea, reported after excessive doses of epidural and intrathecal morphine.

TABLE 92-4 COMMONLY USED ADDITIVES AND RECOMMENDED DOSES IN PEDIATRIC REGIONAL ANESTHESIA

Additive	Recommended Doses	Maximum Doses
Morphine		
Epidural	30 μg/kg	50 μg/kg
Intrathecal	10 μg/kg	20 μg/kg
Fentanyl (epidural)	1-1.5 μg/kg	2.5 μg/kg
Sufentanil (epidural)	0.25-0.5 μg/kg	0.75 μg/kg
Clonidine (epidural or along peripheral nerves)	1-1.5 μg/kg	2 μg/kg
Ketamine* (epidural or occasionally along peripheral nerves)	0.5 mg/kg	1 mg/kg

*Preservative-free ketamine (preferably preservative-free S-ketamine).

Other Additives

Epinephrine 5 mg/L or 1/200,000 concentration is frequently coadministered with local anesthetics to decrease plasma peak concentration[30] and prolong the duration of blockade, especially in children younger than 4 years of age.[41,42] Another benefit expected from epinephrine is early detection of accidental IV injection (test dose) because young children are very sensitive to arrhythmogenic properties of epinephrine. Neuraxial epinephrine has long been suspected to elicit spinal ischemia: even though this fear proved to be unfounded, many anesthesiologists recommend using lower concentrations of epinephrine (2.5 mg/L or 1/400,000) in local anesthetic solutions administered to neonates and infants; at such concentrations, the absorption rate of caudal bupivacaine is decreased by 25%.[42]

Clonidine, like epinephrine, is an α_2-adrenergic agonist that offers several benefits in children when added to local anesthetics either neuraxially[43-45] or peripherally (see Table 92-4)[46]; it increases (by a factor of ~2) the duration of nerve blockade without eliciting hemodynamic disorders, decreases plasma peak concentration of the local anesthetics, and produces a slight sedation for 1 to 3 hours postoperatively (which does not preclude hospital discharge). Addition of clonidine often makes unnecessary the placement of a catheter to prolong postoperative pain relief, thus reducing morbidity and costs. However, its clearance in neonates is approximately one third of that in adults owing to immature elimination pathways[47] and several instances of respiratory depression in neonates and small infants have been reported[48,49]; this additive should be avoided during the first 6 months of life.

Ketamine, especially S-ketamine, is an interesting adjuvant because of its blocking effects on *N*-methyl-D-aspartate receptors and interaction with sodium channels in a local anesthetic–like fashion (it shares a binding site with local anesthetics). Coadministered at a dose of 0.25 to 0.5 mg/kg, ketamine prolongs the duration of analgesia for many hours[44,50] with no significant adverse effects.

Many other agents have been occasionally used as adjuvants to local anesthetics.[51] Even though some of them proved to have analgesic properties (corticosteroids, buprenorphine, neostigmine, tramadol, midazolam, and biodegradable bupivacaine and polyester microspheres), they all produce significant adverse effects that preclude their use in most patients. Furthermore, their administration to pediatric patients raises ethical questions, and they are not approved for pediatric use.

PHYSIOLOGIC FACTORS

Surgery generates a neuroendocrine stress response in neonates, infants, and children,[4,52] resulting in undesirable alterations of the metabolic state and immune function.[53] Epidural anesthesia diminishes or even suppresses this stress response.[54-56] Central blocks do not affect left ventricular function and are virtually free of measurable hemodynamic effects, at least up to the age

of 8 years.[57,58] Epidural anesthesia does not result in systemic or pulmonary hemodynamic changes as measured by mean blood pressure, end-diastolic diameter of the left ventricle, ejection fraction of the left ventricle, and mean velocity circumferential fiber shortening.[59] However, pulmonary Doppler flow velocity is decreased during epidural anesthesia, probably owing to an increase in the pulmonary arterial resistance. Preloading with saline is not recommended in children, and, even in adolescents, fluid therapy or injection of vasoactive agents is rarely required.

PSYCHOLOGICAL FACTORS

Children are frightened by new environmental conditions in the operating room, and most of them cannot cope with their anxiety.[60,61] They feel abandoned by their parents and exposed to strangers who are threatening them with needles. Furthermore, children younger than 10 years of age have not acquired their complete body image and cannot clearly make a distinction between adjacent parts of their body such as forearm and arm. Young patients cannot understand the concepts of paresthesia and differential blockade ("touch" is not "pain"). Thus, localization of nerve trunks and anatomic spaces requires using physical methods independent of the patient's cooperation (loss of resistance seeking, neurostimulation, ultrasound techniques). Infants and most children cannot cope with their anxiety and fear of needles; therefore, sedation or light general anesthesia is mandatory before block procedure to avoid panic attacks and unwanted movements during the procedure.

Regional anesthesia has a significant psychological impact. A pain-free postoperative course improves the morale of the patient, the family, and the nurses. Surgeons are happy to examine quiet, alert, and manageable patients. Occasionally, negative psychological effects can be observed—persistent motor (even sensory) blocks postoperatively may be frightening to some children (3 to 5 years of age especially) and their parents even though precise explanations had been given preoperatively as to the expected course of events during the postoperative period. Offering friendly environmental conditions, empathy, and additional explanations on local anesthetic pharmacology can reduce this postoperative anxiety. It should be kept in mind that a motor block must be avoided when not absolutely required for surgery.

INDICATIONS, CONTRAINDICATIONS, AND COMPLICATIONS

INDICATIONS

Indications for regional anesthesia in children are not identical to those in adults, not only because surgical pathologic processes are quite different but also because regional block procedures are used as techniques of analgesia in anesthetized children rather than in conscious or lightly sedated adult patients.

Anesthetic Indications

Some children and adolescents are occasionally willing to undergo their surgery under regional anesthesia while remaining conscious. If a regional block can provide adequate analgesia, there is no reason to refuse such management, especially for short-duration surgery. Occasionally, such a management approach can be considered in children at risk for severe complications during general anesthesia from certain problems, such as the following[62]:

- Testicular torsion or incarcerated hernia at immediate risk for rupture in nonfasted children
- Inguinal hernia repair in former preterm infants younger than 60 weeks of postconceptual age who are at risk for developing severe postoperative apnea
- Severe acute or chronic respiratory insufficiency
- Emergency conditions in children with severe metabolic or endocrine disorders
- Neuromuscular disorders, myasthenia gravis, or some types of porphyria
- Some types of polymalformative syndromes and skeletal deformities

Cervical instability (making tracheal intubation a risk for tetraplegia) is constant in Chiari syndrome and common in achondroplasia and Down syndrome. Patients with facial deformities, microstomia, and mandible abnormalities can be difficult to intubate, thus making general anesthesia a less attractive technique. Also, infants with epidermolysis bullosa are extremely difficult to manage under general anesthesia; occasionally, regional block procedures may represent an alternative with lower morbidity.[63-65] Trauma patients with extremity lesions may greatly benefit from peripheral nerve block for alleviating pain without impeding monitoring of head trauma or hemodynamic disorders and allowing wound dressing as well as temporary stabilization of fractures, provided that appropriate precautions are taken to avoid hiding development of compartment syndromes (see later).

Intraoperative and Postoperative Analgesia and Procedural Pain

Analgesia is currently the main indication for regional blocks in children because they offer the best benefit-to-risk ratio for many outpatient and inpatient surgeries: orthopedic (including scoliosis surgery), thoracic, urologic, and upper and lower abdominal surgeries.[66-68] Cardiac surgery is a more controversial indication,[69,70] and many anesthesiologists are reluctant to perform neuraxial blocks in children scheduled to receive anticoagulants.

Procedural pain can easily be anticipated and thus prevented mostly by topical anesthesia or infiltration techniques.[71-73] The indications for perineural catheters depend on the expected duration of postoperative pain.[74] Also, surgery associated with intense postoperative pain (major orthopedic surgery, hand or foot amputation) and postoperative pain management or painful physical therapy necessary for several days (knee or ankle arthrolysis, knee ligamentoplasty) are excellent indications for catheters. Nevertheless, it is important to verify the absence of any possible interference in the postoperative course; the catheter technique should not risk compromising the outcome of surgery.

A comparative evaluation of suitability, and benefit-to-risk ratio for most regional techniques is provided in Table 92-5.

Management of Nonsurgical Pain

Relief of pain associated with some medical conditions such as herpes zoster, acquired immunodeficiency syndrome (AIDS), mucosal and cutaneous lesions, and cancer can be achieved using regional block techniques.[75,76] Children with sickle cell disease may greatly benefit from epidural analgesia during vaso-occlusive crisis or thoracic syndromes with intractable pain by other means, provided that pain is localized to limited areas and concomitant fever is not due to bacteremia.[77,78]

Chronic Pain Relief and Palliative Care

Chronic pain is less unusual in children than commonly believed, and regional techniques such as epidural anesthesia, stellate ganglion blockade, or continuous peripheral nerve blocks may help treat this condition, especially in case of phantom limb pain and complex regional pain syndrome, leading to pain reduction (minimal pain scores), physiotherapy facilitation, and functional rehabilitation.[79] Treatment of intractable refractory pain from a chronic dislocated left hip with long-time perineural catheter has been described.[80] Erythromelalgia, a rare but extremely painful condition, can be successfully relieved by continuous epidural analgesia.[81] Cancer pain resulting from either primary tumor or metastases also can be controlled by regional techniques when other medications fail or produce too many adverse effects. Virtually all techniques of regional anesthesia have been reported in this ultimate management of pain in children, from epidural analgesia to intrathecal infusions to celiac or brachial plexus block.[82,83]

Nonanalgesic Indications

For certain medical conditions, analgesia is not the only benefit expected from regional blockade. Sympathetic blockade is essential to protect and improve blood supply to an upper or lower extremity in a context of severe trauma. Also, continuous epidural blockade proved to be effective in treating vascular insufficiency resulting from

TABLE 92-5 EVALUATION OF THE SUITABILITY AND BENEFIT-TO-RISK RATIO AND FEASIBILITY WITH ULTRASOUND GUIDANCE OF MOST TECHNIQUES OF REGIONAL ANESTHESIA IN CHILDREN

Technique	Ease of Performance	Benefit-to-Risk Ratio	Feasibility With Ultrasound	Catheter Placement
Central blocks				
Spinal block	+ to ++	+++	Mild	No
Caudal block	+++	++++	Easy	Occasionally
Lumbar epidural anesthesia	+++	+++	Difficult	Yes
Thoracic epidural anesthesia	+++	+++	Difficult	Yes
Sacral epidural anesthesia	++	++	Difficult	Yes
Cervical epidural anesthesia	Avoid	Very low	Avoid	Avoid
Limb plexus and peripheral nerve conduction blocks				
Interscalene block	++	++	Mild	Occasionally
Parascalene block	+++	++++	Mild	Yes
Subclavicular block	+++	+++	Mild	Yes
Axillary block	++++	++++	Easy	Occasionally
Psoas compartment block	+++	++	Difficult	Occasionally
Femoral block	+++	++++	Easy	Yes
Proximal sciatic blocks	++ to +++	+++	Mild	Yes
Subgluteal sciatic block	+++	++++	Easy	Yes
Popliteal sciatic block	+++	++++	Easy	Yes
Distal block	++ to +++	+++	No	No (except tibial nerve at ankle)
Truncal compartment blocks				
Intercostal block	++	+	No	Occasionally
Intrapleural block	++++	0 to +	No	Yes
Thoracic paravertebral block	++	+	Difficult	Yes
Rectus sheath block	++++	+++	Easy	No
Ilioinguinal-iliohypogastric nerve block	++++	+++	Easy	Occasionally
Transabdominis plane block	++++	+++	Easy	Occasionally
Penile block	++++	++++	Mild	No
Pudendal nerve block	+++	+++	Difficult	No
Facial blocks				
Trigeminal superficial block	++++	++++	Mild	No
Suprazygomatic maxillary nerve block	+++	+++	Mild	Occasionally
Mandibular nerve block	+++	+++	Difficult	No
Other techniques				
Bier block	++ to +++	+	No	No
Wound infiltration	++++	+++	No	Yes
Topical anesthesia	++++	++++ (skin)	No	No

Kawasaki disease, accidental intraarterial injection of an anesthetic drug,[84] penile block with a local anesthetic containing epinephrine, and severe frostbite. Axillary and stellate ganglion blocks have also successfully treated acute vascular insufficiency of the upper limb.[85]

CONTRAINDICATIONS AND LIMITATIONS

Absolute Contraindications to Neuraxial Blocks

Medical conditions that contraindicate neuraxial blocks in children are (1) severe coagulation disorders, which may be constitutional (hemophilia), acquired (disseminated intravascular coagulation), or therapeutic; (2) severe infection such as septicemia or meningitis; (3) hydrocephaly and intracranial tumoral process; (4) true allergy to local anesthetics (a very rare condition even with aminoesters); (5) certain chemotherapies (such as with cisplatin) prone to induce subclinical neurologic lesions that can be acutely aggravated by a block procedure; (6) uncorrected hypovolemia; and (7) cutaneous or subcutaneous lesions, whatever their nature (infection, angioma, dystrophic or tumoral, tattoo) at the contemplated site of puncture. Parental refusal is a nonmedical absolute contraindication.

Depending on the clinical condition of the patient and the possibility to cure (at least temporarily) the impeding disorder, a regional block may be considered in spite of the existence of a contraindication. After correction of hypovolemia, injection of factor VIII to a hemophilic child, or effective antibiotic treatment of a septicemic patient,[86] a central block may be performed, provided that the expected benefits consistently outweigh the risks by comparison with other techniques of analgesia. Also, some authors consider it acceptable to perform a caudal block in children with shunt devices under protection of antibioprophylaxis.[87]

Absolute Contraindications to Peripheral Nerve Block Procedure

True allergy to local anesthetics is the only absolute medical contraindication to peripheral nerve blocks. Coagulation disorders are less hazardous than during neuraxial blocks, but it is prudent to avoid techniques with a danger of arterial trauma, especially in an area where compression is difficult or impossible (supraclavicular brachial plexus block, psoas compartment block). Septicemia does not necessarily contraindicate peripheral nerve blockade if expected benefits are significant. Local skin infection at the puncture site should be considered before performing a peripheral nerve block, especially if a catheter is implanted. Hypovolemia should preferably be corrected but does not preclude peripheral blocks because hemodynamic consequences are minimal.

Patients at Risk for Compartment Syndrome

Because pain is one of the cardinal symptoms of a compartment syndrome, any pain treatment, including regional anesthesia, is often claimed to be contraindicated because it can suppress this manifesting symptom, thus delaying the rescuing surgery. Such a refusal of pain management is not acceptable either medically and ethically.[88] Fractures are very frequent in the pediatric population, whereas compartment syndromes are very rare; whether or not a compartment syndrome is in progress, intense pain is a constant feature. Adequate pain management, including continuous epidural analgesia,[89] does not preclude early diagnosis, and this fact was confirmed by the National Pediatric Epidural Audit in Great Britain.[90]

Excruciating pain is not a "manifesting" symptom but a late—possibly too late—symptom of compartment syndrome. Patients at risk should be monitored adequately, which is not done most of the time even in university hospitals, and precautions must be taken—that is, avoidance of closed plaster casts; elbow immobilization with an angle greater than 90 degrees[91] closed reduction of supracondylar fractures of the humerus, repeat clinical evaluation of the distal perfusion and tissue oxygenation of the limb; and noninvasive monitoring of the intracompartmental pressure, even though this monitoring is not 100% reliable. If the risk is considered high (e.g., displaced humeral fractures, intramedullary nail fixation of tibia or radius, obtunded patients), intracompartmental pressure close to the fracture site should be invasively monitored. The procedure is easy and almost inexpensive, requiring only a venous cannula, an IV line, and a pressure gauge (as for central venous pressure measurement).[92,93]

Hemoglobinopathies

Children with sickle cell disease are prone to develop hemolysis in case of desaturation and undergo repeat episodes of extreme pain as a result of extended microthromboses when local blood flow slows down (e.g., hemoconcentration, shock, surgical tourniquet).[94] In the case of a danger of hypoxemia (respiratory disease) or hemodynamic disorders (surgery known to produce significant blood loss, tourniquet placement), regional (especially neuraxial) blocks should be avoided.

Bone and Joint Deformities

Minor or localized malformations of the spine (hemivertebra, spina bifida occulta, Scheuermann disease) do not preclude neuraxial blocks, whereas extended malformations of vertebrae, spinal fusion, myelomeningoceles, open spina bifida, and major spondylolisthesis are contraindications. Tethered cord syndrome is not unusual and is often misdiagnosed. Neuraxial blockade may increase the overall morbidity of patient management because it facilitates excessive bending or extension of the spine that can occasionally damage the spinal cord permanently. The diagnosis must be suspected if a clump of hairs or a dystrophic lesion of the skin is present at the lower extremity of the spinous process line or in the case of minor neurologic disorders involving pelvic nerves (minimal sphincter disorders, perineal dysesthesia). Even though some authors consider that this condition is not a contraindication,[95] it is preferable to select another technique of analgesia than epidural blockade. Many pediatric syndromes, cerebral palsy, and kyphoscoliosis are associated with bone and joint deformities that represent more of a technical difficulty than a contraindication to performing a regional block.

Preexisting Neurologic Disorders or Diseases

Controlled epilepsy is not a contraindication to regional anesthesia, including neuraxial blockade. Preexisting central nervous system disorders and degenerative axonal diseases have long been considered to be contraindications, at least relative, even though no data support the hypothesis that a regional block could worsen their course.[96] A recent pediatric study involving 139 patients showed that preexisting neurologic disorders were not associated with bad neurologic outcome (rather, the reverse was observed) after central block procedures.[97]

COMPLICATIONS

Complications of regional anesthesia are basically the same as in adults. The complication rate found recently in a large epidemiologic study was 0.12%, with two major risk factors—age and the central blocks.[98] They can be classified as local, regional, and general (or systemic).

Local Complications

The four main types of local complications are as follows:

1. Inappropriate needle insertion damaging the nerve and surrounding anatomic structures
2. Tissue coring and introduction of epithelial cells into tissues where they do not belong and where they can develop as compressive tumors (especially in the spinal canal)[99]
3. Injection of neurotoxic solutions (syringe mismatch, epinephrine close to a terminal artery)
4. Leakage around the puncture site, especially when a catheter has been introduced, which may cause partial block failure and favor bacterial contamination (very rare)

These local complications are easily avoidable by using adequate devices and applying standard precautions (appropriate dressing and bacterial precautions). Tunneling the catheter and applying a slightly compressive dressing can reduce leakage around the catheter.

Local anesthetics are locally toxic. Myelin, effective protection of nerve roots, is less abundant or absent in children, potentially making the nerves more sensitive to local anesthetics. In animals, it has been clearly demonstrated that the sensitivity of nerve fibers to local anesthetics is inversely correlated with age.[100] However, in most cases, perineural injection is around muscle. The myotoxicity of local anesthetics has been previously demonstrated in humans and animals,[101] primarily through mitochondrial damage. This also has been demonstrated in young animals.[102] By comparing continuous bupivacaine perineural administration in adult rats and young rats, the authors showed that muscle, mitochondrial, and ultrastructural toxicity was significantly greater in the juvenile group,[102] thus emphasizing the need to use lower dosages in younger patients.

Systemic Complications

Systemic complications usually result from accidental IV injection of local anesthetics or, less frequently, excessive dosing.[10,103] Systemic toxicity is essentially of two types: neurologic and resulting from heart failure by blocking sodium and potassium channels. Early signs of neurologic toxicity (tinnitus, malaise, metallic taste in the mouth) are unfortunately masked by general anesthesia. The main events are heart conduction disorders, cardiac arrhythmias (bradycardia or tachycardia), and atrioventricular block. QRS widening, bradycardia, and torsade de pointes are followed by ventricular fibrillation, asystole, or both.[104] Nevertheless, signs of cardiac and neurologic toxicity occur at lower plasma concentrations of bupivacaine than ropivacaine.[105] This toxicity may be aggravated by a decrease in plasma binding protein, mainly α_1-glycoprotein acid, resulting in a greater proportion of the unbound form of local anesthetic. The plasma concentration of this protein is low at birth, tends to increase with the age of the child to reach values equivalent to those of adults at the age of 10 months.[106] However, special care must be taken during continuous injections; the dosage of local anesthetic should be systematically reduced in very young children or after prolonged administration (>48 hours).

Systemic complications can be life-threatening and should be managed in the same way as in adults. The major difference between adults and children is that cardiovascular complications are not preceded by neurologic signs but are concomitant with cerebral toxicity.[107] In addition to pharmacokinetic factors, the rapid heart rate of children may increase the risk for cardiac toxicity induced by local anesthetic toxicity. Even if toxic events occur with ropivacaine, small doses of epinephrine should produce rapid recovery. Impaired ventricular conduction is the primary manifestation of local anesthetic toxicity. Treatment includes oxygenation, cardiac massage, and epinephrine, which is given in small incremental boluses beginning with 1 to 2 μg/kg.[108] If ventricular fibrillation persists, defibrillation (2 to 4 J/kg) is performed. Although resuscitation measures must be initiated immediately, the specific treatment of local anesthetic toxicity is rapid administration of Intralipid (Kabivitrum, Stockholm, Sweden). The recommended dose of 20% Intralipid for pediatric patients is 2 to 5 mL/kg by IV bolus. If cardiac function does not return, this dose (up to 10 mL/kg) is repeated.[9]

Epidemiology

Available pediatric information is limited. The first report of the American Society of Anesthesiologists (ASA) closed malpractice claims contained 238 pediatric cases (10% of claims), but only 7 involved children given a regional block procedure[109]; however, at that time regional anesthesia was not commonly used in American children, making this apparently low rate of complications meaningless. In 1996, the 1-year prospective study of the French-Language Society of Pediatric Anesthesiologists evaluated 85,412 pediatric anesthetic procedures, including 24,409 involving regional anesthesia.[110] Twenty-three complications (no sequelae, no death, and no legal consequences) were found, all following neuraxial blocks. In 2000, the Australian Incident Monitoring Study[111] included 2000 claims involving 160 pediatric cases with a regional block procedure (83 epidurals, 42 spinals, 14 brachial plexus, 4 Bier blocks, 3 ophthalmic blocks, and 14 local infiltrations). The largest single cause

of complications was circulatory problems, 24 drug errors (including 10 "wrong drugs" and 14 "inappropriate use") were found. In 2007, the British National Pediatric Epidural Audit[90] reported 96 incidents in 10,633 epidural blocks performed, as follows:

- Fifty-six (0.53%) were associated with the insertion or maintenance of epidural anesthesia, and most were of low severity; only one child had residual effects from cauda equina syndrome (after a programming error of the infusion pump).
- Forty (0.38%), mainly pressure sores,[31] were believed to be associated with the epidural infusion technique.

A significantly higher rate of incidents occurred in the neonatal age group, mainly because of drug errors (13 cases) and local anesthetic toxicity (1 case); these incidents were not related to catheter insertion. Twenty-eight infection-related incidents occurred, of which 85% were relatively minor skin infections; caudal catheters did not result in increased incidence of infections. Six children older than 8 years of age had mild postdural puncture headache. Four patients developed a compartment syndrome, but the condition was not masked by the epidural infusion.

From November 2005 to October 2006, a large epidemiologic study recorded the characteristics and developments of regional anesthesia in children in 47 French hospitals.[98] As previously demonstrated by Rochette and colleagues,[112] the authors reported a radical change in regional practice among French anesthesiologists with a transition from using predominantly neuraxial blocks to peripheral nerve blocks, including catheter techniques. A recent 1-year prospective survey of regional anesthesia evaluated complications and side effects on 31,132 cases of regional anesthesia. Complications (41, involving 40 patients) were rare and usually minor and did not result in sequelae. The study recorded a very low overall rate of complications of 0.12%, significantly six times lower for peripheral blocks than for neuraxial blocks. Age was also a risk factor, because the incidence of complications was higher before 6 months of life than after (0.4% versus 0.1% after 6 months of life). Fifteen cases of cardiotoxicity were observed, of which 87% occurred with a central block. The occurrence of complications does not seem to increase with the use of catheters.

In conclusion, regional block procedures—mainly neuraxial blocks—are associated with the occurrence of adverse incidents (~0.5%) that are mostly minor but occasionally severe. The majority of these complications result from insufficient precautions at the time of the block procedure (drug errors) and postoperatively (pressure sores). Also, of major importance is the fact that compartment syndrome is not hidden by a regional procedure provided that adequate monitoring is guaranteed.

SELECTION OF MATERIALS AND ANESTHETIC SOLUTION

SELECTION OF BLOCK PROCEDURE

Careful selection of block procedures is based first on anatomic considerations. Sensory blockade must cover all areas from which noxious stimuli can originate (e.g., operative field, sites for skin or bone graft tissue, placement of tourniquet or drains). Then, the potential morbidity of the technique, from the medical condition of the patient, the requested positioning, or the "intrinsic" morbidity of the technique itself, must be evaluated. The anticipated duration of postoperative pain is the third most important factor to take into account because the regional technique should provide adequate analgesia until minor analgesics are sufficient. The anesthesiologist will select one of the following approaches:

- A single-shot technique with either a short-acting or a long-acting local anesthetic
- A single-shot technique with local anesthetic and adjuvants
- A catheter technique with repeat or continual injections of local anesthetic

SELECTION OF EQUIPMENT

Epidural anesthesia (sacral, lumbar, or thoracic) is performed using Tuohy needles ranging in size from 22 to 17 gauge and in length from 50 to 90 cm; shorter Tuohy needles (25 cm) would be more appropriate in neonates and infants but are not easily available. Caudal anesthesia has been performed in the past with almost all types of needles. This is no longer acceptable, and only short beveled needles (Crawford needles) with a guide sealing their lumen or IV cannulas with an introducer needle should be used.

Spinal anesthesia in premature infants can be performed using either a neonatal lumbar puncture needle (22 gauge) or, preferably, a thinner spinal needle (shorter than 50 mm). The distal end of the needle does not have the same importance as in adults because the incidence of postdural puncture headache remains (very) low in children and is not influenced by the design of the tip of the needle.[113,114] What matters most is the distance separating the tip of the needle from its distal orifice; this distance must be as short as possible to avoid extradural leakage if the needle has not been introduced far enough through the dura mater. Pencil-point needles have no advantage in infants and young children; they do not improve the results and are even suspected to decrease the success rate by favoring subdural spread of the local anesthetic. A summary of recommended needles for most regional block procedures in pediatric patients is provided in Table 92-6.

SELECTION OF DRUG

The prerequisites for selecting a local anesthetic are not exactly the same in children as in adults because regional techniques are mostly used for analgesic purposes rather than anesthesia. The factors to be considered are (1) site and severity of surgery, (2) expected duration of intense postoperative pain, and (3) hospital stay versus early discharge. Usual doses are listed in Table 92-7.

Lidocaine and mepivacaine are preferred for outpatient surgery. For inpatient surgery, ropivacaine, levobupivacaine, and bupivacaine are commonly used. Nevertheless, it is now recommended that L-enantiomers be used especially

TABLE 92-6 RECOMMENDED DEVICES FOR MOST REGIONAL BLOCK PROCEDURES IN CHILDREN

Block Procedure	Recommended Device	Alternate Device
Intradermal wheals and metacarpal blocks	Intradermal needles (25 gauge)	None
Subcutaneous infiltrations and field blocks	Standard intramuscular needles (21-23 gauge)	Intradermal needles (25 gauge)
Compartment blocks (thoracic paravertebral, rectus sheath, ilioinguinal-iliohypogastric, pudendal, penile)	Short (25-50 mm) and short beveled (45-55 degrees) needles	Epidural needles (intercostal block) Neonatal spinal needle
Peripheral mixed nerve blocks and plexus blocks	Insulated 21-23 gauge short beveled needles of appropriate length connected to a nerve stimulator (0.5-1 mA) Specific catheter (for continuous techniques)	Sheathed pencil-point needles Unsheathed needles only when ultrasound guidance is used Epidural catheter (for continuous techniques)
Spinal anesthesia	Spinal needle (24-25 gauge; 30, 50 or 100 mm long, Quincke bevel, stylet)	Neonatal lumbar puncture needle (22 gauge, 30-50 mm long) Whitacre spinal needle
Caudal anesthesia	Short (25-30 mm) and short beveled (45-degrees) needle with stylet	IV cannula (22-18 gauge), especially for epidural catheter insertion Pediatric epidural (occasionally spinal) needle
Epidural anesthesia	Tuohy needle (22, 20, and 19/18 gauge); LOR syringe and medium epidural catheter	Crawford, Whitacre, or Sprotte epidural needles appropriately sized; LOR syringe and medium epidural catheter

LOR, Loss of resistance.

TABLE 92-7 USUAL AND MAXIMUM RECOMMENDED DOSES OF LOCAL ANESTHETIC FOR CONDUCTION NERVE BLOCKS (EXCLUDING BIER BLOCKS AND SPINAL ANESTHESIA)

Local Anesthetics	Usual Concentration (%)	Maximum Dose of Plain Solution (mg/kg)	Maximum Dose With Epinephrine (mg/kg)
Aminoesters			
Procaine	1-2	7	10
Chloroprocaine	2-3	7	10
Aminoamides			
Lidocaine	0.25-2	5 (or 400 mg)	10 (or 700 mg)
Mepivacaine	0.25-2	5-7 (or 400 mg)	Not available
Bupivacaine	0.125-0.5	2 (or 150 mg)	3 (or 200 mg)
Levobupivacaine	0.125-0.5	3 (or 200 mg)	4 (or 250 mg)
Ropivacaine	0.1-10	3 (or 300 mg)	Not available (and not recommended)

for continuous infusions; they are well known for their lower cardiac toxicity compared with bupivacaine.[115] The pharmacologic characteristics of ropivacaine can achieve a differential nerve block[116] and have limited myotoxicity in contrast to bupivacaine.[117] After extravascular injection, the plasma concentration of ropivacaine peaks later than that of bupivacaine, sometimes up to more than 2 hours after injection.[18] This delay in the peak plasma concentration of ropivacaine usually reduces the maximum plasma concentration, providing some security in terms of toxicity, as demonstrated in some pediatric studies.[18,118] Even if the plasma concentration of free and total ropivacaine is higher in younger children, plasma concentrations of ropivacaine and its main metabolite (2,6-pipecoloxylidide) are not influenced by the duration of infusion of local anesthetics. In infants younger than 3 months of age, epidural infusion of ropivacaine should not be maintained for more than 36 hours.[119] The clearance of ropivacaine increases with age but remains unchanged throughout the infusion in each age category. Ropivacaine seems more appropriate, more predictable, and safer during continuous infusion for 48 to 72 hours than bupivacaine; the plasma concentration of bupivacaine increases and clearance decreases in proportion to the duration of infusion.[120] Studies examining the pharmacokinetics of local anesthetics during continuous perineural administration are rare in children. The safety of continuous regional anesthesia techniques in children relies on the use of low-concentration solutions accompanied by low plasma concentrations of local anesthetics (LAs) and limit the risk for systemic toxicity of these molecules. Addition of clonidine or ketamine helps improve the quality and duration of blockade without precluding early hospital discharge. In many cases, these drugs make it unnecessary to insert a catheter and establish a continuous infusion to provide adequate postoperative pain relief.

For many years, continuous epidural anesthesia was the only suitable technique for treating protracted pain. In recent years, peripheral nerve catheter techniques have proved to be effective,[67] with less morbidity and limitations than continuous epidural blockade, even allowing hospital discharge[79] and management at home in selected pediatric patients. For these techniques, continuous infusion (2 to 5 mL/hr) or on-demand injections (2 to 5 mL) of low-concentration levobupivacaine or ropivacaine (0.1% to 0.2%) represents the best and safest choice.

Patient-controlled administration of continuous infusion seems to be better in children, allowing decrease of the dose of local anesthetics for the same quality of analgesia.[121,122] Duflo and associates[122] comparing standard continuous administration (0.1 mL/kg/hr) and patient controlled regional anesthesia regimen (infusion of 0.02 mL/kg/hr and bolus of 0.1 mL/kg every 30 minutes) of 0.2% ropivacaine in patients undergoing fascia iliaca compartment or sciatic catheters noted lower hourly consumption of ropivacaine in patient-controlled administration. Ropivacaine plasma levels were also lower in this group in contrast to standard administration (0.31 and 0.86 mg/mL at 24 hours and 0.31 and 0.52 mg/mL at 48 hours). In a recent study, plasma levels of ropivacaine were collected and compared with continuous epidural block and continuous psoas compartment block in children.[123] The dose of local anesthetic infusion was 0.2 mg/kg/hr of 0.2% ropivacaine in the continuous psoas compartment block. The median plasma concentrations of ropivacaine did not exceed 0.59 μg/mL in this patient group and was lower than the plasma concentration in the epidural catheter group.

ANATOMIC IDENTIFICATION IN REGIONAL ANESTHESIA

MANUAL APPROACHES

The success of a regional anesthesia technique depends on the administration of a solution of local anesthetic close to the nerve or space limited by anatomic structures and fascial permeable little crosses by blocking nerve structure. Few nerve blocks can be performed using a manual approach without the aid of a nerve stimulator or ultrasound. These techniques are feasible in children anesthetized or sedated.

Some important points for performing regional anesthesia without any devices are as follows:

- Possessing good knowledge of the anatomy of the child according to age and good location of landmarks for the puncture site
- Defining the anatomic space at which the local anesthetic spreads to block the selected nerves
- Ensuring no risks exist for damage to other surrounding structures (e.g., vessels, nerves, organs)

Central blocks (caudal, epidural, or spinal block) are among the blocks that primarily can be achieved without assistance from technical devices, even though ultrasound-guided techniques for punctures are currently proposed. The realization of epidural block is facilitated by the loss of resistance (LOR) technique. For the spinal block, passing into the subarachnoid space is marked by the crossing of the dura mater (tough fibrous structure): a slight jump is felt, and then the flow of CSF. For the caudal block, the passage of the sacrococcygeal membrane is felt by an increase and loss of resistance in the needle. The majority of limb peripheral nerve blocks are performed using a nerve stimulator or with ultrasound guidance. Blocks of the trunk, performed with anatomic landmarks techniques for a long time, benefit greatly from ultrasound guidance for their localization, excepting the penile block (being evaluated with ultrasound guidance). The pudendal block, even if it is done using anatomic landmarks, also can benefit from using the neurostimulator to be closer to the nerve[124] or ultrasound guidance.[125] The superficial trigeminal nerve blocks on the face, described by anatomic landmarks for a long time, can now benefit from ultrasound guidance for the puncture.[126] Finally, further techniques, such as the paresthesia technique, transarterial techniques for the axillary block, and "swoosh" (test of good hand position by auscultation with a stethoscope of the caudal vertebrae low back during the injection of liquid into the needle) test for caudal block, should no longer be used.

Electrical Stimulation

Ultrasound guidance represents a revolution in regional anesthesia in children and adults. Despite its growing use, electrical stimulation remains the gold standard of nerve location in adults and children. Nerve stimulation equipment has largely improved and is clinically safer. The location of needle entry point before puncture can reduce the number of attempts and decrease the potential risk for nerve injury.[127]

For plexus and truncular nerve blocks, the anesthesiologist should use a nerve stimulator to elicit muscle twitches. The positive electrode of the nerve stimulator is placed distant to the nerve location. The nerve stimulator delivers square-wave electric impulses lasting 50 to 100 microseconds at the rate of 1 to 5 Hz. With a starting output of 2 to 2.5 mA, needles are advanced until they elicit the required muscle movement. The position is judged adequate when muscle contractions continue to occur at a current of 0.5 to 0.8 mA, when the tip of the needle is approximately 1 mm from the nerve or within the perineural fascial sheath. In contrast to adults, in whom a current of 0.5 mA or less is considered an acceptable indicator for a successful nerve block,[128] in children, if muscle contractions are still present at a current under 0.5 mA, the needle should be withdrawn to avoid intraneural injection and nerve damage.[129] Gurnaney and colleagues[130] evaluated the relationship between the lowest current amperage used to obtain a motor response, the success rate, and the incidence of neurologic complications with peripheral nerve blocks in pediatric patients under general anesthesia. The authors observed a similar peripheral nerve block success rate with both a low (<0.5 mA) and a high stimulation threshold (0.5 to 1.0 mA). They concluded that it may not be necessary to perform needle manipulation in close proximity to the nerve to achieve a low stimulation threshold (<0.5 mA), because it may increase the risk for intraneural injection. Most importantly, in performing peripheral nerve blocks in

anesthetized children, the needle should not be intrafascicular. The disappearance of the motor response by reducing the intensity under 0.5 mA for 0.1 msec, confirms that the tip of the needle is not in contact with axons. In adults, Bigeleisen and associates[131] revisited the relationship between minimum stimulating current and intraneural needle placement in a clinical investigation comparing intraneural and extraneural stimulation thresholds in ultrasound-guided supraclavicular block. Intraneural stimulation thresholds in excess of 0.2 and less than 0.5 mA were observed in 54% of patients. In 10% of patients, the stimulating threshold exceeded 0.5 mA when the needle was in an intraneural location. Thus, a response obtained for a current intensity less than 0.2 mA for 0.1 msec may be associated with an intrafascicular position of the needle and should be avoided.

Peripheral nerves are not as deep in children as in adults and can be located percutaneously. By using the nerve mapping technique the success rate of peripheral nerve blocks in children can be improved.[132] Nerve mapping helps locate the needle entry point before puncture, thereby reducing the number of attempts and decreasing the potential risk for nerve injury.

Nerve stimulation can be used for ultrasound guidance training. Concomitant use of nerve stimulation can increase the confidence of the trainee while lessening the anxiety of the attending instructor. Other common sources of error during novice practice and beyond include failure to distinguish between adjacent isoechoic structures.[133]

Ultrasound Techniques

Ultrasonographic guidance for regional anesthesia in children has seen considerable interest recently. The benefit of this technique is the visualization of targeted nerves or spaces and the spread of injected local anesthetic.

Today, thanks to the improved resolution of ultrasound machines, the majority of peripheral nerves for regional anesthesia can be visualized in children. However, the nerves are not static structures and can move, depending on the position of the child, pressure of the probe to the skin, and progression of the needle or injection of local anesthetic. In children, the linear ultrasound probe with a 25-mm active surface area (or probes with 38 mm of active surface area in older children), provides a square image that is not deformed. Probes with frequencies of 8 to 13 MHz offer excellent resolution for superficial structures of the upper limb (e.g., axillary block) and good penetration depth for the lower extremity (e.g., popliteal block). The higher frequencies could provide images that will be sharp for superficial structures. In principle, the needles typically used to perform peripheral nerve blocks can be used with ultrasound guidance. In vitro, results have shown that visualization of the needle depends on its diameter and mainly the angle of penetration.[134] Use of a facet-tipped needle for peripheral nerve blocks facilitates precise placement of the needle with minimal pain for child,[135] which seems particularly interesting for blocks performed in children without sedation or general anesthesia. Sterile preparation of the probe and the block site is an important prerequisite for ultrasound-guided blocks. A sterile probe cover should be used for single and continuous block techniques.

The easiest ultrasound-guided blocks are axillary blocks, femoral blocks, fascia iliaca compartment blocks, caudal blocks, ilioinguinal blocks, and paraumbilical blocks.[136] They permit a safe and easy learning curve of these techniques. The main advantage of ultrasound-guided regional anesthesia is the visualization of different anatomic structures and the approximate localization of the tip of needle. The other advantages for ultrasound-guided peripheral nerve blocks in children are faster onset time of sensory and motor block, longer duration of sensory blockade,[137] increase of blockade quality,[137,138] and reduction of local anesthetic injections.[138.139] The use of ultrasonographic guidance for central block allows visualization of different structures, spine, and spinal contents. Spinous process, ligament flavum, dura mater, conus medullaris, and CSF are identifiable, and give some information on spine, epidural space, and the depth between epidural space and skin.[140] Finally, in a caudal block, ultrasound imaging permits evaluation of the anatomy of the caudal epidural space, especially the relation of the sacral hiatus to the dural sac, and the search for occult spinal dysraphism.[141] Recently, ultrasound imaging showed its superiority over the swoosh test when performing a caudal block.[142] Anterior displacement of the posterior dura mater during saline or LA injection is a predictor of block success. This ultrasound-guided puncture improves the efficacy and safety of the central blocks by reducing the number of punctures. Unfortunately, the image quality is rapidly altered with ossification of the structures occurring in older children.[143]

A comparative evaluation of feasibility with ultrasound guidance for most regional techniques is provided in Table 92-5.

SAFETY, PRECAUTIONS AND DISCHARGE CRITERIA

ACCEPTABLE ENVIRONMENTS FOR PERFORMING A REGIONAL BLOCK

Regional techniques are techniques of anesthesia; therefore, they must be performed only in places where all the monitoring, anesthetic, and resuscitation equipment (including anesthetic and emergency drugs) is available. Additionally, the anesthesiologist must be assisted by staff members able to provide adequate patient monitoring and trained to help in emergency situations. The operating theater represents the best location to guarantee safe performance of any type of regional anesthesia.

SEDATION AND GENERAL ANESTHESIA

Regional procedures are performed in conscious adult patients, with or without sedation, but usually not under general anesthesia. In some pediatric patients, the same management can be offered and is sometimes requested by the child.[144] However, most children require being unconscious during the block procedure. If general anesthesia is not medically contraindicated, it is widely accepted that regional blocks be performed with the patient under light general anesthesia.[68,98,145]

PATIENT MONITORING AND SAFETY PRECAUTIONS DURING THE BLOCK PROCEDURE

Monitoring and Anesthesia Chart

Even if general anesthesia is not used and the surgical procedure is primarily based on a regional technique, the anesthesiologist should always apply routine intraoperative monitoring, including electrocardiographic (ECG) tracings and blood pressure, temperature, respiratory rate, and oxygen saturation measurements. An IV line must be established before any injection of local anesthetic,[146] and vital parameters, techniques, and doses of local anesthetics must be reported on a detailed anesthesia chart.

Technique of Injection

Techniques in adults and children are similar. Of prime importance is to evaluate the effects on ECG tracings of a test dose containing epinephrine (0.1 mL/kg up to 3 mL containing 0.5 to 1 μg/kg of epinephrine) for 30 to 60 seconds: Any elevation of ST segment or increase in T-wave amplitude,[147-149] followed by an increase in blood pressure but only occasionally by tachycardia, suggests inadvertent IV injection and necessitates cessation of the procedure; when epinephrine is contraindicated, isoproterenol 0.05 to 0.1 μg/kg should be used instead.[150]

Assessment of the Block

After every block procedure, the quality and extension of analgesia must be evaluated before surgical incision. However, this evaluation is difficult, even in conscious children. Gentle skin pinching is the most dependable technique of sensory testing, especially in lightly anesthetized children. Postoperatively, this evaluation should be comparative (blocked versus nonblocked areas) and requires that the child has gained the confidence of the caregiver, cannot see what is being done, and is not influenced either by the caregiver or the family. Electrical stimulation using a nerve stimulator at different threshold intensities proved to be suitable in healthy volunteers, but data on children are limited. Skin temperature is not suitable, and whether pupillary reflex dilation of 0.2 mm is sensitive to the loss of analgesia is not clinically useful.[151]

Prevention of Irrelevant Medicolegal Claims

In situations of an adverse event after a regional procedure, the first condition incriminated is the block procedure per se, even though most often a closer analysis rarely confirms that the regional block cause the alleged consequence or damage. To minimize irrelevant medicolegal claims, the recommendations listed in Box 92-1 should be followed whenever possible.

BOX 92-1 *Basic Safety Recommendations for Any Type of Regional or Local Anesthesia Aiming to Avoid Irrelevant Medicolegal Claims*

1. Evaluate carefully the physical status of the patient and ask for complementary laboratory, radiographic, or any other examination whenever useful.
2. Select the least hazardous technique for a given block.
3. Provide detailed explanations concerning the scheduled anesthetic management, including beneficial as well as potentially detrimental effects, even in emergency situations.
4. Discuss the possibility of block failure and explain what replacement procedure(s) will then be used.
5. Obtain written consent for anesthesia care.
6. Manage the patient in the same way and with the same monitoring procedures as recommended for the same surgical procedure under general anesthesia.
7. Fill in an anesthesia chart detailing the monitoring procedures, vital parameters, techniques and doses used, and adverse effects if any.
8. Treat all complications and provide full details with precise timing.
9. Transfer all pediatric patients to a pediatric acute care unit, requesting appropriate monitoring of vital functions and repeat evaluations of the extension and quality of blockade. Data are to be reported on a detailed postanesthetic chart, and discharge should be allowed only when objective signs of recovery are obtained.
10. Keep hospitalized at least overnight all patients given epidural or intrathecal morphine in units where their respiratory function will be regularly or continuously monitored (hourly for the first 6 hours, then every 2 hours).

POSTOPERATIVE MONITORING IN THE RECOVERY ROOM

After combined regional and general anesthesia, all children must be transferred to a recovery room (PACU), where the stability of respiratory and hemodynamic status is checked in the same way as after any general anesthesia. In addition to this standard postanesthetic care, they require repeat evaluations of the anesthetized area. In the case of motor blockade, which should be avoided as often as possible, it is important to verify that its distribution corresponds to the area supplied to the blocked nerve. Motor blockade is a stressful condition; therefore, children and their parents should be comforted, and the information that it is just a time-limited condition should be repeated. Patient positioning must be carefully and regularly checked to avoid pressure points. Anesthetized areas must also be protected from the patients' inadequate behavior, imprudence, or attempts to remove dressings. The possibility that a compartment syndrome is evolving must always be kept in mind, and both the hemodynamic status of the relevant limb and the quality of analgesia must be repeatedly evaluated.

Urinary retention can be of concern after neuraxial blocks. In many institutions, however, voiding is not requested before discharging the child. It may be prudent to keep infants and disabled children in the PACU until they have urinated or to check their bladder content with an ultrasound probe, especially after hypospadias repair, because the incidence of urinary retention is greater than usual in this surgery.[152]

Adult surgical patients under regional blockade often bypass the postanesthesia recovery room. In children, even if no sedative has been given, it is not wise to do so, and adequate monitoring and skilled assistance improve recovery from immediate postoperative incidents.[153] After

short procedures, sudden cessation of external stimulation may unmask some compensated adverse effects (hemodynamic and respiratory especially) that are not harmful if detected early. As noted earlier, ropivacaine and, to a lesser extent, levobupivacaine, have a longer T_{max} (up to 2 hours) and C_{max} in infants; therefore, after short-duration surgeries, these patients may leave the operating room before local anesthetic plasma peak concentration has been reached. It is recommended to keep them monitored in a PACU up to 2 hours after the block procedure.

DISCHARGE CRITERIA AFTER SINGLE-SHOT PROCEDURES

The same criteria apply with discharge from the PACU as with after general anesthesia (pediatric adaptation of Aldrete score or specific scoring method in use in the relevant institution); in the absence of motor blockade, children usually may be discharged within 30 minutes. In other cases, discharge depends on the behavior of the child. Partial restoration of motor function is mandatory, even in quiet children with caring families. Boisterous children should not leave before motor functions have been fully restored; additionally, protective dressings (including casts) may help prevent harm to the operated limb. Persistence of sensory blockade is not a contraindication to early discharge unless the familial environment is inadequate. Pain medication should be systematically prescribed and administered on a regular basis to prevent the return of intense pain at home when the sensory block is no longer effective.[154] Most additives do not preclude early discharge except for epidural or intrathecal opioids, especially morphine, which necessitates that the child stay hospitalized overnight.

MANAGEMENT OF CONTINUOUS REGIONAL TECHNIQUES

Children with repeat, on-demand, or continuous epidural infusion should remain hospitalized to be adequately monitored. Occasionally, a few selected patients can be allowed to return home with an epidural catheter, mostly in a context of chronic pain or cancer pain in terminally ill children. Adult patients with continuous techniques of peripheral nerve blockade can be returned home provided surgical care does not require hospital stay. These continuous techniques are rather new in pediatrics[74] and not yet widely used. Pediatric orthopedic surgery is particularly interested in this type of analgesia. Studies on peripheral nerve blocks in children monitored at home have reported a low complication rate and good quality of analgesia.[155,156] In one institution, children suffering from complex regional pain syndrome were treated at home with peripheral nerve catheters.[79] The use of an elastomeric disposable device to infuse local anesthetic allows simplifying the management of children at home and a nursing economy. Such management will probably gain wider acceptance in the near future, but currently it should be considered under evaluation.

NEURAXIAL BLOCKS

CAUDAL ANESTHESIA

Worldwide, the caudal block is likely the most commonly used technique of epidural blockade in children. Nevertheless, it is less used in some countries in favor of peripheral blocks.[98] The technique is described as simple and easy to perform for most, with few complications.

Caudal anesthesia considerably decreases stress hormone response to surgery.[157-159] The rate of complete or partial failure of this technique is 3% to 11%,[160] especially in children older than 7 years of age.

Anatomy of the Sacral Hiatus

Children have a specific anatomic level of the sacrum. Until the age of 1 year, five sacral vertebrae are easily identifiable and have the appearance of the lumbar vertebrae. Each sacral vertebra has five primitive centers of ossification, which will knit by 2 to 6 years of age. This is due to the standing body of the child, who will develop the walking and the mechanical stresses in the vertebrae.

The sacral hiatus is a U-shaped or V-shaped aperture resulting from the lack of dorsal fusion of the fifth and often fourth sacral vertebral arches. It is limited laterally by two palpable bony structures, the sacral cornua, and is covered by the sacrococcygeal membrane (sacral continuation of the ligamenta flava). The distance separating the summit of the sacral hiatus and the dural sac ending is approximately 30 to 10.4 mm (range, 13.6 to 54.7 mm) in children 10 months to 18 years of age.[161] Mean distance from skin to anterior sacral wall is 21 mm (extremes, 10 to 39 mm) between 2 months and 7 years of age.[140] The distance from skin to the epidural space is only slightly influenced by the age and weight of the patient (Fig. 92-1), and 25-mm needles are long enough to reach the sacral epidural space and short enough to prevent inadvertent dural puncture in most patients.

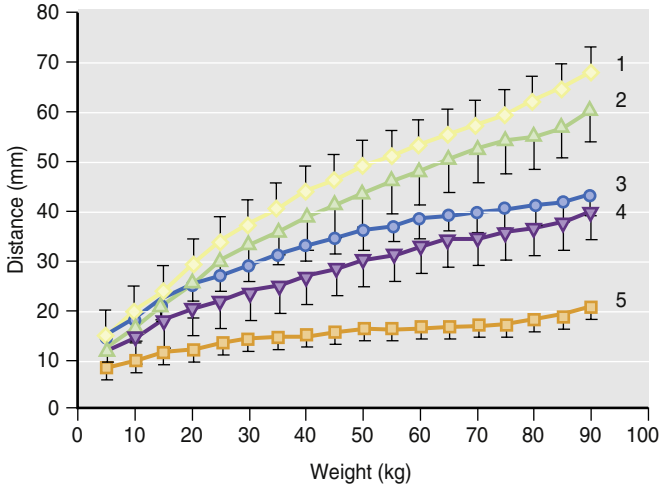

Figure 92-1. Distance from the skin to the epidural and subarachnoid spaces at different intervertebral levels and through the sacral hiatus. *1,* Spinal anesthesia; *2,* lumbar epidural approach (midline); *3,* thoracic epidural approach (midline); *4,* sacral epidural approach; *5,* caudal approach.

With growth, the axis of sacrum changes; the sacral hiatus becomes more difficult to identify and may even close.[162] Concomitantly, the epidural fat becomes more densely packed, thus reducing the spread of local anesthetics. These changes make caudal anesthesia less suitable and more difficult to perform in children older than 6 to 7 years of age.

Indications, Contraindications and Complications. Caudal anesthesia is recommended for most surgical procedures of the lower part of the body (mainly below the umbilicus), including inguinal hernia repair, urinary and digestive tract surgery, and orthopedic procedures on the pelvic girdle and lower extremities.[163] It is usually performed in lightly anesthetized patients but can be used as the sole anesthetic regimen in fully awake former premature infants younger than 50 to 60 weeks of postconceptual age after local anesthesia of the skin covering the sacral hiatus, either as a single-shot technique[164,165] or after placement of an epidural catheter allowing repeat or continuous injection of local anesthetics.[166]

Specific contraindications include major malformations of the sacrum (myelomeningocele, open spina bifida), meningitis, and intracranial hypertension.

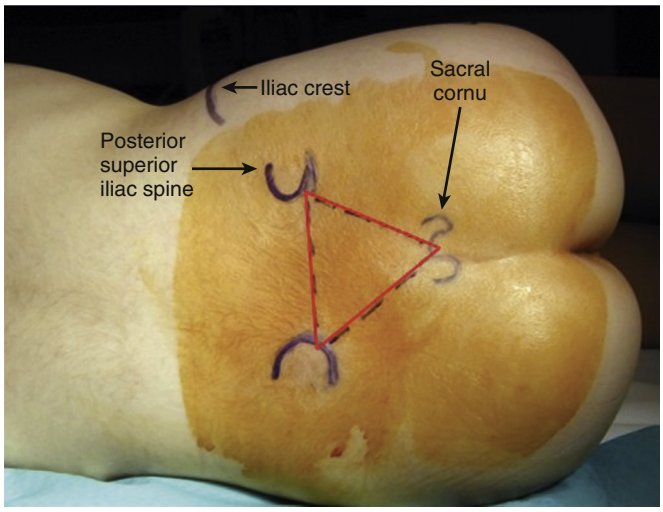

Figure 92-2. Landmarks for caudal block procedure in lateral position. Two posterior superior iliac crests form an equilateral triangle; the top of this triangle indicates V-shaped sacral hiatus limited by two sacral cornua.

Specific complications of caudal anesthesia are infrequent and usually minor[90,98] when adequate devices are used. Notably, dural puncture and subsequent injection of local anesthetic solution can lead to cardiovascular collapse or respiratory arrest (apnea).

Technique

The technique is performed with the patient in the lateral position or, especially in nonanesthetized premature infants, in the prone position either with a rolled towel slipped under the pelvis or with the legs flexed in the "frog" position. The two sacral cornua limiting the V-shaped sacral hiatus are located by palpation along the spinal process line at the level of the sacrococcygeal joint (Fig. 92-2). The hiatus along with the two posterior superior iliac crests is claimed to form an equilateral triangle, but in clinical practice this assumption does not help in locating the hiatus when palpation is not informative. The caudal puncture technique is shown in Figure 92-3.

Caudal anesthesia is basically a single-shot technique. Occasionally, placement of an epidural catheter for repeat or continuous infusion is contemplated. The "normal" length of catheter to be introduced into the epidural space is 2 to 3 cm, as for any epidural block. Because the epidural fat is very fluid in infants, a longer distance can be introduced to reach lumbar or even thoracic levels. This technique should be considered with caution, by experts only. The final position of the tip of the catheter must be controlled; it is misplaced in 28% of cases.[167] This is usually achieved by obtaining a contrast-enhanced radiograph, but the following techniques also are available:

- Neurostimulation at rather high intensities (however, safety of this technique is not established).[168,169]
- Recording ECG tracings from the metallic wire of the catheter and comparing them with those obtained from an electrode placed on the spinous process line, at the level where the tip of the catheter should be placed. The position is correct when the two tracings are identical.[170] This technique is very elegant and noninvasive, but the "second" ECG tracing is not easily readable in some patients (especially when they are conscious and moving).
- Ultrasound guidance[171] is the most promising noninvasive technique.

Catheter tunneling has been recommended to decrease the risk for bacterial contamination.[172] The volume

prescription scheme of Armitage that was published many years ago still remains the most dependable, as follows:

- 0.5 mL/kg: All sacral dermatomes are blocked.
- 1 mL/kg: All sacral and lumbar dermatomes are blocked.
- 1.25 mL/kg: The upper limit of anesthesia is at least midthoracic.

When 1.25 mL/kg is injected, excessive rostral spread (above T4) can occur[173]; it is therefore preferable not to administer more than 1 mL/kg of local anesthetic. Hong and colleagues[174] sought the best compromise between the two regimens of caudal injections in terms of quality of analgesia and spread of local anesthetic. The authors compared the same total dose of local anesthetic (ropivacaine 2.25 mg/kg), a high injection volume and low concentration (ropivacaine 0.15% 1.5 mL/kg), and low injection volume and high concentration (ropivacaine 0.225% 1 mL/kg). Spread of local anesthetic was significantly higher in the high volume and low concentration group in contrast to the other group (T6 [T3 to T11] and T11 [T8 to L2], respectively). In addition to the injection system, high volume and low concentration produced a longer duration of analgesia before the first analgesic request (554.5 minutes versus 363 minutes). When a catheter is inserted, repeat injections must be reduced to avoid systemic toxicity. The second injection should be made no earlier than 60 minutes (for a short-duration local anesthetic) or 90 minutes (for a long-duration local anesthetic) after the first one and should be half of the initial dose. Further injections should be reduced to half of the second dose (i.e., one sixth of the initial dose) while respecting the same delays.

Ultrasound has facilitated the use of caudal block in children, allowing an initial assessment of the anatomy of the sacrum (Fig. 92-4), including the relationship of the sacral hiatus to the dural sac ending, and research of spinal dysraphism.[141] Roberts and associates[171] demonstrated the value of ultrasound imaging with a test dose of saline when performing a caudal block to confirm the correct location of the needle. According to the authors, the displacement of the dura mater during the injection of saline is an indicator of a successful block. They found ultrasound-guided caudal blocks successful with a sensitivity of 96.5%, a specificity of 100%, and a positive predictive value 100%. Ultrasound is also better than the swoosh test to determine the correct location of the needle.[142] Recently, Shin and associates[175] noted that prior anatomic study of the sacral region via ultrasound made it easier to identify the sacral hiatus and determine the level of the dural sac before completion of a caudal block or block-sacred interspinous in children.

INTERVERTEBRAL EPIDURAL ANESTHESIA

Anatomy and Physiology

The epidural space surrounds the spinal cord and the meninges from the foramen magnum to the sacral hiatus. Limited posteriorly by the vertebral laminae and the ligamenta flava, it communicates quite freely with both the paravertebral spaces and the root sleeves. In the dural cuff region, near the spinal ganglia, it is intimately connected with the subarachnoid space owing to protrusion of arachnoid granulations, which are easily traversed by local anesthetics. It contains blood vessels and lymphatics and is filled with loose fat in infants and in children up to 6 to 8 years of age.

One of the major characteristics of the child for the central blocks is a line connecting the two iliac crests—the Tuffier line. This line joining the two iliac crests is proportionally smaller in young children and crosses the spinous process line at the L5 to S1 level in infants up to 1 year of age instead of at L4 to L5 as in older children and adults.[176] Bending the spine (as for performing an epidural block) does change the level at which the Tuffier line crosses the spine in 58.3% of patients. Mobility of the vertebrae and the elasticity of the ligaments in children can change the position of the spinal cord in the spinal canal. The spinal cord tends to move backward and get closer to the vertebral arches in a sitting position, making it more difficult to identify the epidural space. In the lateral position, bending of the spinal cord moves forward, away from the ligamentum flavum and for expanding the epidural space. This is the preferred position for the epidural catheter procedure in children (Fig. 92-5).

Epidural injections result in considerable pressure changes. After placement of a 20-gauge epidural catheter in 20 infants, Vas and associates[177] measured the following changes:

- Pressure on penetrating the epidural space: 1 ± 10 mm Hg (extremes, –17 to + 16 mm Hg)
- Peak pressure during injection of a local anesthetic at 1 mL/min: 27.8 ± 18.6 mm Hg with residual pressure of 12 ± 5.5 mm Hg 1 minute after completion of injection
- Peak pressure during injection of a local anesthetic at 0.5 mL/min: 15.2 ± 9.5 mm Hg with residual pressure of 14.8 ± 5.4 mm Hg 1 minute after completion of injection

The spine presents at birth only one concavity: anterior curvature (kyphosis). Lumbar lordosis appears only with the acquisition of walking. Until the installation of lordosis, the spinous processes are parallel and the introduction of the needle between them in the epidural space is perpendicular to the plane of the back. In addition,

Figure 92-5. Lateral position for epidural puncture in a 10-year-old boy *(left)* and 4-month-old girl *(right)*.

ossification of the lumbar vertebrae is very underdeveloped at birth and risks exist for injury to cartilaginous structures.

Indications and Contraindications

Young children tolerate epidural anesthesia well without significant hemodynamic changes.[58,178] Epidural anesthesia is recommended for all major abdominal, retroperitoneal, pelvic, and thoracic[179,180] procedures, including pectus excavatum repair[181] and scoliosis surgery,[182] preferably with a two-catheter technique.[183] The technique is also used for cardiac surgery in a few institutions,[70,184] but this indication is controversial and most authors consider it contraindicated because of anticoagulation.

The intervertebral level at which the epidural space should be approached is a matter of debate and depends on both the patient's age and the experience of the anesthesiologist. When a single-shot technique is planned for a surgery below the umbilicus, a caudal approach is most often selected in infants and young children and a lumbar approach is used in older patients. When catheter placement is contemplated it is preferable to select a lumbar approach in all patients to decrease the risk for bacterial contamination from anal proximity, even though this is rare.[90]

When sensory blockade of high thoracic dermatomes is required, the most reliable approach is a thoracic epidural block, which requires expertise because the spinal cord could be damaged. When the anesthesiologist is not used to performing thoracic epidural blocks in infants, some authors recommend a caudal approach with cephalic insertion of a catheter over a long distance to reach thoracic levels.[185] This technique, however, requires experience and luck—the catheter is misplaced in almost 30% of cases, even in experienced hands,[167,186] and serious complications are possible (e.g., spinal cord or vessel trauma during insertion, bacterial contamination, breakage, or buckling around a nerve root on removal attempts).[187-189]

Specific contraindications to epidural anesthesia include severe malformations of the spine and spinal cord (not spina bifida occulta), intraspinal lesions or tumors, and tethered cord syndrome. In most instances, epidural anesthesia should be avoided in children with a history of hydrocephalus, elevated intracranial pressure, unstable epilepsy, or reduced intracranial compliance, but these disorders are not absolute contraindications, depending on the context.[190] Also, previous surgery on the spine usually makes epidural (and spinal) anesthesia technically difficult or impossible, but they are not contraindications unless underlying lesions of the spinal cord are present.

Figure 92-6. Lumbar epidural anesthesia by loss-of-resistance technique with saline.

Techniques

Lumbar Epidural Anesthesia. The lumbar epidural is usually performed in anesthetized patients via a midline route below the L2-L3 interspace, which represents the lower limit of the conus medullaris (Fig. 92-6). The technique is essentially as in adults. A paramedian approach can be used instead in cases of spinous process anomaly or spine deformity. The child is positioned in the semiprone position, with the side to be operated lowermost and the spine bent to enlarge the interspinous spaces. The sitting position can be used in conscious patients.

Medium selection for the LOR technique has elicited considerable debate. Both air and saline are advocated for the LOR test to identify the epidural space. Saline is more popular according to the Ames survey[191]; but air (or carbon dioxide) is perhaps more sensitive, especially in neonates and infants.

The distance from the skin to the epidural space is correlated with the patient's age and size (see Fig. 92-1), but 1 mm/kg is a useful approximation for children between 6 months and 10 years of age.[192] An ultrasound probe provides precise measurement of the distance from skin to the ligamenta flava and from skin to the posterior dura mater (Fig. 92-7).

When the tip of the needle penetrates the epidural space, the LOR technique syringe is disconnected, and no reflux of biologic fluid (blood or CSF) should appear at the hub. The next step consists of injecting the local anesthetic at a slow speed, either through the epidural needle or through a catheter. Progressive displacement of the dura mater can be visualized by placing an ultrasound probe in line with the spinous process line during injection in infants younger than 2 years of age.[143] By using ultrasound, the anatomy of the spinal canal, the position of the spinal cord, visualization of the ligamentum flavum, and the space caudal spinous processes can actually be seen (see Fig. 92-7).[193] When a catheter is inserted, it should not be introduced more than 3 cm, to avoid buckling, knotting, and lateralization of blockade or erratic migration. Tunneling the catheter reduces the incidence of accidental removal and bacterial contamination.[194] Catheters inserted over a long distance have to be controlled in the same way as caudal catheters.

The volume of anesthetic solution depends on the upper level of analgesia required for completion of the surgery; approximately 0.1 mL per year of age is necessary to block 1 neuromere.[195] Usual volumes of injectate range from 0.5 to 1 mL/kg (up to 20 mL), and the upper limit of sensory blockade ranges between T9 and T6 in more than 80% of patients.

Single-shot epidural blocks are appropriate for many pediatric surgeries, especially when adjuvants such as clonidine 1 to 2 μg/kg, preservative-free ketamine 0.25 to 0.5 mg/kg, and, in appropriate indications, morphine 30 μg/kg are coadministered. Major operations resulting in long-lasting postoperative pain require placement of an epidural catheter and postoperative infusion of local anesthetics (Table 92-8).

TABLE 92-8 **USUAL DOSES AND INFUSION REGIMENS FOR EPIDURAL ANESTHESIA IN PEDIATRIC PATIENTS**

Agent	Initial Dose	Continuous Infusion (Maximum Doses)	Repeat Injections
Bupivacaine, levobupivacaine	Solution: 0.25% with 5 μg/mL (1/200,000) epinephrine Dose: <20 kg: 0.75 mL/kg 20-40 kg: 8-10 mL (or 0.1 mL/yr/no. of metameres) >40 kg: same as for adults	<4 mo: 0.2 mg/kg/hr (0.15 mL/kg/hr of a 0.125% solution or 0.3 mL/kg/hr of a 0.0625% solution) 4-18 mo: 0.25 mg/kg/hr (0.2 mL/kg/hr of a 0.125% solution or 0.4 mL/kg/hr of a 0.0625% solution) >18 mo: 0.3-0.375 mg/kg/hr (0.3 mL/kg/hr of a 0.125% solution or 0.6 mL/kg/hr of a 0.0625% solution)	0.1 to 0.3 mL/kg every 6-12 hr of a 0.25% or 0.125% solution (according to pain scores)
Ropivacaine	Solution: 0.2% Dose: Same regimen in mL/kg as for bupivacaine (see above)	Same age-related infusion rates in mg/kg/hr as for bupivacaine (usual concentration of ropivacaine: 0.1%, 0.15%, or 0.2%) Do not infuse for more than 36 hr in infants <3 mo	0.1 to 0.3 mL/kg every 6-12 hr of a 0.15% or 0.2% solution (according to pain scores)
Adjuvants	Avoid in infants <6 mo Fentanyl 1-2 μg/kg or sufentanil 0.1-0.6 μg/kg or clonidine 1-2 μg/kg	Select only one additive: Fentanyl: 1-2 μg/mL Sufentanil: 0.25-0.5 μg/mL Morphine: 10 μg/mL Hydromorphone: 1-3 μg/mL Clonidine 0.3 at 1 μg/mL of solution	Morphine (without preservatives): 25-30 μg/kg every 8 hr

In mature children who understand the concept of patient-controlled analgesia and who are willing to use it, patient-controlled epidural analgesia (PCEA) can be an interesting option. A prospective study involving 128 children older than 5 years of age reported a 90.1% success rate; PCEA was stopped in 6.1% of children because of adverse effects and only in 3.8% because of inadequate analgesia.[196] The local anesthetic was either 0.0625% or 0.125% bupivacaine with fentanyl 2 to 10 μg/mL; the background infusion rate was 0.2 mL/kg/hr or less, and 1- to 3-mL bolus doses were permitted every 15 to 30 minutes with a maximum dose of bupivacaine of 0.4 mg/kg/hr.

Another prospective study involving 58 children (age range, 7 to 12 years) undergoing lower extremity orthopedic surgery compared continuous epidural infusion of 0.2% ropivacaine 0.2 mL/kg/hr with PCEA, with background infusion of 1.6 mL/hr and 2-mL bolus doses (lockout interval, 10 minutes) of the same solution. Pain scores were excellent and identical in both groups, but children from the PCEA group required half the doses of ropivacaine on an hourly basis in contrast to the continuous infusion group.[121]

Sacral Epidural Anesthesia. Because sacral interspaces remain nonfused until early adulthood, the sacral epidural space of children can be approached posteriorly via the S2-S3 interspace, which is identified by palpation 0.5 to 1 cm below the line joining the two posterior superior iliac spinous processes, but any other sacral interspace can be used.[197] The procedure is the same as for a lumbar approach. Because sacral spinous processes are atrophic, the Tuohy needle can be oriented cephalad or, preferably, caudad to contact the dura mater with the convex part of the needle tip, thus reducing the danger of accidental dural penetration. The dural sac usually ends at S2, as does the risk for dural puncture. Attention must be paid to the closer skin proximity of the epidural space, in contrast to lumbar approaches (see Fig. 92-1). If mandatory, an epidural catheter can be inserted (using the same technique as for lumbar epidural catheter placement) to provide long-lasting postoperative pain relief.

Sacral epidural anesthesia is an alternative to caudal anesthesia, either in infants when skin lesions contraindicate a caudal approach or in children older than 6 to 7 years of age, in whom caudal anesthesia becomes more difficult and less reliable. The same volumes and doses of local anesthetic as for a caudal anesthesia are administered. Ultrasound imaging can be used to precisely evaluate the distance from skin to epidural space and, in infants mainly, visualize both the progression of the needle and catheter and the spread of the local anesthetic.

Thoracic Epidural Anesthesia. Thoracic epidural blocks are indicated for major operations requiring long-lasting pain relief, thus requiring placement of an epidural catheter to allow repeat injections or continuous infusion of local anesthetic. These are not commonly used techniques in children because indications are limited to thoracic and upper abdominal surgery and spinal cord damage is a risk. In children younger than 1 year of age, the procedure is similar to that for a lumbar approach, with needle insertion perpendicular to the spinous process line, because the spine displays a single flexure, especially when bent. As the patient grows and the flexure develops, the technique becomes progressively similar to thoracic approaches in adults, requiring cephalic orientation of the Tuohy needle up to a 45-degree angle to the skin. A paramedian approach can be used instead, but it is rarely required in children. In infants, ultrasonography makes visible the dura mater, the progression of the Tuohy needle, and, in many cases, the progression and final position of the tip of the epidural catheter.[198]

Cervical Epidural Anesthesia. No surgical indications exist for cervical epidural blockade in children. Very rarely, the technique can be contemplated for patients with chronic pain or to prevent phantom limb pain before an amputation of the upper arm at the scapular level (osteosarcoma of humerus), which is done almost exclusively in adolescents. The block procedure is the same as in adults.

SPINAL ANESTHESIA

Anatomy and Physiology

The spinal cord and dural sac of infants younger than 1 year of age end at a lower level than in older patients (see earlier section on Caudal Anesthesia). Also, the volume of CSF varies considerably according to the patient's age, from more than 10 mL/kg in neonates, to 4 mL/kg in infants weighing less than 15 kg, to 3 mL/kg in children, to 1.5 to 2.0 mL/kg in adolescents and adults. The spinal and cerebral distribution of CSF also varies with age; half the CSF volume is located within the spinal subarachnoid space versus only 25% in adults. This has considerable pharmacokinetic consequences and explains why larger doses of local anesthetics are required for spinal anesthesia in infants and young children.

CSF hydrostatic pressure is lower in infants in the dorsal recumbent position[199] and further decreased during general anesthesia. In performing a spinal block, the progression of the needle must be slow to detect CSF reflux before the needle is advanced farther.

Children older than 5 years of age behave like adults after spinal anesthesia, whereas younger patients remain hemodynamically stable, without significant hypotension or bradycardia,[200] even in cases of cardiac malformations.[201] However, a decrease in mean arterial pressure during the first 10 minutes after injection of 0.8 mg/kg of 0.5% bupivacaine was reported in infants aged 1.5 to 5 months.[202] This decrease was time limited, well tolerated, and rapidly corrected by IV fluids. Similar results with concomitant decrease in cerebral blood flow were reported in former preterm infants of 41 weeks of postconceptual age.[203]

Indications and Contraindications

Spinal anesthesia has limited indications in pediatric patients. One of these is inguinal hernia repair in former preterm infants younger than 60 weeks of postconceptual age[204,205] who are prone to develop postoperative apnea after general anesthesia or even light sedation.[206] However, even after pure spinal anesthesia, apnea may occur postoperatively (as they may preoperatively) and

it is prudent to keep at-risk infants hospitalized. Other indications are scarce, mainly for elective lower abdominal or lower extremity surgery[207-209] and, occasionally, for cardiac surgery or cardiac catheterization,[210,211] but these indications are controversial.

Technique

The technique of spinal anesthesia is similar to lumbar puncture (Fig. 92-8). It can be performed with the patient in the lateral decubitus position or sitting (Fig. 92-9). Currently, hyperbaric tetracaine and bupivacaine are the most commonly used local anesthetics. Isobaric bupivacaine can be used instead.[207] Ropivacaine[212] and levobupivacaine[213] may become the standard of the future but are not currently approved for spinal administration in pediatric patients.

Drugs and Doses

The drugs most frequently used are tetracaine 0.5% and bupivacaine 0.5%. The usual doses are 0.5 to 0.8 mg/kg to achieve low to medium levels and 1 mg/kg to achieve high levels (T2-T4). The duration of the block is approximately 60 to 75 minutes for both drugs. Newborns and infants are at an increased risk for toxicity after the administration of amide local anesthetics; the risk is even greater in the case of jaundice.[214] Usual dosages for neonates to adolescents are given in Table 92-9.

The older the child, the lower is the dose required; in children between 6 months and 14 years, 0.5% hyperbaric bupivacaine at a dose of 0.2 mg/kg has been used with a success rate of 98%. More recently, the successful use of 0.5% ropivacaine in children between 1 and 17 years at 0.5 mg/kg and 0.5% levobupivacaine in children between 1 and 14 years at 0.3 mg/kg has been reported. Clonidine 1 μg/kg, fentanyl 1 μg/kg, and morphine 4 to 5 μg/kg are reported in the pediatric literature as adjuvants to increase the spinal block duration (see Table 92-9).

Adverse Effects and Complications

Spinal anesthesia is technically difficult in neonates and infants; the overall failure rate ranges from 10% to 25%.[206,215] Short duration of blockade and lack of residual analgesia are important limitations, and alternative (awake caudal anesthesia) or complementary techniques (ilioinguinal or iliohypogastric block) are often contemplated. Postdural puncture headache is rare in children younger than 8 years of age but not exceptional, and its incidence may be increased with use of pencil-point spinal needles.[216] All complications reported after lumbar epidural blockade can occur after spinal anesthesia.

Figure 92-8. Spinal anesthesia procedure in sitting position in 1-month-old girl.

UPPER EXTREMITY CONDUCTION BLOCKS

ANATOMIC CONSIDERATIONS

Nerve supply to the upper extremity depends mainly on the brachial plexus formed by the union of the ventral rami of the fifth cervical to the first thoracic spinal nerve roots. Roots emerge from the intervertebral foramina within the interscalene space (between the scalene anterior and scalene middle muscle). As in adults, brachial plexus nerve fibers redistribute first to three trunks (superior, middle, and inferior), then to three divisions between the clavicle and the first rib. These divisions recombine and surround the axillary artery as three cords and are named according to their relation to the artery as the lateral, medial, and posterior cords (Fig. 92-10). Because of this complicated redistribution of nerve fibers, distribution of anesthesia varies considerably depending on the level at which the local anesthetic is injected. Some anatomic knowledge

Figure 92-9. Sitting or lateral position for spinal anesthesia procedure.

is essential to predict the extension of the motor and sensory block and to determine the most appropriate approach for a given surgery (Fig. 92-11).

The most important anatomic difference between infants and adults pertains to the upper part of the lung and apical pleura that penetrates the neck, above the plane formed by the clavicle and first rib (superior thoracic aperture). Subclavian vessels and the lower division of the plexus are encountered in the apical pleura, thus making any perisubclavian approach at major risk for pleural penetration. The concept of perineurovascular sheath has been challenged in spite of strong embryologic and anatomic evidence, but it received additional confirmation in a recent radiologic study, and even the volume of the axillary tunnel could be precisely measured (5.1 to 9.5 mL in adults).[217]

Ultrasound imaging allows precise localization of the parietal pleura and subclavian and axillary vessels, thus improving the safety of supraclavicular and infraclavicular approaches, provided the tip of the block needle can be continuously seen during the procedure. Nerve stimulation may be used in conjunction with ultrasound guidance to confirm the localized nerve and prevent an intraneural injection.

Roberts[136] recommended initially performing simple blocks. Interscalene and periclavicular approaches are considered difficult and must be done by trained operators. The axillary and forearm blocks seem easier, especially for those who are new to ultrasound-guided regional anesthesia.

Indications for brachial plexus blocks include emergency and elective surgery of the upper extremity in conscious or anesthetized children.[218-220] These blocks are useful for outpatient surgery and elicit a high degree of patient satisfaction.

- The axillary block is the most common approach to the brachial plexus in pediatric patients, especially when the lesions involve the forearm and the hand. Advantages of this block include an easy and safe procedure with a high rate of success and very low rate of complications.
- The infraclavicular paracoracoid approach is being increasingly used with the development of ultrasound guidance. The technique provides complete blockade of the upper extremity, catheter placement is easier and

TABLE 92-9 USUAL DOSES OF LOCAL ANESTHETICS FOR SPINAL ANESTHESIA

Local Anesthetic	Dose	Duration
Neonates		
Tetracaine 0.5%	0.6-1 mg/kg	60-75 min
Bupivacaine 0.5%	0.5-1 mg/kg	65-75 min
Ropivacaine 0.5%	1.08 mg/kg	50-70 min
Levobupivacaine 0.5%	1 mg/kg	75-90 min
Infants to Adolescent		
Bupivacaine 0.5%	0.4 mg/kg (5-15 kg)	
Tetracaine 0.5%	0.3 mg/kg (<15 kg)	
Levobupivacaine 0.5%	0.4 mg/kg (5-15 kg)	
Ropivacaine 0.5%	0.3 mg/kg (>15 kg)	
	0.4 mg/kg (5-15 kg)	
	0.3 mg/kg (15-40 kg)	
	0.25 mg/kg (>40 kg)	
	0.5 mg/kg (maximum 20 mg)	
Adjuvant		
Clonidine	1 μg/kg (neonates)	
Fentanyl	1 μg/kg (infants <1 yr)	
Morphine	4-5 μg/kg (all ages)

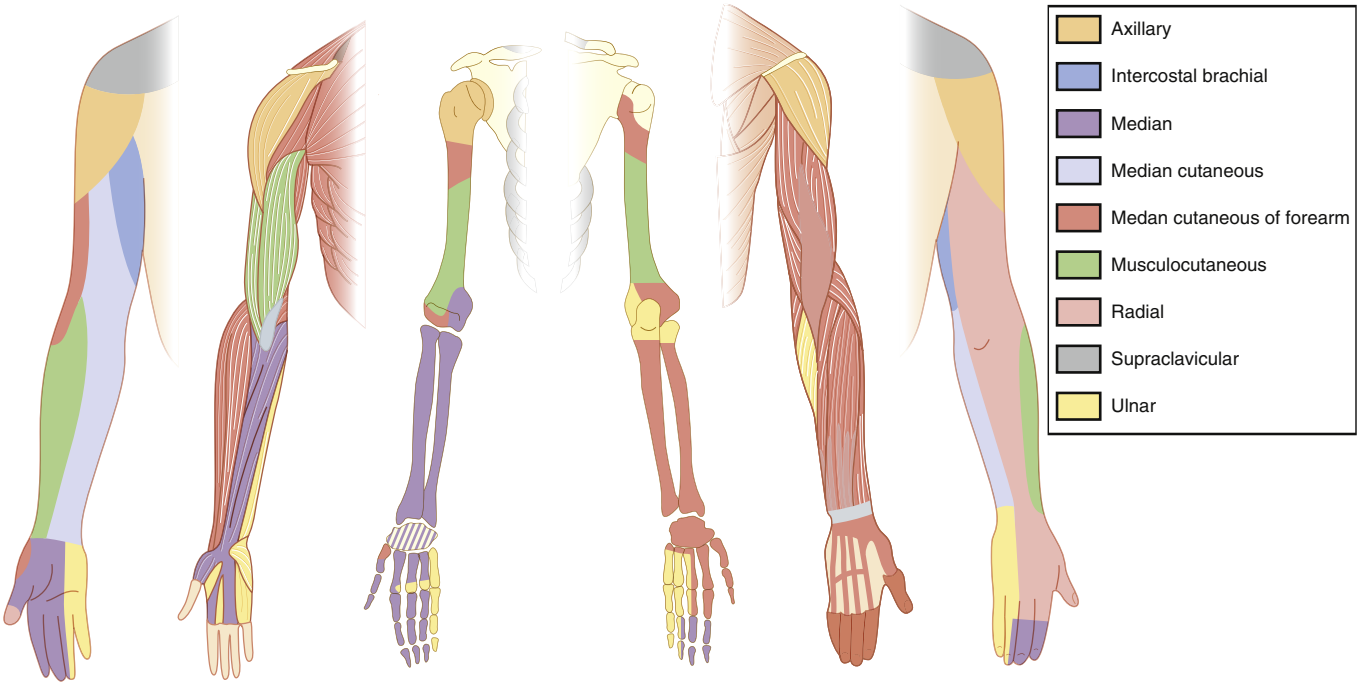

Figure 92-11. Cutaneous, muscle, and bone innervations of the upper extremity.

more comfortable than at axillary levels, and catheter immobilization and protection against accidental removal are also easier.

- Supraclavicular approaches are indicated when the lesion is located on the shoulder or on the proximal part of the arm, including the elbow. Perisubclavian approaches should be used in infants with extreme caution because of the proximity of the apical pleura; ultrasound imaging reduces the risk for complications such as vascular or pleural incidental punctures. Before the use of ultrasound-guided nerve block, the parascalene and the modified interscalene approach (the tip of the block needle is placed virtually at the same place in the interscalene space with both techniques) were considered as safe alternative procedures.
- Distal nerve blocks are used either for distal lesions (surgery involving the hand or one finger only) or as complementary block when distribution of anesthesia is incomplete after a more proximal block.

CERVICAL BRACHIAL PLEXUS BLOCKS

Cervical brachial plexus approaches are not commonly used in children because of potential adverse effects (pneumothorax, vertebral artery injection, intrathecal injection) and the low incidence of isolated shoulder surgery in this population.

Interscalene Approach

The interscalene approach aims to enter the interscalene space at its upper extremity, close to the transverse process of C6. The child is placed in the dorsal recumbent position with the arms extended alongside the thorax and head slightly turned to the contralateral side.

The landmarks are the cricoid cartilage, the anterior ramus of the C6 transverse process (Chassaignac tubercle), and the interscalene groove. The puncture site is located at the skin projection of Chassaignac tubercle in the interscalene groove, just posterior to the lateral border of the sternocleidomastoid muscle. The needle is inserted at an 80-degree angle (not perpendicularly) to the skin; that is, dorsally and slightly caudal pointing toward the midpoint of the clavicle, until one of the primary trunks (instead of roots) of the brachial plexus is located by elicited muscle twitches in the upper arm. Any distal motor twitch and biceps, triceps, or deltoid muscles are adequate (Fig. 92-12). Contraction of the diaphragm indicates phrenic nerve stimulation and anterior placement of the needle tip. Alternatively, trapezius muscle stimulation indicates that needle placement is too posterior. Borgeat and colleagues[221] described a modified technique in adults that can be used in children. The block needle is inserted at the same puncture site, but the needle is oriented laterally, pointing toward the midpoint of the clavicle until one of the primary trunks (instead of roots) of the brachial plexus is located and twitches are elicited in the upper arm. The interscalene block is not very popular in children because of its adverse effects—ipsilateral phrenic nerve blockade, danger of vascular damage (vertebral artery and vein), and accidental cervical epidural and intrathecal penetration.

Ultrasound imaging improves the safety of this approach by showing the great vessels of the neck, aponeuroses of scalene muscles, and C5-C6-C7 brachial plexus roots.[137,222] The probe is placed in a transverse oblique plane at the level of the cricoid cartilage (Fig. 92-13). The trunks and roots of the brachial plexus can be identified in the interscalene groove as distinct round-to-oval hypoechoic structures between the scalene anterior

and middle muscles, both deep to the sternocleidomastoid muscle. The internal jugular vein and carotid artery can be visualized medially (Fig. 92-14). Using combined ultrasound-guided nerve stimulation techniques, the needle is advanced with an in-plane alignment from lateral (posterior) to medial (anterior) side of the probe, toward the target nerves. Precise needle placement may limit the dose of local anesthetic required.[223]

Parascalene Approach

The parascalene approach described by Dalens and colleagues[224] aims to penetrate the interscalene space at a distance from the apical pleura and great vessels of the neck. The landmarks are the midpoint of the upper border of the clavicle and the transverse process of C6

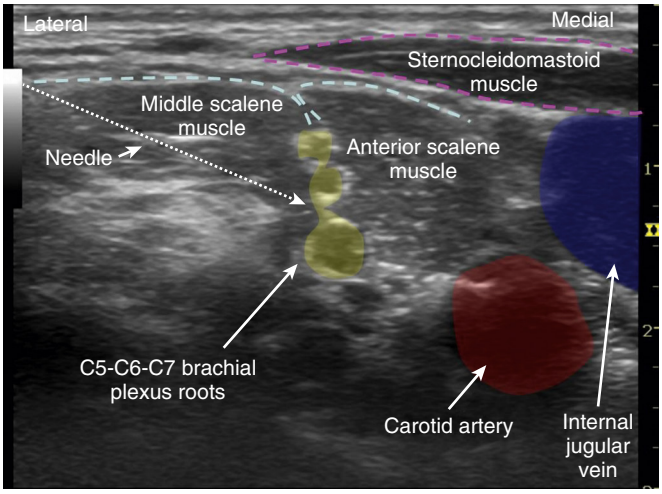

Figure 92-14. Ultrasound interscalene block imaging

located by palpation in the interscalene groove, just posterior to the sternocleidomastoid muscle, at the level of the cricoid cartilage. The puncture site is identified at the junction of the upper two thirds, with the lower third of the line joining the skin projection of the C6 process and the midpoint of the clavicle (Fig. 92-15). The success rate for this approach is very high, with a good safety record. Occasionally, blockade of the lower cord (ulnar nerve or medial branch of the median nerve) can be incomplete. The morbidity of this technique is virtually nil.[225]

SUPRACLAVICULAR BRACHIAL PLEXUS BLOCK

In contrast to other brachial plexus blocks, risk for pneumothorax is increased because of the proximity of the lung parenchyma at this level. Use of ultrasound guidance with an in-plane approach is strongly recommended and allows real-time viewing of the needle tip, thus avoiding inadvertent pleural puncture.

Ultrasound-guided supraclavicular block in adults has been described in several articles, but few reports are available in the pediatric literature.[226,227] The brachial plexus trunks gather at the lower part of the interscalene space, where they surround the subclavian artery. This level carries the advantage of being the area where the trunks are most compact. With a high-frequency probe placed parallel and against the clavicle in the coronal oblique plane (Fig. 92-16), the brachial plexus (trunk or division) appears as a cluster of hypoechoic nodules located lateral, posterior, and superior to the subclavian artery (hypoechoic and pulsatile) and just above the underlying first rib (hyperechoic and curvilinear) (Fig. 92-17). Care should be taken to avoid intravascular injection of surrounding vessels (i.e., the suprascapular artery or dorsal scapular artery) by using color Doppler (Fig. 92-18). The needle is slowly advanced under direct visualization with an in-plane approach (from lateral to medial) toward the angle formed by the first rib and the subclavian artery (see Fig. 92-17). The goal of the supraclavicular technique is to see the spread of local anesthetic reaching the angle between the first rib and the subclavian artery.

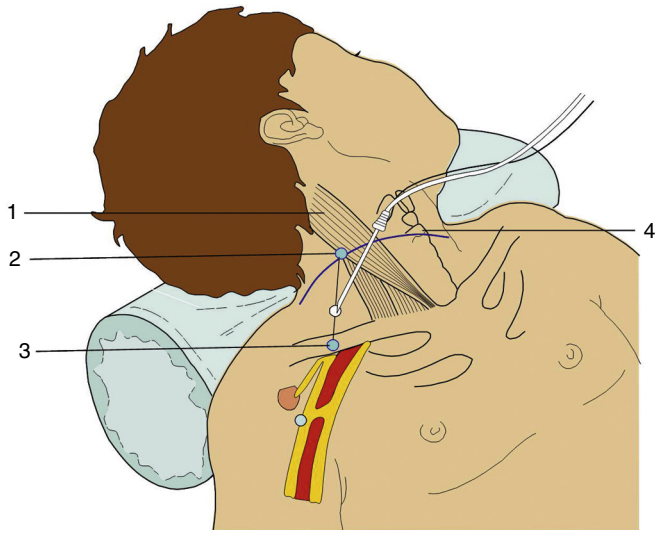

Figure 92-15. Parascalene approach to the brachial plexus. *1,* Sternocleidomastoid muscle; *2,* skin projection of the Chassaignac tubercle; *3,* midpoint of the clavicle; *4,* cricoid cartilage.

Figure 92-16. Supraclavicular block procedure. Probe position and in-plane needle insertion.

Ultrasound guidance has increased the safety profile of the supraclavicular approach so that in experienced hands this may be one of the most reliable and effective blocks of the brachial plexus.[223]

INFRACLAVICULAR BRACHIAL PLEXUS BLOCKS

Infraclavicular Approaches

Infraclavicular blocks have gained considerable interest, especially with the development of ultrasound guidance. They consist of approaching the divisions (close to the clavicle) or the cords (close to or below the coracoid process) of the brachial plexus. The two main approaches are midclavicular and paracoracoid, both performed with the patient in the dorsal recumbent position.[228] A catheter

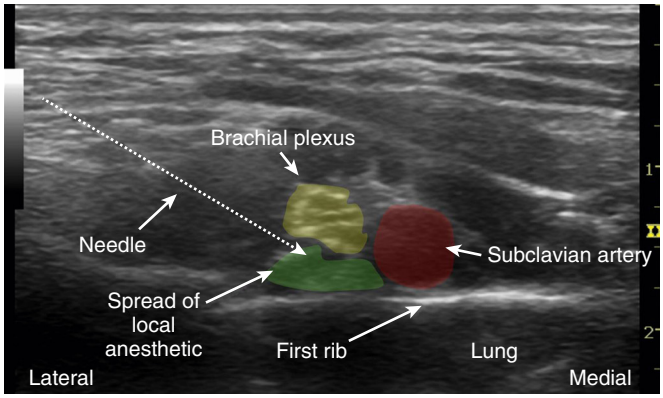

Figure 92-17. Ultrasound supraclavicular block imaging.

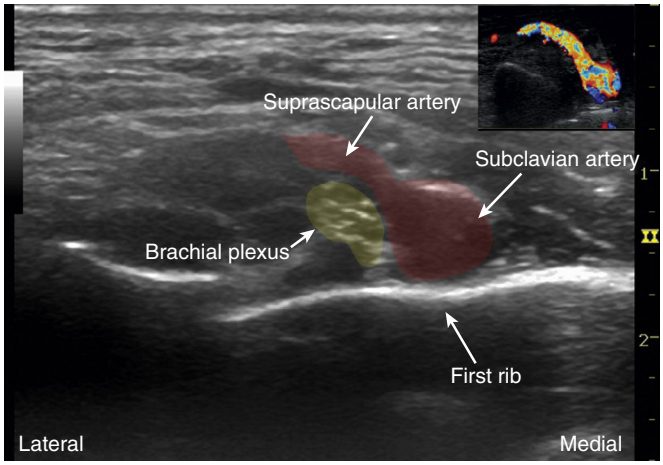

Figure 92-18. Ultrasound supraclavicular block imaging and surrounding vessels by using color Doppler.

can be easily inserted and safely secured, which is not the case in the axilla area.

Midclavicular Approaches

Two midclavicular approaches, vertical and anterolateral, have been described. The vertical midclavicular approach is performed by inserting the needle at a right angle to the skin, immediately below the midpoint of the lower border of the clavicle, until twitches are elicited in the upper extremity. Even though use of this technique was reported in pediatric patients without apparent complication,[226,229] the path followed by the needle threatens the apical pleura and lung, thus contraindicating this approach in children.

The anterolateral midclavicular approach can be safely used in children lying supine with the ipsilateral arm alongside the thorax. The landmarks are the coracoid process of the scapula, the lower border of the clavicle, and the deltopectoral groove (Fig. 92-19). The block needle is introduced 1 cm below the midpoint of the lower border of the clavicle at a 30- to 45-degree angle dorsally and a 30-degree angle laterally, aligned with the deltopectoral groove, in direction to the axilla. The objective is to enter the neurovascular sheath 1.0 to 1.5 cm medially to the coracoid process of the scapula until twitches are elicited in the arm, forearm, or hand.

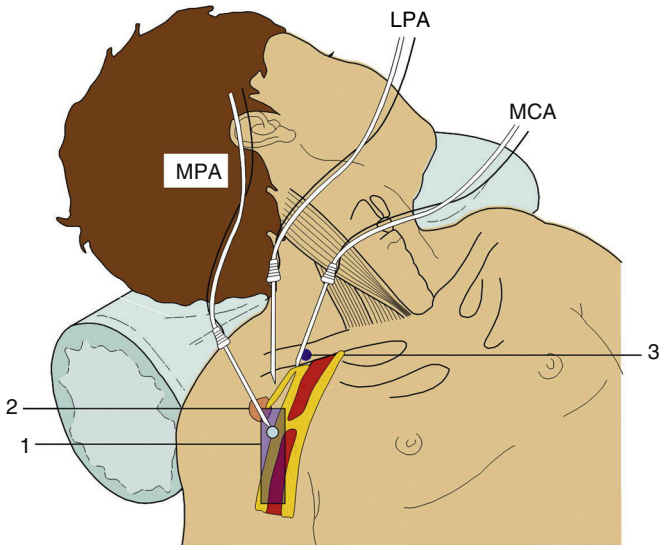

Figure 92-19. Infraclavicular approaches to the brachial plexus. *LPA,* Lateral paracoracoid approach; *MCA,* midclavicular approach; *MPA,* median paracoracoid approach; *1,* ultrasound probe; *2,* coracoid process of the scapula; *3,* midpoint of the clavicle.

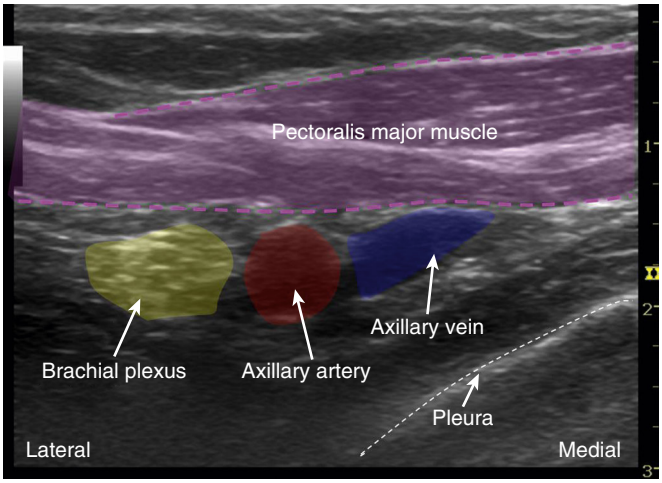

Figure 92-20. Ultrasound infraclavicular block, infraproximal approach. At this proximal level, the pectoralis major is the main muscle seen superficial to the neurovascular bundle. The pectoralis minor is located distally to this ultrasound section. Among the neurovascular bundle structures the axillary vein is the most medial, followed by the axillary artery and then the divisions of the plexus most laterally.

Paracoracoid Approaches

The medial paracoracoid approaches are currently the most popular techniques of infraclavicular blockade in children. It is the reference technique with neurostimulation and the one with the lowest morbidity. The puncture site is located at the caudal extremity of the deltopectoral groove, 1 to 2 cm (according to patient's age) both caudally and medially to the coracoid (see Fig. 92-19). Abducting the upper arm at 90 degrees instead of placing it alongside the thorax brings the plexus closer to the skin and favors circumferential spread of local anesthetic.[230] The needle is inserted perpendicularly to the skin until twitches are elicited in muscles of the upper extremity.

Ultrasound Infraclavicular Block

The lateral paracoracoid approach under neurostimulation is technically feasible but unsafe if concomitant ultrasound imaging is not available, because of the danger of pleural penetration. The technique can be performed with the arm extended alongside the thorax or abducted 110 degrees and the elbow flexed by 90 degrees,[228] thus taking away the neurovascular sheath from the parietal pleura and loosening it to favor circumferential spread of the local anesthetic. Useful ultrasound landmarks are the axillary artery and vein, which are located deep and medial to the cords, with the vein positioned medial and caudal to the artery. Pectoralis major and minor muscles are most superficial overlying the neurovascular structures.

Two main infraclavicular approaches are used. One is a proximal approach with the probe placed parallel and immediately below the clavicle, and the cords are located lateral to the axillary artery (Fig. 92-20). The second is a paracoracoid approach with the probe placed in a parasagittal plane immediately medial and inferior to the coracoid process, allowing a short-axis view of the brachial plexus (Fig. 92-21). A great deal of individual anatomic variation occurs in the location of the cords around the artery. Commonly, the lateral cord is most easily viewed, the medial cord lies between the artery and vein, and the posterior cord is deep to the artery and frequently difficult to individualize. The needle is introduced using an in-plane approach from lateral (superior) to medial (inferior), and advanced aiming to place local anesthetic posterior to the axillary artery near to the posterior cord (Fig. 92-22).

Axillary Approach

The axillary block is the most common approach to the brachial plexus in pediatric patients, aiming to approach the plexus at the level of its terminal branches in the axilla. It is a relatively easy and safe procedure to control perioperative pain in elbow, forearm, and hand surgeries. In children, several variants of the axillary approach have been described, with no difference in clinical outcomes regardless of the technique selected. In contrast to the procedure in adults, the transarterial approach is not used in children because of the higher incidence of vessel spasm and potential risk for ischemia. Unlike in adults, a single injection is sufficient to block all the nerves of the forearm and hand, with the exception of the musculocutaneous nerve in 50% of cases.[231] To overcome this problem, the most useful variant of this technique is the transcoracobrachialis approach. The child is placed in the supine position with the ipsilateral arm both supinated and abducted by 90 degrees.[218] The block needle is introduced posteriorly at the crossing of the coracobrachialis muscle with the lower border of the pectoralis major muscle (Fig. 92-23). The needle is advanced posteriorly toward the medial border of the humerus through the upper and lateral part of the coracobrachialis muscle (within which runs the musculocutaneous muscle). With neurostimulation, the musculocutaneous nerve is usually the first nerve encountered (it will be preferably blocked on removal of the needle); the needle is moved deeper until it crosses the perineurovascular sheath[217] and elicits twitches in the muscles of the hand and forearm. At this level the cords have split into terminal nerves, and the median nerve is usually contacted first. The local anesthetic is then injected, and the needle is removed while a small volume (0.1 mL/kg up to 5 mL) is injected close to the musculocutaneous nerve. All tourniquet pain (intercostobrachial nerve) can be ablated with subcutaneous injection in the axilla.

With ultrasound guidance, a high-frequency probe is placed perpendicular to the major axis of the arm to obtain a short-axis view of the neurovascular bundle. The ultrasound-guided axillary approach to the brachial plexus is strictly a multiinjection technique. At this level, median, radial, and ulnar nerves are situated close to the axillary artery and vein. Great variation exists on the anatomic relationship of nerves with axillary location.[232] Generally, the median nerve is located between the lateral aspect of the artery and the brachial biceps muscle, the ulnar nerve is located more superficial and medial to the artery, and the radial nerve lies deep to the artery. Sliding the probe from distal arm to axilla area should help identify the nerve. The needle can be visualized throughout the procedure as it progresses in the plane of the ultrasound beam (Fig. 92-24); its tip can be precisely placed close to each of the three main nerves and, on removal of the needle, close to the musculocutaneous nerve between the coracobrachial and short head of the biceps muscles.

Axillary blocks are very safe. Accidental arterial puncture is the most undesirable incident, which may occasionally result in transient vascular insufficiency or a compressive hematoma. Intraneural injection is the most feared complication. It is usually thought to be the main cause of permanent nerve damage and mostly undetected in the patient under general anesthesia. In a prospective study on volunteers (that surprisingly got approval from an ethics committee), Bigeleisen and associates[131] deliberately attempted to penetrate axillary nerve trunks under ECG guidance. Deliberate intraneural injections were made, and the patients were evaluated after the injection and 6 months later. No motor or sensory deficits were observed. Regardless of whether the design of this study

TABLE 92-10 **USUAL LOCAL ANESTHETIC BOLUS DOSES OF ROPIVACAINE 0.1% (NEONATE) TO 0.2% OR LEVOBUPIVACAINE 0.125% (NEONATE) TO 0.25% AND INFUSION RATES FOR BRACHIAL PLEXUS NERVE BLOCKS**

Conduction Block	Bolus Doses (mL/kg)	Infusion Rates
Brachial plexus above and below clavicle	0.3-0.5	0.1-0.2 mL/kg/hr
Any nerve trunk at elbow	0.1-0.2	—
Any nerve trunk at wrist	0.05-0.1	—

is debatable, the results are interesting in showing that intraneural injection might not be as detrimental as commonly believed and might even be innocuous provided no intrafascicular injection (which elicits strong resistance to injection and excruciating pain) is made. However, such intraneural injections should be avoided, especially when ultrasound imaging is suggestive (tip of the needle within the nerve path and increase in nerve diameter when a fraction of the local anesthetic is being injected).

When continuous analgesia is required, a catheter may be introduced into the axillary neurovascular sheath, but its fixation and immobilization are difficult. Usually, perclavicular or interscalene approaches are preferred, with safe immobilization and increased patient comfort at these levels.

The volume of injectate is critical and depends on the approach and technique used to locate the nerves (Table 92-10). With neurostimulation, no information is obtained regarding the circumferential spread around nerve trunks; thus, recommended volumes of injection are based on the probability to obtain complete blockade. With ultrasound-guided techniques, the circumferential spread of local anesthetics can be clearly seen as a complete "donut" surrounding the relevant nerve trunk. In clinical practice, the use of ultrasound for nerve block must be associated with a significant reduction in the volume of local anesthetic.

DISTAL CONDUCTION BLOCKS

Elbow and Forearm Approaches

In pediatrics, approaching the radial, median, or ulnar nerve at the elbow or wrist is still not very common. These approaches are rather difficult with neurostimulation only, and their failure rate is relatively high when blind subcutaneous injections are made. Indications have long been limited to complementation of partially failed brachial blocks.

Ultrasound imaging is widening the field of indications for these techniques because these superficial nerves are easy to identify and approach with ultrasound guidance, the more so as very small amounts of local anesthetic (0.05 mL/kg up to 1 to 2 mL) are sufficient to produce complete nerve blockade. It is possible to block median and ulnar nerves at any point of their route from the wrist to the axilla, but at the level of the wrist, caution is necessary because it is often difficult to distinguish the nerves from the tendons owing to their similar appearance.

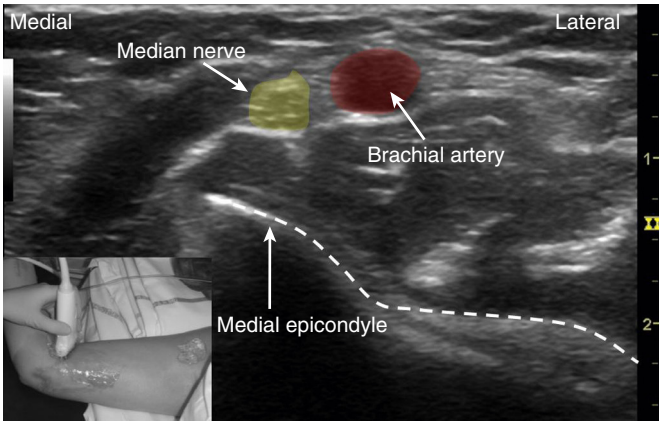

Figure 92-25. Ultrasound view of median nerve at the elbow level.

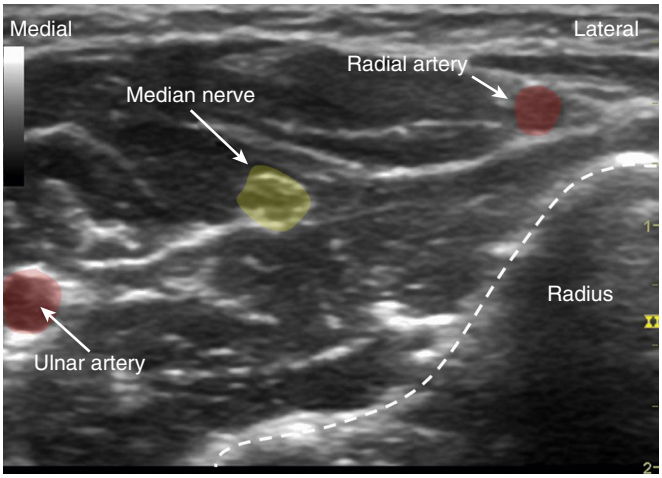

Figure 92-26. Ultrasound view of median nerve at the midforearm.

- The median nerve is located in the antecubital fossa just medial to the brachial artery (Fig. 92-25). In the middle of the midforearm, the median nerve is medial to the radial artery and medial and superficial to the radius (Fig. 92-26). At the wrist, the medial nerve is located between the tendons of the palmaris longus and the flexor carpi radialis but the distinction between the nerve and tendons may be difficult.
- The ulnar nerve can be blocked several centimeters above (Fig. 92-27) or below the elbow but never in the cubital tunnel, the groove between the olecranon and the medial epicondyle, because it can be compressed in this poorly compliant space. At the wrist, the ulnar nerve appears as a small hyperechoic triangle in close proximity to the medial side of the ulnar artery (Fig. 92-28, *A*). To facilitate and secure the procedure, we prefer to track the ulnar nerve proximally until it separates away from the artery (see Fig. 92-28, *B*).
- The radial nerve travels posterior to the humerus to the lateral side of the elbow, where it divides into superficial and deep branches. When scanning the posterolateral aspect of humerus just above the elbow, the radial nerve can be visualized below the brachial muscle in close proximity to the humerus (Fig. 92-29).

DIGITAL BLOCKS

Traditional digital ring blocks are almost never used in children, at least by anesthesiologists, because of technically safer alternatives such as the transthecal or metacarpal block and subcutaneous infiltration.

Transthecal blocks[233] consist of injecting a local anesthetic within the small space between the synovial sheath of each digital flexor tendon and the fibrous sheath that surrounds it and is attached proximally to the head of the metacarpal bone of the three median fingers (this sheath is more extended at the levels of the thumb and forefinger). In contrast to digital nerve blocks, it is safer because no terminal artery is close enough to cause complications, it is simpler because only a single injection is required, and it is less painful in conscious patients, even though the injection is not pain free. Caution should be taken in the case of infection to avoid bacterial contamination of the synovial sheath; in this case, the technique is contraindicated. The landmark is the head of the relevant metacarpal bone located by palpation of the palm while the hand is supinated. Then a 25- to 27-gauge intradermal needle is inserted perpendicularly to the palm, right in the center of the skin projection of the metacarpal head at the level of the distal palmar crease (Fig. 92-30), until bone contact is made. The needle is then slightly withdrawn (to avoid subperiosteal injection) and the local anesthetic (1% or 2% lidocaine without epinephrine) is injected.

A single, subcutaneous digital block was developed with the rationale of avoiding introduction of fluid into the digital flexor tendon sheath and a theoretic risk for infection. The subcutaneous block was performed by a single injection with a 25-gauge needle into the palmar skin at the base of the finger.[234]

Note that these palmar techniques, including single subcutaneous palmar block and transthecal block, carry a risk for anesthetizing only the last two phalanges and the ventral aspect of the proximal phalanx of the fingers.

LOWER EXTREMITY CONDUCTION BLOCKS

LUMBAR PLEXUS NERVE BLOCKS

Anatomic Considerations

The lumbar plexus is formed by the union of the anterior rami of the first four lumbar nerves (L1-L4) with variable input from the 12th thoracic nerve (T12) and L5. The lumbar plexus lies in the psoas compartment in the paravertebral space, with the anterior border formed by the psoas major muscle and the posterior border formed by the quadratus lumborum muscle. As it emerges from this space, it divides into the four nerves that innervate the anterior portion of the upper aspect of the lower extremity—the femoral, lateral cutaneous,

Figure 92-30. Transthecal nerve block. The head of the metacarpal bone is located by palpation.

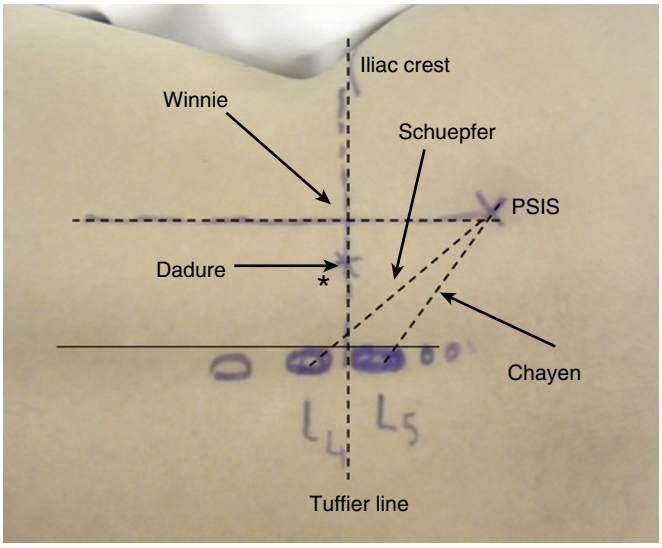

Figure 92-31. Landmarks of psoas compartment block with different procedures described in the pediatric literature. *PSIS, posterior superior iliac spine.*

genitofemoral, and obturator nerves. These nerves run a variable part of their course just below the fascia iliaca, which is the common fascia covering psoas and iliacus muscle. A sufficient volume of local anesthetic injected at the inner surface of this fascia will spread along it and reach these nerves, thus producing a fascia iliaca compartment block.

Psoas Compartment Block (Direct Lumbar Plexus Block)

Psoas compartment block is performed with the child turned in the lateral decubitus position with the operated side uppermost. The landmarks are the iliac crests, the ipsilateral posterior superior iliac spine, and the L5 spinous process. The following three puncture sites can be used (Fig. 92-31):

1. The midpoint of the line joining the posterior iliac spine to the L5 spinous process (modified Chayen approach)
2. A point located on the intercristal line (Tuffier line), three quarters of the distance between the spinous process of L4 and a line parallel to the spinal column passing through the posterior superior iliac spine[235]
3. A point located at medial two thirds and the lateral one third on a line from spinous process of L4 to the posterior superior iliac spine[236]

Whatever the puncture site used, the block needle is inserted perpendicularly to the skin until twitches are elicited in the ipsilateral quadriceps muscle. Complications, including cardiac arrest from intravascular injection, psoas muscle hematomas, epidural anesthesia, and retroperitoneal injection if the needle is inserted deeper than recommended, have been reported.[237,238] Consequently, this regional technique should be performed only by trained anesthesiologists, taking into consideration the depth of the lumbar plexus estimated according to the patient's age or weight and the proximity of important anatomic structures to the psoas compartment.

The usual indications for this block are surgeries on the hip or femoral shaft (femoral and hip osteotomies). These operations require blockade of the three main nerves innervating the hip joint: femoral, lateral femoral cutaneous, and obturator nerves. Psoas compartment block can produce excellent postoperative pain management during the first 48 hours. A recent study using sonography of the lumbar plexus in children showed that the depth of the lumbosacral plexus correlated with weight rather than age.[239] Continuous psoas compartment block provides good management of pain relief in major hip or femoral surgeries in children.[123,235,240] Continuous psoas compartment block has been compared with continuous epidural block in hip and femoral surgery in children.[123] Continuous psoas compartment block provided the same quality of postoperative analgesia with significantly less adverse events and required decreased doses of ropivacaine than continuous epidural block.

Femoral Nerve Block

Femoral nerve blocks are performed while the child lies supine, preferably with the ipsilateral limb slightly abducted. The landmarks are the inguinal ligament and the femoral artery. The puncture site is located 0.5 to 1.0 cm both below the inguinal ligament (not the inguinal crease) and lateral to the femoral artery (Fig. 92-32). The block needle is inserted posteriorly, either perpendicular to the anterior aspect of the thigh or, especially when a catheter has to be inserted, at a 45-degree angle cephalad, pointing to the umbilicus, until twitches are elicited in the quadriceps muscle when neurostimulation is used.

Ultrasound imaging makes the technique even easier.[139] The probe is placed slightly above and parallel to the inguinal ligament (Figs. 92-33 and 92-34).

The main surgical indications are femoral shaft or knee surgeries. The introduction of a catheter for continuous analgesia can be achieved by the direct perivascular (femoral) approach[241] or the fascia iliaca compartment approach.[242,243] These two approaches have never been

Figure 92-32. Figure 92-33. Probe location for ultrasound in-plane femoral block procedure.

compared in terms of efficacy in children.[244] The fascia iliaca technique, which does not require the use of a nerve stimulator or mobilization of the limb, seems easier to perform in fractures of the femur with less accidental vascular puncture.

Fascia Iliaca Compartment Blocks

The technique consists of injecting a local anesthetic below the fascia iliaca.[244] The injectate spreads at the inner surface of the fascia and, depending on its volume, spreads around the nerves emerging from the lumbar plexus that supply the lower extremity. The technique is performed with the child lying supine (see Fig. 92-32). With this technique, the femoral and lateral cutaneous nerves are almost constantly blocked. The local anesthetic usually reaches the upper division branch of the obturator nerve, which is the branch giving a twig to the hip joint. The anesthetized area also includes areas supplied by upper branches of the lumbar plexus in more than 70% of procedures, such as the genitofemoral nerve.

Perivascular femoral nerve and fascia iliaca compartment approaches have never been compared in terms of efficacy in children.[244] The fascia iliaca compartment block was superior in terms of blockade for lateral cutaneous, obturator, and genitofemoral nerves. The perivascular approach provides a risk for significant vascular puncture. Moreover, the fascia iliaca technique, which does not require the use of a nerve stimulator or mobilization of the limb, seems easier to perform in femur fracture surgeries.

Performing this block using ultrasound showed several advantages, including extension of the duration of postoperative analgesia and decrease in the volume of injected local anesthetic in contrast to that with neurostimulation technique.[139] Local anesthetic injected volumes were decreased by two—0.15 versus 0.3 mL/kg—in ultrasound-guided techniques and nerve stimulation. The duration of analgesia was significantly increased to approximately

508/178 minutes versus approximately 335/69 minutes for all blocks using the same techniques.[139]

Usual doses of local anesthetic are 0.2 to 0.5 mL/kg in single-shot or induction bolus and 0.1 to 0.2 mL/kg/hr in postoperative continuous infusion of long-acting local anesthetic. Patient-controlled regional anesthesia can be used with bolus of 0.1 mL/kg (up to 5 mL, and maximum 3 boluses per hour). Local anesthetics with epinephrine produce significantly lower plasma concentrations and should be preferred whenever possible. Addition of clonidine (1 to 2 μg/kg) significantly prolongs the duration of analgesia.[46]

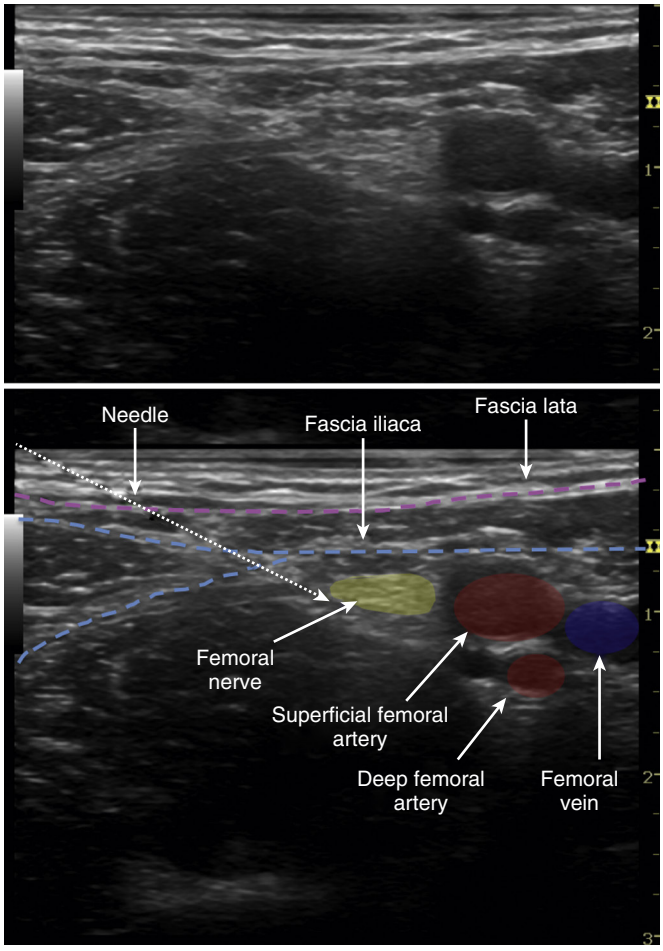

Figure 92-34. Ultrasound picture of femoral nerve block procedure.

In fascia iliaca compartment and femoral nerve block, placement of a catheter is easy and allows long-lasting pain relief (Fig. 92-35) and is improved with ultrasound guidance. Recently, Lako and associates[243] compared continuous fascia iliaca block and intravenous morphine in terms of analgesia and side effects in children undergoing pelvic osteotomy. The authors noted excellent postoperative pain relief, with less sedation and a better return of appetite in the regional analgesia group in contrast to the morphine group. On the other hand, Paut and colleagues[242] determined plasma concentrations of bupivacaine during continuous fascia iliaca block in children after major femur or knee surgery or femoral fracture. The regimen of local anesthetic administration was a bolus dose of 0.25% bupivacaine with epinephrine followed by continuous administration of 0.1% bupivacaine for 48 hours. They concluded that the plasma concentrations of bupivacaine during continuous fascia iliaca compartment block are within the safety margins for children (0.71 ± 0.4 g/mL and 0.84 ± 0.4 g/mL at 24 hours and 48 hours, respectively).

Other Lumbar Plexus Nerve Blocks

Saphenous Nerve Block. Saphenous nerve blocks are used as a complement to sciatic blocks with small amounts of local anesthetic. Because the saphenous nerve is a purely sensory nerve, it is not identifiable by neurostimulation. Many block procedures have been published, all resulting in a high failure rate (30% or higher). Ultrasound imaging, currently underevaluated in this indication, is a promising technique.

The classic approach is performed at knee level with the patient supine. The anterior edge of the medial head of the gastrocnemius muscle and the tibial tuberosity are identified by palpation. A line is drawn at a 45-degree angle with the intercondylar line, from the tibial tuberosity to the anterior edge of the gastrocnemius muscle. The technique consists of subcutaneously injecting local anesthetic along this line. This very simple technique is virtually free of complications, but its failure rate is rather high.

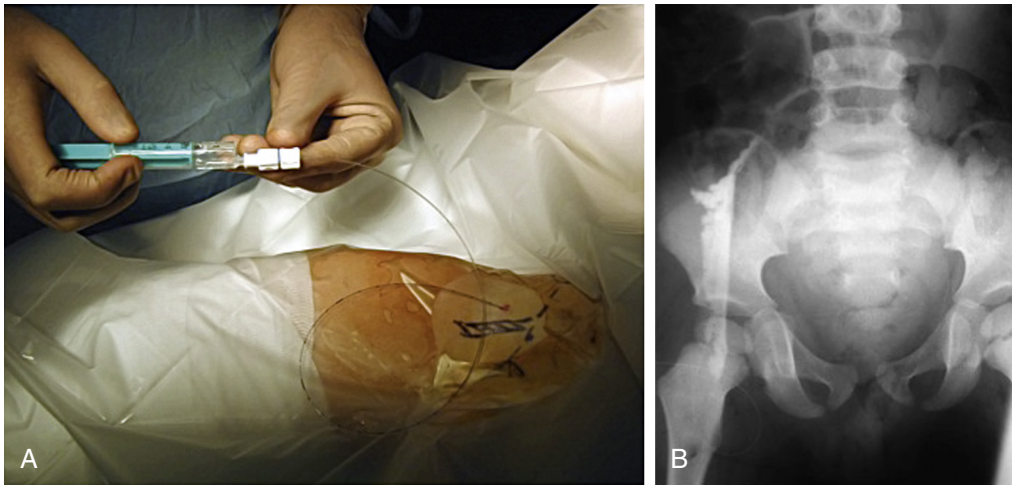

Figure 92-35. Femoral nerve catheter placement (**A**) and spread of contrast medium solution after injection into the catheter (**B**).

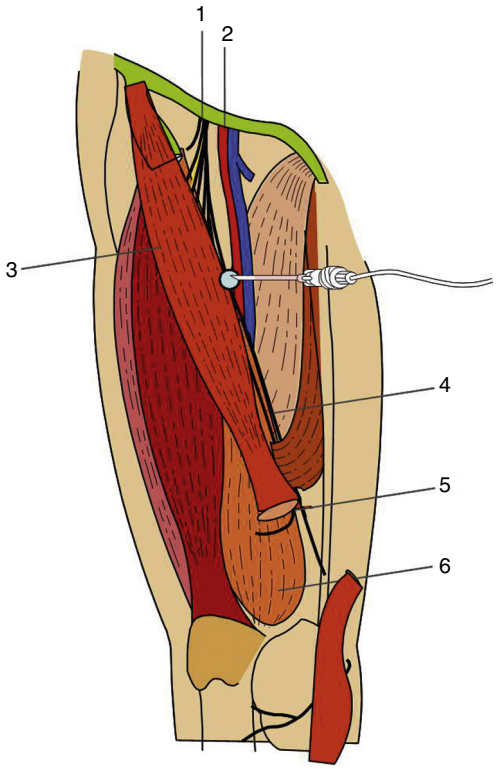

Figure 92-36. Saphenous and vastus medialis nerve block. *1,* Femoral nerve; *2,* femoral artery; *3,* sartorius muscle; *4,* saphenous nerve; *5,* motor nerve supplying the sartorius muscle; *6,* vastus medialis muscle.

The saphenous and vastus medialis nerve block takes advantage of the proximity of the vastus medialis and saphenous nerves within the adductor canal in the upper part of the thigh. Being a mixed nerve, the vastus medialis nerve can be located easily by neurostimulation, and injecting a local anesthetic results in concomitant blockade of the two nerves. The landmarks are the femoral artery, the inguinal ligament, and the upper border of the sartorius muscle (Fig. 92-36). A short and short-beveled insulated needle is inserted perpendicularly to the skin, 0.5 cm lateral to the femoral artery just above the upper border of the sartorius until twitches are elicited in the vastus medialis muscle. Injecting 0.1 to 0.2 mL/kg of a local anesthetic is sufficient to block the two nerves and obtain complete analgesia of the medial aspect of the leg and foot.

The transsarterial approach aims to infiltrate the fat pad located between the inner aspect of the sartorius muscle and great adductor tendon. The puncture site is situated at the level of the upper border of the patella, on the medial aspect of the sartorius muscle located by palpation. The block needle is inserted medially and slightly posteriorly with a 45-degree angle caudally, in the direction of the medial femoral condyle until a loss of resistance is felt as the subsartorial fat pad (through which runs the saphenous nerve) is penetrated. The paravenous approach, originally described as a "blind" infiltration technique on both sides of the saphenous vein in the upper part of the medial aspect of the leg, is considerably improved by ultrasound imaging because the saphenous vein is easy to locate. Inserting the needle along the major axis of the probe allows clear visualization of needle progression toward the vein and circumferential spread of the local anesthetic.

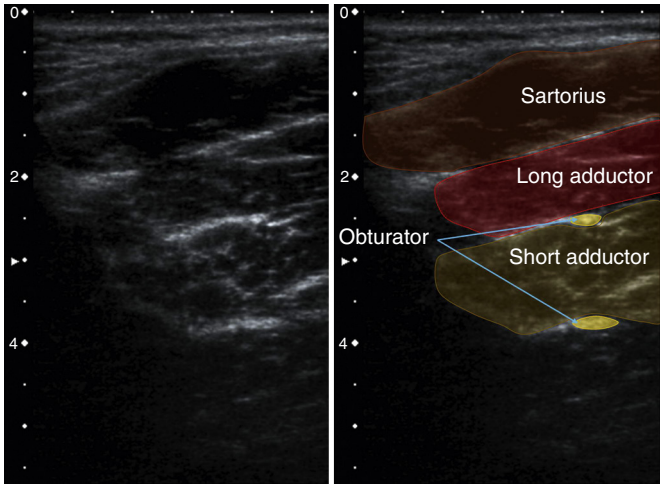

Figure 92-37. Obturator nerve block, with ultrasound imaging of the anterior and medial aspect of the thigh.

Lateral Cutaneous Nerve Block. A specific lateral cutaneous nerve block is rarely used in children; its main indication is as a technique complementary to a femoral block. Ultrasound guidance can be used.

Obturator Nerve Block. This procedure is performed with the child supine and the thigh slightly abducted and externally rotated (if possible). The landmarks are the groove between the tendon of the long adductor muscle and medial border of the pectineus muscle. The puncture site lies in this groove at the level of the greater trochanter of the femur. With neurostimulation, the needle is inserted following a strict anterior to posterior path until twitches are elicited in the long and short adductor muscles (stimulation of the anterior division branch of the obturator nerve). The needle is further advanced dorsally over 1 to 2 cm until twitches are elicited in the great adductor (posterior branch). Half of the local anesthetic solution (of a total of 0.1 mL/kg up to a maximum of 5 mL per nerve) is injected; the needle is then removed until stimulation of the anterior branch is obtained again and the second half of the anesthetic is injected.

The same technique can be performed with ultrasound imaging. The probe is placed below the pubic tubercle, with its major axis parallel to the inguinal ligament. The aponeuroses of the sartorius and long and short adductors are easily identified. The anterior branch can be easily found between the long and short adductors, and the posterior branch lies between the short and great adductors (Fig. 92-37).

SCIATIC NERVE BLOCKS

Anatomic Considerations

The sacral plexus is formed by the anterior rami of the fourth and fifth lumbar nerves and the first three sacral nerves with variable input from the fourth sacral nerve.

Figure 92-38. Position and ultrasound visualization of the in-plane subgluteal approach to sciatic nerve.

The sacral plexus lies on the surface of the sacrum anterior to the piriformis muscle. The sacral plexus gives rise to the other two nerves that innervate the lower extremity: the posterior cutaneous nerve of the thigh (otherwise known as the small sciatic nerve) and the sciatic nerve. Peripheral blockade of these two nerves is considered together as blockade of the sciatic nerve. These two nerves travel together in the same sheath as they exit through the greater sciatic foramen into the posterior aspect of the upper part of the leg. The sciatic nerve runs in the midline of the posterior aspect of the thigh to the apex of the popliteal fossa. At the level of this fossa, it divides, at a variable distance, into the common peroneal and the posterior tibial nerves. The common nerve continues its descent around the head and neck of the fibula. The terminal branches form the superficial and deep peroneal nerves. The tibial nerve runs in the internal face of the leg and emerges laterally and behind the tibial artery at the level of the lateral malleolus. Its terminal branches are the lateral and medial plantar nerves.

Indications and Contraindications

Sciatic nerve blocks are recommended for operations on the foot and the leg (a complementary saphenous nerve block is often required because this nerve provides cutaneous innervation of the medial aspect of the leg). Depending on the surgery, the sciatic nerve will be approached in the popliteal fossa or more proximally. Sciatic blocks have no specific contraindications. As with other extremity nerve blocks, patients at risk for compartment syndrome require close monitoring and use of diluted solution to avoid motor blockade.

Proximal Sciatic Nerve Blocks

Numerous techniques have been described for which the associated morbidity can differ significantly. When successful, they provide the same distribution of anesthesia. When contemplating a proximal sciatic block, the anesthesiologist must consider (1) morbidity of the technique, (2) positioning of the patient, (3) technique used to locate the nerve, (4) necessity for catheter placement, and (5) experience of the anesthesiologist with this particular technique.

Subgluteal Approach. The subgluteal approach is a common proximal way to the sciatic nerve in children. This

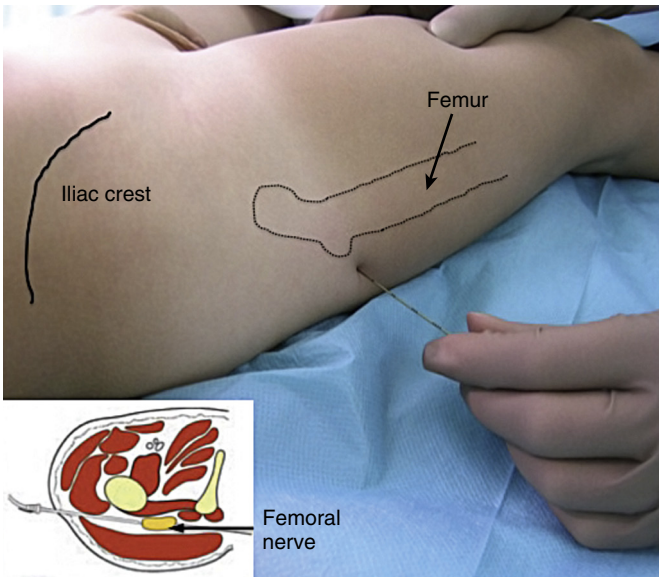

Figure 92-39. Proximal sciatic lateral block procedure.

block can be performed in a supine, lateral, or prone position. In supine position, the leg is flexed to 90 degrees at the hip with the knee flexed at 90 degrees (Fig. 92-38). This position is preferable in small children. In older ones, the lateral or prone position is preferred. The point of puncture is located at the midline joining the ischiatic tuberosity and the greater trochanter of the femur. The needle is inserted at right angles to the skin toward the femur until twitches are elicited in the foot. The nerve is easily accessible, is relatively superficial, and lies in a palpable groove.

Ultrasound guidance with or without neurostimulation facilitates the success of this block.[245] Continuous subgluteal block can be easily performed and permits good postoperative pain management in major ankle or foot pediatric surgery.[245]

Lateral Approach. A lateral approach to the sciatic nerve has been described for use in patients lying supine[246] with the relevant leg slightly rotated medially. The needle is inserted horizontally toward the lower border of the femur (Fig. 92-39). If bone contact is made, the needle is withdrawn and reinserted slightly more posteriorly until

twitches are elicited in the leg and the foot. The distance at which the sciatic nerve is found can be correlated with patient age (Fig. 92-40).

Proximal lateral sciatic nerve blocks have been described for major foot surgery in children, but with high doses of local anesthetics and catheter migration or dislodgement maintained during patient mobilization.[247,248] It has been described in children with the same landmarks and technique of puncture described later. The catheter can be fixed with transparent dressing or tunneled to permit more stable fixation and prolonged administration.

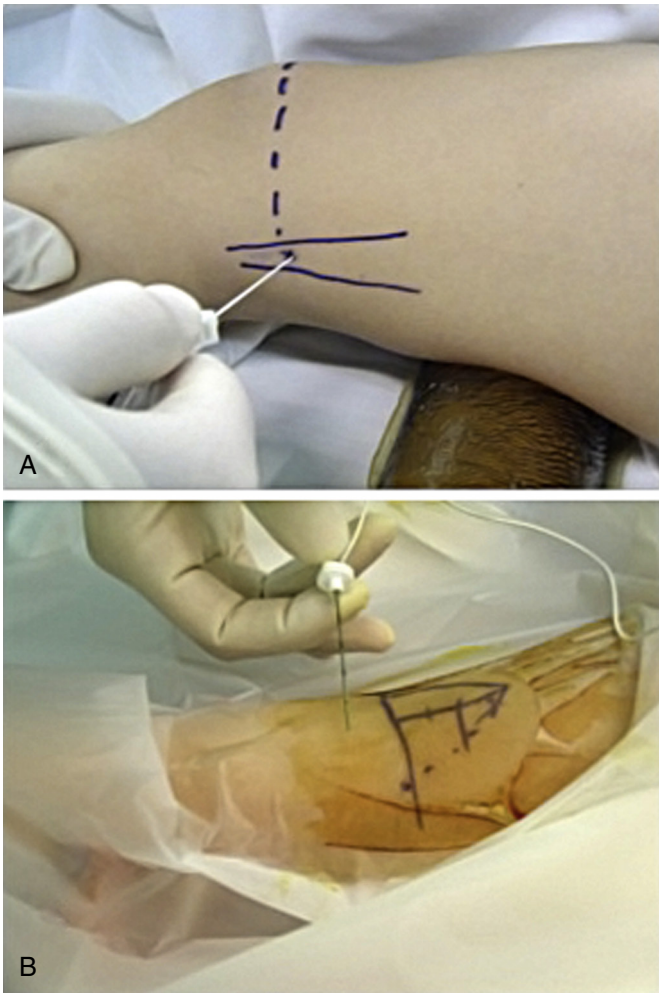

Figure 92-40. Sciatic popliteal nerve block with lateral approach (**A**) and posterior modified Singelyn technique approach (**B**).

Popliteal Sciatic Approach

Popliteal nerve block is a particularly simple, safe, and effective method, providing good analgesia with small amounts of local anesthetics. This approach is the first choice for major foot and ankle surgeries in children to ease the introduction of the catheter. The two approaches to the sciatic nerve in the popliteal fossa are the lateral and posterior approaches. The child may remain in the supine position for the lateral approach. The landmark for lateral distal sciatic nerve approach is the groove between the vastus lateralis muscle and the tendon of the long head of the biceps femoris muscle at the level of the superior edge of the patella (Fig. 92-41, *A*). In the posterior approach, the child is placed in the prone or, preferably, the semiprone position, resting on the nonoperated side. A popliteal sciatic nerve block with posterior approach is performed using the landmarks of Singelyn and colleagues[249] adapted to children (see Fig. 92-41, *B*). A nerve stimulator may be used to assist the practitioner to identify the nerve. Correct needle placement is identified when an output 0.6 mA elicits a characteristic motor response corresponding to either tibial (dorsiflexion of the foot) or common peroneal (foot eversion) nerve stimulation.

Ultrasound guidance is easy at this level, allowing an in-plane or out-of-plane approach depending on the habits of the practitioner. Ultrasound scanning permits the location of the sciatic nerve and its division in popliteal fossa.[245,250] The sciatic nerve is usually located laterally and superficially to the popliteal artery (Fig. 92-41). Ideally, the sciatic nerve should be blocked before its division into tibial and common peroneal nerves to obtain the best result.

Pain management for major foot and ankle surgery requires continuous sciatic nerve block. The distal approach is particularly interesting because of the ease of performance and the quality, power, and duration of analgesia with low doses of local anesthetics.[67,156,251,252] Continuous popliteal nerve block was compared with continuous epidural block in children undergoing major foot and ankle surgery.[252] Both techniques were associated with excellent postoperative analgesia in this study, but continuous popliteal nerve block led to less urinary retention, less discontinuation of local anesthetic infusion, and less

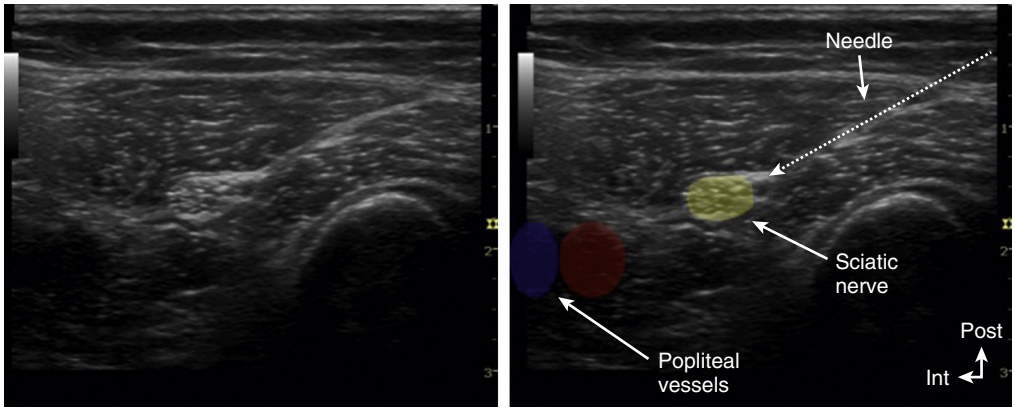

Figure 92-41. Ultrasound of sciatic popliteal nerve block. Sciatic nerve is usually located laterally and superficially to the popliteal vessels.

nausea and vomiting. The popliteal catheter is the location most frequently used to treat children at home.[79,155,156]

Transthecal and Metatarsal Blocks

The metatarsal (or midtarsal) block is an easy technique for providing good pain relief for surgical procedures on the toes. The child is placed supine, and the head of the relevant metatarsal is palpated on the sole. The technique consists of inserting a standard intramuscular needle dorsally on the dorsum of the foot in close contact with the medial border of the base of the metatarsal until the tip of the needle is felt and seen as it pushes the skin of the sole. A volume of 1 to 3 mL of local anesthetic is then injected while the needle is slowly withdrawn. The same procedure is repeated along the lateral border of the same metatarsal to provide full anesthesia of the relevant toe.

The transthecal technique as described for finger procedures can be transposed to the sole of the foot by palpating the head of the relevant metatarsal bone and injecting a small volume of local anesthetic in the fibrous sheath surrounding the tendinous sheath of flexor tendons. However, except for the greater toe, the landmarks are more difficult to identify and, because of the thickness of the sole, the infiltration is technically more difficult and less precise.

BLOCKS OF NERVES SUPPLYING THE TRUNK

Surgeries of the trunk are some of the most common surgeries performed in children. Traditionally, central blocks are the regional analgesia frequently used for these procedures. Nevertheless, central blocks have some adverse effects, including unwanted motor block, urinary retention, pruritus, nausea and vomiting, and risk for spinal cord trauma or epidural hematoma. Internationally, peripheral nerve blocks are increasingly taking place in the practice of pediatric anesthesia.[98] An epidemiologic study found that truncal blocks are the most commonly employed in children, even preferred over central blocks, because of their low morbidity. Abdominal wall blocks are known as effective techniques to provide adequate analgesia for minor abdominal surgery in children. Moreover, these techniques are readily accessible to ultrasound guidance.

PERIPHERAL BLOCKS FOR ABDOMINAL WALL SURGERY

Rectus Sheath and Paraumbilical Block

The rectus sheath and paraumbilical block technique consists of injecting a local anesthetic within the substance of the rectus abdominis muscle along the course of the terminal branch of the tenth intercostal nerve , which supplies sensory innervation to the periumbilical area. It provides efficient pain relief for umbilical or other midline surgical incisions, as well as umbilical and epigastric hernia repair, laparoscopic surgery, and pyloromyotomy. Today, this regional anesthetic technique has become increasingly popular.

Two punctures, on each side of the abdomen, are necessary. A short beveled needle inserted at 45-degree angle is necessary to perceive the passage of different planes. Long-acting local anesthetics are usually used with a low concentration (0.2% to 0.5%). The total volume of anesthetic solution injected is 0.1 to 0.5 mL/kg of body weight in each side. This dose of local anesthetic is widely decreased with ultrasound guidance.

The landmark for the fascia-click technique is the midline between the outer border of rectus muscle and the umbilicus. Two methods have been described in pediatric literature with a sensation of fascial click when the needle pierces the anterior rectus sheath.

Performing this block under ultrasound guidance can avoid intraperitoneal punctures and erratic needle position.[253] In contrast to the fascial-click method, ultrasound guidance significantly increases correct needle position (88% versus 44%) and decreases the rate of intraperitoneal or injections that are too superficial (11.5% versus 34.5% and 0% versus 20.9%, respectively, for ultrasound-guided techniques and fascial click).[254] Both aponeuroses of the rectus muscle and the parietal peritoneum are very echoic. The probe is placed horizontally over the umbilicus, and the block needle is inserted medially in long-axis orientation. The superficial fascia is bent and then crossed by the tip of the needle, which should be moved forward until it contacts the deep fascia (to favor the longitudinal spread of the anesthetic). The anesthetic is then injected and can be visualized in the form of an expanding biconvex black shadow (Fig. 92-42).

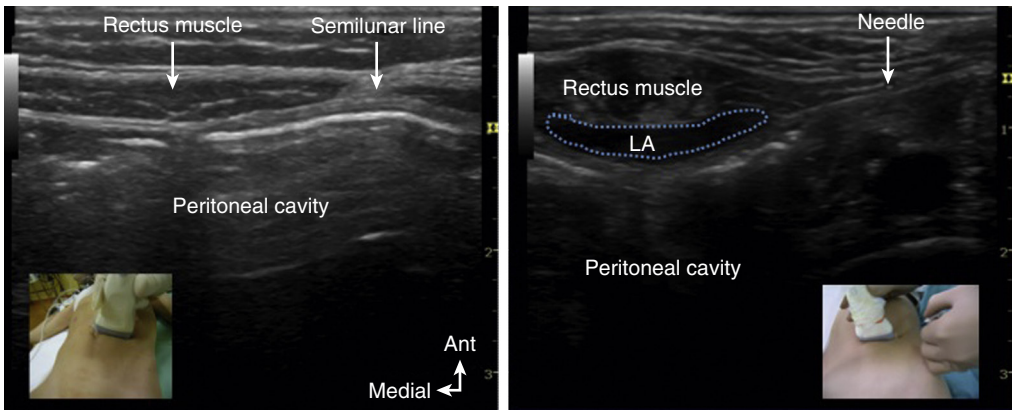

Figure 92-42. Ultrasound of paraumbilical block. Insertion of the needle close to the posterior fascia of the rectus muscle and injection of the local anesthetic creating a biconvex black cloud.

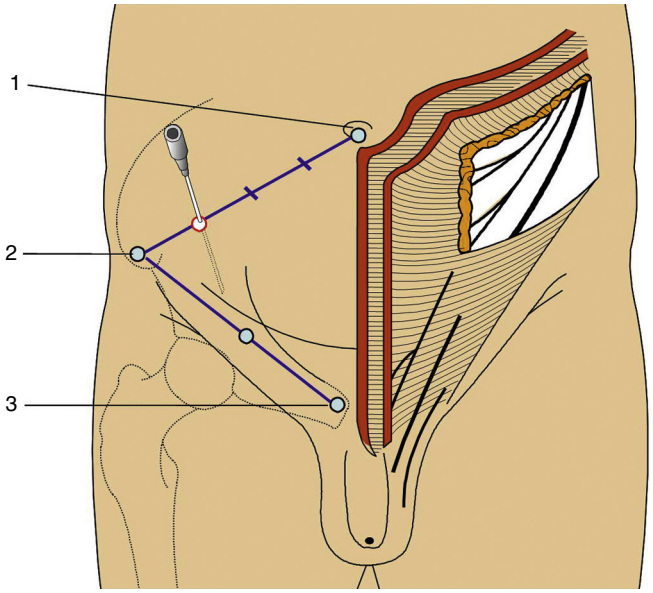

Figure 92-43. Iliohypogastric and ilioinguinal nerve blocks. *1,* Umbilicus; *2,* anterior iliac crest; *3,* pubic spine.

Ilioinguinal and Iliohypogastric Nerve Blocks

The three nerves supplying the inguinal area are the ilioinguinal, iliohypogastric, and genitofemoral nerves. In 50% of patients, sensory innervation of the inguinal canal depends exclusively on the genital branch of the genitofemoral nerve (also termed the external spermatic nerve in males). Several publications focusing only on the ilioinguinal and iliohypogastric nerves have appeared in the literature, especially with the development of ultrasound imaging.[138,255] Not surprisingly, the quality of analgesia produced is often unsatisfactory because a major contributor to sensory innervation remains unchanged.

The inguinal procedure, as well as inguinal hernia repair, orchiopexy, hydrocele repair, or cord cyst, may benefit from intraoperative and postoperative pain management with ilioinguinal-iliohypogastric block. This technique, widely described in the literature, is a fascial-click technique. A single-injection technique can safely and reliably block the three relevant nerves at once because these nerves are located in the same fascial plane close to the subcutaneous inguinal ring formed by the aponeurosis of the external oblique muscle. The landmarks are the umbilicus, ipsilateral anterior superior iliac spine (ASIS), and midpoint of the inguinal ligament. The ASIS-umbilicus line is divided into four equal parts; the puncture site is located at the union of the lateral fourth with the medial three fourths (Fig. 92-43). A short-bevel needle is essential to perceive the passage of the various planes. The two main risks are intravascular injection (very low) and the crossing of three muscle layers with penetration into the abdominal cavity or intraperitoneal organ. In addition, the extension of the territory femoral anesthesia is a complication reported after ilioinguinal-iliohypogastric block with an incidence of up to 10%.[256] The usual dose is 2.5 mg/kg of long-acting local anesthetic. Puncture may be bilateral if the surgery requires.

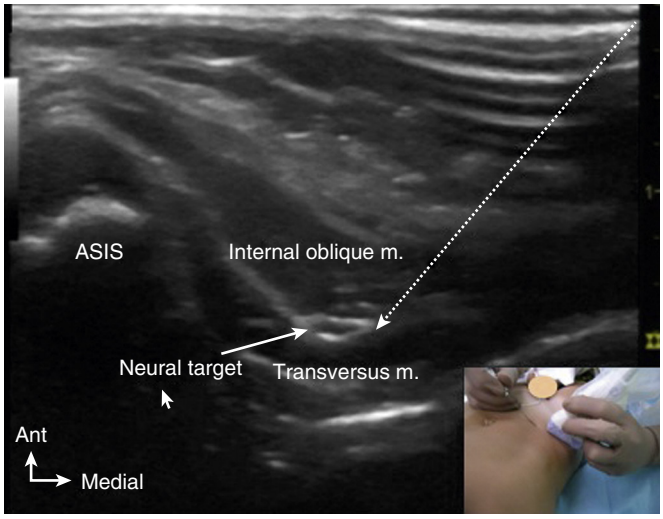

Figure 92-44. Ultrasound. Ilioinguinal and iliohypogastric block imaging and probe placement for in-plane needle insertion. *ASIS,* Anterior superior iliac spine; *m.,* muscle.

Ultrasound guidance of this block has advantages in terms of quality of analgesia and dose reduction of local anesthetics. The probe is located on the line between the ASIS and umbilicus close to ASIS. Two muscles of the abdominal wall are visible at this level: the transverse muscle and internal oblique muscle. The neural target is located between both these muscles (Fig. 92-44). The needle insertion can be performed with an in-plane or out-of-plane technique. Willschke and associates[138] showed that the total volume of local anesthetic used in the ultrasound group was significantly lower than in the fascial-click technique (respectively, 0.19 mL/kg versus 0.3 mL/kg of 0.25% levobupivacaine). They concluded that the local anesthetic optimal minimum volume for this ultrasound-guided block was 0.075 mL/kg of 0.25% levobupivacaine.[257] Using the traditional fascial-click technique causes erratic needle location in 85% of cases and 45% of blockade failures.[258]

Transversus Abdominis Plane Block

The transversus abdominis plane (TAP) block presents a very interesting alternative to the ilioinguinal and iliohypogastric nerve block for inguinal surgery in children.[259] It has become incredibly popular for analgesia in abdominal wall surgery. One objective of this technique is to block the segmental nerves T9 to T12 and ilioinguinal and iliohypogastric nerves by spread of local anesthetic in the plane separating the transverse abdominal muscle and internal oblique muscle by a single injection.

The lumbar triangle of Petit (a space bounded by the iliac crest, latissimus dorsi muscle, and external oblique muscle) is used as a landmark, and a sensation of two "pops" indicates the correct needle position. The first pop occurs after penetration of the fascia of the external oblique muscle, and the second occurs after penetration of the internal oblique muscle. In general, the blind TAP block technique is described as easy to perform and having few complications.

In children, ultrasound guidance to perform this block is recommended. The block is accomplished by

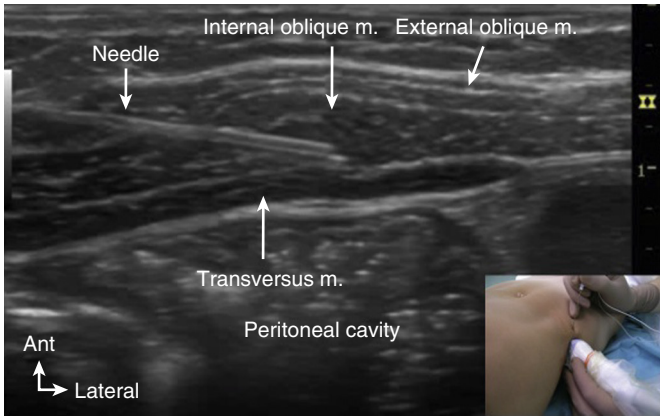

Figure 92-45. Ultrasound transversus abdominis plane block imaging and probe placement for in-plane needle insertion. *m.,* Muscle.

positioning the probe on the midclavicular line between the iliac crest and the last rib, allowing a puncture in plane (Fig. 92-45). Ultrasound guidance provides greater safety when performing this block by direct visualization of different muscle planes, the needle and its correct position, and distribution of local anesthetics in this plane.[260] Visualization of different muscle planes is sufficient and does not require identification of neural structures itself. The TAP block has been compared to the ultrasound-guided block and ilioinguinal and iliohypogastric ultrasound-guided block for hernia surgery in children.[261] The ilioinguinal and iliohypogastric block produces better postoperative analgesia, probably due to inefficient blockage of the genital branch of the genitofemoral nerve with the TAP block technique.

PERIPHERAL BLOCKS FOR PENILE SURGERY

Penile Block

Surgery of the prepuce and penis surgery is common in children. This surgery may need advanced pain control for 12 to 24 hours, and is usually done on an outpatient basis. Nerve supply to the penis depends mainly on the dorsal nerve of the penis, which is a terminal branch of the pudendal nerve. The penile block by subpubic approach with long-acting local anesthetic for prolonged analgesia is a good indication for this type of surgery. The usual dose is 0.1 mL/kg (maximum 5 mL) of local anesthetic on each side. The technique is to inject an appropriate volume of local anesthetic in the two compartments of the potential subpubic space behind the Scarpa fascia (Fig. 92-46). Puncture is performed perpendicularly to the skin. Gentle traction is exerted on the penis to tension the Scarpa fascia and better feel the fascial click (Fig. 92-47). This block procedure is easy and its learning curve is particularly short.[262] Ventral injections of the perineal nerve can be combined with dorsal penile nerve block for circumcision surgery to overcome the failure rate of the dorsal nerve block of the penis.

Crossing of the Scarpa fascia also can be verified by ultrasound imaging.[263,264] Ultrasound-guided penile nerve block improved the efficacy of the block in contrast to the fascia-click technique in terms of the postoperative

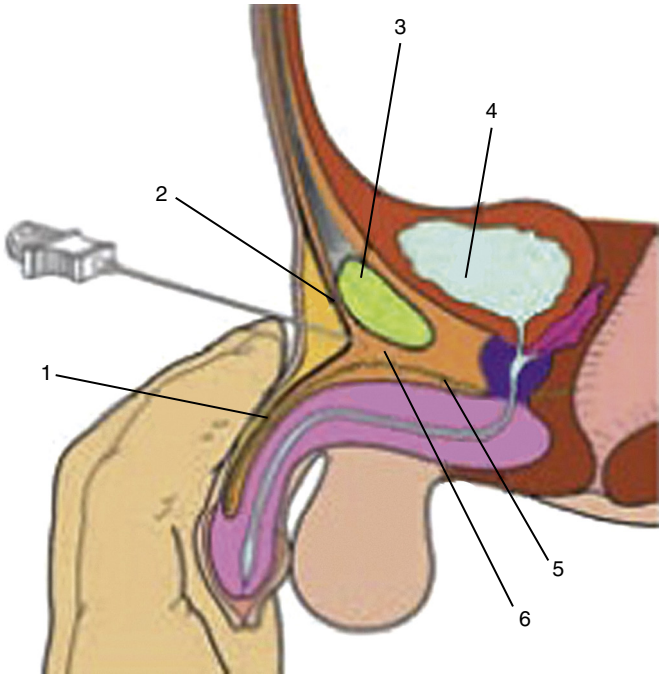

Figure 92-46. Anatomic puncture for penile block via the subpubic space. *1,* Buck fascia; *2,* Scarpa fascia; *3,* pubic bone; *4,* bladder; *5,* dorsal nerve of penis; *6,* subpubic space.

pain during the first postoperative hour and the time to the first requirement for postoperative analgesia.[265]

The morbidity is extremely low (almost nil when a local anesthetic without epinephrine only is used), whereas complications have been reported after attempts to block the nerves by infiltration of a local anesthetic below the Buck fascia at the dorsal part of the penis.

The use of adrenaline and skin infection at the puncture site are the main contraindications of this block. Serious complications are the consequence of a lesion of the dorsal artery in case of median puncture and the risk for injury to the cavernosus corpus with local anesthetic injection equivalent to an intravenous injection of local anesthetic.[266]

The usual indications are elective surgery such as circumcision and phimosis cure or emergency surgery such as reduction of a paraphimosis or release of a foreskin stuck in a zipper pants.

Pudendal Nerve Block

Given the random effectiveness of penile block for surgery of the prepuce in children, some teams advocate the use of pudendal block. The pudendal nerve provides sensory and motor innervation to the pelvic cavity and its contents, including external genital organs. The landmarks are the two ischial tuberosities and anus (Fig. 92-48). The distribution of anesthesia depends on the volume of injectate. With 0.1 mL/kg (up to 5 mL), anesthesia is usually limited to the perineal nerve that supplies the posterior part of the scrotum (this is enough to complement an ilioinguinal, iliohypogastric, and genitofemoral nerve block when a scrotal incision is required). With 0.3 to 0.4 mL/kg on each side (up to 15 mL), all division branches of the pudendal nerve are blocked, thus providing complete

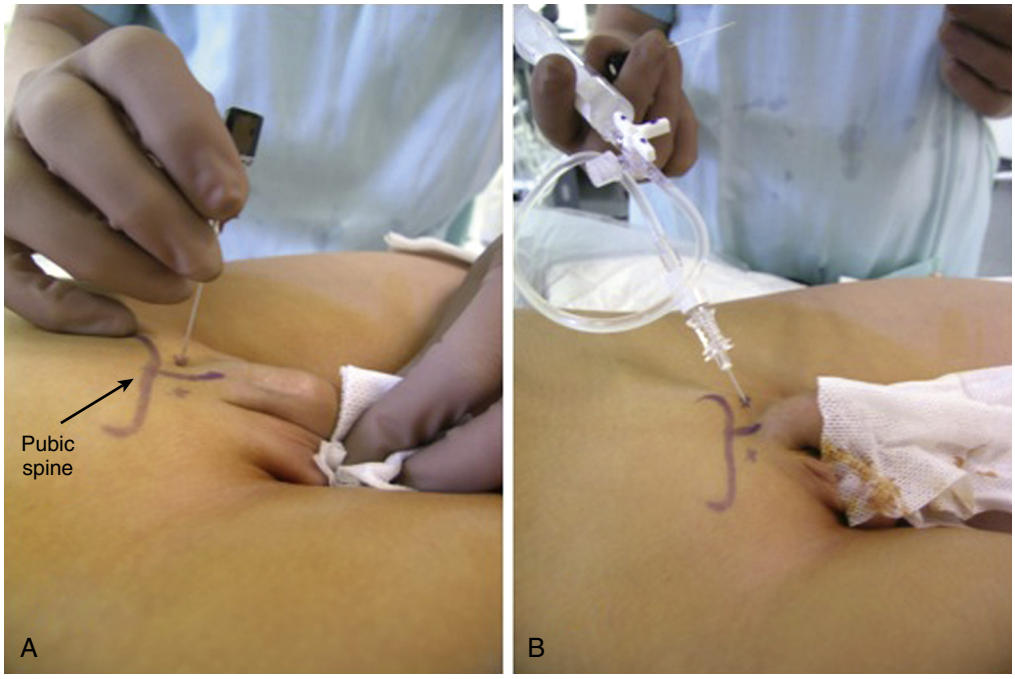

Figure 92-47. Penile block technique procedure. Gentle traction is exerted on the penis to tension the Scarpa fascia and better feel the fascial click (**A**). Injection of local anesthetic is easy without resistance (**B**).

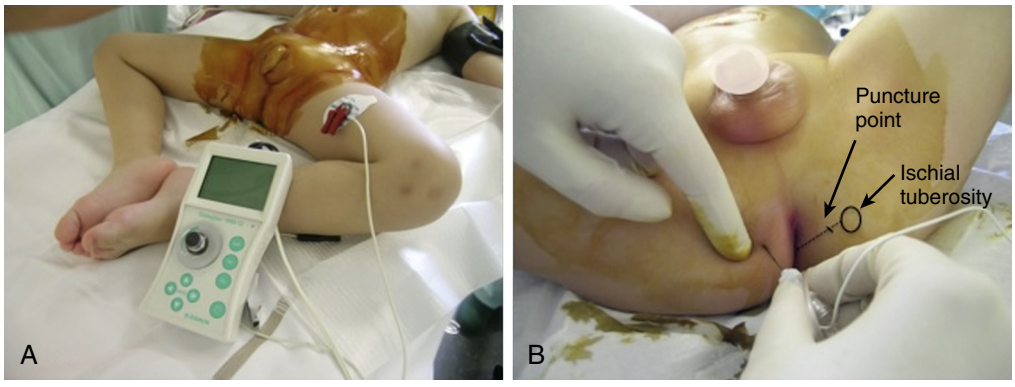

Figure 92-48. Position for pudendal block procedure (**A**) and landmarks and puncture (**B**).

analgesia of the perineum, including blockade of the dorsal nerve of the penis.

Because the pudendal nerve is a mixed nerve, a nerve stimulator can be used to locate it more precisely if this is deemed useful[267] (see Fig. 92-48, *A*). The expected motor response is a contraction of the external anal sphincter. It is recommended to start at an intensity of 1.5 to 2.0 mA. The position of the needle is considered adequate if the muscle response is obtained for an intensity of between 0.5 and 0.8 mA (0.1 to 0.2 msec, 1 Hz).

Ultrasound guidance has been used in adults, but identification of the pudendal nerve was possible in only half of the procedures.[268] Because this nerve is accompanied by a terminal artery (pudendal artery), local anesthetics with ephedrine must be avoided.

Naja and associates[269] compared nerve-stimulated pudendal block and dorsal penile nerve block with the fascia-click technique in 60 children undergoing surgery for circumcision. The authors showed a significant decrease in pain scores and analgesic consumption in the group with a pudendal block, with higher parental and surgical satisfaction. Perineal nerves appear to play an important role in the innervation of the penis, and it is the recommended block for circumcision surgery. The perineal and dorsal nerves are terminal branches of the pudendal nerve. The pudendal nerve block has the ability to block the dorsal and perineal nerves with only one single injection.

INTERCOSTAL NERVE BLOCK

Intercostal nerves run along the lower border of each rib, within the intercostal space, a triangular space, with (1) a medial border formed by the posterior intercostal and innermost intercostal muscles, endothoracic fascia, and parietal pleura; (2) a lateral border formed by the internal and external intercostal muscles and intercostal membrane (thickening of the inner fascia of external intercostal muscles); and (3) a base formed by the lower rib. Intercostal nerve block is obtained by injecting a local anesthetic within the intercostal space and, provided several adjacent intercostal spaces are infiltrated, adequate intraoperative and postoperative pain relief is obtained for thoracotomy,[270] liver transplantation, pleural drainage, and management of rib fractures.

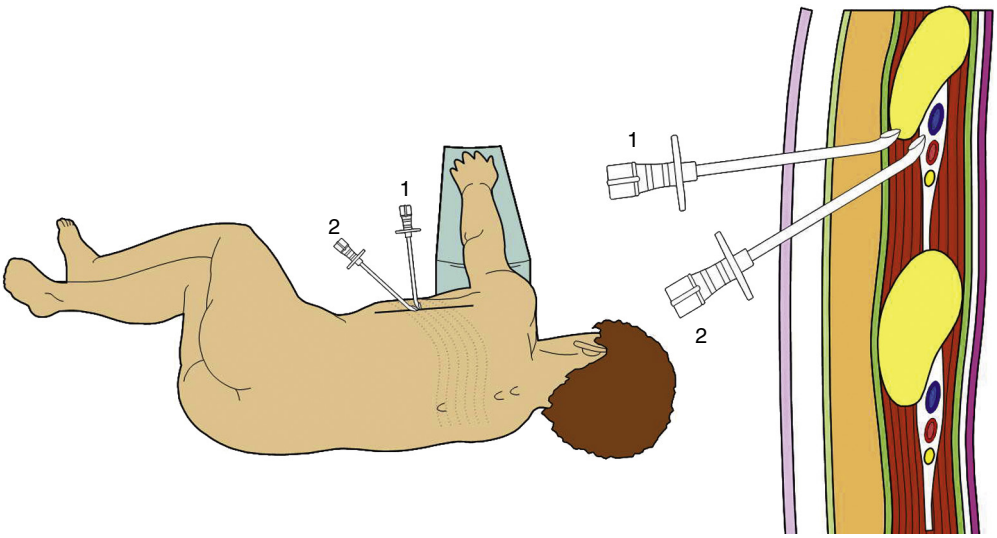

Figure 92-49. Intercostal nerve block. *1,* Insertion of the needle at an 80-degree angle to the skin; *2,* caudal and dorsal redirection of the needle.

This block must be avoided in the presence of impaired oxygenation or gas exchange, and it requires that all patients be kept under intensive medical observation because of the danger of clinically delayed pneumothorax. It is not suitable for outpatient surgery.

The safest approach to the intercostal space is along the midaxillary line with the child lying semiprone using a short 22- or 20-gauge Tuohy needle (intradermal needles are not appropriate) (Fig. 92-49).

A catheter can be introduced in the intercostal space located at the center of the area to be anesthetized to allow reinjections; the catheter also can be inserted intraoperatively under direct vision by the surgeon.[271,272] However, the safety of continuous techniques is questionable because of high systemic uptake of local anesthetic.[273] Spread of large-volume anesthetic solution can reach distant intercostal spaces (even contralateral ones), probably via the paravertebral space, thus providing adequate duration of pain relief with a single injection in some patients. Spread to the epidural space also can occur. Thus, the patient should be admitted to the intensive care unit for careful monitoring of respiratory function and for delayed pneumothorax.

THORACIC PARAVERTEBRAL SPACE BLOCK

Paravertebral block in children was first described 30 years ago[274] and many studies have been done on this block. This technique uses local anesthetic to infiltrate the paravertebral space by a posterior approach, and simultaneously to block several unilateral dermatomes with a single injection, in the manner of a plexus block. A catheter can be introduced into this space to maintain analgesia over an extended period. Paravertebral block will allow a somatic and sympathetic block (sympathetic chain being located in space infiltrated). The dosage is 0.5 mL/kg of long-acting local anesthetic, followed by a continuous infusion of 0.2 to 0.25 mL/kg/hr of the same solution.

Anatomic landmarks are the spinous processes of thoracic vertebrae. The puncture site is located parallel to the vertebral axis at the level of the spinous process

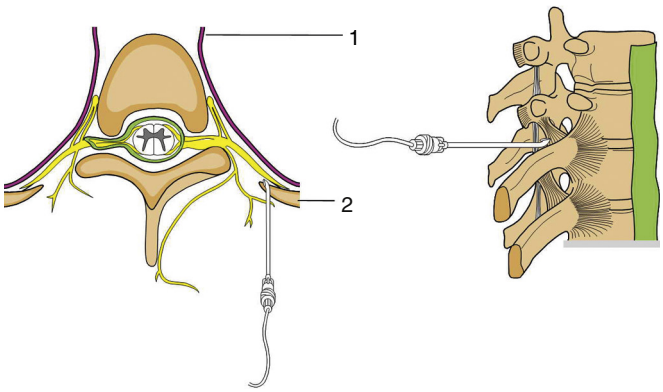

Figure 92-50. Block of the thoracic paravertebral space. *1,* Parietal pleura; *2,* rib.

(Fig. 92-50). The needle must contact the transverse process of a vertebra. The landmarks are defined in children as follows[275]:

- Point of puncture: 10.2 mm + (0.12 × weight in kg) laterally to the spinous process
- Depth of the space: 18.7 mm + (0.48 × weight in kg)

The puncture of the paravertebral space is related to the level of surgery and is usually for a T5-T6 for thoracotomy surgery and T9-T10 for subcostal surgery. The LOR method is used to locate the paravertebral space with the Tuohy needle crossing the costotransverse ligament. It is also possible to identify the spinal nerve with neurostimulation through space at the chosen level. Ultrasound guidance is used to identify the transverse process, the costotransverse ligament, and measure the distance from skin to parietal pleura before performing the block.[276]

Indications for thoracic paravertebral block in children are postoperative analgesia after thoracotomy[277] and upper abdominal surgery with unilateral subcostal incision (kidney surgery, cholecystectomy, splenectomy).[278] This block has been also described for unilateral inguinal hernia repair in children.[279] Contraindications for this technique are a history of ipsilateral thoracotomy with an increased risk for pneumothorax or parenchymal lung

puncture and the deformation of the spinal column, increasing the risk for pleural puncture. This block also must be avoided in cases of serious potential risk for complications (risk for pneumothorax in patients suffering from respiratory diseases with poor gas exchange).

Paravertebral block requires an anesthetist with good technical skills. An alternative to this block is thoracic epidural anesthesia, which has less risk for direct spinal cord injury.

OTHER NERVE BLOCKS OF THE TRUNK

Interpleural (or intrapleural) blocks that consist of injecting a local anesthetic within the pleural cavity without creating a pneumothorax elicited enthusiasm some years ago but was never established in pediatric anesthesia. Other blocks of nerves of the trunk, including paravertebral ganglion, genitofemoral, paracervical (uterosacral), and transsacral nerve blocks, are not used in pediatric patients.

FACE, HEAD, AND NECK NERVE BLOCKS

NERVE BLOCK OF THE FACE

All sensory innervation of the face is under the dependence of the trigeminal nerve (fifth cranial nerve, or vagus nerve) associated with the C2-C4 cervical nerve roots that constitute the superficial cervical plexus.

Anatomic Considerations

The fifth cranial nerve provides sensory and a motor components. The sensory component is combined in the trigeminal ganglion (semilunar or gasserian ganglion), which lies in the Meckel cave, an invagination of the dura mater near the apex of the petrous part of the temporal bone in the posterior cranial fossa. Postganglionic fibers exit the ganglion to form three nerves, as follows:

1. The ophthalmic nerve (V1), innervating the forehead, eyebrows, upper eyelids, and anterior area of the nose
2. The maxillary nerve (V2), innervating the lower eyelid, upper lip, lateral portion of the nose and nasal septum, cheek, roof of the mouth, bone, teeth, sinus of the maxilla, and soft and hard palates
3. The mandibular nerve (V3) innervating the anterior two thirds of the tongue and the skin, mucosa, teeth, and the bone of the mandibular.

These terminal sensory nerves can be blocked either at their emergence point from the cranium, as deep procedures (V2 and V3), or more distally when they exit the facial bone as superficial blocks (V1, V2, V3) (Fig. 92-51).

Superficial Trigeminal Nerve Blocks

For superficial trigeminal nerve blocks, the local anesthetic solution should be injected in close proximity to the three individual terminal superficial branches of the trigeminal nerve divisions: the frontal nerve (of ophthalmic nerve, V1 division), infraorbital nerve (of maxillary nerve, V2 division), and mental nerve (sensory terminal branch of mandibular nerve, V3 division). Each nerve is anatomically close to its respective foramen, which is usually on a line perpendicular through the center of the pupil.

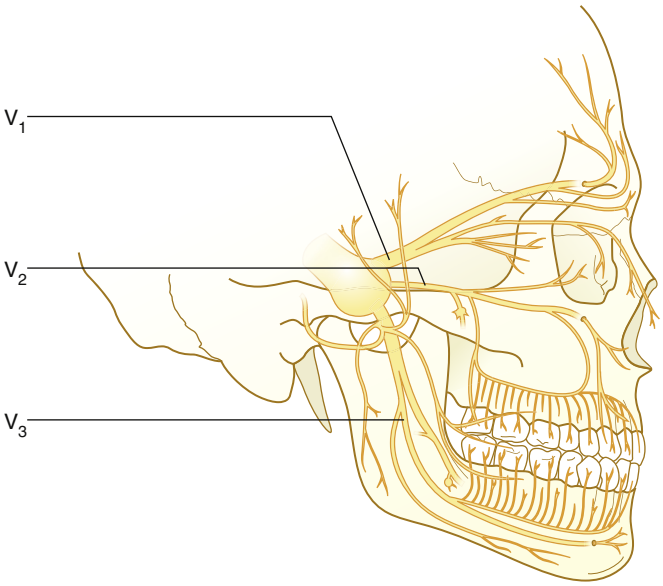

Figure 92-51. Facial nerves distribution.

The supraorbital foramen can be easily palpated by following the orbit rim 2 cm from the midline in adults (union of the medial third and lateral two thirds). The needle (intradermal needle, 25 gauge in adults to 30 gauge in children) is introduced a half centimeter under the inferior edge of the eyebrow and is directed medially and cephalad. When the needle tip is near the supraorbital notch, after test aspiration and with caution to not penetrate the foramen, local anesthetic solution (0.5 to 1 mL) can be injected, creating a subcutaneous wheal. For supratrochlear block, the landmarks are the top of the angle formed by the eyebrow and the nasal spine where the nerve is in contact with the bone. The supratrochlear nerve can be blocked without removal by directing the needle approximately 1 cm toward the midline and injecting an additional 0.5 mL of local anesthetic.

The terminal branch of the maxillary nerve (second division of the trigeminal nerve), is called the infraorbital nerve when it reaches the infraorbital fossa. The infraorbital artery and vein run parallel in close proximity to the nerve. Its innervation involves the skin and mucous membrane of the upper lip, lower eyelid, and the cheek. Two approaches can be used to perform this block: the intraoral and extraoral approaches. Regardless of the technique, it is necessary to prevent penetration of the foramen or eventual damage of the eyeball by palpating the foramen.

For the intraoral approach, the external landmarks include the foramen localized by palpation, the incisor, and the first premolar. The needle (25 or 27 gauge) is inserted at the buccal mucosa in the subsulcal groove at the level of the canine or the first premolar and directed upward and outward into the canine fossa. A finger is placed over the infraorbital foramen to assess the proper location of the needle tip and avoid damage of the pupil.

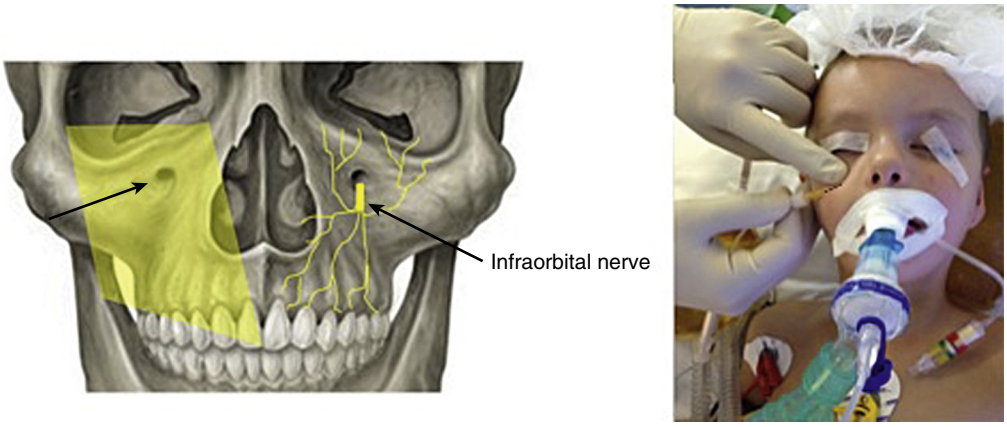

Figure 92-52. Infraorbital nerve block procedure.

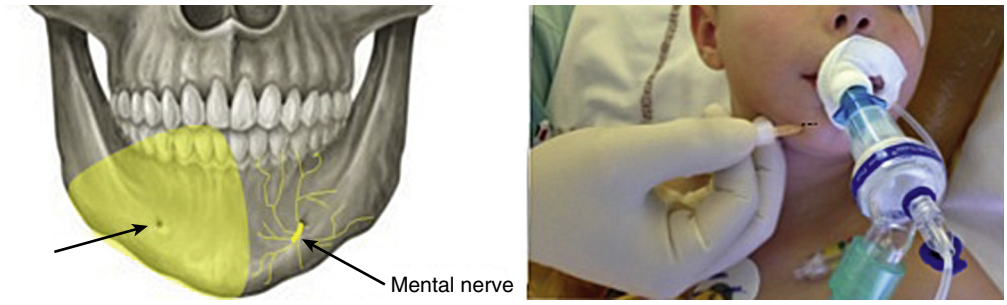

Figure 92-53. Mental nerve block procedure.

For the extraoral approach, the infraorbital foramen is palpated just below the orbital rim, at the intersection of a vertical line drawn caudally through the center of the pupil and a horizontal line through the alae nasae. The needle (25 or 27 gauge) is advanced perpendicularly with a cephalic and medial direction toward the foramen until bony resistance is met (Fig. 92-52).

The main surgical indication in children is cleft lip repair with good perioperative pain management and a decrease in opioid use.[280-282]

The mental nerve is the terminal branch of the alveolar nerve (the largest branch of the mandibular nerve). It emerges at the mental foramen. The mental foramen is located in line with the pupil on the mental process of the mandible, in regard to the inferior premolar tooth. Puncture is 1 cm lateral to the foramen palpated. The 25- or 27-gauge needle is directed with a lateral-to-medial direction to avoid foramen penetration (Fig. 92-53).

After negative aspiration, 1 to 3 mL of local anesthetic is injected for these different approaches. Complications are hematoma, persistent paresthesia of the innervated territory, prolonged numbness, and intravascular injection.

Ultrasound guidance can be used to locate the foramina for superficial trigeminal nerve blocks.[126] It appears as an easy and safe modality. The ultrasound imaging of foramina is the classic disruption of the bone table (Fig. 92-54).

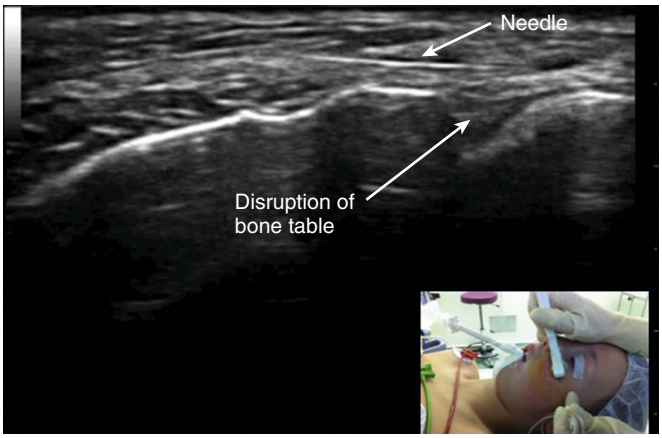

Figure 92-54. Ultrasound of infraorbital nerve block and probe position on face. Disruption of bone table indicates foramen of trigeminal nerve.

Maxillary Nerve Block

The maxillary nerve exits the skull through the foramen rotundum and gives its terminal branches. Except for the middle meningeal nerve, innervating the dura mater, all branches (zygomatic branches, superior alveolar nerve, pterygopalatine and parasympathetic branches, palatine and pharyngeal branches) arise in the pterygopalatine fossa to the face. At the upper part of the pterygopalatine fossa, the maxillary nerve is accessible for a complete maxillary block. The nerve territory blocks are the lower eyelid, ala of the nose, cheek, upper lip, cutaneous zygomatic and temporal zone on the face and superior teeth, palatine zone, maxillary bone.

The suprazygomatic approach to the maxillary nerve in pterygopalatine fossa seems to be the safest and is easily reproducible in children.[283] The patient is supine, with the head in neutral position or turned slightly to the opposite side. The needle entry point is situated at the angle formed by the superior edge of the zygomatic arch

below and the posterior orbital rim forward (Fig. 92-55). The needle (22 to 25 gauge) is inserted perpendicular to the skin and advanced to reach the greater wing of the sphenoid at a depth of approximately 10 to 15 mm. The needle is then reoriented in a caudal and posterior direction and advanced 35 to 45 mm deep to the pterygopalatine fossa (Fig. 92-56). After a negative aspiration test for blood, 0.15 mL/kg to a maximum of 5 mL of local anesthetic solution is slowly injected.

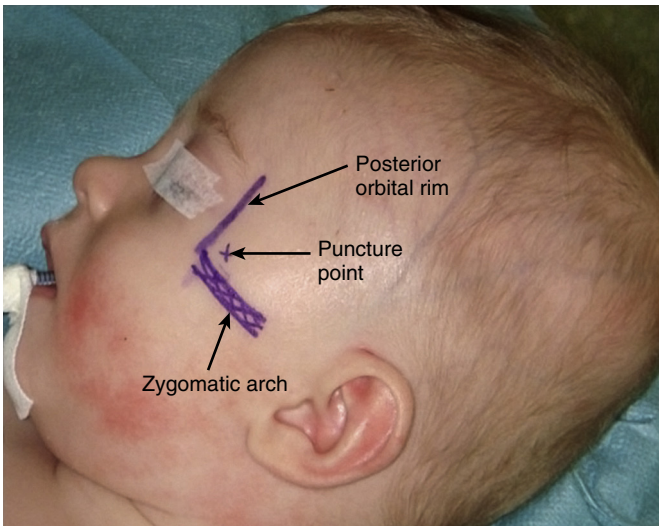

Figure 92-55. Suprazygomatic maxillary nerve block landmarks.

Ultrasound guidance technique is possible with the ultrasound transducer located in the infrazygomatic area, over the maxilla, with an inclination of 45 degrees in both the frontal and horizontal planes (Fig. 92-57). The probe location allows visualization of the pterygopalatine fossa, limited anteriorly by the maxilla and posteriorly by the greater wing of the sphenoid. The needle is advanced using an out-of-plane approach. This real-time ultrasound-guided technique is easy and ensures the correct location of local anesthetic injection in the pterygopalatine fossa (Fig. 92-58).[284]

Mandibular Nerve Block

The mandibular nerve, the largest branch of the trigeminal nerve, exits from the cranium through the foramen ovale of the greater wing of the sphenoid. The anterior trunk is formed with branches serving mainly motor innervation to temporalis, masseter, pterygoids, mylohyoid, and tensor tympani and palati muscles and the buccal nerve. Auriculotemporal, lingual, and inferior alveolar nerves comprise the posterior trunk.

Figure 92-56. Suprazygomatic maxillary nerve block technique. The needle was inserted perpendicular to the skin (**A**) and advanced to reach the greater wing of the sphenoid at approximately 10 to 15 mm depth (**B**). Reorientation of needle in a caudal and posterior direction (**C**) and advancement of 35 to 45 mm deep to the pterygopalatine fossa (**D** and **E**).

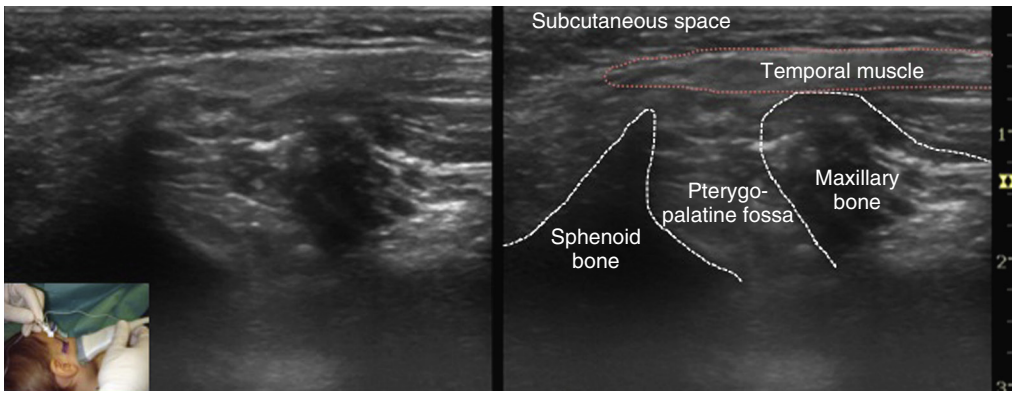

Figure 92-57. Ultrasound imaging of suprazygomatic maxillary nerve block.

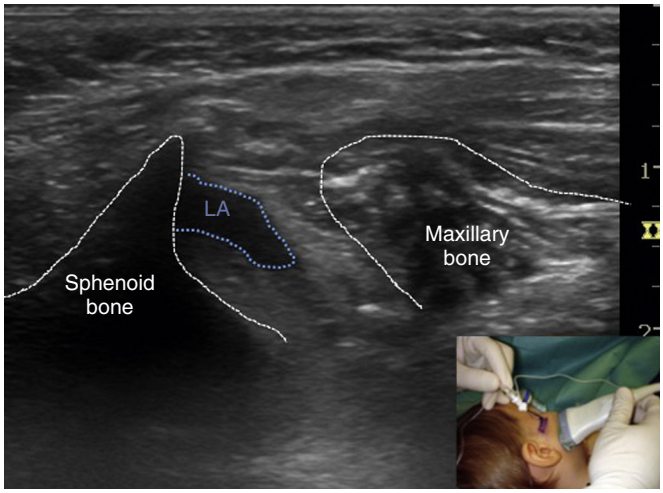

Figure 92-58. Ultrasound imaging of suprazygomatic maxillary nerve block with local anesthetic (*LA*) injection.

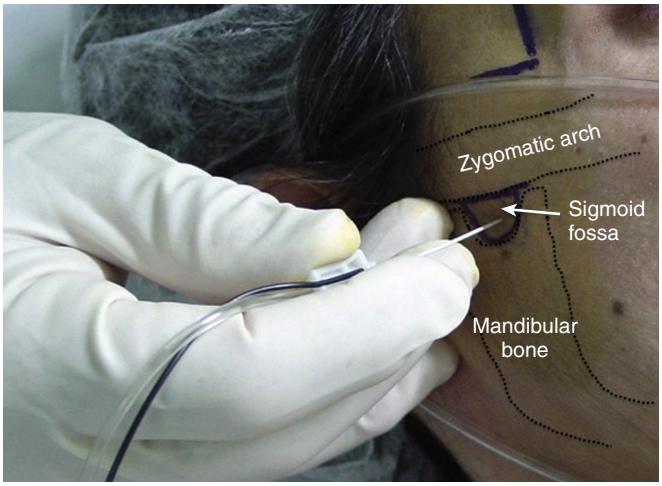

Figure 92-59. Mandibular nerve block procedure.

The puncture area is bounded by the zygomatic arch at the top and the mandibular notch just anterior to and below the tragus of the ear (Fig. 92-59). The needle entry point is located in the sigmoid fossa between the coronoid and condylar process of the ramus of the mandible. To avoid the risk for arterial puncture, it is recommended to prick as high as possible in the space between the zygomatic arch and the center of mandibular notch (see Fig. 92-59). After perpendicular skin penetration, toward the lateral pterygoid plate (to a distance of 2 to 4 cm of depth), the needle (22 to 25 gauge) is advanced posteriorly and inferiorly maintaining the same depth, guided by mandible ascension twitch. The minimal intensity of stimulation (~0.5 mA) is determined, and 0.1 mL/kg to a maximum of 5 mL of local anesthetic solution is slowly injected after negative repeated blood test aspirations. This transcutaneous procedure with neurostimulation appears easier and has a high success rate.

Block of the Nose: Nasociliary Nerve Block and External Nasal Nerve Block

The innervation of the nose and nasal cavity is quite complex, implicating both the ophthalmic (V1) and maxillary (V2) branches of the trigeminal nerve.

The nasociliary nerve is blocked before its division into nasal branches of the anterior ethmoidal nerve and the infratrochlear nerve, and near the ethmoidal foramen. A 25- or 27-gauge needle is inserted 1 cm above the medial canthus, halfway between the posterior palpebral fold and the eyebrow. It is then directed medially and backward in contact with the bony roof of the orbit. At a depth of 1.5 cm the needle should be at the anterior ethmoidal foramen, and a maximum of 2 mL of local anesthetic solution is then slowly injected after a negative aspiration test.

The external nasal branch of the anterior ethmoidal nerve can be blocked by infiltration at the junction of nasal bone with cartilage. Combined with infraorbital nerve block, the external nasal nerve block is very effective for perioperative pain control in cleft lip repair.[285]

Nerve Blocks of the External Ear

Anatomic Considerations. The innervation of the pinna of the ear is complex. Both the trigeminal nerve and the cervical plexus mainly provide innervation.

The auriculotemporal branch of the mandibular division of the trigeminal nerve supplies the superior two thirds of the anterior surface. The auriculotemporal nerve passes through the parotid gland to ascend anterior to the auditory canal with the superficial temporal artery and passing superiorly superficial to the zygomatic arch.

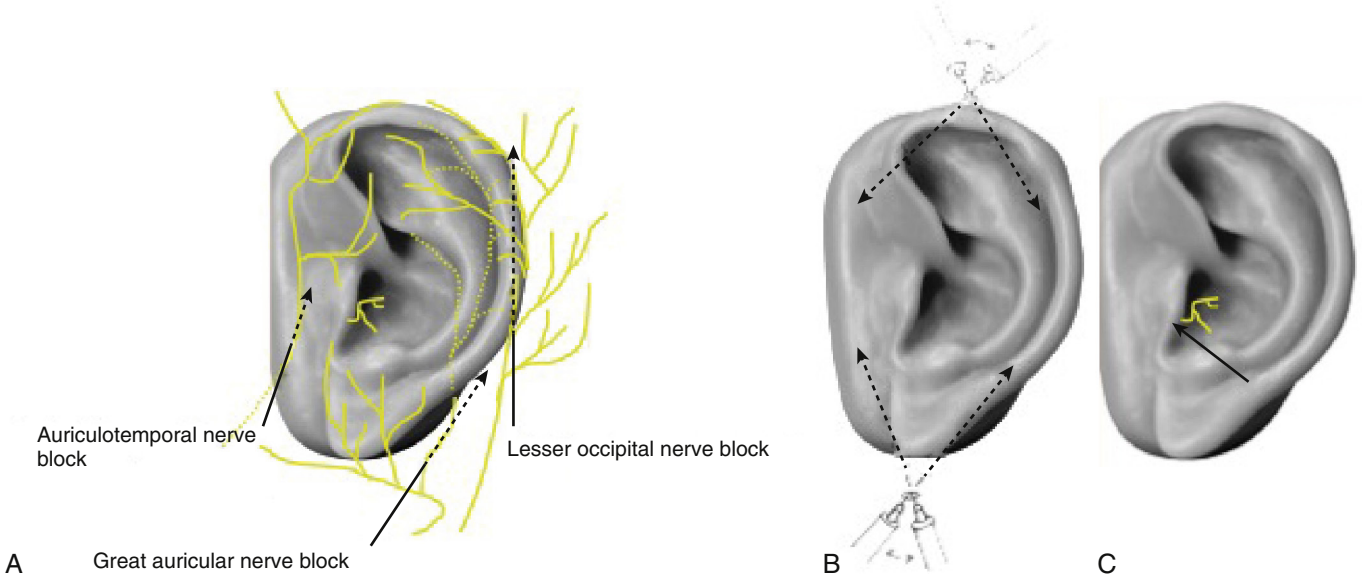

Figure 92-60. A, Regional field block of ear. **B,** Ring block of ear. **C,** Block of the auricular branch of the vagus nerve.

The posterior surface of the ear and the lower third of its anterior surface depend on the great auricular nerve and the lesser occipital nerve, two branches of the cervical plexus.

The great auricular nerve arises from the second and third cervical nerve roots, emerges from the posterior border of sternocleidomastoid muscle, and ascends (dividing into anterior and posterior branches) to the mandibular, parotid gland, and pinna. It supplies the lower back of the auricle, the lobule, and the skin of the angle of the mandible (in complement to the mandibular nerve).

The lesser occipital nerve arises from the ventral primary rami of the second and third cervical roots and gives the innervation of the upper part of the ear lobe and lateral occipital zone.

The auricular branch of the vagus nerve (nerve of Arnold) innervates the concha, most of the posterior wall of the external auditory meatus (zona of Ramsay Hunt), and inferior portion of the tympanic membrane.

Regional Anesthesia Techniques. Regional field block around the auricle allows anesthesia of each nerve branch involved in external ear sensory innervation except the Ramsay Hunt area (Fig. 92-60, *A*).

The auriculotemporal nerve can be blocked by injecting local anesthetic solution above the posterior portion of the zygoma, anterior to the ear and behind the superficial temporal artery. The needle (27 gauge) is inserted anterior and superior to the tragus. Caution is necessary because of the vicinity of the temporal artery.

The great auricular nerve and the lesser occipital nerves can be blocked distally over the mastoid process posterior to the ear. The needle is inserted behind the lower lobe of the ear and advanced following the curve of the posterior sulcus.

Infiltration with the ring-block technique also provides an additional efficient analgesia of the external ear (see Fig. 92-60, *B*).

The superficial cervical plexus block is a widely described proximal approach that anesthetizes two of its terminal branches, the lesser occipital nerve and the great auricular nerve (see also Chapter 57). Several painful procedures of the ear can benefit from this analgesic block, such as incision and drainage of an abscess or hematoma,[286] suture of a large laceration of the ear or the skin surrounding the ear,[287] postauricular incision as in tympanomastoid surgery and cochlear implants,[288] otoplasty,[289] and surgical correction of "bat" ears.[280]

For tympanomastoid surgery, a great auricular nerve block provides good analgesia with reduction of opioid use and a decrease in postoperative nausea and vomiting[288] (see also Chapter 96).

The block of the auricular branch of the vagus nerve is used for pain control after myringotomy and tube placement, tympanoplasty, and paper patch for ruptured tympanic membrane.[286] To perform this block, the tragus is everted, a 30-gauge needle is inserted into the tragus, and, after an aspiration test, 0.2 mL of local anesthetic solution is injected (see Fig. 92-60, *C*).

Nerve Block of the Head

Greater Occipital Nerve Block. The greater occipital nerve arises from the second cervical nerve root that emerges between the atlas and the axis. It ascends between the obliquus capitis inferior and semispinalis capitis before piercing the latter muscle. It then becomes subcutaneous by piercing the trapezius aponeurosis, slightly inferior to the superior nuchal line. At this point, the greater occipital nerve is most often located immediately medial to the occipital artery. The greater occipital nerve provides cutaneous innervation to a major portion of the posterior scalp from the level of the external occipital protuberance to the vertex.

The landmarks to perform the greater occipital nerve block are located at approximately two thirds of the distance on a line drawn from the center of the mastoid to

the external occipital protuberance along the superior nuchal line, where it lies medial to the occipital artery. The pulsation of the occipital artery is easy to palpate. Palpation in this area may elicit a paresthesia or uncomfortable feeling in the distribution of the nerve. Usually a 25- or 27-gauge needle can be used depending on the size of the patient. The needle is directed at a 90-degree angle toward the occiput and, after aspiration, 1 to 3 mL of local anesthetic is injected. When the needle is withdrawn, pressure should be maintained over the site of injection to promote the nerve impregnation and to achieve hemostasis. Numbness over the top of the head, after the injection, is a sign of a successful greater occipital nerve block.

An ultrasound-guided technique of greater occipital nerve block has been described recently with good visualization of the nerve.[290]

Scalp Blocks. The scalp block is classically described with potential blockade of seven nerves, including branches from cervical spinal rami and from trigeminal division.

The greater occipital, lesser occipital, and great auricular nerves originate from ventral and dorsal rami of C2 and C3 spinal nerves. The greater occipital nerve travels up to the vertex, and the lesser occipital nerve innervates skin behind the ear.

The ophthalmic division of trigeminal nerve gives off, by the frontal nerve, supraorbital and supratrochlear nerves that innervate the skin from the forehead to the lambdoidal suture.

The zygomaticotemporal nerve is one of the two branches of the zygomatic nerve that arises from the maxillary division of the trigeminal nerve. It innervates a small area of the forehead and temporal area.

The auriculotemporal nerve arises from the mandibular division of the trigeminal nerve. It innervates the posterior portion of the skin of the temple.

Scalp block is used in adults and children for a variety of head and neck procedures and in neurosurgery or chronic pain diagnostic and therapeutic management (many headache disorders of muscular and nervous etiology). Common reasons for providing anesthesia to the scalp are repair of a laceration, foreign body removal, exploration of scalp wounds, and drainage of abscesses or subdural hematomas.

Most of the time, infiltrative anesthesia is used to perform scalp blocks. All the nerves involved in the scalp's sensitivity become superficial and accessible to the anesthetic. To block the entire scalp, a circumferential infiltration of local anesthetic solution (with 1:200,000 epinephrine), above an imaginary line drawn from the occipital protuberance to the eyebrows, passing along the upper border of the ear, is necessary. Approximately 30 mL is required to perform this ring block around the scalp.

The most common complications associated with scalp anesthesia are hematoma formation at the site of injection and the risk for intravascular injection.

Nerve Block of the Neck

Cervical Plexus Block. Cervical plexus blocks have few but specific indications in pediatric surgery—cervical lymph node biopsy, excision of thyroid nodules,[291,292] and surgery of vocal cords.[293] Only the superficial branches are blocked by a subcutaneous infiltration along the lateral border of the sternocleidomastoid muscle.

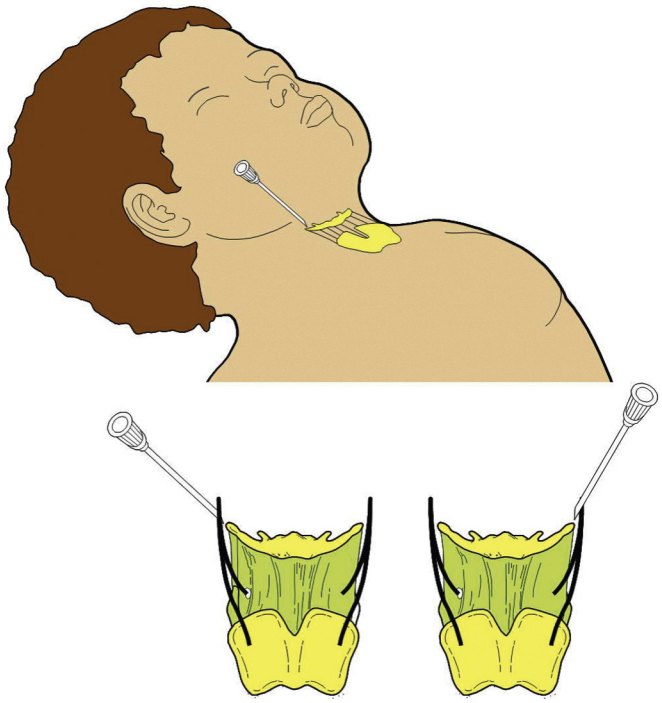

Figure 92-61. Laryngeal nerve block.

Laryngeal Nerve Block. Laryngeal nerve blocks can be used for short-duration laryngoscopic examinations in conscious patients or to facilitate awake intubation when difficult intubation is suspected. It also can be used to prevent or treat laryngospasm.[294] Several techniques have been described, but the easiest consists of subcutaneous injection of a local anesthetic just lateral to the dorsal ending of the hyoid horns (on each side) (Fig. 92-61). A 27-gauge intradermal needle is inserted close to the hyoid horn ending until contact is made with cartilage. The needle is then slightly withdrawn and 0.1 to 0.2 mL/kg (up to a maximum of 8 mL) of 1% lidocaine is injected subcutaneously. Excellent laryngeal block is usually obtained.

Cervicothoracic (Stellate) Ganglion Block. Stellate ganglion block is a rather dangerous procedure with very few but very specific indications in children: (1) ventricular tachyarrhythmia resulting from congenital long-QT syndrome[295,296] (a left stellate block is recommended) and (2) severe ipsilateral circulatory disorders of the upper extremity. Patients with certain acute pain syndromes such as herpes zoster ophthalmicus[76] or rare chronic pain syndromes such as sympathetically maintained pain syndrome[297,298] may benefit from the technique.

OTHER PROCEDURES

INTRAVENOUS REGIONAL ANESTHESIA

Intravenous regional anesthesia (Bier block) has never been very popular in pediatric anesthesia. Currently, the

technique is outdated, even though it is still used in some institutions mainly for fracture repairs (often in emergency departments).[299-301] The technique is the same as in adults. The limb is exsanguinated by an Esmarch bandage or simple gravitation. A tourniquet is placed around the proximal part of the arm and inflated at two to three times the systolic pressure before the Esmarch bandage is removed and 1 mL/kg of 0.5% lidocaine (not exceeding 3 mg/kg) is injected. Prilocaine can be used instead in adolescents. Children tolerate the pain produced by the inflated tourniquet very poorly, and this technique was responsible for several deaths in the past.

Intradermal Wheals

Intradermal wheals are routinely used in adult patients to anesthetize the skin covering deeper structures to be approached. The technique is used less often in children, except for anesthetizing the puncture site of a regional block procedure in nonanesthetized children. It consists of inserting a 25-, 27-, or 30-gauge interdermal needle almost tangentially to the skin, with the bevel facing downward, without penetrating the subcutaneous layers. A small amount (<0.5 mL) of local anesthetic (0.5% to 1% lidocaine or prilocaine, with or without epinephrine) is then injected. The skin covering the wheal looks like an orange peel and almost immediate anesthesia of the relevant area is obtained. The only drawback of this technique is that the injection is moderately painful.

Wound Infiltration

In adults, some studies have shown benefits of continuous wound catheters.[302,303] Today, publications on continuous wound catheters in children are limited. Ouaki and co-workers[304] evaluated continuous infusion of ropivacaine through an iliac crest catheter for bone graft postoperative pain relief in children undergoing a maxillary alveolar graft. The catheters were placed close to the iliac periosteal bone at the donor site and infused with 0.125 mL/kg/hr of 0.2% ropivacaine for 48 hours with a disposable elastomeric pump. The findings of Ouaki and co-workers showed optimal pain relief with a low pain score and a decrease of chronic pain symptoms after 3 months in contrast to reports in the literature.

In their study, Dashow and associates[305] placed a bupivacaine-soaked absorbable sponge in addition to periincisional bupivacaine infiltration at the anterior iliac crest donor site for the management of postoperative pain in children. Their results showed that this regional anesthesia method significantly reduced the postoperative pain score, pain medication requirement, and length of hospital stay.

Precautions must be taken to avoid bacterial contamination and overdosage, especially in cases with extensive wounds or reinjections.
